[5]Iceland GeoSurvey, Grensásvegur 9, 108 Reykjavík, Iceland

The risks associated with geologic carbon storage can be considerably reduced by subsurface carbon mineralization.

The CARBFIX project in Iceland is a field scale pilot study where CO_2 and H_2S emissions from the Hellisheidi geothermal power plant are dissolved in groundwater and injected into a permeable basalt formation at ~500 m depth below surface [1]. We are using non-reactive (sodium fluorescin, amidhorhodamine G, SF_5CF_3, and SF_6) and reactive (^{14}C and ^{13}C) tracers in an on-going injection project to characterize subsurface CO_2 transport and in situ CO_2-water-rock reactions. In early 2012, 170 tons of pure CO_2 tagged with ^{14}C and SF_6 were dissolved in water and injected into a confined basalt aquifer. Samples were collected from injection and monitoring wells in evacuated serum bottles with butyl stoppers and analyzed by AMS and mass spectometry for carbon isotopes, by fluorometry for Na-fluorescien and by gas chromatography for SF_6 and SF_5CF_3. The multi-tracer approach allows us to separate various injection experiments and differentiate between dilution and reaction. While the bulk of the injected CO_2 has not yet arrived at the monitoring wells, a fraction following a fast flowpath appeared within less than a month. $\delta^{13}C$ shows an initial rise attributed to dissolution of aquifer carbonates and then a drop due to carbonate precipitation. The $^{14}C/SF_6$ ratio is lower than the injection ratio providing additional evidence for carbonate precipitation. The bulk of the injected CO_2 is expected to arrive by the summer of 2013 and we will extend the time series accordingly. Our study demonstrates the value of tracers as a monitoring, verification and accounting tool in reactive geological carbon storage systems.

Robust Calibration Systems Based on Syringe Pumps for Water Vapor Isotopologue Measurements

ERIC STUTZ[1]*, JANEK LANDSBERG[2], LASZLO SARKOZY[1], ELISABETH MOYER[1] AND ERIK KERSTEL[2]

[1] Department of the Geophysical Sciences, University of Chicago, Chicago, IL 60637, USA (*correspondence: ejstutz@uchicago.edu)
[2] J. Fourier University of Grenoble Laboratoire Interdisciplinaire de Physique, (UMR 5588 CNRS-UJF), 38402 Grenoble, France

Advances in spectroscopic instrumentation mean that laser-based absorption spectroscopy (both direct and cavity enhanced) is increasingly used for isotopic measurements in environmental sciences. For studies involving water, this technique offers the advantages of speed and non-destructive sampling, allowing for new applications in water vapor measurements [e.g. 1] and for the support or replacement of mass spectroscopy in studies of ice cores [e.g. 2]. In both uses, instrument accuracy is tied to instrument calibration and therefore dependent on the availability of suitable calibration systems. We describe here a new calibration technique based on syringe pumps for producing air streams of known and constant water content and isotopic composition. Syringe pumps offer advantages over previous methods such as capillary flash-evaporation, water vapor "bubbling", or microdrop generation [e.g. 2,1,3], including greater control and reliability. We show the stability and time response of two calibration systems, built at the University of Chicago and the J. Fourier University of Grenoble and designed for high and low flow rates (0.1 -10 slm) and a water vapor dynamic range of 3-10,000 ppm. We discuss the optimization of parameters such as pressure, injection rate step shape, temperature and hydrophobic coatings. The designs are robust and readily modified for instrument-specific configurations, suggesting they may find wide use in the community.

Biogeochemical controls on the product of microbial U(VI) reduction

MALGORZATA STYLO[1], DANIEL S. ALESSI[1], PAUL PAOYUN SHAO[1], JUAN S. LEZAMA-PACHECO[2], JOHN R. BARGAR[2] AND RIZLAN BERNIER-LATMANI[1]

[1]Environmental Microbiology Laboratory, École Polytechnique Fédérale de Lausanne, CH-1015, Lausanne, Switzerland

[2]Chemistry and Catalysis Division, Stanford Synchrotron Radiation Lightsource, SLAC National Accelerator Laboratory, Menlo Park, CA 94025, USA

Biologically mediated immobilization of radionuclides in the subsurface is a promising strategy for the remediation of U-contaminated sites. During this process, soluble U(VI) is reduced by indigenous microorganisms to sparingly soluble U(IV). The crystalline U(IV) phase uraninite, or UO_2, is the preferable end-product of bioremediation due to its relatively high stability and low solubility in comparison to the non-crystalline biomass-associated non-uraninite U(IV) species. However, non-uraninite U(IV) species have been reported to be a predominant U(IV) product formed under field relevant conditions. Therefore the goal of this study was to delineate the biogeochemical conditions that promote the formation of non-uraninite U(IV) versus uraninite, to decipher the mechanisms of its preferential formation and to apply this knowledge to environmentally relevant cases. Batch experiments as well as biofilm reactors were set up to test the influence of biogeochemical conditions on U(IV) product formation. U(IV) products were analyzed with X-ray absorption spectroscopy (XAS), scanning transmission X-ray microscopy (STXM) and various wet chemical methods. As a result of batch experiments, we report an increasing fraction of non-uraninite U(IV) species with decreasing initial U concentration. Additionally, the presence of several common groundwater solutes (sulfate, silicate and phosphate) promote the formation of non-uraninite U(IV). Our experiments revealed that the presence of specific solutes promotes the formation of bacterial extracellular polymeric substances (EPS) and increases bacterial viability, suggesting that the formation of non-uraninite U(IV) is due to a biological response to the presence of these solutes during U(VI) reduction. Ongoing biofilm studies focus on the characterization and origin of U(IV) species formed under field relevant conditions, i.e., in the flow-through systems, under alternating redox regimes with controlled biotic and abiotic processes.

Arsenic immobilization and transformation by zerovalent iron

CHUNMING SU

National Risk Management Research Laboratory, U.S. Environmental Protection Agency, 919 Kerr Research Drive, Ada, OK 74820

Introduction and Experiments

Both graular [1] and nanosized zerovalent iron (NZVI) [2] are effective in removing arsenic from water. Granular ZVI also has been used as permeable reactive barrier media to intercept and remove As from contaminated groundwater at a smelting site [3] and as a filter material for removing As from Bangladesh tube well water [4]. This study focus on As removal mechanisms by NZVI. Batch tests were conducted using 25-nm NZVI to remove As(V) and As(III) under anaerobic conditions as a function of time and pH with or without phosphate and silicate. Minerals were identified.

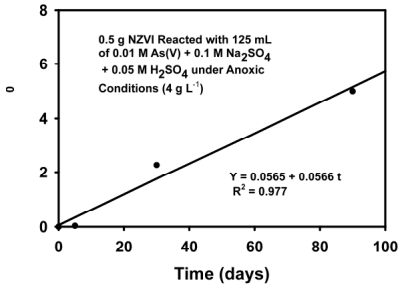

Figure 1. Plot of pseudo-second order removal kinetics for As(V) in the long term test.

Results and Discussion

Both As(V) and As(III) removal increased with increasing time to approach a steady state after 4-5 days in the short-term test. There was generally more removal of As(III) than As(V). Complete or near complete removal of As(V) and As(III) was achieved at pH levels less than 10. Competition of phosphate and silicate against As(V) and As(III) was observed at alkaline pHs. New solid phases formed such as parasymplesite in the As(V) system and vivianite in the phosphate system. This study demonstrated that As(V) removal involves both solid precipitation and adsorption; whereas, As(III) removal only involves surface adsorption.

Evidence of underground water for the forming mechanism of high sulfur condensate reservoirs, Example from the Tazhong area

JIN SU, SHUICHANG ZHANG, GUANGYOU ZHU AND YU WANG

PetroChina Research Institute of Petroleum Exploration and Development,Beijing 100083, China, (susujinjin@126.com)

Condensate gas reservoirs with high content of hydrogen sulfide have been discovered on a large scale in deep marine carbonate formations in the Tarim Basin, which contain formation water with high salinity. Investigations show that, in the Tazhong area, the average negative and positive ion contents in the lower Ordovician to Cambrian formation water are higher than that in the upper Ordovician formation water. Yingshan formation with high-sulfur condensate reservoir is similar to the lower Ordovician to Cambrian formation in water properties, that is to say, the content of Mg^{2+} and SO_4^{2-} and PH value are higher than those in the upper Ordovician formation; these mineral ions and PH are crucial to thermochemical sulfate reduction. Hydrogen sulfide content in Yingshan condensate reservoir and Mg^{2+} content of formation water correlates well in the Tazhong area, which indicates a presumable TSR-origin of hydrogen sulfide according to the reaction theory of contact ion-pair. Besides, the total salinity and pH value of formation water are positively correlated with hydrogen sulfide content in the condensate reservoir, which may indicate that high salinity and pH value are important to activate and maintain TSR reaction. High sulfur condensate reservoirs are all located near the No. I faulted zone and strike-slip faults which are the major pathway for deep fluid migration in the area, showing that the formation water in condensate reservoirs may communicate with high salinity fluid in the lower Ordovician to Cambrian formation and hydrogen sulfide flowed upwards with formation water from deep zones along fractures to form condensate reservoirs with high sulfur content and high salinity. The discovery reveals the forming mechanism of high sulfur condensate reservoirs in the Tazhong area and will be helpful to predict the reservoir fluid properties.

Tectonic setting of the Xigaze ophiolite complex in Tibet based on the characteristics of boninite

SU LI[1,2], BAO PEISHENG[3], SONG SHUGUANG[4] AND NIU YAOLING[2]

[1] Institute of Earth Science, China University of Geosciences, Beijing, 100083, China
[2] Department of Earth Sciences, University of Durham, Durham, DH1 3LE ,UK
[3] Institute of Geology, Chinese Academy of Geological Sciences, Beijing, 100037, China
[4] Department of Earth Sciences, Beijing University, 100871, China

The Xigaze ophiolite complex contains the best preserved ophiolite blocks in the middle section of the Yarlung Zangbo ophiolite belt. It composes of several fragments and extends about 200 km long and ~ 8 km wide. The ophiolite complex consist of five lithologic units, including mantle peridotite, melanocratic to leucocratic cumulates, sheeted dyke complex, pillow lavas and diabase dykes. Most of the basic lava and sheeted dyke complex from the Dejixiang ophiolite are calc-alkaline with variable SiO_2 ranging from basalt to andesite. Their LREE-depleted REE patterns show affinity of N-type MORB (or BAB). The diabase dike samples exhibit low TiO_2 (<0.5%), high MgO (up to 18.24 wt%) and $Mg^{\#}$ (68.3-83.7) and remarkably high mantle compatible elements Cr, Co and Ni. They exhibit low REE abundances and LREE-depleted REE patterns with [La/Sm]n = 0.63–0.90, which are distinct from the U-shaped REE patterns of typical boninites that occur in forarc settings but similar to the boninites from the back-arc basin [1,2,3]. Ol, Sp and Opx were observed in these rocks. We conclude that (1) the Dejixiang ophiolite formed in a backarc basin setting, rather than in the mid-ocean ridge (MOR) or in a fore-arc environment and (2) the boninites are high-Ca type that formed in the late stage of back-arc basin environment during continuous extension of the spreading center that caused further melting of the depleted mantle, these melts intruded as diabase dykes into the former oceanic crust that formed the Dejixiang ophiolite during the early spreading stages of the back-arc-basin. These ophiolite blocks reflect the transition from spreading ridge to arc of the Tethys ocean.

Subducted continental crust materials in the SW Tianshan HP-LTMB

SU WEN, LIU XIN, GAO JUN, LI JILEI AND JIANG TUO

[1]Institute of Geology and Geophysics, CAS, Beijing, China

The SW Tianshan HP/UHP-LT metamorphic belt(MB) in NW China occurs along a suture zone between the Yili and the Tarim blocks. It is mainly composed of blueschist, eclogite and greenschist-facies metasediments, metavolcanics, resembling typical mélange lithologies. Chemical compositions of mafic rocks are similar to those of typical oceanic basalts, which formed at a seamount setting in the South Tianshan ocean (Gao & Klemd, 2003). The belt has been interpreted as the typical deeper subduction of the oceanic crust in the world (Zhang *et al*., 2007). Recent 2450-1880Ma age obtained for detrital zircons of metasediments, core of zircons of meta-basalts, implying the SW Tianshan HP/UHP-LTMB may contain subducted continental crust. Here, we therefore performed a geochemical investigation on the intimately associated eclogites and blueschists which may represent continental crust materials.

Both eclogite and blueschist have similar geochemical characteristics: an enrich LREE, flated HREE, weak negative Eu anomalies REE patterns, depleted in Ba, Sr, Nb, Ta, Ti, high Th/Yb, indicating a continental crustal source of the rocks on a Zr/Hf -Nb/Ta diagram (Pfander *et al*., 2007). Sr-Nd isotopic data of both rocks is relatively constant with $\varepsilon Nd(t)$=-7.701 to -4.55, whereas $(^{87}Sr/^{86}Sr)_i$=0.7091 to 0.7107. All $\varepsilon Nd(t)$ values and Sr ratios are different with those reported for meta- N-MORBs, E-MORBs, OIBs in the Tianshan HP MB (Ai *et al*., 2006), but within range of the continental crust. Concerning with tectonic implication for continental crust materials in the HP/UHP-LTMB, two possible mechanisms are proposed here: 1) the fragments of arc basalts derived for a Paleozoic active margin with Precambrian basement have been involved into the subduction process; 2) the continental crust of the Tarim was involved during the collision process. Although present data cannot give a clear explaination to the tectonic background, geochemical and isotopic results demonstrate some continental crust materials have been subducted in formation of HP/UHP-LTMB in the SW Tianshan orogen.

Biochar determination in soils by applying Pyrolysis GC-MS analysis and Black Carbon (BC) concentration trough dichromate and permanganate oxidation

MANUEL SUÁREZ-ABELENDA[1], JOERI KAAL[2], HEIKE KNICKER[3], MARTA CAMPS-ARBESTAIN[4] AND FELIPE MACÍAS[1]

[1]Department of Soil Science and Agricultural Chemistry, Biology Faculty, Santiago de Compostela University, Spain (manuel.suarez@usc.es). [2]Instituto de Ciencias del Patrimonio (Incipit), CSIC, Santiago de Compostela, Spain.

[3]Instituto de Recursos Naturales y Agrobiología de Sevilla (IRNAS-CSIC), Sevilla, Spain. [4]Institute of Agriculture and Environment, Massey University, Palmerston North, New Zealand.

Distinguishing pyrogenic and non-pyrogenic SOM components is a difficult task as non-selective pyrolysis products such as MAHs, PAHs and phenols can derive from multiple sources. However, black carbon (BC) may contribute significantly to the MAHs and PAHs in a given pyrolysate, especially if BC is more abundant than alternative sources. In this study, samples from a soil rich in pyrogenic material in NW Spain were subjected to $K_2Cr_2O_7$ and $KMnO_4$ oxidation and the residual SOM was NaOH-extracted and analyzed using analytical Py-GC-MS in order to study the susceptibility of different SOM fractions (fresh, degraded/microbial, aliphatic and specially BC) towards this oxidation agent. Besides solid-state ^{13}C CP MAS-NMR was also performed to support theses results. Non-oxidized samples following the same NaOH-extraction procedure were also analyzed. From Py-GC-MS, residual SOM after $K_2Cr_2O_7$ oxidation contained BC, N-containing BC (BN) and aliphatic structures whilst carbohydrate products and lignocellulose were completely oxidized. This was corroborated by a relatively intense resonance of aromatic C and some signal of alkyl C (supporting the presence of a non-pyrogenic fraction mainly consisting of aliphatic structures) in ^{13}C NMR spectra. Thus $K_2Cr_2O_7$ effectively concentrates MAHs, PAHs and BN derived from BC. For $KMnO_4$, both techniques indicated that this reagent promotes the oxidation of carbohydrate products, mostly from degraded/microbial SOM but slightly oxidized lignocellulose and aromatic structures (pyrogenic and non-pyrogenic) not providing a good assessment of the BC signal.

Contrasting patterns of bacterial weathering of granite, granulite and gabbro from tropical regions of south India

R. SUBASHRI[1], J. K. DASH[2], S. BALAKRISHNAN[2]*, AND N. SAKTHIVEL[1]

[1]Department of Biotechnology, Pondicherry University,
[2] Department of Earth Sciences, Pondicherry University, Puducherry – 605014, India
(*correspondence: balakrishnan.srinivasan@gmail.com)

Bacterial weathering of various rock forming minerals have been studied in detail. Such studies on bulk rocks are essential to better understand bacterial weathering. Results of four different bacterial activity on three different rock types are presented.

Biotite granite, garnetiferrous felsic granulite and gabbro from tropical region of south India were collected and powdered to < 120 μm. The bacterial strains, RB 9, 15, 21 and 24, isolated from the rhizoplane of *Ficus* which grew on rocks were identified as *B. multivorans, C. malonaticus, E. aerogens* and *P. pleccoglossicida* respectively. They were grown for 28 days in a medium containing glucose and rock powder as the carbon and nutrient sources, respectively. Rock and abiotic controls were included. The residual pellets devoid of bacteria and other contaminants were analysed using XRD and ICP-MS.

Bacterial action on the biotite granite weathered biotites completely while microcline and albite were altered to varying degrees by different bacteria. All the major elements were depleted (30-50 %), while 25-40 % reduction of trace elements and REE were observed. P_2O_5 and Ni reduction varied with individual strains.

Felsic granulite showed removal of almandine garnet and reduction in albite and orthoclase to a larger extent. RB15 exerted moderate reduction (10-30 %) and did not fractionate major elements. Whereas, other bacteria showed considerable depletion of MgO (> 60 %). RB24 and RB25 were found to mobilise HREE (~ 30 %) while RB15 released relatively more Eu and trace element release was bacterial dependent.

The gabbro consisting of orthopyroxene, clinopyroxene and plagioclase did not show detectable change in the mineralogy. All the strains enriched Mn while RB9 depleted it. RB25 was found to enrich more HREE compared to LREE and Eu was depleted by RB9. Each bacteria followed unique patttern in release of trace elements.

Microbial weathering of granite, felsic granulite and gabbro show distinct patterns of minerological and chemical changes. Each bacterial strain had unique signature in altering the major and trace element abundances of a given rock.

LabData-GC: a database sub-system for post-processing and quality control of CFC and SF_6 measurements

AXEL SUCKOW[1]*

[1]CSIRO Land and Water, Urrbrae, SA 5064, Australia
(*correspondence: Axel.Suckow@csiro.au)
[2] National Centre for Groundwater Research and Training (NCGRT), Flinders University, Adelaide

Low-level gas-chromatography measurements, as they are needed for groundwater dating using CFCs and SF_6 often use commercial software for signal detection, peak detection and integration. The raw data and the parameters used during integration as well as the standards and blanks used to determine the absolute concentrations of unknown samples need to be stored for traceability of results.
A database sub-system to the LabData LIMS [1] is presented that covers:

1. storage of all raw data (signal versus time)
2. storage of parameters of peak integration
3. storage of all attribute data of the measurement (sample-ID, origin, project context etc.)

The corresponding graphical user interface and post-processing algorithms allow the calculation of absolute concentrations in water from

1. blank time series
2. sensitivity time series from standard measurements
3. linearity measurements (dependence of sensitivity from peak area)
4. graphical display of all relevant result by export to MS Excel

The database sub system is integrated in a multi-user client server architecture using MS SQL server as back-end and a graphical user interface based on MS Access. The existing modelling capabilities of age distributions using a lumped parameter approach are an add-on. The source code is public domain software and available under the GNU-GPL licence agreement.

Abiotic methane formation not from H_2 but from H_2O in the serpentinite-hosted Hakuba Happo hot spring

K. SUDA[1]*, Y. UENO[1,2] AND S. MARUYAMA[1,2]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Meguro, Tokyo, 152-8551, Japan (*correspondence: suda.k.ag@m.titech.ac.jp)
[2]Earth-Life Science Institute, Tokyo Institute of Technology, Meguro, Tokyo, 152-8551, Japan

Serpentinite-hosted hydrothermal system is considered to be important for prebiotic synthesis as well as habitat for the earliest life. Fluids derived from serpentinites are characterized by high concentrations of H_2 and CH_4 [e.g. 1]. It is generally assumed that the methane and hydrocarbons are produced abiotically from the H_2 and CO_2 via Fischer-Tropsch Type (FTT) synthesis [e.g. 1,2]. However, the production mechanism of the methane is not adequately understood yet. We report systematic isotopic study of a new serpentinite-hosted hydrothermal system: Hakuba Happo hot spring in the Shiroumadake area, Japan. The hot spring water was directly collected from 500-1000 m deep two drilling wells that show high pH over 10 and rich in H_2 and CH_4. The δD values of H_2 and H_2O from both wells are almost the same, whereas the δD-CH_4 values are different by approximately 80‰. The CH_4-H_2-H_2O hydrogen isotope systematics indicates at least two different mechanisms are required for the methane formation. The higher δD-CH_4 with respect to equilibrium relation is similar to other serpentinite-hosted system reported earlier and demonstrates that the source of hydrogen of CH_4 cannot be H_2 but directly derived from H_2O. This implies that the CH_4 is not produced via the FTT synthesis, but instead, likely produced by hydration reaction of olivine. On the other hand, lower δD-CH_4 with respect to equilibrium relation suggests incorporation of biological methane. Based on the comparison of δD systematics between our result and other serpentinite-hosted hydrothermal system, we suggest that dominant methane formation mechanism in a general serpentinite-hosted system is not FTT reaction. Hydration of olivine may play more significant role for abiotic methane production than previously thought.

Microbial synthesis of nanoparticles is an innovative process for precious metal recovery and preparation of nanocatalysts for transformation of environmental contaminants. Here, we report preparation of microbiologically synthesized palladium (Pd) nanoparticles (Bio-Pd) using *Clostridium* sp. BC1 [1] and microbial granules (MG) under fermentative growth conditions [Fig. 1]. Microbial granules were cultivated in bubble column sequencing batch reactors [2]. Reduction of dissolved Pd (II) to insoluble, black colored Pd (0) by BC1 or MG was instantaneous and complete. Removal of Pd (II) via sorption by BC1 or MG was negligible. Reduction of Pd (II) was mediated by the microbially generated hydrogen and the Pd (0) nanoparticles were predominantly associated with the bacterial cells or MG. The Bio-Pd catalysed the reduction of Cr (VI) to Cr (III) and the transformation of *p*-nitrophenol to *p*-aminophenol [Fig. 2]. Fermentatively produced hydrogen continued to act as the reducing agent for contaminant transformation. Our results demonstrate the potential use of MG for synthesis of Bio-Pd (0), Pd (II) recovery and efficient treatment of toxic contaminants in acidic environment. We also investigated the potential application of Bio-Pd in nitrate reduction.

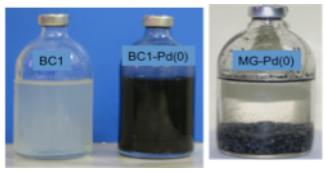

Fig 1. *Clostridium* sp. BC1 culture, Pd (0) nanoparticles associated with BC and microbial granules (MG).

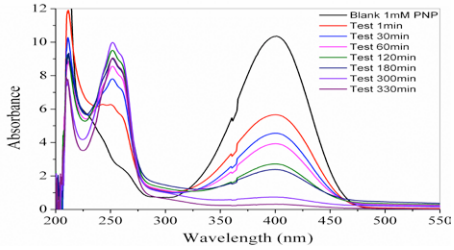

Fig 2. Bio-Pd mediated transformation of *p*-nitrophenol to *p*-aminophenol.

Effect of K_2O Addition on the Viscosity of $CaO\text{-}SiO_2\text{-}Al_2O_3$ Melt

S. SUKENAGA[1]*, T. HIGO[2], H. SHIBATA[1], N. SAITO[2] AND K. NAKASHIMA[2]

[1]IMRAM, Tohoku University,
(*correspondance: sukenaga@tagen.tohoku.ac.jp)
[2]Dept. Mater. Sci. & Eng., Kyushu University

In general, viscosity of silicate melts decreased with the addition of alkali oxides [1], which is due to the deplolymerization of the silicate anions. In the case of aluminosilicate melts, the viscosity depends on not only the polymerization degree but also the average bond strength of aluminosilicate framework [2]. Roy and Navrotosky [3] reported that the average bond strength of the aluminosilicate framework could be higher when cations with lower cationic field strength (such as K, Rb, Cs) were present. Therefore, the effect of K_2O on the viscosity of $CaO\text{-}SiO_2\text{-}Al_2O_3$ (CAS) melt was investigated to clarify relationship between the viscosity and cationic field strength using rotationg cylinder method.

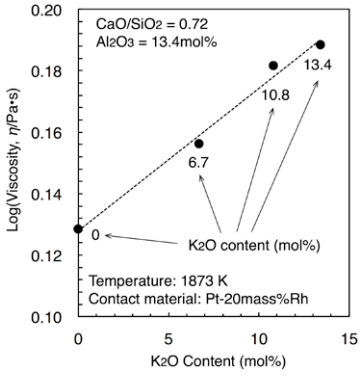

Figure 1: Effect of K_2O addition on the viscosity of the $36.1CaO\text{-}50.5SiO_2\text{-}13.4Al_2O_3$ (mol%) melt at 1873 K. CaO/SiO_2 ratio and Al_2O_3 content were kept constant.

Viscosity of the CAS melt increased with the increase of K_2O. On the other hand, the polymerization degree of aluminoslicate anions should be decreased. (Fig.1) This viscous behavior could be explained by an increase in the average bond strength of aluminosilicate framework with the addtion of K_2O.

Fluid flow and mineral reaction mechanisms at high pressures: Tauern window, Eastern Alps

MIROSLAV ŠULÁK[1]* AND DAVID DOLEJŠ[1]

[1]Institute of Petrology and Structural Geology, Charles University, 128 43 Praha 2, Czech Republic
(*correspondence: miroslav.sulak@natur.cuni.cz)

Aqueous fluids play major role as mass transport agents in the lithosphere but diverse approaches such as direct analysis of fluid inclusions, applications of transport theory to reaction progress, experimental mineral solubilities, time scales retrieved from isotopic tracers and microscale observations of dissolution-precipitation mechanisms still do not provide a self-consistent picture about the fluid flow mode and magnitude of intergrated fluid fluxes. We investi-gate synmetamorphic hydrothermal replacements, segrega-tions and veins developed in eclogites of the Tauern Window, Eastern Alps, as a model case study to address the conditions and modes of fluid flow and efficiency of fluid-mineral reactions at very high pressures (up to *c*. 610 °C, 21 kbar). These hydrothermal products record a continuous sequence from volume-conserved rock-buffered replacements to fluid-buffered precipitates in open space with unidirectional growth textures recording local anisotropic stress field at peak pressures. We observe: (1) quartz-kyanite-omphacite-rutile-clinozoisite multicomponent segregations indicating nearly congruent mass transport at local scale, controled by rheo-logical heterogeneities, where extraction volume for im-mobile elements (e.g., Ti) does not exceed 2-3 centimeter in size, (2) nearly monomineralic omphacite selvages recording focused fluid flow, (3) extensional quartz veins with euhedral omphacite crystals at the wall contact and (4) large transport veins composed of kyanite and quartz, showing little or no chemical exchange with wall rock. Chemical zoning patterns of garnet and omphacite are texture-independent and indicate local interconnectivity *via* the fluid phase, from low-permeable intergranular replacements to fluid-focusing chan-nels and transport veins. Oscilatory zoning patterns in vein omphacite and kyanite reflect pulsed flushing probably related to pressure fluctuations in crack-seal cycles. Modal variations interpreted by conventional transport theory would yield integrated fluid fluxes reaching *c*. 10^5 m^3 m^{-2} but these will not be required when considering coupling of diffusional and advective mass transfer driven by pressure gradients, where precipitation is controlled by distribution and size of permeability inhomogeneities vs. extensional cavities. The observed phenomena provide a cautionary example against simple inversions of reaction progress to flux estimates.

To investigate the hydrologic and landscape controls on shale weathering and their influence on first-order stream solute fluxes, we coupled a numerical chemical weathering model, WITCH, with a physically-based land surface hydrologic model, Flux-PIHM (Penn State Integrated Hydrologic Model). Using this approach, we were able to simulate vertical water and chemical fluxes across two representative landscape features (planar or swale hillslopes). We extrapolate the results from the soil profiles to estimate the chemical loads to the stream over a 32 year period (1980-2012) at the Susquehanna Shale Hills Critical Zone Observatory (SSH-CZ0). Observed soil water (10 cm increments) and stream water chemistry collected between 2006-2011 were used to validate the modelling results. The simulation predicted the saturation state of soil water with respect to illite, smectite and kaolinite. Saturation was driven by seasonal drying, with supersaturated conditions persistent around the rooting zone (25-70 cm) during the summer months. As expected, the modelled weathering rates of illite, chlorite and k-feldspar were elevated near the soil surface where fluids were dilute, especially at the onset of fall when solute fluxes (eg. Mg, Na and Si) reached their maximum. Results from Flux-PIHM suggest a more extensive hydrologic connection between the swale hillslopes and the stream as compared with the planar hillslopes. WITCH then documented the role of this hydrologic connection on the stream water chemistry, with swales contributing bigger solute fluxes.

Sediment phosphorus dynamics in a marine coastal lake: Response to seasonal bottom water anoxia

FATIMAH SULU-GAMBARI[1], DORINA SEITAJ[2], FILIP MEYSMAN[2] AND CAROLINE P. SLOMP[1]

[1]Utrecht University, Utrecht, the Netherlands
[2]NIOZ, Yerseke, the Netherlands

Low-oxygen conditions are expanding in bottom waters of many coastal systems. Increased availability of the nutrient phosphorus (P) is often important in the development and sustainment of hypoxia. However, the controls on the recycling and burial of P in hypoxic and anoxic marine settings are not well understood. Here, we present results of a detailed study of the sediment biogeochemistry and P dynamics at a site in the seasonally anoxic marine Lake Grevelingen, in the Netherlands. Monthly water column and pore water profiles of oxygen and sulphide for 2012 show a short (1 month) but intense period of bottom water anoxia. Strong seasonality in the pore water profiles of dissolved Fe^{2+} and phosphate is seen. In spring, when bottom waters were oxic, our pore water data indicate dissolution of iron sulfides and calcium carbonate due to activity of electrogenic bacteria [1]. Consequentially there is a strong release of Fe^{2+} to the pore water without an associated release of dissolved phosphate. In this period, most released phosphate remains in the sediment. Upon the onset of anoxia, phosphate release from the sediment to the water column is enhanced, both in absolute terms, when compared to the prior oxic period and relative to dissolved inorganic carbon (DIC) and ammonium. With the return of oxic conditions, Beggiatoa establish at the sediment-water interface and the benthic flux of phosphate is again reduced. Sediment P analyses indicate most P in the sediment is present in the form of organic- and iron-bound P, even at depths where sulphide is present at high concentrations throughout the year. This suggests the presence of a reduced Fe-P phase as found recently in euxinic sediments from the Baltic Sea [2]. Further work will focus on the identification of the sedimentary Fe-bound P forms and a reconstruction of the role of the sediment as a P source and sink over past decades.

Noble gas and halogen recycling at subduction zones

H. SUMINO*[1], M. KOBAYASHI[1], D. CHAVRIT[2], L. JEPSON[2], A. SHIMIZU[3], J.-I. KIMURA[4], R. BURGESS[2] AND C. J. BALLENTINE[2]

[1]GCRC, Univ. Tokyo, Tokyo 113-0033, Japan (*correspondence: sumino@eqchem.s.u-tokyo.ac.jp)
[2]SEAES, Univ. Manchester, Manchester M13 9PL, UK

[4]IFREE, Japan Agency for Marine-Earth Science and Technology, Yokosuka 237-0061, Japan

Recent findings of subducted halogens and noble gases with seawater and sedimentary pore-fluid signatures in exhumed mantle wedge peridotites [1], as well as seawater-derived heavy noble gases (Ar, Kr and Xe) in the convecting mantle [2], provide observations that allow us to investigate the processes that control the return of volatile and highly incompatible elements into the mantle. To verify whether and how such subduction fluids modify the composition of the mantle beneath subduction zones, we are investigating noble gas and halogen compositions of olivines and mantle-derived xenoliths in arc lavas from Western-Pacific subduction zones (Izu, Kamchatka and N. Philippines) and those of seafloor sediments and basalts from NW margin of the Pacific plate.

MORB-like $^{3}He/^{4}He$ and halogen ratios of the olivines indicate insignificant contributions to the arc magmas of radiogenic ^{4}He and pore-fluid-like halogens, both of which are observed in the subduction fluids released from a slab at a depth of 100 km [1]. In contrast, mantle-derived xenoliths exhibit pore-fluid-like halogens and heavy noble gases but MORB-like He. The high I/Cl ratios of pelagic clays and radiolarian cherts can account for the enrichment of iodine in subduction fluids relative to sedimentary pore-fluids [1], whereas contributions of halogens and noble gases from altered oceanic basalts are limited.

The significantly smaller contributions of subducted noble gas and halogen in the arc magmas relative to those in the mantle wedge peridotites may result from a difference in the P-T condition of the slab in each subduction zone, or from dilution by mantle-derived halogens and He when the subduction fluid induced partial melting. The former implies a relatively small amount of the pore water subduction fluids would be released from a cold slab at a sub-arc depth resulting in further subduction of halogens, heavy noble gases and potentially water, to great depths in the mantle.

Formation of Magnetite within aquifer sediments and its effects on Arsenic mobility

JING SUN[1]*, STEVEN CHILLRUD[2], BRIAN MAILLOUX[3] AND BENJAMIN BOSTICK[4]

[1]Columbia University, New York, U.S.A, jingsun@ldeo.columbia.edu
[2]Lamont-Doherty Earth Observatory, Palisades, U.S.A, chilli@ldeo.columbia.edu
[3]Barnard College, New York, U.S.A, bmaillou@barnard.edu
[4]Lamont-Doherty Earth Observatory, Palisades, U.S.A, bostick@ldeo.columbia.edu

One commonly attempted remediation approach for groundwater Arsenic (As) contamination involves stimulating iron (Fe) mineral transformations that affect aqueous As concentration. However, successful strategies are difficult to develop and implement, in part because many Fe minerals are only stable under a narrow window of redox conditions. Magnetite (Fe_3O_4) is a promising target mineral for As remediation due to its stablity over a wide range of Eh-pH conditions. Recent studies have found that magnetite is capable of retaining As through surface adsorption and also trapping arsenate As(V) into its structure. However, the factors that promote magnetite fromation and As incorporation and adsorption are poorly established.

Here, we did a series of columns, loaded with reduced aquifer sediments from the Dover Landfill Superfund site. We stimulated the formation of As-bearing magnetite, tested its ability of maintaining As retention and evaluated its capability of sequestering additional As. All columns were conducted at circumneutral pH, similar to site conditions but much lower than is normally considered ideal for magnetite formation. The columns were equilibrated with continuous oxygen-free artificial groundwater containing lactate and sodium arsenite As(III), during which As release was observed. Then sodium nitrate and ferrous sulfate were added to the same influent groundwater, which sequestered As on solids quickly and yielded considerable magnetite as suggested by magnetic separations of a sacrifised column. (Synchrotron X-ray absorption spectroscopy as well as sequential extraction will be used to identify and quantify solid-phase Fe and As speciation). These amended columns were able to maintain low aqueous As concentrations even when influent groundwater with high lactate concentration (and no As) were introduced to encourage reduction and also able to continue to retain As after subsequent arsenite and lactate additions.

Porphyry deposits and oxidized magmas

WEIDONG SUN[1], HUAYING LIANG[1], MING-XING LING[1], HONG ZHANG[2] AND XIAO-YONG YANG[3]

[1]Guangzhou Institute of Geochemistry, CAS, Guangzhou 510640, China (weidongsun@gig.ac.cn)
[2]Northwest University, Xi'an 710069, China
[3]University of Science and Technology of China, Hefei 230026, China

Porphyry deposits supply most of the world's Cu, Mo resources. Here we show that all the porphyry deposits are associated with oxidizing magmas. Oxidation promotes the destruction of sulfides in the magma source and thereby increases initial chalcophile element concentrations[1,2]. Sulfide remains undersaturated during the evolution of oxidized sulfur-enriched magmas where sulfate is the dominant sulfur species, leading to high chalcophile element concentrations in evolved magmas. The final porphyry mineralization is controlled by sulfate reduction, which starts with magnetite crystallization, accompanied by decreasing pH and correspondingly increasing fO_2. Hematite forms once sulfate reduction lowered the pH sufficiently and the fO_2 reaches the hematite–magnetite oxygen fugacity buffer, which in turn increases the pH for a given fO_2. In addition to the oxidation of ferrous iron during the crystallization of magnetite and hematite, reducing wallrocks may also contribute to sulfate reduction and mineralization. For porphyry Cu deposits, slab melts (adakite) characterized by high Sr/Y is another controlling factor. Subduction of young ridge forms adakites with high fugacity, such that is the best geological process for porphyry Cu deposits[3,4]. Mo deposits are likely related to Mo-enriched metasediments.

The global flux of calcium into and out of marine sediments

XIAOLE SUN[1]* AND ALEXANDRA V. TURCHYN[1]

[1]Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK, xs243@cam.ac.uk (*presenting author)

Fundamental to understanding Earth's climate is an understanding of the removal of carbon from the surface into the rock reservoir. This removal of carbon is achieved through burial of carbon-bearing minerals, both carbonate and organic carbon, in marine sediments. Much of the organic carbon buried in marine sediments is oxidized back to inorganic carbon, which may react with subsurface calcium to precipitate authigenic carbonate, or may return via diffusion to the overlying ocean. The precipitation of authigenic carbonate has recently been invoked as a critical process in the long-term carbon cycle[1].

We use a compilation of 674 pore fluid profiles acquired through the various drilling programs to calculate the flux of aqueous calcium across the sediment-water interface. In coastal regions and other areas of high organic-carbon supply to marine sediments, we calculate a flux of calcium into marine sediments; this calcium consumption is linked to the production of *insitu* authigenic carbonate. Parts of the ocean are dominated by a flux of calcium out of marine sediments, where calcium is produced in the subsurface through carbonate recrystallization, ion exchange, alteration of volcanic ash, or rarely subsurface gypsum dissolution. Our compilation suggests regional heterogeneity in the subsurface calcium (and carbon) cycle, as well as a global flux of calcium between the ocean and marine sediments that is significant in the global calcium cycle.

Kerogen-generated bitumen as a source of shale gas: Experimental results and mass balance calculation

YONGGE SUN AND LIUJUE XIE

Department of Earth Science, Zhejiang University, Hangzhou 310027, P. R. China. Email: ygsun@zju.edu.cn

It is well known that most of shale gases discovered to date are thermogenetic within the late phase of hydrocarbon generation. This phenomenon was brought into questions with the fact that there is less gas potential of kerogen-cracking throughout the oil & gas window for most type I and II kerogens. Using a high pressure, semi-closed pyrolysis system, one shale from the Songliao basin, NE China with a TOC of 3.29% was selected to probe the gas generation processes throughout the oil & gas window. The results showed that there are at least two processes involved for the gas generation, which were characterized by distinctive characters of dryness ($C_1/\sum C_{1\text{-}5}$) and $\delta^{13}C_{methane}$. The first one is associated with kerogen thermal degradation and occurs at the main phase of oil generation. The second starts at the late phase of oil generation with a decrease of dryness and 13C depleted methane, which is in contrast to the theoretical prediction as the increasing trend of dryness and $\delta^{13}C_{methane}$ accompanying thermal evolution. It suggests that this process should be mainly related to the cracking of kerogen-generated products retained in shale due to the lack of aliphatic carbon in kerogen at this stage, as evidenced by FTIR and curie Py-GC-MS analyses. A rapid decreasing of polar fraction in retained bitumen could be another indicator of the process. Mass balance calculation using hydrogen content demonstrated that bitumen retained in this shale can contribute 2-3m^3HC gas/ t rock to shale gas during the stage of 1.3-1.7%*R*o and has implications for maturity map-making and shale gas resource assessments before exploration.

Phytoremediation for co-contaminated soils of polycyclic aromatic hydrocarbons and cadmium using willow

Y.Y. SUN[1], H.X. XU[1]*, J.H. LI[2], J.C. WU[1]

[1]School of Earth Science and Engineering, Nanjing University, Nanjing 210093, China (sunyy@nju.edu.cn, *correspondence: hxxu@nju.edu.cn, jcwu@nju.edu.cn)

[2]Jiangsu Maritime Safety Administrations, Nanjing 210003, China (huadavid2002@163.com)

To investigate the effect of PAHs on the cadmium (Cd) phytoremediation efficiency using willow, field experiments were conducted in the lower reaches of the Yangtze River, China. Based on our previous study, an native willow (*Salix×aureo-pendula* CL 'J1011') was selected, owing to its easy propagation, fast growth, extensive root system, toleration of temporarily waterlogged environments, etc. Results showed that the growth of willow was negatively affected by PAHs (phenanthrene and pyrene) and Cd. The amendment of ethylenediaminetetraacetic acid (EDTA) and ethyl lactate could not only increase the accumulation of Cd in willow tissues, but also promote the degradation of PAHs. After 45 days, the combined treatment willow-EDTA and willow-EDTA-ethyl lactate significantly decreased the concentrations of PAHs and Cd in the soils ($p < 0.05$). Willow could also accumulate phenanthrene (PHE) in tissues, while accumulation of Cd in plants was much higher than that of PHE. The effectiveness of pyrene (PYR) absorption in willow was very week and there was no detectable PYR in willow shoots. Under the same treatment, the presence of PAHs increased the Cd accumulation in willow shoots, especially for treatment willow-EDTA, while it had no significant influence on the removal of Cd from soils ($p > 0.05$). The results indicate that the native willow *Salix×aureo-pendula* CL 'J1011' together with EDTA and ethyl lactate could be used for phytoremediation of PAHs-Cd co-contaminated soils.

Chemical and bacteria leaching of a low-grade and high-fluorine uranium ore in column reactors

ZHANXUE SUN*, YAJIE LIU, JIANG LI, XUELI LI AND WEIJUN SHI

East China Institute of Technology, Nanchang, Jiangxi 330013, China (*Correspondence: zhxsun@ecit.cn)

The purpose of the Study and Mineralogy

The purpose of the study is to investigate the technical feasibility of using bioleaching on a low-grade and high-fluorine uranium ore from China, which is not economically exploitable with conventional technologies. The ore contains 0.19% uranium and 1.0% fluorine. Uranium is present primarily as pitchblende and secondarily as coffinite and infrequently as brannerite and uranothorite.

Column Bioleaching Experiments

52-day column bioleaching experiment was conducted with finely ground ore (−0.8 mm) at ambient temperature to study the effect of bacteria on uranium extraction. For the sake of contrast, column chemical leaching experiment was also conducted at same time. The chemical leaching experiment used only sulfuric acid, but the bacteria leaching experiment used sulfuric acid and A. ferrooxidans as well.

Results

The leaching rate of U is 91.8% for the bacteria leaching experiment and is only 78.5% for the chemical leaching experiment. The sulfuric acid consumption is 4.73% and 4.97% for bacteria leaching and for chemical leaching respectively. The microorganism used in the bioleaching test resisted high concentration of total fluorine ranging from 1.8g/L to 2.0g/L in the leachate. The experiments suggested the feasibility of bioleaching for extraction uranium from this kind of uranium ore.

This work was financially supported by International Science and Technology Cooperation Project of China (2011DFR60830) .

Flow dynamics and $^{3}H/^{3}He$ ages of deep groundwater at Gardermoen (Oslo Airport, Norway)

A. SUNDAL[1]*, P. AAGARD[1], B. WEJDEN[2] AND M.S. BRENNWALD[3]

[1]Dep. of Geosciences, University of Oslo, Norway *Corresponding author: anja.sundal@geo.uio.no

[2]Oslo Airport, Water and Soil Dep., Gardermoen, Norway

[3]Eawag, Dep. of Water Resources and Drinking Water, Swiss Federal Institute of Aquatic Science and Technology, Switzerland

Sandy, quaternary, deposits at Gardermoen constitue the central part of Norway's largest unconfined aquifer. The steady influx of temperate, nutrient rich groundwater is essential for ecology and geomorphology of local conservation areas. The establishment of Oslo Airport (OSL) at Gardermoen in 1998 was therefore approved by the authorities on the condition that the groundwater quality would not be deteriorated. Extensive, continuous monitoring of groundwater quality and fluxes is performed at OSL and numerous research projects have been carried out. Knowledge about the deeper parts of the aquifer, however, is limited.

The total water balance in the study area is well constrained. The sandy deposits form a ridge, with relatively permeable sediments in the North-East and decreasing permeability towards the South-West. The aquifer is solely precipitation fed (40 cm/a net recharge). The groundwater flow is directed towards the North-East (80% of flux) and South-West (20% of flux), away from a crescent shaped groundwater divide and into the effluent rivers Risa and Sogna.

In this study water samples from 20 wells (1.5 – 30m below phreatic groundwater table) have been analyzed for major ions, ^{3}H and noble gases (He, Ne, Ar, Kr, Xe). The tritium concentrations range from 8–52 TU and the $^{3}H/^{3}He$ water ages from 1.5–53 years. The water ages generally increase with depth and distance from the groundwater divide. The hydraulic head in some wells deviates from hydrostatic conditions due to underpressure in lower (semi-) confined units. Using water ages in multi-level wells for calibration of flow models (2D grid sections), we investigate different scenarios with respect to flow separation and vertical flow components due to geological heterogeneities. Using ionic content and water ages as tracers is complicated by indication of mixing with fossil seawater (9.5 ka BP) from basal silt deposits.

Interactions between As(V), Fe(III) and natural organic matter

A. SUNDMAN*, T. KARLSSON AND P. PERSSON

Department of Chemistry, Umeå University, SE-901 87 Umeå, Sweden (*Correspondance: anneli.sundman@chem.umu.se, torbjorn.karlsson@chem.umu.se, per.persson@chem.umu.se)

As is naturally occuring mainly as solid $FeAs_xS_{2-x}$ and as adsorbed species on Fe and Al hydroxides, but it is also found associated with natural organic matter (NOM) [1]. Under oxic conditions, it has been hypothesized that, ternary complexes of As(V), Fe(III) and NOM are formed and that these play a key role in As biogeochemistry. Recently, spectroscopic evidence for the formation of these complexes in peat humic substances was published [2]. We have further investigated the fundamental properties of the interactions between As(V), Fe(III) and NOM. The experimental range covers different kinds of NOM, concentrations between 6485 and 67 243 ppm Fe, pH 3-7 and Fe(III) to As(V) ratios between 0.5 and 100. Synchrotron based Fe and As K-edge extended X-ray absorption fine structure (EXAFS) spectroscopy in combination with infrared (IR) spectroscopy have been used as molecular probes.

Results and Discussion

The NOM suppressive effect on Fe precipitation [3] is reduced in the prescence of As(V). At low pH and Fe concentration, the Fe EXAFS spectrum resembles Fe-NOM reference samples (see Figure 1). At higher Fe concentrations, i.e. 22 916 ppm Fe (or 0.085 mol Fe per mol of carboxylic functional groups), Fe(III):As(V) 1:1 quantitative Fe EXAFS results indicate a precipitated $FeAsO_4$ phase. As EXAFS and IR data provide further support for these findings. They indicate precipitated $FeAsO_4$ at high pH and fractions of soluble, unbound $H_2AsO_4^-$ at low pH.

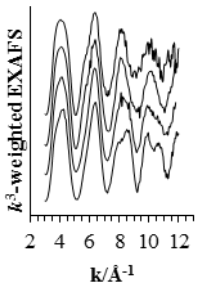

Figure 1. Fe EXAFS data for Suwannee River NOM samples, a) 6489 ppm Fe, pH 5.0, b) 6485 ppm Fe, Fe(III):As(V) 1:1, pH 5.0, c) 22 916 ppm Fe, Fe(III):As(V) 1:1, pH 5.3 and d) precipitated $FeAsO_4$.

Coupled radiogenic and stable Sr isotope variations in oceanic basalts

CHELSEA N SUTCLIFFE[1]*, KEVIN W BURTON[2], IAN J PARKINSON[3], DON PORCELLI[1] AND ALEX N HALLIDAY.[1]

[1] Department of Earth Sciences, University of Oxford, Oxford, UK. (* presenting author; chelsea.sutcliffe@st-annes.ox.ac.uk)

[2] Department of Earth Sciences, Durham University, Durham, UK.

[3] Bristol Isotope Group, School of Earth Sciences, University of Bristol.

The formation of basaltic crust at mid-ocean ridges and ocean islands provides a window into the compositional variations in Earth's upper mantle. If basalts are in equilibrium with their mantle source, then the composition of long-lived radiogenic isotopes should be identical and unaffected by partial melting or magmatic processes. Consequently, variations in the isotope composition of Sr, Nd and Pb of oceanic basalts are usually attributed to the existence of compositional heterogeneity in the mantle. In contrast, stable isotope variations can arise from mass dependent processes including partial melting, diffusional exchange or fractional crystallisation [1]. Taken together, radiogenic and stable isotopes can be used to unravel source variations from melting and magmatic processes [2].

Radiogenic Sr ($^{87}Sr/^{86}Sr$) is a widely used tracer of mantle chemistry and when paired with stable Sr ($^{88}Sr/^{86}Sr$) offers a unique opportunity to trace melt compositions. Moreover, using the double spike-TIMS technique, both radiogenic and stable isotopes can be measured to a high precision. However, to date there is little precise data for the stable $^{88}Sr/^{86}Sr$ composition of mantle melts and variations cannot be detected at the precisions of existing studies [3]. This study presents high precision DS-TIMS $^{87}Sr/^{86}Sr$ and $^{88}Sr/^{86}Sr$ data for a geographically widespread suite of young MORBs and OIBs, including MORBs from the FAMOUS ridge section. Resolvable variations in $\delta^{88}Sr$ of ~0.14‰ are found for MORB and within the FAMOUS segment. In contrast, OIB possess a relatively restricted range of compositions from $\delta^{88}Sr$ =+ 0.224 ± 0.008 to + 0.280 ± 0.008 ‰. The extent to which coupled $^{87}Sr/^{86}Sr$ and $^{88}Sr/^{86}Sr$ data can be used to disentangle source heterogeneity from variations due to the effects of partial melting and magmatic processes will be discussed, as well as reasons accounting for differences in the trends seen between MORB and OIB.

Terrestrial $\Delta^{33}S$ and the S cycle during the Archean: Evidence from paleosols

SALLY J. SUTTON[1], J BARRY MAYNARD[2], DOUGLAS RUMBLE III[3] AND ANDREY BEKKER[4]

[1]Department of Geosciences, Colorado State University, Fort Collins CO 80523-1482 USA, ssutton@mail.colostate.edu
[2]Department of Geology, University of Cincinnati, Cincinnati OH 45221-0013 USA, maynarjb@gmail.com
[3]Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch Rd., NW, Washington, D.C., 20015-1305 USA, rumble@gl.ciw.edu
[4]Department of Geological Sciences, University of Manitoba, 125 Dysart Road, Winnipeg, MB R3T 2N2 Canada, bekker@cc.umanitoba.ca

Determination of multiple sulfur isotopes in Archean paleosols and diamictites shows the widespread presence of mass-independently fractionated S in the regolith developed on the pre-2.5 Ga Earth. All values of $\Delta^{33}S$ are negative, indicating that the Archean surface environments incorporated atmospheric S as SO_4^{2-}, which carried a negative $\Delta^{33}S$ signal. This S was subsequently converted to sulfide by sulfate reduction, most likely bacterial with terrestrial organic matter as a reductant. Pyrite with similar S isotope systematics has been reported from flood-plain deposits. Grains from these two sources were recycled into detrital pyrites now found in sandstones and conglomerates deposited before the rise of atmospheric oxygen. We suggest that atmospherically-generated S8 was not similarly contained on the continents, rather was lost to the oceans, creating a continental S reservoir with dominantly negative $\Delta^{33}S$ values and a predominantly positive S reservoir in marine sediments.

High Energy Synchrotron X-ray Geochemical Probes

S.R. SUTTON[1,2], M. NEWVILLE[2], A. LANZIROTTI[2], M.L. RIVERS[1,2] AND S. WIRICK[2]

[1]Department of Geophysical Sciences
[2]Center for Advanced Radiation Sources (CARS) University of Chicago, Chicago, IL USA [sutton@cars.uchicago.edu]

High energy synchrotron facilities produce x-radiation with high brightness making them extremely powerful tools for a wide variety of spatially-resolved geochemical research. The primary techniques, X-ray fluorescence (XRF) analysis, X-ray absorption fine structure (XAFS) spectroscopy, X-ray diffraction (XRD) and computed tomography (CT), are used to determine properties of earth, environmental and planetary materials including chemical and mineralogical compositions, crystallographic and other physical structures, oxidation states and fluid flow characteristics.

These X-ray probes are common instruments at virtually every synchrotron facility, are highly complementary in their capabilities and are typically heavily oversubscribed. Analyses at various spatial scales are required for this research necessitating the availability of a suite of instruments each optimized for analyses at different scales.

Focused X-ray beams can be produced using techniques that rely on collimation, refraction, diffraction, or reflection. The most common devices found in synchrotron X-ray probes are those based on diffraction or reflection. Flood-field modes are also utilized where high spatial resolution is achieved via the detection components. “Fly-scanning” approaches have greatly reduced mapping times.

Research using these X-ray probes has led to important insights into the geochemistry of toxic metals and metalloids in contaminated sediments and tailings, the efficiencies of contaminant remediation strategies, how bio-accumulation processes affect the distribution of trace toxic metal species and manufactured nanoparticles in soils and organisms, flow properties of porous media and valence states of multivalent elements in igneous materials, for example.

This presentation will describe currently operating instruments and recent experiments at some US synchrotron facilities, primarily at the Advanced Photon Source (APS, Argonne National Laboratory, IL USA), as well as new, advanced capabilities soon to be available at the National Synchrotron Light Source (NSLS-II, Brookhaven National Laboratory, NY USA).

Formation of glycine from carboxylic acid and ammonia by shock conditions: Implication to chemical evolution in primitive oceans

C. SUZUKI[1]*, Y. FURUKAWA[1], T. KOBAYASHI[2], T. SEKINE[3] AND T. KAKEGAWA[1]

[1]Graduate School of Science, Tohoku University, Japan (*correspondence: b2sm6018@s.tohoku.ac.jp)
[2]National Institute for Materials Science, Japan
[3]Graduate School of Science, Hiroshima University, Japan

Origins of amino acids on the early Earth have been debated by many investigators. Previous literatures indicate that intensive impacts of extraterrestrial objects had occurred during 3.8-4.0 billion years ago. These impacts seem to have delivered and produced prebiotic organic compounds including amino acids, amines and carboxylic acids as well as ammonia [1, 2]. However, the variety of biomolecules experimentally formed in the simulation of these processes was limited compared with that of the protein-constituent amino acids. In this study, we focused on the low-molecular-weight organic compounds (LOC) such as amines and carboxylic acids supplied by one impact process. LOC must have experienced further shock wave due to successive impacts in oceans. We demonstrated impact experiments on a solution of formic acid and ammonia to investigate whether amino acids form from LOC by oceanic impacts on the early Earth.

Shock-recovery experiments were performed with a single-stage propellant gun using an sample container. Starting material is a mixture of ^{13}C-formic acid and ammonia. After the impact experiments, soluble organic compounds were extracted into water. Then amines and amino acids were analyzed with liquid chromatography-mass spectrometty. Glycine, methylamine and ethylamine whose carbons are composed of ^{13}C were identified in all of the samples. The amounts of glycine were almost constant regardless of the impact velocity (0.7-0.8 km/s). The amounts of produced amines increased depending on the impact velocity. These results suggest that shock wave converts a LOC into larger-molecular-weight organic compounds including an amino aicd. The successive impacts might have contributed to chemical evolution providing variety in biomolecules on the prebiotic Earth.

[4]Waseda University, Tokyo, Japan, (izasaya@ruri.waseda.jp)
[5]Waseda University, Tokyo, Japan, (owadas@waseda.jp)

This study investigated removal mechanisms of silicate in the wastewater using aluminum hydroxide coprecipitation method. To investigate detailed silicate uptake mechanism during coprecipitation with aluminum hydroxide, adsorption process and coprecipitation process were distinguished exactly in this study [1].

In adsorption experiment, aluminum hydroxide was previously prepared at pH 9 and combined with silicate solution while pH was strictly controled at pH 9. All sorption isotherms of silicate in adsorption experiments indicated BET like unsaturation type. Especially, dominant removal mechanisms changed from simple layer adsorption to another sorption phenomena, which was equivalent to multi-layer adsorption when Si/Al molar ratio was 2–5. XRD analysis represented the precipitation of kaolinite, which suggested that silicate uptake during adsorption experiment using aluminum hydroxide consisted of two kinds of mechamisms; one was surface complexation of silicate with aluminum hydroxide and another was precipitation of kaolinite. Results from zeta potential measurement and FT-IR analysis supported these suggestion about silicate uptake mechanism. However, in adsorption experiments, residual concentration of silicate in solution was higher than calculated value from chemical equilibrium of kaolinite precipitation. This results suggested dissolution of aluminum hydroxide to precipitate kaolinite required substantial time.

On the other hand, in coprecipitation experiments, alkaline solution consisted of aluminum and silicate ions was prepared and pH was dropped to 9. In this case, residual silicate concentration gave close aggrement with calculated value from chemical equilibrium of kaolinite precipitation. This results suggested coprecipitation process was more appropriate for silicate remival than adsoprtion process because kaolinite could precipitate rapidly.

Immobilization of selenium by biofilms of *Shewanella putrefaciens*

Y. SUZUKI[1]*, H. SAIKI[1], A. KITAMURA[2], AND H. YOSHIKAWA[2]

[1] Graduate School of Bionics, Tokyo University of Technology, 1404-1 Katakura-cho, Hachioji, Tokyo 192-0982, Japan (*correspondence: yosuzuki@stf.teu.ac.jp)

[2]Geological Isolation Research and Development Directorate, Japan Atomic Energy Agency, 4-33 Muramatsu, Tokai, Naka, Ibaraki 319-1194, Japan

The microbial reduction of the selenite and selenate has been widely studied using planktonic bacteria. Although bacteria are predominantly found within surface-associated cell assemblages, or biofilms in natural settings, there are little information on the interaction between biofilms and selenium. In this study, biofilms of *Shewanella putrefaciens*, which is an iron-reducing bacteria, were formed and their structure was investigated by a confocal laser scanning microscopy (CLMS). Then reduction of selenite by the biofilms was examined.

Biofilms of *S. putrefaciens* were made on circular cover glasses. Formation of biofilms was observed by CLMS. To investigate the reduction of selenite by the biofilms, a solution containing 100 μM sodium selenite as an electron acceptor, 20 mM sodium lactate as an electron donor was added to the biofilms under an anaerobic condition. After 34 h, the selenium concentration in the solution was measured by ICP-AES. Se K-edge XANES spectra of the precipitates appeared on the biofilms were measured at the Beamline 12C, Photon Factory, KEK (Tsukuba, Japan).

The CLMS observation revealed that thickness of the biofilms was about 10-20 μm and the cells were heterogeneously distributed in the biofilms. After 34 h incubation of the biofilms with selenite, the red precipitates were observed at the place where the biofilms were formed. The precipitates were not dissociated from the biofilms by washing with a deionized water indicating that they associated tightly with the biofilms. The selenium concentration in the solution was under detection limit. The Se K-edge XANES spectrum of the red precipitates showed that they were elemental selenium. These results suggest that the biofilms with iron-reducing bacteria in the environment can strongly immobilize the selenium on the biofilms through selenite reduction to elemental selenium.

Prediction of Surface Organic Species at the Mineral-Water Interface vs. Spectroscopy

D.A. SVERJENSKY[1]

[1]Johns Hopkins University, Baltimore, MD 21218, USA (*correspondence: cestrada@jhu.edu, sver@jhu.edu)

Surface complexation models have been widely used to model adsorption data for organic species at the mineral-water interface. However, the goal of developing truly predictive models in which the number of surface species, the nature of the surface species attachments and the variations of the proportions of the surface species as functions of environmental conditions such as pH, ionic strength and surface loading has not been reached. Recent advances in the theory and application of the extended triple-layer model (ETLM), in particular taking into account the electrical work associated with desorption of chemisorbed water molecules released during the formation of inner-sphere attachments [1] have enabled substantial progress.

For example, when the ETLM is applied to batch adsorption data referring to a wide range of environmental conditions, typically only a few reaction stoichiometries are able to fit the data. This is in marked contrast to more traditional surface complexation models that lead to highly ambiguous results. From the reaction stoichiometries, model surface species can be inferred. However, few direct *in situ* tests of such results are available. In the present study, two direct tests are described involving experimental adsorption data for the amino acids glutamate and dihydroxyphenylalanine (DOPA) on titanium dioxide. The predicted glutamate surface species and their behavior established using the ETLM [2] were tested with ATR-FTIR spectroscopy and quantum chemical calculations [3]. For DOPA the ETLM results [4] were tested with surface enhanced Raman spectroscopy (SERS) [5]. Excellent agreement is obtained between the number of surface species, the nature of their attachment to the surface and the dependence of the surface speciation on environmental conditions.

Catalytic Structure of the Hammerhead Ribozyme in a Clay Mineral Environment

JACOB B. SWADLING[1], JAMES L. SUTER[1], DAVID W. WRIGHT[1] AND PETER V. COVENEY[1] .

[1]Department of Chemistry, University College London, London, WC1H 0AJ.

The hammerhead ribozyme is an RNA molecule that performs self cleavage as part of a replicative cycle [1]. We use the enhanced sampling of replica exchange molecular dynamics (REMD) performed on petascale computers to study the folding pathway and the catalytically active structure of the full-length hammerhead ribozyme in both aqueous solution and a clay mineral environment. We simulated 100 replicas of each system producing a total of 10 μs of fully atomistic molecular dynamics simulation. Our aim was to understand the solution structure, dynamics and mechanism of the ribozyme in order to resolve hitherto open questions related to the catalytic activity of the ribozyme including the role of metal ions in mediating the reaction and to asses the effect the mineral environment has on the catalytic activity.

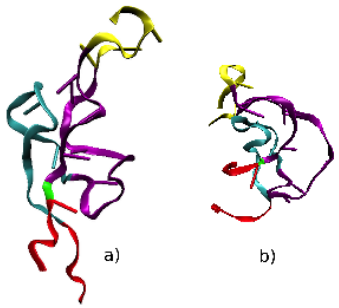

Figure 1. The dominant principal component (PC1) projected

The dominant mode of motion is a junction-bend Figure 1, which alters the availability of the catalytically competent conformations of the active site. We have characterized a set of highly populated structures that reveal a pathway to the native catalytically active site. We show how the montmorillonite clay environment significantly alters the structure and kinetics of the hammerhead ribozyme and discuss the implications this has on the RNA world [2].

^{10}Be derived catchment denudation rates from the Garhwal Himalaya

ZACHARY SWANDER[1], ANTHONY DOSSETO[1], DAVID FINK[3], JAN HENDRIK MAY[1] AND OLIVER KORUP[3]

[1]Wollongong Isotope Geochronology Lab, University of Wollongong, NSW, Australia (*correspondence to zjs785@uow.edu.au)

[2]Australian Nuclear Science & Technology Organization, Lucas Heights, NSW, Australia

[3]Institute of Earth & Environmental Science, University of Potsdam, Potsdam, Germany.

Despite numerous Quaternary paleoclimatic resconstructions based on stable isotope records from ice core, speleothems, etc., relatively little is known about the climatic influence on terrestrial landscape processes beyond the Last Glacial Maximum (LGM). Specifically, how will changes in temperature and precipitation affect erosion rates on orbital and sub-orbital timescales? To address this question, we are measuring the concentration of *in situ* ^{10}Be, in 15 independently dated Himalayan alluvial terrace samples[1], to quantify paleo denudation rates over the past 50ka.

Within the montane landscape of the Garhwal Himalaya, the Alaknanda River endures extreme monsoon precipitation that totals greater than 2,000mm·a^{-1} at orographic foci. The intensity of such extreme hydrologic conditions have varied spatially and through time, which should exhibit a quantifiable effect on integrated catchment erosion rates.

This research follows in the fundamental footsteps of Bierman & Steig[2] and Schaller *et al*.[3] who first utilized ^{10}Be in deciphering paleo-erosion rates from European terrace alluvium. Erosion rates are derived from the inherited TCR concentration integrated over the upstream catchment area and the, which incorporates time spent within the weathering profile, during transit and all other time before compete shielding. When measuring ^{10}Be within shielded alluvium, subsequent erosion rates may be inferred from the time of burial.

By studying how catchment wide average denudation rates have varied across the LGM transition and correlating this to regional paleoclimatic records; we will be able to quantitaviely assess how erosion in the the Himalayan respond to climatic variability. Thus providing geochemically derived evidence linking climatic variability with the geomorphic evolution of Himalayan landscapes.

The quantitative contribution of oxygenic photosynthesis to Fe(II) oxidation in Precambrian oceans

ELIZABETH D. SWANNER[1]*, WENFANG WU[1,2], BETTINA VOELKER[3], RONNY SCHOENBERG[1] AND ANDREAS KAPPLER[1]

[1]Department of Geoscience, University of Tuebingen, Germany, *elizabeth.swanner@ifg.uni-tuebingen.de

[3]Department of Chemistry and Geochemistry, Colorado School of Mines, USA

Evidence for oxidation of Fe(II) and deposition of Fe(III)-bearing minerals in anoxic or stratified Precambrian oceans has received support from decades of sedimentological and geochemical investigation of Banded Iron Formations (BIF). However, the exact mechanisms by which Fe(II) was oxidized and stabilized in anoxic sediments remain equivocal. The oxidation of Fe(II) by abiotic reaction with O_2 produced by oxygenic photosynthetic cyanobacteria is consistent with evidence for an iron chemocline in some Precambrian BIF basins. However, if oxygenic photosynthesis oxidized Fe in the Archean, O_2 release to the atmosphere must have been minimal, consistent with geochemical evidence for an anoxic atmosphere prior to 2.3 Ga.

We evaluate the hypothesis that Fe(II) oxidation and deposition was mediated by O_2 with laboratory experiments using *Synechococcus* PCC 7002 to represent an early marine cyanobacterium [1]. Our initial results confirm that this strain can grow in Fe(II) concentrations up to 5 mM. The kinetics of Fe(II) oxidation are consistent with an abiotic reaction between Fe(II) and O_2 and not via direct use of electrons from Fe(II) in photosynthesis. We also measured the isotopic fractionation factor between aqueous Fe(II) and precipitated Fe(III) during growth of *Synechococcus* PCC 7002 with Fe(II), which is similar to fractionation factors in abiotic experiments. Microscopic and spectroscopic analysis of the cell-mineral aggregates also inform the location of Fe(II) oxidation and the speciation, mineralogy and spatial relationship of iron to carbon in the resulting precipitates. Our efforts are now focused on quantifying the rates of O_2 production and Fe deposition in a laboratory-scale model of a ferruginous water column where Fe(II) upwells into an engineered photic zone. Our intent is that these results will provide a mechanistic and quantitative framework for evaluating the geochemical consequences of perhaps life's greatest metabolic innovation.

Size-dependent reactivity of magnetite nanoparticles: A bridge between lab and field investigations

A.L. SWINDLE[1]*, A.S. MADDEN[1] AND I.M. COZZARELLI[2]

[1]University of Oklahoma, Norman, OK (*correspondance: aswindle@ou.edu, amadden@ou.edu)
[2]US Geological Survey, Reston, VA (icozzare@usgs.gov)

Research on nanoparticles has exploded in recent years as we have begun to understand the extensive role these materials play in natural systems as well as their potential benefits and risks to human society. However, the very nature of nanoparticles makes them challenging to study, particularly in a field setting. As a result, many questions remain to be to answered concerning how nanoparticles behave in a natural environment and how accurately laboratory results reflect reactions that occur in the field.

In this investigation magnetite nanoparticles with average diameters of 6 nm, 44 nm and 90 nm were synthesized and throughly characterized. The nanoparticles were emplaced in the anoxic groundwater zone of the leachate plume in the subsurface of the USGS Norman Landfill Site with custom-built TEM grid-holders. Laboratory analog experiments were also conducted using nanoparticles and synthetic groundwater modeled on the chemistry of the groundwater from the landfill site, but omitted DOC. Finally, a series of magnetite-chromate adsorption experiments was conducted with varying amounts of DOC added to investigate the impact of organics on the surface reactivity of the magnetite nanoparticles.

The field investigation revealed that a thin coating of organics developed on the particles surfaces that occluded the particles from the groundwater and inhibited dissolution. This is supported by geochemical models indicating that magnetite is not thermodynamically stable under the given chemical conditions and by the laboratory analogs which provided evidence of magnetite dissolution in the absence of organics. The chromate adsorption experiments showed that DOC concentrations as low as 1 mg/L can impact the surface reactivity of magnetite even when an excess of mineral surface area is present.

The results of this investigation revealed that under the field conditions, magnetite dissolution decreased as particle size decreased, while this trend was reversed in the laboratory experiments. Adsorption experiments indicate that this reversal is likely due to dissolved and particulate organics. Together, these experiments show that organics play a significant role in the surface reactivity of nanoscale minerals and remain integrally important to understanding the environmental fate of nanomaterials.

U/Pb zircon age of Mistastin Lake crater, Labrador, Canada – implications for high-precision dating of small impact melt sheets and the end Eocene extinction

PAUL J. SYLVESTER[1], JAMES L. CROWLEY[2] AND MARK D. SCHMITZ[2]

[1]Department of Earth Sciences, Alexander Murray Building, Memorial University, St John's NL A1B 3X5 Canada
[2]Department of Geosciences, 1910 University Drive, Boise State University, Boise, ID 83725 USA

Accurate and precise dating of the impact cratering record on Earth is important for determining the duration of periods of intense bombardment and their role in causing climatic perturbations and biotic extinctions. Unfortunately only four terrestrial craters are well dated by the U-Pb zircon method; all are large structures, *ca*. 100–300 km in diameter [1]. We investigated the 28-km wide, Mistastin Lake crater [2], Labrador, Canada, in order to determine whether magmatic zircon forms in small-volume impact melt sheets and may be dated precisely and accurately. A sample was collected from Discovery Hill, an 80-meter thick, wedge-shaped butte of columnar-jointed impact melt rock. An age of 36 ± 4 Ma (2σ) for Mistastin was reported by [3] based on $^{40}Ar/^{39}Ar$ dating.

In addition to large elongated to equant (~100–500 μm) zircon inherited from the country rocks, the melt rock contains tiny, elongate (~25 μm wide x ~100–175 μm long), prismatic "needle" zircon with narrow, brown-colored melt channel "spines" running through the centers of the crystals. Eleven needles were analyzed by CA-TIMS using the EARTHTIME tracer solution. With only 1-4 pg of radiogenic Pb per needle, it was critical to have low Pb blanks (~0.4 pg) for high-precision dating. $^{206}Pb/^{238}U$ dates are equivalent with a weighted mean date of 37.83 ± 0.05 Ma (internal error, MSWD = 1.0) that is interpreted as the crystallization age of the impact melt. The results demonstrate that magmatic zircon can crystallize in impact melt from small craters. The new radiometric age for Mistastin makes it now the most precisely and accurately dated small crater on Earth. The Mistastin U/Pb date is significantly older than $^{40}Ar/^{39}Ar$ dates for the two largest (~100km) Eocene craters, Popigai (35.7±0.2 Ma, 2σ) and Chesapeake Bay (35.5±0.3 Ma, 2σ) [1] and the end Eocene mass extinction event (~34 Ma).

Modification of synthetic zeolites and characteristics of their properties

B. SZALA[1]*, P. TUREK[1] AND T. BAJDA[1]

[1]Department of Geology, Geophysics and Environmental Protection, AGH University of Science and Technology, Krakow, Poland (*bszala@geol.agh.edu.pl)

Synthetic zeolites are increasingly likely to be used in advanced chemical processes and industry due to their attractive properties. Ongoing research is trying to establish a way improve some of their properties, for example, the process of sorption. This process is low because it takes place only on the outer surface of the crystallites. To increase the chemical affinity of the zeolite's surface to the organic compounds, modification of zeolites' surface is necessary. The aim of the study was to perform modifications of a synthetic zeolite and evaluate its sorption properties. The material used was an X-type zeolite prepared from coal fly ash. For modification of the zeolites' surface quaternary, ammonium salts with single or double carbon chain length, such as: dodecyltrimethylammonium bromide (DDTMABr), tetradecyltrimethyloammonium bromide (TDTMABr), hexadecyltrimethylammonium bromide (HDTMABBr) and octadecyltrimethylammonium bromide (ODTMABr) were used. Surfactants were adsorbed onto a synthetic zeolite in amounts of 1.0 and 2.0 of the external cation exchange capacity (ECEC) in quantities of 24.4 and 48.8 mmol per 100g of zeolite respectively. Quantitative characterization of organo-zeolites and characterization of their properties has been performed. The effectiveness of the modification has been determined based on the content of carbon, hydrogen and nitrogen combined with X-ray Diffraction and IR spectroscopy. Simultaneously, the effectiveness of maximum sorption capacity on organo-zeolites in terms of organic compounds such as benzene, toluene, xylene has been established. The results obtained show an improvement of the sorption properties of the organo-zeolite modified in an amount of 2.0 ECEC in relation to the 1.0 ECEC and unmodified material. Also the carbon chain length surfactants show their importance during the modification. The results of this research can be used in environmental protection and for further studies into the properties of surfactant-modified synthetic zeolites and their potential industrial applications; for example, in petrochemistry.

We gratefully acknowledge the support of NCBiR having provided grant PBS1/A2/7/2012.

10.1180/minmag.2013.077.5.19

Petrogenesis of andesites in Mesoarchaean supracrustal belts of SW Greenland: Geodynamic implications

KRISTOFFER SZILAS[1] AND J. ELIS HOFFMANN[2]

[1]Lamont-Doherty Earth Observatory, Palisades, New York, USA

[2]Institut für Geologie und Mineralogie, Universität zu Köln, Zülpicher Str. 49b, 50674 Köln, Germany

We present an overview of geochemical data for the Mesoarchaean supracrustal belts from the Tasiusarsuaq terrane, SW Greenland. These ultramafic, basaltic and andesitic enclaves are located within younger tonalite-trondhjemite-granodiorite (TTG) orthogneisses and are mainly dominated by tholeiitic basalts. However, calc-alkaline andesites are also present and comprise up to ca. 50% of individual supracrustal belts. These two lithological groups can roughly be divided into tholeiitic and calc-alkaline affinity by having La/Sm ratios less than, or over 3.5, respectively. While the mafic rocks have flat trace element patterns with negative Nb- and Ta-anomalies, the andesitic rocks have strongly fractionated trace element patterns, with distinctly negative Nb-, Ta- and Ti-anomalies, as well as positive Hf- and Zr-anomalies. Thus, they are not related by fractional crystallisation and no gradational transitions between the two groups have been observed. Assimilation of pre-existing continental crust can also not explain the trace element variations of the andesites. Modelling suggests that simple binary mixing of a mafic magma and a TTG-type component in a 1:1 ratio can explain most of the variation that the andesites display. This is confirmed by Hf-isotope modelling that support the large mixing ratio and therefore that actual melting of the local felsic crust must have occurred. We suggest that the hotter conditions during the Mesoarchaean could explain the significant proportion of melting of the lower crust during addition of juvenile mafic magmas. Overall, the geochemical data are compatible with a modern-style subduction zone environment, for which recent studies have also concluded that substantial magma mixing is a significant process.

Compacted Nanoparticles for Quantification in LA-ICPMS

DANIEL TABERSKY[1], NORMAN LUECHINGER[2], SAMUEL HALIM[2], MICHAEL ROSSIER[2] AND DETLEF GÜNTHER[1]*,

[1]ETH Zurich, Department of Chemistry and Applied Biosciences, Laboratory of Inorganic Chemistry (*correspondence: guenther@inorg.chem.ethz.ch)
[2]Nanograde, Staefa, Switzerland

Gray *et al*. did first studies of LA-ICPMS in 1985 [1]. Ever since, extensive research has been performed to overcome the problem of so-called "non-stoichiometric sampling" and/or analysis, the origins of which are commonly referred to as elemental fractionation (EF). EF mainly consists of laser-, transport- and ICP-induced effects, and often results in inaccurate analyses as pointed out in, *e.g*. references [2,3].

A major problem that has to be addressed is the lack of reference materials. Though the glass series of NIST SRM 61x have been the most commonly reference material used in LA-ICPMS, heterogeneities have been reported for some sample charges [4,5]. In addition, geological relevant elements such as Ti, Fe and Mg are present in very low concentrations only and thus not well suited for calibration. Elements such as Rh, Ru, Pd, Pt and Au (PGEs) are either absent or present in very low concentrations.

The production procedure of glass limits the implementation of these elements into the glass matrix at concentrations required for many applications. Therefore, alternative methods for the production of calibrants were studied concerning the implementation of PGEs into Silicates, Carbonates, and Iron-Sulfides, which are homogeneous at the spatial resolution commonly used in microbeam techniques.

Flame synthesis was used to reproduce the NIST 610 matrix at similar concentrations. Furthermore, PGEs and other elements were added to the matrix. The resulting powder consists of nanoparticles in the size range of 20-50 nm, which is well below the commonly crater diameters used in LA-ICPMS. The PGE concentration is for most of the elements around 500 mg/kg. Multiple analyses of these powders provide a RSD for PGEs in the order of 1-3 %.
The difference between the pressed powder analysis and calcinated pellets shows indistinguishable results for most of the elements. The setup of production, preliminary results and first figures of merit will be discussed.

Evaporation behavior of forsterite (Mg_2SiO_4) in a H_2O-H_2 gas

S. TACHIBANA[1]* AND A. TAKIGAWA[2]

[1]Department of Natural History Sciences, Hokkaido University, N10 W8, Sapporo 060-0810, Japan. (*correspondence: tachi@ep.sci.hokudai.ac.jp)
[2]Carnegie Institution of Washington, Department of Terrestrial Magnetism, 5241 Broad Branch Road NW, Washington DC, 20015 USA.

Forsterite (Mg_2SiO_4) is one of the most abundant crystalline silicates in extraterrestrial materials and in circumstellar environments, and its evaporation behavior has been intensively studied in vacuum and in the presence of low-pressure hydrogen gas [e.g., 1-4]. It has been known that the evaporation rate of forsterite is controlled by a thermodynamic driving force (i.e., equilibrium vapor pressure), and the evaporation rate increases linearly with $pH_2^{1/2}$ in the presence of hydrogen gas due to the increase of the equilibrium vapor pressure. The deviation of the actual evaporation rate from the ideal evaporation rate, which is given by an equilibrium vapor pressure and the kinetic theory of gases, is expressed as an evaporation coefficient (=Actual rate/Ideal rate) ranging from 0 to 1 (a measure of kinetic hindrance for evaporation). The evaporation coefficient is 0.1-0.01 for evaporation of forsterite in vacuum and in hydrogen gas depending on temperature and crystallographic orientation of the evaporating surface [e.g., 1-4]. Besides the free-evaporation dominated regime [FED] (evaporation in vacuum) and the hydrogen-reaction dominated regime [HRD] (evaporation in hydrogen gas), Tsuchiyama *et al*. [5] proposed another evaporation regime called H_2O/H_2 buffer-dominated regime [HBD] as a dominant evaporation regime for forsterite in protoplanetary disks at temperatures of <1400 K and under H_2O-rich conditions. In the HBD regime, the equilibrium vapor pressure of forsterite is not controlled by $pH_2^{1/2}$, but by the H_2O/H_2 ratio in the ambient gas. In spite of its potential importance, no experimental study has been done to investigate the evaporation kinetics in the HBD regime. We have performed evaporation experiments on forsterite at low pressures with controlled H_2O/H_2 ratios, and have found that the evaporation rates are controlled by the H_2O/H_2 ratio as proposed by [5] and that the evaporation coefficient is consistent with that in FED and HRD regimes.

Southern Hemisphere orbital forcing and its effects on CO_2 and tropical Pacific climate

K. TACHIKAWA[1], A. TIMMERMANN[2], L. VIDAL[1], C. SONZOGNI[1] AND O. ELISON TIMM[2]

[1] Aix-Marseille Université, UMR7330, CNRS, IRD, CEREGE UM34,13545 Aix en Provence, France, kazuyo@cerege.fr
[2] IPRC, SOEST, University of Hawaii, Honolulu, HI 96822, USA

The western Pacific warm pool (WPWP) is an important heat source for the atmospheric circulation and influences climate conditions worldwide. Understanding its sensitivity to past radiative perturbations may help better contextualize the magnitudes and patterns of current and projected tropical climate change. Here we present a new Mg/Ca-based sea surface temperature (SST) reconstruction over the past 400 kyr from the Bismarck Sea, off Papua New Guinea, along with results from a transient earth system model simulation. Our results document the primary influence of CO_2 forcing on glacial/interglacial WPWP SSTs and secondary effects due to changes in wind-driven tropical boundary currents. In addition to the SST, deep ocean temperature reconstructions from this core are linked with Southern Ocean temperature and sea-ice variations on timescales of ~23 kyr. It is proposed that Southern Hemisphere insolation changes serve as pacemaker for sea-ice variations in the Southern Ocean, which in turn modulate windstress curl-driven upwelling of carbon-rich waters, hence controlling atmospheric CO_2 and tropical WPWP temperatures.

CO_3, OH, and halogen microanalysis in apatite group minerals

R. CHRIS TACKER[1]

[1]North Carolina Museum of Natural Sciences, 11 W. Jones St., Raleigh, NC, USA 27601-1029, christopher.tacker@naturalsciences.org

The last three years have seen a re-evaluation of microanalytical methods for apatite, including standards. This presentation presents new data and reviews recent results for analytical methodology for C, OH, and halogens for apatite minerals.

Initial documentation of anisotropic beam-driven halogen diffusion [1] in apatites, long ignored, has been confirmed and shown to be more complex for varying F and Cl concentrations [2]. Quantitative analysis requires constraints on crystal orientation for *both unknowns and standards*, as well as controlled history under the electron beam. Analytical methods presented here use accelerating voltages <10keV and short analytical durations to clearly define the rise and fall in count rates for zero-time regression. Data in hand show that F and Cl are rapidly lost from the apatite during analysis at 15 and 20 keV in all crystal orientations. Analyses are unlikely to be valid without regression-to-zero techniques for unknown and standard. Uncertainties in electron microprobe halogen analyses are magnified in OH caclulated by the difference method.

Problems with FTIR analysis of apatite (strongly polarized OH stretching, crystal size, sample thickness) have been overcome to allow analysis of unpolished mineral separates and experimental products. Polarized radiation is preferred for OH analysis, but unpolarized radiation can be used on (100) sections [3] and euhedral synthetic crystals. The A and B type carbonate substitutions are not strongly polarized, allowing use of unpolarized radiation.

Carbonate and OH standards for apatite are lacking. A large FTIR dataset for naturally occurring apatites shows homogeneities or complexities precluding their use as standards. For example, Durango fluorapatite shows trimodal OH distribution (n=5570). Synthetic standards are under development.

Previously published apatite studies should be carefully evaluated in the light of these results.

Thermochronological investigation of seismogenic fault zones: an overview and examples from Japanese Islands

TAKAHIRO TAGAMI [1]

[1] Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, Sakyo-ku, Kyoto, 606-8502, Japan. tagami@kueps.kyoto-u.ac.jp

The timing of faulting episodes can be constrained by radiometric dating of fault-zone rocks. Fault-zone material suitable for dating is produced by tectonic processes, such as (1) fragmentation of host rocks, followed by grain-size reduction and recrystallization to form mica and clay minerals, (2) secondary heating/melting of host rocks by frictional fault motions, and (3) mineral vein formation as a result of fluid advection associated with the fault motions. The thermal regime of fault zones consists primarily of the following three factors: (a) regional geothermal structure across the fault zone and background thermal history of studied province bounded by fault systems, (b) frictional heating of wall rocks by fault motions, and (c) heating of host rocks by hot fluid advection in and around the fault zone. Thermochronological methods widely applied in fault zones are K-Ar ($^{40}Ar/^{39}Ar$), fission-track, and U-Th methods. The thermal sensitivities of individual thermochronological systems are briefly reviewed, which critically control the response of each method against the thermal processes. Based on the knowledge above, representative examples as well as key issues are highlighted to date fault gouges, pseudotachylytes, mylonites and carbonate veins, placing valuable constraints upon geological, geomorphological and seismological frames. Finally, the results from Japanese Islands are presented, including the Shimanto belt, as examples for multiple applications of thermochronological methods.

Geobotany and biogeochemistry of Sungun Copper deposit, northern Iran: An implication to mineral exploration

B. TAGHIPOUR [1] AND M. HEMMATI [1]

[1]Department of Earth Sciences, Shiraz University, Shiraz, Iran (taghipour@shirazu.ac.ir)

Sungun porphyry copper deposit is located in the east of Azarbaidjan, NW of Iran. Geobotany is one of the important methods in mineral exploration. In this method the plants represented paid a heavy metal track. Geochemical prospecting has been carried out on distribution of Zn, Pb, Cu, As, Cd and Mo in the plant species and soil of the Sungun Cu-Mo deposit. Field prospecting has been indicated that Anthemisnobilis, Crepsis sancta and Picnomonacarna are the main plant species in the area. Geochemical results indicated enrichment of Mo, As and Cu (Cu >Mo > As) which is correlated with concentration of the metals in associated soil. Anthemisnobilis has been shown the greatest capability for accumulating Cu and Mo in its tissues through soil so it could be used as a bioindicator for mineral exploration. This plant with other plant species such as Crepsis Sancta and Picnomonacarna have high scavenging ability for Mo and Cu from the soil and could cause serious environmental and health problems in the living organisms of the area.

Density control on formation of crustal magma storage system

BENOIT TAISNE[1]*

[1]Earth Observatory of Singapore, 50 Nanyang Avenue, Singapore 639798
(*correspondance: btaisne@ntu.edu.sg)

Magma reservoirs probably grow by repeated sill-like intrusions. We investigate the conditions for repeated crustal intrusions at the same depth by a feeder dike before a permanent molten reservoir can form. Sill formation requires that magma within a dike develops an overpressure large enough to overcome the strength of surrounding rocks. An efficient mechanism to achieve this involves ascent through layers with decreasing density, such that magma becomes negatively buoyant above some structural interface. To significantly affect dike ascent, the density change in country rock must occur over a thickness of the order of the length-scale for the inflated nose region that develops below the dike tip. This characteristic length depends on the elastic properties of the host rocks, on magma buoyancy and on the flux of magma. It is usually around 1 km for basaltic magmas, comparable to the typical thickness of sedimentary strata and volcanic deposits. The overpressure that develops at the density inversion level is determined by the vertical extent of the inflated dike nose region above that level, and hence is related to the volume of magma in that region. Thus, sill formation also requires that the total volume of magma available in an individual intrusion event exceeds a threshold value.

Pressure variations in metamorphic rocks: Implications for the interpretation of petrographic observations

L. TAJČMANOVÁ

Department of Earth Sciences, ETH Zurich, Switzerland, (lucataj@gmail.com)

During mineral reaction, the overall mechanical state of a rock is very important. Rock strength may control the reaction progress from 0 to 100% which may result in the development of stress, and therefore pressure, variation on all scales. Hence, considering the interplay of metamorphic reaction and mechanical properties is critical for correctly interpreting microstructural observations in metamorphic rocks and correct quantification of the processes.

Stresses that develop during deformation of geologic materials can be responsible for the formation and preservation of GPa-level pressure variations. Considering that the typical value of the lithostatic pressure at the base of the continental crust is ~1 GPa, GPa-level variations make the interpretation of depth from pressure problematic for crustal metamorphic rocks. Such pressure perturbations are more apparent on a small scale (nm to mm), where, in some cases, they can be directly measured by spectroscopic methods. However, the non lithostatic pressure variations can also be relevant to larger (crustal) scales. Schmalholz and Podladchikov [1] have recently shown that even when rocks are deformed in a "weak" crustal- scale shear zone, force balance across the shear zone requires that pressure will not be smoothly varying with depth but it will be paradoxically higher within the shear zone.

The recent microstructural observations and mechanical models question our current quantification approach in metamorphic petrology based on the lithostatic assumption. The recent data have therefore opened horizons for new approaches and new physically rigorous and geologically realistic interpretations of our petrographic observations. Such approaches would contribute to our better understanding the processes in the Earth interior.

Structural simulation on silica crystals and glasses

TAKADA[1]

[1]Research Center, Asahi Glass Co., 1150 Hazawa-cho, Yokohama, 221-8755, Japan (akira-takada@agc.com)

Molecular dynamics simulation has been used to investigate the similarity and dissimilarity in dynamical structural changes between silica crystals and glasses. Many simulation studies have been performed for quartz, cristobalite and silica glasses [1-3], however, there is scarcely any simulation studies on tridymite. The structural building block is the same between in tridymite and cristobalite, neverthless, structural changes due to the thermal effects is more complex in tridymite than in cristobalite. Such complexity hinders the theoretical study. First, the structural chages of tridymite phase due to thermal effects are investigated by using molecular dynamics simulation. Next, the calculated complex structural changes are compared with those of the other structures such as cristobalite and glasses. Firnally, we discuss the similarities and dissimilarities in dynamical structural changes in terms of microscopic structure.

Ontogenetic stable isotope records of modern planktic foraminifers from Sagami Bay, Japan

H. TAKAGI[1]*, K. MORIYA [1,2], T. ISHIMURA [3,4], A.SUZUKI[4] H. KAWAHATA [5] AND H. HIRANO [1]

[1]Waseda University, Tokyo 169-8050, Japan (*corespondence: harurah-t@fuji.waseda.jp)

[3] Ibaraki National College of Tech., Ibaraki 312-8508, Japan
[4]Geological Survey of Japan, AIST, Ibaraki 305-8567, Japan
[5]AORI, The University of Tokyo, Chiba 277-8564, Japan

Stable oxygen ($\delta^{18}O$) and carbon ($\delta^{13}C$) isotopes recorded in planktic foraminiferal tests are widely used as proxies for paleoceanography and species ecology. Of such isotopic investigations, ontogenetic isotopic profiles are thought to record foraminiferal ecological information such as depth habitat or symbiotic relationship. Though size-related isotopic series, achieved by analyses of a series of shieved fractions, seem to reflect otogenetic profiles of species, isotopic profiles through "individual ontogeny" have rarely been examined. In this study, we report ontogenetic isotopic information of individual specimens, together with *in situ* water column oceanographic information ($\delta^{18}O_{sw}$, $\delta^{13}C_{DIC}$, temperature, salinity, nutrient, and chlorophyll-a).

We examined ontogenetic stable isotopic profiles of planktic foraminifers by performing chamber-by-chamber analyses within a single individual. Each chamber is dissected from an individual and anlyzed by specially designed continuous-flow mass spectrometry system [1]. Instead of size-related analyses, this method enables us to reveal individual ontogenetic information free from mixing of seasonal variability. Four modern species, obtained by vertical towing at Sagami Bay, Japan, were analyzed; *Globigerinoides sacculifer*, *Globigerinoides conglobatus*, *Neogloboquadrina dutertrei*, and *Globorotalia inflata*.

The ontogenetic $\delta^{18}O$ profiles showed overall increase for all species, suggesting the ontogenetic deeper migation commonly found in modern species. While $\delta^{13}C$ showed steep increase especially in a juvenile stage for all species, the increase continued to the last chambers only in symbiont-bearing globigerinoidid species. $\delta^{13}C$ of asymbiotic species becomes decrease after the rapid increase in the juvenile stage. Comparing these records to water column chemical and physical data, regardless of their adult habitat depths, all foraminifers analyzed start their calcification, hence their ontogeny, near the thermocline, which corresponds to chlorophyll maxima and nutrient-depleted depth.

Magma feeding system of Fuji volcano, Japan

E.TAKAHASHI[1]*, K.ASANO[1] AND J.NAKAJIMA[2]

[1] Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo 152-8551, Japan (*presenting author: etakahas@geo.titech.ac.jp)
[2] Research Center for Prediction of Earthquakes and Volcanic Eruptions, Tohoku University, Sendai, Japan

Fuji volcano is known for its perfect cone shape and it is the largest among Japanese Quaternary volcanoes. In the last 100kya, Fuji has erupted only basalt magma (>>99 vol%), but its eruption style changed (from debris flow and tephra dominant Ko-Fuji or Older Fuji, to lava flow dominant Shin-Fuji or Younger Fuji) at ~15 kya BP. Origin of the voluminous yet monotonous basalt production in Fuji volcano have been discussed but remain unanswered. Here we report the first high-pressure melting experimental results on Fuji basalt (Hoei-IV, AD1707) and demonstrate that its main magma chamber is located at ca.25km depth. We show seismic tomographic images of Fuji volcano for the first time, which reveals the existence of strong upwelling flow in the mantle and its connection to the voluminous lower crustal magma chamber (see Fig.1).

Very frequent low frequency earthquakes just above the magma chamber (open circles in Fig.1) may be due to the injection of basalt magma and/or fluids. The total lack of silica-rich rocks (basaltic andesite and andesite) in Fuji volcano must be due to the special location of the volcano. The plate boundary between the Eurasia plate and the subducting Phillipine sea plate is located just beneath Fuji volcano (~5 km depth). Large tectonic stress and deformation associated with the plate boundary inhibit the survival of a shallow level magma chamber, which would allow the evolution of basalt to silica-rich magma (as observed in all other volcanoes in Japan, e.g., Hakone, Izu Oshima).

Migration of radiocesium and radioiodine in soil-water-river system related to Fukushima-Diichi Nuclear Power Plant Accident

Y. TAKAHASHI*, Q. FAN, A. SAKAGUCHI, YOKO S. TOGO AND K. TANAKA

Hiroshima University, Hiroshima 739-8526, Japan (*correspondence: ytakaha@hiroshima-u.ac.jp)

Radionuclides such as radiocesium and radioiodine were emitted from the Fukushima Daiichi Nuclear Power Plant (FDNPP) accident caused by the Great East Japan Earthquake and Tsunami on March 11, 2011. Highly contaminated areas spread in the northwest direction from FDNNP in Fukushima Prefecture, which mainly resulted from the distribution of the wet deposition on March 15 [1]. After the deposition, vertical profiles of the radionuclides in soil in Fukushima showed that radioscesium and radioiodine have been retained within 5 cm from the surface. Analysis of particulate matters and sedimentl partlces in rivers in the region showed that radiocesium is enriched in finer fractions.

These results suggested that radiocesium and radioiodine have high affinity to soil particles. For radiocesium, adsorption on clay minerals have been indicated. Thus, extended X-ray absorption fine structure (EXAFS) spectroscopy has been used (i) to characterize structure of surface complex of cesium with 2:1 phyllosilicate and (ii) to understand the reduction of the adsorption in the presence of humic substances. We also found a correlation between (i) the fraction of inner-sphere complex among total cesium species adsorbed on the soil particles and (ii) Radiocesium Interception Potential (RIP) value, which suggests that RIP is dependent on the mieral content and humic substances.

About 30% of radioiodine leached by NaOH solution (pH 10.5) from the soil collected one month after the accident [2]. When the NaOH solution was acidified to pH 2, more than 60% of radiodine in the solution precipitated possibly with humic materials that can bind iodine in the polyorganic structure. This leaching-precipitation behavior suggests that a part of iodine is in the organic form in the soil, which can be a reason for the low leaching rate in the soil by water. The formation of organic iodine in natural soil has been suggested also by XAFS using X-ray microbeam [3]. The formation of organo iodine species proceeds in a relatively short period, such as within a week or a month. Thus, the formation of organo iodine is possible for radiodine in the soil.

Seasonal change of Iron species and concentration of soluble Iron in the atmosphere in Northwest Pacific region based on the analysis of aerosols collected in Tsukuba, Japan

Y. TAKAHASHI* AND T. FURUKAWA

Hiroshima University, Hiroshima 739-8526, Japan (*correspondence: ytakaha@hiroshima-u.ac.jp)

Atmospheric iron (Fe) can be a significant source of nutrient for phytoplankton in remote ocean, which in turn has a large influence on Earth's climate. Whether Fe in aerosol can be a bioavailable or not depends mainly on the soluble fraction of Fe. However, factors controlling the soluble fraction of Fe have not been understood fully, since there can be many factors controlling the fraction. In this study, Fe species, chemical composition, and soluble Fe concentration in aerosol collected at Tsukuba through a year were investigated to identify the factors controlling the amount of soluble Fe supplied into ocean. The concentration of soluble Fe in aerosol is correlated with those of sulfate and oxalate which originate from anthropogenic sources, suggesting that soluble Fe is mainly derived from anthropogenic sources. Moreover, the concentration of soluble Fe (%) is also correlated with enrichment factors (EF) of vanadium (V) and nickel (Ni) emitted by fossil fuel combustion. These results suggested that the degree of Fe dissolution is controlled by the magnitude of anthropogenic activity such as fossil fuel combustion. In addition, XAFS was performed in this study to identify the Fe species in aerosols. The fitting of XAFS spectra coupled with micro-XRF showed that main Fe species in aerosols in Tsukuba were illite, ferrihydrite, hornblende, and Fe(III) sulfate. Moreover, soluble Fe fraction to total Fe in each sample measured by leaching experiment is closely correlated with the Fe(III) sulfate fraction determined by XAFS, suggesting that the presence of Fe(III) sulfate is primarily important for the supply of soluble Fe into the ocean. Another possible factor, total concentration of Fe(III) in the atmosphere in terms of the amount of supply of soluble Fe into ocean was high in spring due to the high concentrations of mineral dust in the period in East Asia, but this factor does not contribute to the amount of soluble Fe to a larger degree than the effect of Fe(III) sulfate. Thus, it was concluded that the most significant factor controlling the supply of soluble Fe in North Pacific can be the concentration of anthropogenic Fe species such as Fe(III) sulfate.

Vertical profiles of copper isotopic composition in the ocean

SHOTARO TAKANO[1], MASAHARU TANIMIZU[2], TAKAFUMI HIRATA[3] AND YOSHIKI SOHRIN[1]

[1]Institute for Chemical Research, Kyoto University, Gokasho Uji, Kyoto 611-0011, Japan (Correspondence: shotaro@inter3.kuicr.kyoto-u.ac.jp)
[2]Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, 200 Monobe Otsu, Nankoku 783-8502, Japan
[3]Division of Earth and Planetary Sciences, Kyoto University, Kitashirakawa Oiwake-cho, Kyoto 606-8502, Japan

Copper is an essential trace metal that shows a vertical recycled-scavenged profile in the ocean. To elucidate the biogeochemical cycling of Cu in the oceans, it is important to determine the profiles of Cu isotopes in the ocean. However, precise isotopic analysis of Cu has been impaired by the low concentrations of Cu as well as co-existing elements that interfere with measurements by multi-collector inductively coupled plasma mass spectrometry (MC-ICP-MS). We have developed a precise and simple method for determining the isotope composition of dissolved Cu in seawater[1]. Dissolved Cu was preconcentrated using a Nobias Chelate-PA1 resin and purified using an AG MP-1 anion exchange resin. The concentration and isotopic composition of copper were measured using an Element 2 HR-ICP-MS and a Neptune MC-ICP-MS, respectively. Cu isotopic composition data were expressed as $\delta^{65}Cu$, where $\delta^{65}Cu$ (‰) = $[(^{65}Cu/^{63}Cu)_{sample}/(^{65}Cu/^{63}Cu)_{NIST\ SRM\ 976} - 1] \times 10^3$.

We have determined $\delta^{65}Cu$ in the western North Pacific and Japan Sea. In the western North Pacific, $\delta^{65}Cu$ values were +0.45–0.53‰ above the thermocline. Below the thermocline, $\delta^{65}Cu$ values were increased to +0.49–0.71‰. In the Japan Sea, $\delta^{65}Cu$ values were +0.48–0.57‰ above the thermocline, which were similar to that of the western North Pacific. Below the thermocline, however, $\delta^{65}Cu$ values were lighter (+0.28–0.56‰) than that of the western North Pacific. We will also reveal the distribution of $\delta^{65}Cu$ in the eastern North Pacific and central Indian Ocean. We are going to constrain biogeochemical cycles of Cu using $\delta^{65}Cu$ and Cu concentration data. Our hypotheses at present is that $\delta^{65}Cu$ above the thermocline is balanced by biological removal of light Cu and aeolian supply of light Cu, and that $\delta^{65}Cu$ below the thermocline become heavy with the increase in AOU because of preferential removal of light Cu.

Influence of surface condition on data quality of U–Pb zircon dating

M. TAKEHARA[1]*, K. HORIE[2], T. HOKADA[2], H. KAIDEN[2] AND S. KIYOKAWA[1]

[1]Kyushu University, 6-10-1, Hakozaki, Higashi-ku, Fukuoka 812-8581, Japan (*correspondence: 3SC12025R@s.kyushu-u.ac.jp, kiyokawa@geo.kyushu-u.ac.jp)

[2]National Institute of Polar Research, 10-3, Midoricho, Tachikawa, Tokyo 190-8518, Japan (horie.kenji@nipr.ac.jp, hokada@nipr.ac.jp, kaiden@nipr.ac.jp)

U–Pb zircon dating using microbeam such as SIMS and LA-ICP-MS has played a pivotal role in geochronology. Many analysts empirically believe that accuracy and precision of microbeam analysis strongly depend on surface condition of analytical spots. Especially, existence of cracks within the analytical spots decreases quality of results, but there is no quantitative evidence that the crack decreases the data quality. In this study, we quantitatively discuss influence on the data quality from the surface condition of the analytical spots. AS3 and FC1 zircons collected from gabbroic anorthosites of the Duluth Complex, Minnesota, USA, were used in this study. Previous work reported that some grains in AS3 zircons yield discordant data due to Pb loss caused by thermal diffusion [1].

Observation of thin sections by optical microscope and electron microprobe reveals chloritization of amphibole in AS3, which suggests hydrothermal alteration. U–Pb analyses of some AS3 zircon grains yielded discordant data. The analytical spots that yield discordant data can be classified into (1) altered domains characterized by high contents of LREE and non-formula elements, such as Ca, Al, and Fe, and (2) domains containing undersurface cracks. In the case that analytical depth is close to the undersurface cracks, the second domains also show high LREE contents. When the cracks in zircon worked as channels of hydrothermal fluid [2], there are possibilities that some residuals of the fluid exist in the cracks and/or that areas around the cracks was altered by the fluid. Therefore, selection of the analytical spots for U–Pb zircon dating should be based on observation of cracks not only on the surface but also under the surface. When AS3 and FC1 zircon are used as U-Pb standard material, it is important to carefully choose analytical spots on the basis of the backscattered electron and optical microscope images for achieving more precise analysis.

Lower crustal metasomatism of the NE-Japan arc inferred from crustal xenoliths from Ichinomegata crater

MIYUKI TAKEUCHI[1]* AND SHOJI ARAI[1]

[1] Dept. Earth Sci., Kanazawa Univ., Kanazawa 920-1192, Japan (*correspondence: takeuchi-miyuki@stu.kanazawa-u.ac.jp)

Ichinomegta crater, Megata volcano, the NE-Japan arc is a famous locality of ultramafic-mafic xenoliths, and there have been a lot of studies about mantle metasomatism (= metasomatism on mantle-derived ultramafic xenoliths) (e.g., Abe *et al*., 1992, Abe *et al*., 1999). However, there have been little documents on metasomatism in crust-derived xenoliths.

Coarse-grained mafic xenoliths from the Ichinomegata crater contain a large amount of pargasite. Some of the pargasite grains are obviously of secondary origin, replacing primary clinopyroxene in hornblende-pyroxene gabbros and pyroxene gabbros. And clinopyroxenes in pyroxene-spinel symplectites, which are a reaction product of olivine and plagioclase, are also replaced with pargasite.

Plagioclase shows a wide raige of Ca content (An87-98 in hornblende-pyroxene gabbros, An64-90 in pyroxene gabbros), and are poor in Na around the rim. Pargasites are depleted in TiO_2, but discrete pargasite grains show higher TiO_2 contents (1.0-2.4 wt.%) than secondary grains (0.8-1.7 wt.%). Spinels have been enriched with Ti and Fe (especially Fe^{3+}), and separated into two phases, Ti, Fe^{3+}-rich magnetite and Al-rich spinel by cooling. Ti has been also added to the mineals in pyroxene-spinel symplectites.

The metasomatic formation of hydrous minerals was accompanied with addition of, at least, Ti, Na and K. Clinopyroxenes contain very low amounts of Rb, Ba, Nb (below detection limits of our LA-ICP-MS). The secondary pargasite is enriched in these elemants, but not in HFS elements relative to clinopyroxenes. The hydration is characterized by enrichment of LIL elements but not of HFS elements. This was caused by infiltration of fluids related to hydrous arc magmas.

Hydration and cooling processes observed in the lower crustal gabbros are also recorded in peridotite and websterite xenoliths of upper mantle origin from the Northeast Japan arc. This means widespread modification of mineral chemistry and mineral assemblage from the upper mantle to the lower crust beneath the arc.

Geochemistry of spinel-hosted amphibole inclusions in abyssal peridotite : Embedded evidence for melt-peridotite reaction process?

A. TAMURA[1]*, T. MORISHITA[1], S. ARAI[1] AND S. ISHIMARU[2]

[1]Dept. Earth Sciences, Kanazawa University, Kanazawa 920-1192, Japan (*aking826@staff.kanazawa-u.ac.jp)
[2]Dept. Earth and Environmental Sciences, Kumamoto University, Kumamoto 860-8555, Japan

Trace-element compositions of spinel-hosted amphibole inclusions (20-40 μm) were determined by using LA-ICP-MS to more throughly understand the melt-peridotite reaction.

Spinel-hosted hydrous minerals (e.g., amphibole and phlogopite) have been documented in ultramafic rocks from the ocean floor and ophiolitic complexes [1, 2]. They are commonly observed in dunite, troctolite and chromitite, to which formation the melt-peridotite reaction contributed significantly. However, the role of formation of the inclusions has been ever constrained well within the framework of melt-peridotite reaction. Arai *et al*. [1] pointed out that the mineral inclusions are formed from a melt enriched in incompatible elements, e.g., TiO_2 and Na_2O, and H_2O, produced by zone refining effects in the melt-peridotite reaction. Until now, trace-element compositions of the inclusions have been rarely examined [2, 3] due to difficulty in establishing their geochemical systematics because of complicated multi-scale uncertainties on the reaction mechanisms, such as melt and rock compositions and geological setting.

A core interval (70 cm) of the residual harzburgite cut by gabbro recovered from the Atlantis Massif, Mid-Atlantic Ridge 30°N shows inhomogeneous compositions caused by reaction with melt forming the gabbro [4]. Pargasitic amphibole inclusions in concentric spinel grains are only observed in the harzburgite near the gabbro contact (10 cm) where depleted residual harzburgite reacted with N-MORB-like melt beneath the ridge. Because the geological and petrological context is well constrained there as above, the pargasite geochemistry will give us a good reference for the systematics of relevant reaction and origin of inclusions. Together with trace-element data of spinel-hosted amphibole inclusions in reacted rocks, we discuss the significances of inclusions on the melt-peridotite reaction processes.

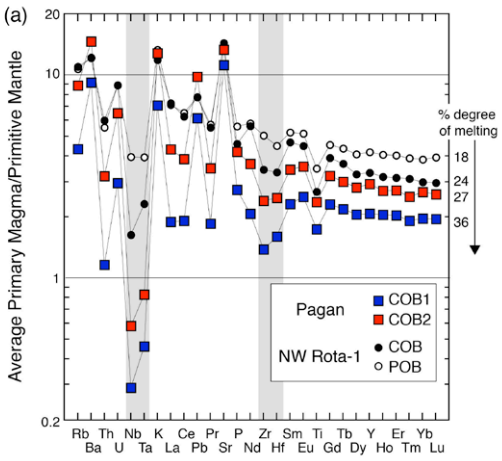
It is often mentioned that arc basalts are highly depleted in high-field strength elements (HFSE), such as Nb, Ta, Zr and Hf. In the spidergram, which shows four types of primary magmas in the Mariana arc (Tamura *et al*., 2011; Tamura *et al*., submitted) (Fig. 1), it is worth mentioning that North West Rota-1 (NWR1) POB, which is the driest and least depleted primary magma type among the four, is not as depleted in Nb, Ta, Zr and Hf as are the other three varieties and contains about 4x more of these HFSE than primitive mantle and are comparable to their HREE contents. On the other hand, the differences in Nb and Ta contents between NWR1 POB and more depleted COB are much larger than those expected from the different degrees of melting. This is also the case for Pagan COB1 and COB2 and comparing Pagan and NWR1. Apparently, Nb and Ta decrease unusually when the fraction of melting increases or when primary magmas become more hydrous from POB through COB and COB2 to COB1.

When the melting conditions are 'dry' as is true for POB,



phlogopite would not be present and Nb and Ta would become highly incompatible. It could be possible that highly depleted hydrous residual mantle wedge of the subduction zone could be phlogopite bearing dunite and harzburgite, which causes depletion of HFSE in wet and depleted arc magmas.

Circulation effect: Response of precipitation $\delta^{18}O$ to the ENSO cycle in monsoon regions of China

MING TAN

Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences. No.19 Beitucheng West Road, Chaoyang District, Beijing, 100029, China, (tanming@mail.iggcas.ac.cn)

Based on an analysis of the relationships between the time series of amount-weighted mean annual $\delta^{18}O$ in precipitation ($\delta^{18}O_w$) and meteorological variables such as temperature, precipitation as well as atmospheric/oceanic circulation indices, it is recognized that the El Niño-Southern Oscillation (ENSO) cycle appears to be the dominant control on the inter-annual variation in $\delta^{18}O_p$ in the Monsoon Regions of China (MRC). Further analysis shows that the trade wind plays a role in governing $\delta^{18}O_w$ through affecting the intensity of the different monsoon circulations which are closely linked to the weakening and strengthening of the trade wind and gives the $\delta^{18}O_w$ different values at or over inter-annual timescales. The southwest monsoon (SWM) drives long-distance transport of water vapor from Indian Ocean to the MRC, and along this pathway increasing rainout leads to more negative $\delta^{18}O_w$ via Rayleigh distillation processes. In contrast, the southeast monsoon (SEM), which is consistent with the changes in the strength of the West Pacific subtropical high, drives short-distance water vapor transport from the West Pacific Ocean to the MRC and leads to less negative $\delta^{18}O_w$. Therefore, the $\delta^{18}O_w$ value directly reflects the differences in influence between the SWM, which is strong when the SE trade wind is strong, and the SEM, which is strong when the SE trade wind is weak. In addition, the South China Sea Monsoon also transports local water vapor as well as plays a role in achieving the synchronization between the $\delta^{18}O_w$ and ENSO. The author thus terms the $\delta^{18}O_p$ rhythm in the MRC the "circulation effect".

Particle-size dependent distribution of radiocesium in river sediments after the FDNPP accident

KAZUYA TANAKA[1]*, HOKUTO IWATANI[2], AYA SAKAGUCHI[2], YOSHIO TAKAHASHI[2] AND YUICHI ONDA[3]

[1] Institute for Sustainable Sciences and Development, Hiroshima Univ., Higashi-Hiroshima, 739-8530 Japan (Correspondence: kt0830@hiroshima-u.ac.jp)

[2] Department of Earth and Planetary Systems Science, Hiroshima Univ., Higashi-Hiroshima, 739-8526 Japan

[3] Center for Research in Isotopes and Environmental Dynamics, Univ. of Tsukuba, Tsukuba, 305-8572, Japan

It was reported that most of fallout radiocesium emitted by the Fukushima Daiichi Nuclear Power Plant (FDNPP) accident stayed within 5 cm of surface soil layers [1,2]. Such accumulated radiocesium at the very surface on the ground is possibly being eroded into rivers by surface runoff, and finally goes into the Pacific Ocean. Particle size is an important factor in transportation of radiocesium in river systems. In this study, therefore, we investigated the dependence of radiocesium concentration on particle size and the distribution of particle size in river sediments.

River sediment samples were collected at 8 points in the Abukuma River and Kuchibuto River, which is one of the branches of the Abukuma River. River sediments were divided into 11 fractions with different particle sizes, > 2000 μm, 850 – 2000 μm, 500 – 850 μm, 250 – 500 μm, 125 – 250 μm, 63 – 125 μm, 40 – 63 μm, 20 – 40 μm, 10 – 20 μm, 2 – 10 μm and < 2 μm size fractions. Radiocesium concentration in each fraction was measured with γ-ray spectrometry using a planar type germanium semiconductor detector.

Smaller particle fractions contained a large amount of radiocesium possibly because of the following two factors. One is the specfic surface area, and the other is the mineralogy of the sediments. Smaller particles have larger specific surface areas, providing more sorption sites for radiocesium. Also, a large amount of clay minerals, on which radiocesium is strongly sorbed, are contained in smaller fractions. On the other hand, the contribution of each particle-size fraction to radiocesium in bulk sediment is also affected by the mass distribution of sediment particles among different particle sizes as well as radiocesium concentration in each particle-size fraction. In this sense, the contribution of relatively large size fraction to total radiocesium concentration is not negligible in bulk sediment.

A study on adsorption mechanism of organoarsenic compounds onto ferrihydrite

MASATO TANAKA[1]* AND YOSHIO TAKAHASHI[1,2]

[1] Graduate School of Science, Hiroshima University, 1-3-1 Kagamiyama, Higashi-Hiroshima 739-8526, Japan(*correspondence: tanamasa@hiroshima-u.ac.jp)
[2] Key Laboratory of Petroleum Resources, Chinese Academy of Sciences, Donggang Road, Lanzhou 730000, China

The inorganic arsenic compounds are cause of groundwater pollution in the world. In addition, organoarsenic compounds also have potential of the water pollution. It is important to know the adsorption structures of arsenic compounds to understand the migration of arsenic compounds in environments. In this study, adsorption structures of methyl and phenyl substituted organoarsenic compounds onto ferrihydrite, one of the most active adsorbents for anions in nature, were studied by the extended X-ray absorption fine structure (EXAFS) measurement and density functional theory (DFT) calculations.

Methylarsonic acid (MMA), dimethylarsenic acid (DMA), phenylarsonic acid (PAA), and diphenylarsinic acid (DPAA) were adsorbed on ferrihydrite at 25 ℃, pH 4 and 7. As K-edge EXAFS spectra of organoarsenic solution and adsorbed on ferrihydrite samples were collected by BL01B1 at SPring-8 and BL-12C at KEK Photon Factory (PF).

The EXAFS spectra suggest that all organoarsenic compounds treated in this study form inner-sphere complexes with ferrihydrite regardless of bulky functional groups. The interaction energy analysis using DFT calculations indicate that the steric hindrance between organoarsenic compounds and surface functional groups of ferrihydrite dominate the adsorption structures and adsorption amounts.

Internal ^{238}U-^{230}Th isochron method for dating young basaltic eruptions

RYOJI TANAKA[1]*, TETSUYA YOKOYAMA[1,2] AND EIZO NAKAMURA[1]

[1]PML, ISEI, Okayama Univ., Misasa, 682-0192, Japan (*correspondence: ryoji@misasa.okayama-u.ac.jp)
[2]Deptartment of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, 152-8551, Japan

Dating of young (Late Pleistocene to Holocene) volcanic eruption gives valuable information in volcanology, environmentology, and archaeology. Although several geochronological methods such as ^{40}Ar/^{39}Ar, (U-Th)/He, and ^{14}C, and U-series disequilibrium, have been applied for dating, there exist many analytical limitations in these methods especially for young basaltic volcanics.

This study demonstrates the applicability of ^{238}U-^{230}Th internal isochron methods for the determination of eruption age from young basaltic volcanics using chemically-separated groundmass phases. Groundmass phases of basaltic lava collected from Laguneta volcano, El Salvador, were separated into several fractions with different magnetic susceptibility, followed by leaching in hydrochloric acid solution. Hydrochloric acid solution congruently dissolves olivine, titanomagnetite, and phosphorous-bearing minerals; incongruently dissolves anorthite-rich plagioclase; and does not dissolve augite, albite-rich plagioclase, and alkali-feldspars in the examined groundmass phases. During acid leaching, the range of (^{238}U/^{232}Th) increased from 0.2 (unleached groundmass fractions) to 1.8 (leachates and residues). No, or little, preferential leaching between U and Th occurs by the acid-leaching treatment. Thus, the linear regression line obtained by leachate, residue, and unleached groundmass fractions can be regarded as an isochron, the slope of which indicates the eruption age. The ^{238}U-^{230}Th internal isochron age for two individual samples gave an identical value within the error. Using all the fractions from two samples, the most precise ^{238}U-^{230}Th isochron age was determined as 14 ± 1 ka (2σ). This age agrees with the degassing-induced external ^{238}U-^{230}Th isochron age obtained by whole rock samples when the error is considered. This study also revealed that acid-leaching preferentially fractionates Ra/Th because of incongruent dissolution of plagioclase. Thus, ^{230}Th-^{226}Ra isotope systematics cannot be used for acid-leached samples. The significance of this study lies in the development of precise geochronological method for any type of volcanics which erupted between ~3 and ~300 ky.

Characteristics and driving factors of surface water chemistry of Wujiang watershed

CONG-GUO TANG AND CONG-QIANG LIU

State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China

The changes of water chemistry of rivers can reflect influence of anthropogenic activities on water environment in some extent. In order to understand the relationship between the spatial distribution of eco-environment of the watershed and the characteristics of water chemistry and geochemistry of rivers, firstly, the digital Wujiang watershed was built, and then the sub-watersheds were delineated, taking the sample points as sub-watershed outlets based on GIS. Secondly, using the function of spatial analyst of GIS, the statistical features of eco-environment (such as lithology and land use/cover) of each sub-watershed were calculated according to their respective classification. Finally, the correlation between the spatial distribution of lithology of the sub-watersheds and their corresponding $^{87}Sr/^{86}Sr$ ratio of river water, the correlation between NO_3^-/HCO_3^-, Cl^-/HCO_3^-, SO_4^{2-}/HCO_3^- and anthropogenic activities respectively, and the correlation between the fraction of green vegetation of the sub-watershed and their corresponding flux of TDS (total dissolved solids) were analyzed quantitatively. The results justify that the $^{87}Sr/^{86}Sr$ ratio of river water is highly dependent on the lithologic feature of the watershed and indicate that anthropogenic activities are one of the main sources of NO_3^- and SO_4^{2-} of river waters, the output of TDS is highly dependent on the percentage of vegetation cover of the watershed.

Evaluation of kinetic effect on clumped isotope fractionation (Δ_{47}) during inorganic calcite precipitation

To date, published Δ_{47}-temperature calibrations using different inorganic calcite precipitation and biogenic carbonates, as well as obtained by theoretical calculations, are not consistent. Here we present a set of Δ_{47} data measured from inorganic calcites grown at well-controlled experimental conditions. We show that measured Δ_{47} values are strongly influenced by pH during calcite precipitation. When pH is between 8.3 and 9.0, measured Δ_{47} values (1) generally increase with decrease of temperature, (2) are not sensitive to the change of precipitation rate, and (3) are not sensitive to variation in ionic strength. The Δ_{47}-temperature equation calibrated by our Δ_{47} values for inorganic calcite grown at pH between 8.3 and 9.0 can be written as,

$$\Delta_{47} = (0.0367 \pm 0.0033) \times 10^6/T^2 + (0.2743 \pm 0.0376)$$

where Δ_{47} values were reported in the absolute reference frame. The slope of our calibration line is very similar to theoretical line (0.0392, Schauble *et al*., 2006; Guo *et al*., 2009). If pH ≥10, the Δ_{47} values for calcite grown at 5ºC significantly drift from the Δ_{47}-temperature line. In this case the comparison of $\delta^{18}O$ and Δ_{47} values of calcite grown at pH ≥10 to that grown at pH≤9 indicates that every 1‰ depletion in $\delta^{18}O$ values results in 0.0155‰ enrichment in Δ_{47} values. We argue that any observed kinetic effect on carbonate clumped isotope fractionation is mainly due to isotopic non-equilibrium occurring in the solution during CO_2-H_2O (de)hydration and (de)hydroxylation.

Geochronology and geochemistry of Early-Middle Triassic magmatism in the Argun Massif, NE China: Constraints on the tectonic evolution of Mongol–Okhotsk suture belt

JIE TANG, WEN-LIANG XU*, FENG WANG, WEI WANG, MEI-JUN XU AND YI-HAN ZHANG

College of Earth Sciences, Jilin University, Changchun 130061, China (893335234@qq.com; (*correspondence: xuwl@jlu.edu.cn)

The Mongol–Okhotsk suture belt is located between the North Asian and the North China cratons and played an important role in the formation and tectonic evolution of eastern part of the Eurasian continent during Mesozoic. However, it remains debated whether the southward subduction of the Mongol-Okhotsk oceanic plate beneath the Argun Massif happened. In this paper, we undertook zircon U–Pb dating and geochemical data of the Early-Middle Triassic intrusive rocks in the Argun Massif which is bounded by the Mongol–Okhotsk suture belt to the northwest, with the aim of addressing the above-mentioned question.

Zircons from five representative intrusions in the Argun Massif are euhedral–subhedral, and display fine-scale oscillatory growth zoning in CL images, implying a magmatic origin. Zircon U-Pb dating demonstrates an Early-Middle Triassic magmatism in the Argun Massif, aged between 241 and 247 Ma. The Early-Middle Triassic rocks are composed of a suit of diorite, granodiorite, monzogranite, and syenogranite. They have SiO_2 = 57.71–72.86 wt.%, Mg# = 19–52, K_2O = 2.39–5.00 wt.%, and Na_2O = 3.28–4.28 wt.%. Chemically, they belong to the high-K calc-alkaline series. Moreover, they are characterized by enrichment in light rare earth elements (LREEs) and large ion lithophile elements (LILEs), and depletion in heavy rare earth elements (HREEs) and high field strength elements (HFSEs) such as Nb, Ta, and Ti. Their LREEs/HREEs ratios range from 9.68 to 21.56, and their δEu values vary from 0.61 to 1.31. Taken together, these Early-Middle Triassic intrusive rocks are similar to those from an active continental margin setting. Therefore, we conclude that the Early-Middle Triassic magmatism in the Argun Massif could be generated under an active continental margin setting related to the southward subduction of the Mongol-Okhotsk oceanic plate beneath the Argun Massif, which is also supported by the occurrence of the coeval porphyry Cu-Mo deposits such as the Erdenet Cu-Mo deposit in Mongolia and Taipingchuan Cu-Mo deposit in the Argun Massif, NE China.

This research was financially supported by the National Key Basic Research Program of China (Grant 2013CB429803) and the Natural Science Foundation of China (41272077).

Theoretical calibration of Δ_{47} values of ^{13}C-^{18}O clumps for carbonates

MAO TANG, SI-TING ZHANG AND YUN LIU*

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, China. (Correspondence*: Liuyun@vip.gyig.ac.cn)

Equilibrium clumped isotope distribution has been suggested as a new thermometer for various low temperature systems. With the help of a newly developed cluster-model based method for solids, we re-check equilibrium Δ_i values of ^{13}C-^{18}O clumps of those important carbonate minerals: calcite, aragonite, dolomite, nahcolite and magnesite. Although our method is totally different from the method of Schauble *et al*. (2006), our results generally agree with what Schauble *et al*. (2006) predicted except for nahcolite ($NaHCO_3$). For example, Δ_i values of ^{13}C-^{18}O clumps for calcite and aragonite at 25 C degree predicted by Schauble *et al*. (2006) were 0.41 and 0.43 (in per mil), our results are 0.436 and 0.445, respectively. It confirms that the results of calcite and aragonite are close to each other and there is only marginal difference between them. However, the result for nahcolite from Schauble was 0.41, as same as their result for calcite. Our result for nahcolite is 0.454 which is different from the result of calcite.

Furthermore, there are kinetic effects of isotope fractionation during phosphoric acid digestion of carbonates. The calculated kinetic isotope effect on Δ_{3866} was found about 0.22 per mil for acid digestion processes and can be used to explain the offset between theoretical results and the experiments (i.e., Guo *et al*., 2009). However, the theoretical calibration lines provided by Guo *et al*. (2009) were still different from the experimental calibration line suggested by experiments (e.g., Ghosh *et al*. 2006) in terms of both position and slope. Recently, a new experimental calibration line was suggested (e.g., Dennis *et al*., 2011). Here, we used higher theoretical levels to re-check the theoretical calibration lines and found deviations from the previous ones. Our kinetic isotope effect results are obviously larger than what Guo *et al*. (2009) predicted. Combining our results of equilibrium Δ_i values of carbonates and the kinetic isotope effects by acid digestion, we can obtain theoretical calibration lines for Δ_{47} of carbonates. If put our calibration line into the absolute reference frame diagram suggested by Dennis *et al*. (2011), our calibration line is far above the previous theoretical line and falls between the two experimental lines suggested by Caltech and Harvard groups. The slope of our calibration line is smaller than that of Caltech group but very slightly larger than that of Harvard group.

[5]The University of Tokyo, Kashiwa, Japan

Fluxes of dimethyl sulfide (DMS) and acetone between the ocean and the atmosphere were measured in the subtropical South Pacific Ocean and the equatorial Pacific Ocean in January-February, 2012. Vertical profiles of these gases were obtained above the ocean surface by measurements at 7 heights from 1 to 1400 cm with a profiling buoy aboard R/V Hakuho-Maru during the KH-11-10 and KH-12-1 (EqPOS) cruises. The concentrations of DMS and acetone in gas samples were monitored by a proton transfer reaction-mass spectrometry (PTR-MS). The concentrations of DMS and acetone in the surface seawater and air were continuously measured with PTR-MS during the cruises. The mean sea surface concentration of DMS in the subtropical ocean (2.1±0.5 nM) was slightly lower than that in the equatorial ocean (3.2±1.0 nM). The DMS fluxes substantially varied in the range of 3.6–13.1 and 0.1–18.9 μmol m^{-2} d^{-1} in the subtropical and equatorial oceans, respectively. The magnitude of DMS fluxes was dependent of wind speed. The gas transfer velocities of DMS were calculated from the fluxes and the seawater DMS concentrations. We will discuss gas transfer velocities in comparison to previous studies. The air-sea fluxes of acetone will be also presented and discussed.

Partitioning of Nb between rutile and $NaAlSi_3O_8$-, NaCl- and NaF- aqueous fluids at 1-5 GPa and 300-600ºC

E.A. TANIS[1,2] , A. SIMON[1], O. TSCHAUNER[2,3] P.CHOW[4], Y. XIAO[4], J. HANCHAR[5], G. SHEN[5] AND Y. ZHAO[5]

[1]Earth &Environmental Sciences, University of Michigan

[3]Department of Geoscience, University of Nevada Las Vegas
[4]HPCAT, Carnegie Institute of Washington, Argonne IL
[5]Earth Sciences, Memorial University of Newfoundland

Rutile (TiO_2) has been proposed as an important host for high field strength elements (HFSE) such as Nb and Ta in high-pressure, moderate temperature metamorphic environments, including subduction zone systems. The observed depletion of HFSE in arc magmas can be explained if rutile is chemically inert with respect to aqueous fluids evolved during progressive metamorphism of subducted slab materials. However, both field observations and experimental studies [1] suggest that titanium, as well as HFSE can be soluble in aqueous fluids. Published experimental data were obtained by performing experiments at temperatures >700°C and pressures <2.5 GPa, conditions not entirely relevant to fluid loss in many arc systems. Here, we report new data that constrain directly the partitioning of Nb between fluid and rutile at 1 to 5 GPa and 300-600°C, conditions applicable to fluid evolution during the blueschist to eclogite transition.

We investigated systematically the partitioning of Nb between aqueous fluid and Nb-rutile (1wt% Nb) by adding albite ($NaAlSi_3O_8$), 10 and 20 wt % NaCl, and 4 wt % NaF to the fluid phase. The concentration of Nb in aqueous fluid was measured directly by using a hydrothermal diamond anvil cell and synchrotron X-ray fluorescence at the HPCAT 16-IDD beamline at the Advanced Photon Source.

Fluid	Pressure (GPa)	Temperature (ºC)	Nb Concentration (ppm)
10% NaCl	1.2-2.8	300-700	9-23
20% NaCl	1.7-4.7	300-600	24-86
$NaAlSi_3O_8$	1.0-5.8	300-600	100-1050
4% NaF	3.0-6.5	300-500	260-1075

Our data indicate that dissolved NaF and albite, relative to pure water and NaCl, have a much greater effect on enhancing Nb concentration and transport in dense, moderate temperature, aqueous fluid. Our findings are consistent field studies such as [1] that document HFSE mobility in aqueous fluids evolved during the blueschist to eclogite transition.

Properties and structural role of iron in silicate melts and glasses

ISABELLE TANNOU[1,2]*, MARIE JEFFROY[1], DOMINIQUE DE LIGNY[3] AND DANIEL R. NEUVILLE[2]

[1] Saint-Gobain Recherche, 39 quai Lucien Lefranc, 93303 Aubervilliers cedex, France (correspondence: tannou@ipgp.fr)
[2] Institut de Physique du Globe de Paris, 1 rue Jussieu, 75238 Paris cedex 05, France (neuville@ipgp.fr)
[3] Université Claude Bernard Lyon1, UMR5306 CNRS, 12 rue Ada Byron, 69622 Villeurbanne, France (dominique.de-ligny@univ-lyon1.fr)

Iron is an important element to probe the properties and the structure of silicate melts. In earth science most of lava contain more than 10% of iron whereas the proportion is much smaller in industrial materials. Iron usually occurs in two different valence states (Fe^{2+} or Fe^{3+}), and three coordination: 4, 5 and 6 for these different redox states. Thus, the influence of iron oxide on the melt properties is complicated. Consequently, the redox ratio of silicate glasses and melts is an important parameter which role must be properly studied to understand the physical and chemical properties of these materials.

The coordination of iron may evolve as a function of the redox state. These changes are due to the fact that iron is essentially present in the form of Fe^{3+} in tetrahedral position at lower temperatures whereas it mainly occurs as Fe^{2+} in 6-fold coordination at higher temperatures. These changes in the iron coordination may influence the short range order around network modifier, such as Na or Ca. Our goal is to understand the importance of those coordination modifications caused by the change in iron redox.

X-ray absorption spectroscopy experiments are very valuable to determine short-range order. It should allow us to study the iron valence and coordination, as well as the sodium and calcium environment. However this technique is not always accessible. Therefore, other experimental methods must be used to study the network modifications such as Raman spectroscopy and electron microprobe.

We focused our work on the changes which happen in the glass during the transition between different redox states. Especially with regard to the network structure and the local environment of network-modifier elements.

Temporal variations in the composition and age of terrestrial organic carbon transported by the Yellow River

SHUQIN TAO[1,2], TIMOTHY IAN EGLINTON[2], DANIEL MONTLUCON[2], CAMERON MCINTYRE[2] AND MEIXUN ZHAO[1]

[1]Ocean University of China, Qingdao 266100, China
[2]ETH Zürich, 8092 Zürich, Switzerland

The Yellow River is the World's highest turbidity major fluvial system, delivering over 1×10^9 t of sediments annually into the Chinese marginal seas, accounting for ~7% global sediment flux to the ocean. Organic carbon carried by the Yellow River therefore may play a significant role in the global and regional organic carbon cycle.

The focus of the present study is to develop an understanding of the sources, composition and age of terrestrial organic carbon that is carried by the Yellow River and supplied to the adjacent Bohai Sea and Yellow Sea. Near-surface suspended particulate matter samples were collected nearby the Lijing Station, ~50 km upstream of the river mouth (Dongying), as part of a sampling campaign between June 2011 and June 2012 in order to assess seasonal variations in fluvial supply. In addition to bulk properties, the abundance and carbon isotopic composition of source-specific biomarkers (fatty acid & alkanes) were measured.

The concentrations of higher plant-derived long-chain ($\geq C_{24}$) *n*-alkanes, *n*-fatty acids and particulate organic carbon (POC) co-varied with total suspended solid (TSS) concentrations, with peak abundances during summer and early autumn, indicating plant-derived organic carbon is controlled by the overall flux of terrestrial sediments, which in turn is influenced by flood events and human activities.

POC in the Yellow River exhibits relatively uniform $\delta^{13}C$ values (-23.94 to -24.37‰), and old radiocarbon ages (4000 to 4600 ^{14}C years). Radiocarbon ages of short-chain (C_{16}, C_{18}) fatty acids were variable but generally modern (from 560 years to greater than modern), suggesting they are sourced from fresh terrestrial debris, but more likely from aquatic productivity during warm and low-turbidity periods. In contrast, long-chain fatty acids display a relatively narrow and pre-aged range from 1550 to 2080 years.

These results, and associated molecular and isotopic information, indicate that the aged OC – likely sourced from soils on the Chinses loess plateau within the drainage basin – contributes significantly to the suspended load of the Yellow River.

[4]Durham University, Durham, United Kingdom

The presence of diamonds with transition zone (TZ) inclusion parageneses in a growing number of kimberlites worldwide is generally considered evidence for an ultradeep origin of kimberlites. However, combined geochemical and experimental evidence, including mantle redox constraints, suggests that kimberlite magma formation is best explained by volatile-fluxed melting of refertilized depleted upper mantle domains.

We analysed the Sr-Nd-Hf isotope compositions of fresh hypabyssal kimberlites from the 75-to-55 Ma Lac de Gras (LDG) field of the central Slave craton that contains TZ diamonds. The LDG kimberlites show the most extreme Nd-Hf isotope decoupling reported from global kimberlites. Isotopic modelling suggests that the steep-angled array in Nd-Hf isotope space is best explained by mixing of convecting upper mantle-derived CO_2-rich melt with minor amounts of alkali silicate melt derived from an isolated mantle reservoir with extremely unradiogenic Hf. Our data indicate that OIB-type material stored in the transiontion zone for >2 Gyr can be the source of the alkali silicate melt component. Given that the nearby 170 Ma Jericho kimberlites contain neither TZ diamonds nor anomalously unradiogenic Hf, we suggest that onset of fast and steep subduction along the western margin of North America at 100 Ma caused significant entrainment of ancient TZ material into the upper mantle beneath the region. Recycled ancient OIB-type material partially melted during the subduction-triggered upward mantle flow, and locally refertilized the depleted convecting upper mantle. Subsequent CO_2- and H_2O-fluxed redox melting of refertilized domains gave rise to kimberlite magma formation beneath the thick cratonic lid in the LDG area starting at 75 Ma. Model calculations indicate that ancient TZ diamonds could have been brought to the Slave craton base by vigorous mantle flow near a subduction zone within <25 Myr, such that they were available for sampling by the ascending upper mantle-derived LDG kimberlite magmas at 75 Ma [1].

A Possible Route to K^+-Enriched Aqueous Solutions on Early Earth

O. TARAN,*[1] H. LANGE[1] AND G.M. WHITESIDES[1,2]

[1] Department of Chemistry and Chemical Biology, Harvard University, Cambridge, MA 02138, USA.
[2] Wyss Institute for Biologically Inspired Engineering, Harvard University, Cambridge, MA 02138, USA. (correspondence: otaran@gmwgroup.harvard.edu)

All known living organisms have a K^+-rich intercellular medium, while usually existing in a Na^+-enriched environment [1]. High K^+ concentrations are required for the proper function of numerous essential enzymes and ribozymes [2]. This difference between cation concentrations is translated to potential difference used for energy storage and signalling. Most of the natural terrestral envinroments are known to be enriched in Na^+ due to its higher abundance and high solubility of its salts. The Na^+/K^+ mole ratio inside living cells varies around 1/10, which is roughtly the opposite ratio of these ions in seawater (47/1). In this work we show that one of the processes leading to the enrichment of groundwaters in K^+ can occur during acid weathering of Aluminium rich clays and zeolites and the fractional secondary precipitation of alunite and Na-alunite

Zeolites and montmorillonites were treated by acidic (0.1-1M H_2SO_4) solutions (K^+/Na^+ mole ratio 1/5) at temperatures 20°-50°C. The clay/acid mixtures were left to evaporate. During the drying process octagonal crystals were formed from coalecent brines on the surface of the clays. The crystals were identified by X-ray diffraction and ICP analysis as $KAl(SO_4)_2$ The remaining interstitial brine was enriched in Na^+ and close to saturation with respect to $NaAl(SO_4)_2$. Fast washing from the final mixture surface leads to the enrichment of K^+ in the formed solution by orders of magnitude depending on pH, temperature and a mineral type.

This proposed scenario leads to envinroments rich in potassium and can also be applied for accumulation of other prebiotic components, such as phosphate and small organic molecules. We suggest that acid weathering could be a process to accummulate essential components for the chemical origin of life.

How much magmatic water is transported by volcanic gases?

YURI TARAN[1] MIKHAIL ZELENSKI[2] AND ILYA CHAPLYGIN[3]

[1]Institute of Geophysics, Universidad Nacional Autónoma de México, México D.F., 04510, México
[2]Institute of Experimental Mineralogy, RAS, Chernogolovka, Moscow Dstr.142432, Russia
[3]Institute of Ore Deposits, RAS, Moscow, 119017, Russia

Gases sampled from volcanic fumaroles and from the surface of lava lakes and lava flows are characterized by temperatures from boiling point of water up to 1100°C. The main component of volcanic gases is water vapor with concentrations from ~50 to 99 vol% . The fraction of magmatic water in volcanic gases is estimated using the isotopic composition of volcanic vapor. For the highest temperature fumaroles of subduction-type volcanoes D/H ratios on average ~ -25‰ (V-SMOW) and $^{18}O/^{16}O$ are close to the corresponding values of the whole rock, usually from +6 ‰ to +9‰. In many cases volcanic vapors of arc volcanoes with t>800°C are represented by almost pure magmatic water. However, there are numerous exceptions from this rule when a >800°C volcanic gas is a mixture of magmatic water with up to 50% of meteoric or seawater vapors. Most of the arc fumarolic gases demonstrate a single trend of mixing between magmatic and meteoric end members in their chemical and isotopic compositions. Much more complicated are cases related to volcanic gases from hot spot and rift volcanoes with magmas much less water abundant that arc magmas. Low and medium-temperature fumaroles of Kilauea (Hawaii) and Sierra Negra (Galapagos) discharge gases with a low content of water vapor (50-70 vol%) but all these vapors apparently have meteoric origin and thus the real proportion of magmatic water and its isotopic composition in gases of these hot spot volcanoes is impossible to determine. The new data on the high-temperature (> 1000°C) volcanic gas from a hornito of the Erta Ale lava lake (Zelenski *et al*., submitted) make possible to estimate the isotopic composition of magmatic water for this continental rift volcano. The Erta Ale volcanic vapor derived from the liquid lava lake seems to be about half diluted by meteoric water and has the isotopic composition between that of local meteoric water and water with $\delta D < -60‰$ if to accept $\delta^{18}O = +6‰$, like in the Erta Ale whole rock samples. However, this suggestion assumes the absence of the oxygen isotope exchange between CO_2 and H_2O during sampling when the ~1:1 H_2O+CO_2 mixture is cooling from the vent to condensate temperature.

Important factors for geochemical research of stream sediments near storm water outflow sites

R. TARAŠKEVIČIUS, R.ZINKUTĖ* AND Ž.STANKEVIČIUS

Nature Research Centre, Akademijos 2, Vilnius LT-08412, Lithuania (*correspondence: zinkute@geo.lt)

Urban storm sewer system is an important pathway of transfer of contaminants to the hydrosphere. Presuming that each storm water outflow (SWO) can increase the content of potentially harmful chemical elements (PHE) in stream sediments, matched pairs of samples can be taken upstream and downstream from SWO. Water flow rate differences lead to variability of lithological composition (from clay to sand) and geochemical changes even within short distance. It is useful to find out the advantageous grain size fraction for revealing the geochemical changes due to influence of SWO.

Thirty nine samples of Neris river sediments including 12 matched pairs of samples near SWO sites of Vilnius city were taken. The contents of Pb, Zn, Cu, Ni, Cr (PHE) and rock forming elements Al, Ca, Mg, Na, K, Fe, Si, P, S, Ti, Mn were determined in the bulk fraction (<2.0 mm) and fractions <0.1 mm, 0.1-0.25 mm, 0.25-0.50 mm by x-ray fluorescence.

In most samples the fraction 0.1-0.25 mm (average is ~57%) and <0.1 mm (30%) prevails. In sequence of fractions <0.1 mm, 0.1-0.25 mm, 0.25-0.50 mm the contents of most elements decrease due to dilution by quartz and plagioclases.

Using Wilcoxon matched pairs test for the bulk fraction the differences between samples upstream and downstream from SWO are insignificant for all 5 PHE, meanwhile for the <0.1 mm fraction they are significant for Pb, Zn and Cu. The increase of Cr and Ni contents is insignificant, because they are not the main in pedogeochemical anomalies of Vilnius.

Analysis of <0.1 mm fraction seems to have advantages in comparison with the bulk fraction <2 mm for indicating places of storm water outflow. For refinement of results, not only enrichment factors should be calculated by normalising to clay-related (Al, Mg, K, Ti) or biophylic (S, P) elements, but also the dilution factor by sand (Si) taken into account.

NanoSIMS Pb/Pb dating of tranquillityite in lunar basalts

R. TARTÈSE[1]*, M. ANAND[1,2] AND T. DELHAYE[3]

[1]Planetary and Space Sciences, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK (*correspondence: Romain.Tartese@open.ac.uk)
[2]Department of Earth Sciences, The Natural History Museum, Cromwell Road, London, SW7 5BD, UK
[3]Plateforme ONIS/NanoSIMS, Université de Rennes 1, Campus de Beaulieu, 35042 Rennes Cedex, France

Ion microprobe U-Th-Pb geochronology was first carried out three decades ago [1-2] to date phosphates and Zr-rich minerals from lunar samples, but was hampered by the limited mass resolution of the instrument. Subsequent analytical developments improved the accuracy and precision of *in-situ* Pb isotope measurements. In lunar samples, *in-situ* U-Pb dating has mostly been focused on zircon (e.g., [3] and refs therein), which occurs in rock types mainly representing the lunar highlands [3], while it is rare in mare basalts in which U and Th, are mostly hosted by baddeleyite, zirconolite and tranquillityite. This latter group of minerals can also yield precise and accurate Pb/Pb ages [4-9]. However, their small sizes often pose serious challenges to application of *in-situ* dating techniques.

We have used the NanoSIMS 50 at the University of Rennes 1 to carry out high-resolution Pb/Pb dating in tranquillityite in mare basalts. The 120-140 pA primary O^- beam produced ~ 3 μm spots. We obtained average $^{207}Pb^*/^{206}Pb^*$ dates of 3713 ± 8 Ma, 3769 ± 8 Ma and 3736 ± 10 Ma for samples 10044, 75055 and 74255, respectively, which we interpret as the crystallisation ages of these basalts. These ages are consistent with previous but provide tighter constraints on the crystallisation of these basalts. The high-spatial-resolution achieved in our dating protocol using the NanoSIMS 50 and the common occurrence of tranquillityite in lunar basalts have opened up a new avenue for carrying out rapid, accurate and precise age dating of mare basalts.

Evidences of paleoproterozoic metamorphism in the NW region of the Quadrilatero Ferrifero area, Minas Gerais, Brazil: Implications for gold mineralizations

COLOMBO C. G. TASSINARI[1]*, MARTA E. VELÁSQUEZ [2], JOSÉ M. U. MUNHÁ[4], LYDIA M. LOBATO[5], ANTONIO M. MATEUS[4] AND WILLIAM F. CAMPOS[5]

[1]Instituto de Geociências da Universidade de São Paulo, Rua do Lago, 562, 05508-900, São Paulo, SP, Brasil, CNPq correspondence:ccgtassi@usp.br
[2]Departamento de Geologia da Universidade Federal do Amazonas,
[3]Departamento de Geologia, Faculdade de Ciências, Universidade de Lisboa, Portugal
[4]Instituto de Geociências Universidade Federal de Minas Gerais
[5]Jaguar Mining Group

It was characterized a paleoproterozoic medium-grade metamorphism related to the gold mineralizations in the NW area of the Iron Quadrangle (Quadrilatero Ferrífero), in Minas Gerais State, Brazil. The gold ores are hosted by sericite-chlorite quartz schist from the upper metasedimentary unit of the Rio das Velhas Supergroup, These rocks are metamorphosed under transitional greenschist-amphibolite facies conditions and comprise garnet + staurolite + cummingtonite, biotite + chlorite + plagioclase + quartz; the metamorphic peak is at ca. 600ºC and 6.6 kb. The ore consist of arsenopyrite, pyrite, pyrrhotite and free gold in a gangue made of quartz, carbonates, graphite and oxides (hematite, magnetite and ilmenite). The age of the metamorphism was characterized by Sm-Nd ages for garnet-whole rock and Rb-Sr whole rock isochron with an ages around 2.2 Ga. The 1,9 Ga Rb-Sr age of biotite suggest that high geothermal gradients were sustained for a long period of time. The ore minerals are dated by Rb-Sr and Pb-Pb methods, which give an ages of 2.15 and 2.0 Ga. Rb-Sr applied to hydrothermal sericite – whole rock pair, yielded an age of 1928 ± 2.6 Ma. The 2.1-2.0 Ga ages could be related to the first stage of mineralization at 600 ºC. The age of 1.9 Ga could be related to the boiling episode that occurs at ~340ºC. Pb, Sr and Nd isotopic compositions of the ore minerals suggest that the hydrothermal fluids represents mixing between several reservoirs, like the mantle, lower and upper continental crust. The metamorphism must have sustained elevated crustal geotherms for at least 100 Ma, promoting hydrothermal fluids circulation during the orogenic time.

Mo-W-Re-Au-Cu partitioning between vapor, brine and felsic melt: Super-solidus to sub-solidus

BRIAN TATTITCH[1]*, JON BLUNDY[1], PHILIP CANDELA[2], AND PHILIP PICCOLI[2]

[1]Bristol Earth Experimental Studies, University of Bristol, Bristol BS8 1RJ, (Brian.Tattitch@bristol.ac.uk)*
[2]Laboratory for Mineral Deposits Research, University of Maryland, College Park, USA

The exsolution of metal-bearing "proto-ore fluids" from magmas initiates at super-solidus conditions and continues throughout cooling and decompression to solidus conditions for the parental magma. The range of exsolution conditions for a particular magma will affect the efficiency by which each ore metal is removed from the melt, the metal ratios in the exsolved fluid(s), the mass of metals available for transport, and ultimately the grade of the deposits.

Experiments performed at a range of P-T conditions across the solidus for a given magma composition provide insight into the behavior of these metals that is not readily accesible by study of natural samples. We have performed exploratory experiments to investigate the effect of the super-solidus to sub-solidus transition on metal partitioning between melt and volatile phases under ore-mineral saturated conditions. These experiments examine Mo-W-Re-Au partitioning, and wolframite-molybdenite solubility, at super-solidus (800ºC 100 MPa), near-solidus (725ºC 100MPa) and sub-solidus (700ºC 75MPa) conditions. New techniques are in development to refine data reduction and account for the complex behavior of our Mo-Fe-W-bearing fluid inclusions. However, the early results may be broadly interpreted as showing that Mo and W partitioning between vapor, brine and melt is strongly influenced by the super-solidus to sub-solidus transition.

The impact of the transition is more pronounced for W ($D^{v/m}$ = 11 ± 5 and 210 ± 120) compared to Mo ($D^{v/m}$ = 10 ± 4 and 50 ± 25) as the temperature drops from 800ºC to 725ºC. These data are consistent with fractionation of Mo from W across the super-solidus to sub-solidus transition. The molybdenite- and wolframite-saturated fluids have W/Mo ratios that increase from 20 to 30 to 60 in the brine and 15 to 25 to 50 in vapor, for 800ºC-100MPa to 725ºC-100MPa to 700ºC-75MPa, respectively. While these results are tentative, new experiments are in progress that include Mo, W, Re, Au, and Cu. These new experiments and new data analysis techniques will provide further insight into the effect of the super-solidus to sub-soldius transition on the composition and ore-mineral solubility limits of proto-ore fluids.

The silicon isotope record of early silica diagenesis

M. TATZEL[1]*, F. VON BLANCKENBURG[1], J. A. SCHUESSLER[1] AND G. BOHRMANN[2]

[1]German Research Center for Geosciences, GFZ Potsdam, Germany (*correspondence: mtatzel@gfz-potsdam.de)
[2]Department of Geosciences, Universität Bremen, Germany. (gbohrmann@marum.de)

During diagenesis, silica is converted to quartz through dissolution-reprecipitation reactions which are likely influenced by isotope fractionation effects.

To assess the impact of diagenesis on the silicon isotope composition of chert, we explored the silicon isotope record of Plio- and Pleistocene siliceous sediments of the South Atlantic that are hosting the youngest products of the incipient stages of silica diagenesis found to date.

High δ^{30}Si values of 2.26 ± 0.18 ‰ (n= 5) and 1.97 ± 0.06 ‰ (n= 4) characterize two bulk porcelanite (opal-CT) layers found in two drill cores from Maude Rise and the Southwest Indian Ridge, respectively. Bulk δ^{30}Si values of surrounding siliceous oozes are lower and range between -0.34 ± 0.08 ‰ (n= 4) and 0.60 ± 0.08 ‰ (n= 7), and 0.16 ± 0.08 ‰ (n= 4) and 1.45 ± 0.11 ‰ (n= 6), respectively.

Within these types of siliceous sediments, diatoms constitute both the compartment most prone to dissolution and heaviest in δ^{30}Si consistent with [1]. Their dissolution together with isotope fractionation through rapid precipitation of inorganic opal (opal A') during the ascent of pore fluids can produce isotopically heavy diagenetic fluids.

From these fluids porcelanite is precipitated only in narrow ranges of the host sediment characterized by extremely low detrital mineral contents.

High-spatial resolution analyses along profiles through two porcelanite layers by fs LA-MC-ICP-MS show opposing trends of δ^{30}Si and Al/Si ratios and indicate a kinetic control on the isotope fractionation factor, varying in response to the chemical composition of the fluid.

We identified processes of fluid generation, isotope fractionation, and chemical controls on precipitation during early stages of silica diagenesis that can well be extrapolated to conditions of ancient chert formation. The understanding of these processes can help discerning diagenetic fingerprints from source signals in the silicon isotope record of chert.

U-Pb, Lu-Hf and Sm-Nd isotope systematics during polymetamorphism in the Ancient Gneiss Complex, Swaziland

J. TAYLOR*, A. GERDES AND A. ZEH

Institute of Geoscience, Frankfurt University, Altenhöferallee 1, 60438 Frankfurt
(*correspondence:jeannerocks@gmail.com, gerdes@em.uni-frankfurt.de, a.zeh@em.uni-frankfurt.de)

This study aims to resolve some of the potential complexity associated with Archaean polymetamorphic gneiss terranes, with specific application to high-grade paragneisses from the Ancient Gneiss Complex (AGC) in Swaziland. Archaean zircons and monazites which have experienced multiple growth and/or alteration episodes, typically display a complexity in their zonation and U-Pb ages which is near impossible to resolve. However, Gerdes & Zeh [2] showed that the radiogenic Hf content of zircon, for example, remains constant during alteration, and changes only during new zircon growth; providing a robust tool to constrain the exact number of metamorphic cycles a rock has been through. The Sm-Nd system could provide a similarly useful tool. Monazite, allanite, apatite, rutile and titanite are U, Th and light-REE bearing phases, making them highly amenable for Sm-Nd and U-Pb isotope analysis [1]. This study represents a first attempt at investigating the simultaneous behaviour of the U-Pb, Lu-Hf and Sm-Nd isotope systems in accessory phases during polymetamorphism, by in situ LA-MC-ICP-MS analysis.

We investigate metasedimentary granulites from two separate, spatially related areas of outcrop in south-central Swaziland, which were subjected to multiple high-grade events throughout the Mesoarchaean [3]. Zircons and monazites from these gneisses are particularly interesting in terms of the complexity in their zonation and U-Pb ages, with dominant age peaks at 3.51 Ga, 3.43 Ga, 3.40-3.39 Ga, 3.35 Ga, 3.33 Ga, 3.23-3.21 Ga, 3.18 Ga, 3.16 Ga, 3.11-3.07 Ga, and 2.99 Ga. The U-Pb, Lu-Hf and Sm-Nd isotope record in these grains may inform on: (1) the provenance of sediments from the south-eastern Kaapvaal Craton and the nature of the Archaean/Hadean hinterland; (2) the number of metamorphic episodes recorded; and (3) Archaean geodynamic processes during key events associated with early lithosphere assembly and crustal differentiation.

Timing of ultra-high temperature (UHT) metamorphism and formation of incipient charnockites in the Kerala Khondalite Belt (KKB), southern India

R. TAYLOR*, C. CLARK AND I.C.W. FITZSIMONS

Dept of Applied Geology, Curtin University, Perth, Australia, (*richard.taylor@curtin.edu.au)

The Kerala Khondalite Belt, also known as The Trivandrum Block (TB), makes up the southernmost tectonic unit of the Indian Subcontinent and the southern extension of the microcontinent Azania. The TB is dominated by high-grade metasedimentary rocks typically either grt-bt felsic gneisses (locally referred to an leptynites) and graphite-bearing grt-crd-sill gneisses (khondalites). The leptynites and khondalites, together with a variety of igneous rocks, have been metamorphosed to granulite facies. Metamorphic conditions vary, with the lowest pressures and temperatures in the centre of the block (5 kbar, ~750°C), and a systematic increase to the north and south up to 8-9 kbar and <1000°C

Charnockites within the Trivandrum block typically form large-scale, orthopyroxene-bearing granitic bodies, such as those seen in the Nagercoil Block at India's southernmost tip. However the appearance of incipient charnockites is more enigmatic, forming metre-scale "patches" within host leptynites, one classic locality being near Kottavattom [1]

Charnockitisation in these rocks is identified as a late stage process related to fluid migration through the host rocks, resulting in some of the youngest ages for accessory phases in the KKB. SHRIMP U-Pb data for both zircon and monazite in the host leptynite and incipient charnockite patches, combined with rare earth elements (REE) in zircon, monazite and garnet have been used to investigate the timing of charnockitisation in relation to the UHT metamorphism in the region.

Determination of strontium-90 in seawater using TODGA chelating resin

HIROFUMI TAZOE[1]*, TAKEYASU YAMAGATA[2], HAJIME OBATA[3] AND MASATOSHI YAMADA[1]

[1]Institute of Radiation Emergency Medicine, Hirosaki University Aomori, Japan (*Correspondence. tazoe@cc.hirosaki-u.ac.jp)

[2]Atomosphere and Ocean Research Institute, The University of Tokyo, Tokyo, Japan

[3]College of Humanities and Sciences, Nihon University, Tokyo, Japan

Strontium-90 has been observed maximum values at late 1950s, which originated global fallout from nuclear weapons tests, and gradually reduced to about 1mBq/L in the Pacific Ocean (Pavinec *et al*., 2012). The accidents of the Fukushima Daiichi Nuclear Power Plant in Japan and the leak of contaminated water released various radioactive nuclides. Casacuberta *et al*. (2012) estimated that amount of Sr-90 release to the sea based on the observed Sr-90/Cs-137 ratio and Cs-137 by modeling data was 90 - 900 TBq. However, Sr-90 data are limited because of its complicated analytical procedure. Determination of Sr-90 in seawater generally requires preconcentration of Sr and separation from Ca and other beta emitters. In this study, rapid and robust purification technique for the daughter radionuclides yttrium-90 of Sr-90 using TODGA chelating resin (Eichrom) without separation of Sr from Ca. TODGA resin shows high distribution coefficient in high HCl and HNO_3 concentrations.

Sr in seawater (20L) was preconcentrated by oxalate coprecipitation. Precipitates was decomposed to carbonate at 550°C and dissolved in HCl and conducted Fe hydroxide coprecipitaion. After 2 weeks for ingrowth of Y-90, sample was conducted Fe hydroxide coprecipitaion. Pricipitate was filtered and redissolved in 7 mL of 12M HCl. Sample solution was flowed to the column combined anion exchange resin (3mL) and TODGA resin (2mL). Most of seawater matrix such as Sr, Ca and Mg were removed by Fe hydroxide coprecipitation and easily eluted 8M HCl from TODGA resin column. Fe and Bi were adsorbed to anion exchange resin. Pb and Bi were also eluted in 8M HCl fraction. Y was eluted by 20 mL of 0.1 M HCl. Y-90 was measured by low background gas flow proportional counter (Canberra LB-4100).

This analytical procedure was applied to seawater from the Pacific Ocean near the Japan Islands in Janually 2013. Averaged surface Sr-90 concentration was 0.95 ± 0.12 mBq/L, which is comparable to that before the accidents.

Regional modelling of Saharan dust

INA TEGEN[1] AND BERND HEINOLD[1]

[1]Leibniz Institute for Tropospheric Research, Leipzig, Germany

The Sahara desert in northern Africa is the world's largest source of dust aerosol. Regional-scale models help to understand processes involved in dust emission, transport and deposition, and are suited for comparisons with results of field studies like the SAharan Mineral DUst experiment (SAMUM) that aimed at improving the estimates of Saharan dust radiative forcing, or at understanding of dust deposition in the oceans. Models of modern atmospheric dust still often show considerable deviations from observations. One cause can be inadequacies in simulated meteorological fields that are used to compute dust emission fluxes. In contrast to global-scale dust models, regional dust models are expected to better reproduce individual dust events due to their higher grid resolution. Still, the representation of dust emission events that are related to precipitation events (haboobs, density currents) is problematic at grid resolutions that require parameterization of wet convection processes. New remote sensing products, together with the observations from recent field studies promise an improved understanding of dust regimes and are expected to lead to considerably improved dust models. We summarize findings of recent multi-year regional dust model studies and discuss open questions.

The halogen (F,Cl, Br) budget of continental granitoid plutonic rocks

H.TEIBER[1]*, M.A.W. MARKS[1], T. WENZEL[1], W. SIEBEL[1], R. ALTHERR[2] AND G. MARKL[1]

[1]Universität Tübingen, Mathematisch-Naturwissenschaftliche Fakultät, FB Geowissenschaften, Wilhelmstrasse 56, D-72074 Tübingen (*correspondence: holger.teiber@uni-tuebingen.de)

[2]Ruprecht-Karls-Universität Heidelberg, Institut für Geowissenschaften, Im Neuenheimer Feld 234-236, D-69120 Heidelberg

The main goal of this study is to decipher the contribution of various volatile-bearing minerals to the whole-rock halogen (F, Cl, Br) budget of continental granitoid plutonic rocks and how this budget is governed by primary and secondary minerals. For this purpose, we investigated various granitoids with different volatile-bearing silicate mineral assemblages: (1) hornblende + biotite, (2) only biotite and (3) biotite + muscovite. Furthermore, accessory apatite is present in all samples, whereas fluorite and titanite occur only sporadically.

Halogens (F, Cl, Br) were extracted from the whole-rock powders by Pyrohydrolysis and subsequently analyzed by Ion Chromatography. Volatile-bearing minerals were analyzed for F and Cl by means of Electron Microprobe Analysis and for Br by Total Reflection X-ray Fluorescence.

All the investigated rock samples lie in the range of 500-3000 μg/g F and 50-900 μg/g Cl, respectively. In several samples, F and Cl contents of the whole-rocks roughly correlate with the halogen contents of apatite, biotite and mica and with the presence of fluorite. Br in the whole-rock powders is always <1 μg/g and quantifiable Br concentrations were only found in few hornblende and apatite separates.

Importantly, detailed calculations of the whole-rock halogen budget (based on modal analysis) show strong misfits for many samples and indicate that appreciable amounts of F and Cl are not incorporated in the minerals mentioned before. Indeed, detailed X-ray mapping and short-term leaching experiments (2 minutes) confirm that significant amounts of F and Cl are present (1) in tiny secondary mineral phases, (2) in fluid inclusions and (3) potentially located along grain boundaries. These cannot be accounted for budget calculations based on modal amounts of the various minerals.

Thus, our study shows that great care has to be taken when using the halogen contents of whole-rocks for petrogenetic models, since significant amounts of halogens in whole-rocks might be of secondary origin.

U-Pb geochronology of detrital zircons from metasedimentary rocks from Formation of Desejosa, Serra do Marão, Portugal

R. J. S. TEIXEIRA[1,2], C. COKE[1,3], , M. E. P. GOMES[1,2], R. DIAS[3,4] AND L. O. MARTINS[1,2]*

[1] Department of Geology, University of Trás-os-Montes e Alto Douro, Vila Real, Portugal, (ccoke@utad.pt, rteixeir@utad.pt, mgomes@utad.pt,) (lisa_martins@hotmail.com) (*presenting author)

[3] Centro de Geofísica de Évora, Universidade de Évora

[4] Universidade de Évora, Escola de Ciências e Tecnologia, Departamento de Geociências, Portugal, rdias@uevora.pt

The Serra do Marão area is located in the Central Iberian Zone and is dominated by an Ordovician sequence that rests on parallel unconformity on Cambrian/Neoproterozoic metasediments, belonging to Group of Douro. Two samples were collected from the upper formation of this Group (Formation of Desejosa): 1) a metapsamite from the top of this formation, which is characterized by a sucession of metasiltitic and phyllitic layers, and 2) an intraformational metaconglomerate. The U-Pb geochronological data obtained in detrital zircons by Laser Ablation-Quadrupole-Inductively Coupled Plasma Mass Spectrometry will help to constrain their maximum depositional age.

The U-Pb data set (52 detrital zircons with 99–107% and 33 detrital zircons with 85–103% concordant ages for metaconglomerate and metapsamite, respectively, is dominated by Neoproterozoic ages (84.6 % and 57.6 %), but there are few Cambrian (9.6 % and 9.1 %) and Paleoproterozoic (5.8 % and 3.0 %) ages. Mesoproterozoic detrital zircons are also present (6.1 %) in the metapsamite. Furthermore, a cluster of Ordovician ages in the metapsamite (24.2 %) yield a concordia age of (465 ± 16 Ma), which may reflect some Pb loss induced by the Early Ordovician felsic volcanism (470.1–474.6 Ma) in the area.

The detrital zircon population of both samples record a long-lived Neoproterozoic magmatic episode, probably located near or at the northern Gondwana margin. However, the contribution of other sources containing Mesoproterozoic (1151–1088 Ma) and Paleoproterozoic (2257–1821 Ma) zircons must be considered. The U-Pb concordia age suggest a maximum depositional age of 522 ± 26 Ma for the metaconglomerate and an preliminar interval from 537 ± 22 Ma to 516 ± 25 Ma for the metapsamite.

U-Pb, Nd-Sr and geochemical fingerprints of granitic magmatism inside the Paleoproterozoic Mineiro belt, Southern São Francisco Craton: Evidence from the Ritápolis batholith

[1]WILSON TEIXEIRA, [2]CIRO A. ÁVILA, [3] EVERTON M. BONGIOLO, [1] MARIA H. HOLLANDA [4] AND NATALI BARBOSA

[1] Inst. Geociências, USP, wteixeir@usp.br; hollanda@usp.br

[3] Inst. Geociências, UFRJ, (ebongiolo@geologia.ufrj.br)
[4] PhD program; Inst. Geociências, USP, natali@usp.br

The Mineiro belt (2.45-2.00 Ga) was created through accretionary arcs, ocean closure and eventual continent-continent collision. We document the case of the Ritápolis batholith (RB) – for which the U-Pb and Nd-Sr signatures and geochemistry provide new insights for the evolution of this belt. Dikes of the RB truncate the rocks of the so-called Resende Costa (2.36-2.33 Ga) arc. RB rocks vary from equigranular (fine-medium to coarse grained) to porphyritic with fenocrystals of plagioclase and microcline, showing igneous banding and different types of xenoliths (amphibolite, diorite, gabbro). LA-ICPMS U-Pb zircon dates yielded a crystallization age of 2149 ± 10 Ma (MSWD = 0.8) whereas the analyses from metamorphic rims yielded a lower intercept age of 662 ± 65 Ma, in agreement with the petrographic evidence. Seven Sm-Nd T_{DM} ages fall between 3.5-3.6 and 3.1-3.3 Ga with -4.9 to -7.7 $\varepsilon_{Nd(t)}$ values, suggesting that Archean protholiths participated in magma genesis. The RB samples show calc-alkaline and peraluminous to light metaluminous signatures, although a few ones resemble trondhjemites. The observed gaps between the high- and low K_2O phases may be explained either by coeval rocks derived from different batches of at least two magma sources. High- and low K_2O phases show roughly similar chondrite-normalized REE patterns, but with peculiar features (e.g., strong negative Eu anomalies for the high K_2O group like evolved calc-alkaline rocks). This group also has low fractionated patterns in spider diagrams with enriched ratios when one considers the incompatible elements (e.g., Nd, Sm, Dy, Y, Yb and Lu). We conclude that the RB melts were derived in continental arc at 2150 Ma, placed opposite to the Serrinha intra-oceanic arc (2.23-2.20 Ga), as supported by geologic, isotopic and tectonic correlation.

Re-Os isotope and Platinum Group Element composition of Louisville Seamounts Chain, Pacific Ocean

M.L.G. TEJADA[1]*, T. HANYU[1], A. ISHIKAWA[1,2], R. SENDA[1] AND K. SUZUKI[1]

[1]IFREE, Japan Agency for Marine-Earth Science and Technology, Yokosuka, 237-0061 Japan (*Correspondence: mtejada@jamstec.go.jp)

The Louisville Seamount Chain (LSC) is a ~4300 km-long hotspot trail believed to have been formed by passage of the oceanic lithosphere over a long-lived mantle upwelling in the south Pacific Ocean. Previous dredging on this hotspot chain recovered alkalic basalts that are fairly homogeneous in composition for the last 80 m.y. and geochemical data suggest affinity with the focal zone mantle end-member (FOZO) for the LSC. Recent IODP Expedition 330 recovered transitional to alkalic basalts from the ~50-77 Ma seamounts. This study aims to characterize the mantle source of the LSC in terms of Re-Os isotope and platinum group element (PGE) abundance and to gain knowledge on the temporal geochemical variation.

Our preliminary results from the older, ~65-77 Ma seamounts along the chain suggest that the Os isotopic composition (0.1270-0.1307) of the LSC basalts is close to estimates for the primitive upper mantle (PUM, 0.1262 [1] and 0.1296 [2]) and do not vary with the age of the seamounts sampled. This range of Os isotopic composition is similar to those of Rarotonga (0.124-0.139) and Samoan shield (0.1276-0.1313) basalts and tends to be lower than those of Cook-Austral (0.136-0.155) and Hawaiian shield (0.1283-0.1578) basalts. The PGE concentration in the LSC basalts are less fractionated than the Kilauea basalts but their Pt and Pd contents are much lower for the same range of MgO values. These differences in the relative abundances of the PGE may suggest low-degree melting of a mantle previously depleted of Pt and Pd for the source of the LSC.

Ceria (CeO_2) NPs are largely used as oxidation catalysts, gas sensor, polishing materials, but also as UV absorber. Their attractiveness comes from the high oxygen storage capacity related to the easy Ce(III)/Ce(IV) redox cycle. The presence of Ce(III) within the structure of CeO_2 NPs enhance reactivity towards living organisms (prokaryotic and eukaryotic cells). Within the ANR-P2N MESONNET project, we determined the behavior of CeO_2-based nanoparticles (NPs) within aquatic mesocosms simulating a pond environment. Another challenge was to work with NPs contamination representative of concentrations expected in natural aquatic environments. Consequently, NPs were chronically applied to water column (0.1 mg L^{-1} per injection). After 4 weeks, we determined the distribution of Ce in water, sediments and biota, speciation with X-ray absorption spectroscopy and oxidative stress in organisms was measured. Over time, NPs tend to hetero-aggregate and accumulate at the surface of sediments. A partial reduction of Ce from oxidized CeO_2 NPs was observed in the sediment. Bioaccumulation of major Ce(III) was also detected in digestive gland of pond organisms (snail, Planorbarius corneus) and correlated with a significant oxidative stress. In addition, using two kinds of CeO_2 Nps for experiments (organic-coated CeO_2-NPs used as paint additives (Nanobyk®), and "bare" CeO_2-NPs (Rhodia®), we highlighted the influence of CeNPs surface formulation on their fate into mesocosms and their reactivity towards organisms.

Effect of solution supersaturation and presence/absence of seeding crystals on the precipitation kinetics of celestite and strontianite

L. TEMGOUA[1]*, A. CHAGNEAU[1,2,3]; H. GECKEIS[1] AND T. SCHÄFER[1,2]

[1] KIT-INE, P.O. Box 3640, 76021 Karlsruhe, Germany. (*correspondence: louis.temgoua@kit.edu) (aurelie.chagneau@kit.edu); (thorsten.schaefer@kit.edu)

In general, precipitation kinetic experiments allow us to determine parameters such as critical saturation index (SI_{crit}), rates of precipitation (R_{precip}.) and induction time (t_{ind}) of nucleation. The objectives of this study follow a two-side approach: First we quantify the precipitation kinetics of the isostructural minerals celestite and strontianite over variable saturation indexes (SI) using the method of mixed flow reactors (MFR) in the presence of homogeneous seed crystals. Building on the findings of precipitation kinetics, we will investigate the sorption/incorporation of trivalent actinides/lanthanides in these Sr-minerals under comparable R_{precip} extending the work of [1]. In MFR experiments, equimolar solutions of $SrCl_2$ and Na_2SO_4 or Na_2CO_3 in 0.1M NaCl (background electrolyte) were fed through seperate inlets in the reactor ($v_{outflow}$ = 0.6 ml/min). Solution composition was monitored via ICP-OES and IC. R_{precip} of Celestite were calculated using the mass-balance equation to be ranging from $4*10^{-9}$ to $20*10^{-9}$ mol/ (m^2s) for SI's from 0.2 to 1.4, respectively. Plotting R_{precip} vs. SI's showed a parabolic trend suggesting a surface controlled precipitation mechanism at low SI and 2-D nucleation at higher SI. The SI_{crit} was found to be at 0.5 for $SrSO_4$. t_{ind} between mixing of solutions and formation of the first cluster/colloid were determined by laser-induced breakdown detection (LIBD) in the absence of seeding material. t_{ind} decreased with increasing SI and two linear regressions could be performed with a change of slope at SI ~1.1. This SI is considered as the threshold for the transition between homogeneous and heterogeneous nucleation. The precipitation kinetics of celestite and strontianite will be compared and discussed with respect to nucleation mechanisms and metal uptake.

Elemental sulfur biomineralization and preservation in glacial sulfide springs

TEMPLETON, A.S.[1]*, LAU, G.[2], WRIGHT, K.[3], WILLIAMSON, C.[4], SPEAR, J.[5] AND GRASBY, S.[6]

[6]Canadian Geological Survey (sgrasby@nrcan.gc.ca)

Microbial activity can control the abundance and distribution of sulfur species in environments far from chemical equilibrium, including the precipitation of intracellular and extracellular elemental sulfur in association with organic structures such as surface coatings, cell surfaces, filaments and sheaths. However, the potential for the generation and preservation of S^0 mineral deposits that could serve as biosignatures of microbial sulfur cycling has not been extensively investigated. We will present a combination of synchrotron based x-ray spectroscopic, Raman, and pyrosequencing-based 16S rRNA and metagenomic data obtained from elemental sulfur deposits produced annually on the ice surface at Borup Fiord Pass in the Canadian High Arctic to define feed-backs between the geochemistry, microbial community composition, gene abundance, production of organic rich matrices and the chemical speciation of S^0-rich deposits during their rapid precipitation and long-term preservation. This presentation will integrate findings from recently papers by Gleeson *et al*. [1], Wright *et al*. [2], Grasby *et al*. [3], as well as data from sulfur speciation mapping and x-ray absorption spectroscopy of modern sulfur deposits and "paleo" spring systems preserved in permafrost (Lau *et al*., unpublished).

Habitability and Hydrogen Generation in Perditotite Aquifers

TEMPLETON, A.S.[1], MAYHEW, L.E.[1]*, MILLER, H.[1], STREIT, L.[2] AND KELEMEN, P.[2]

[1]University of Colorado (*lisa.mayhew@colorado.edu)
[2]Lamont-Doherty Earth Observatory, Colubmia University.

The habitability of peridotite aquifers depends upon the rate of generation of energy sources such as H_2 and CH_4 during low-temperature water-rock interactions, as well as the availability of oxidants and nutrients required for microbial growth. Recent work by Mayhew *et al*. [1] suggests that olivine and pyroxene can produce substantial H_2 during water-rock interactions at $\leq$ 100ºC through a surface-promoted mechanism where trace spinel phases such as magnetite, chromite and gahnite mediate electron transfer reactions between adsorbed Fe(II) and water. Mayhew *et al*. [1] also hypothesize microbial activity will be spatially localized to sites of H_2 production adjacent to spinel surfaces.

We will present this conceptual model for H_2-generation during low-temperature peridotite hydration, including synchrotron-based Fe K-edge multiple-energy μXRF and μXANES mapping of altered olivine, pyroxene and San Carlos peridotite before and after H_2 generation. We will also demonstrate that Oman harzburgites, which contain abundant Cr-spinels, produce the highest concentrations of H_2 measured in low-temperature water-rock reactions. Changes in the Fe-speciation associated with experimental H_2 generation by Oman peridotite will be compared against μXRF and μXANES data for samples that have experienced hydration and carbonation at near-surface temperatures in the Oman ophiolite [2]. Altogether, we suggest that extensive hydrogen generation should proceed at temperatures as low as 30ºC during modern water-rock interaction in Oman and other peridotite aquifers, giving rise to an enormous potential for subsurface microbial activity when oxidants such as CO_2 are available to sustain microbial growth and methanogenesis.

Effect of Solution Chemistry on the Kinetics of Step Growth

H. HENRY TENG AND MINA HONG

Department of Chemistry, the George Washington University, Washington, DC 20052, USA (hteng@gwu.edu)

Crystal growth from solution propagates through the attachment of atoms/molecules (in the classical theory) to the growing surfaces or aggregation of nano building clusters (in the non-classical approach) to each other. While the thermodynamic driving force for the growth is well-understood and can be precisely determined via the saturation level of the solution, our grasp of the effect of other solution chemistry parameters, such as ionic strength and stoichiometry, on the growth kinetics remained loose. In the classical approach, the net growth rate of mono-molecular layers (ie, step velocity v_s) is assumed to to determined by the difference between fluxes of species attaching to and detaching from kinks along step edges. Such treatment leads to the development of the wide used relationship of $v_s = \beta[(a-a_e)/a_e]$ which states that v_s scales linearly with the solute activity a relative to its equilibrium value a_e (the kinetic coefficient β characterizes the enthalpic and entropic barriers for solute incorporation, including desolvation of growth sites and solute particles). It then follows that v_s should be controlled solely the solution saturation under similar T and P conditions. Yet, literature data from numerous cases argued strongly against this supposition. In this study, we conducted a series of in situ AFM experiments to interrogate the effect of solution chemistry parameters other than supersaturaiton on step kinetics using calcite as a model system. We found step kinetics were strong affected by solution pH, ionic strength SI, and the $[Ca^{2+}]/[CO_3^{2-}]$ ratio, and the impact differs in different directions (obtuse va. acute steps on the {104} cleavage faces). For example, while the v_s of acute steps decreased with increasing pH, the obtuse step rate showed little response to pH change. More interestingly, both sides exhibited a sharp trend transition (varied degree of positive v_s – pH dependence) starting at pH ~9.5. In addition, step velocity in both directions decreased with increasing SI, but the trend became significantly weakened in the acute direction when SI > 0.1. The effect of cation-anion ratio on step kinetic appeared to be more complex. A maximum speed was achieved at different values of $[Ca^{2+}]/[CO_3^{2-}]$ for obtuse and acute steps, and the ratio seemed to decrease with increasing pH. These observations strongly suggest that, although supersaturation is the driving force for aqueous phase crystallization, solution chemistry plays critical roles in controlling the actual growth rate and needs to be taken into consideration in kinetic studies of crystallization.

Are molybdenum concentrations and isotopes a tracer for anthropogenic pollution in the atmosphere?

A. TENNANT[1], S. LANE[1], B. PROEMSE[2] AND M.WIESER[1]*

[1]Department of Physics and Astronomy, University of Calgary, 2500 University Drive NW, Calgary, Alberta, Canada, T2N 1N4 (*presenting author, mwieser@ucalgary.ca)

[2]Department of Geoscience, University of Calgary, 2500 University Drive NW, Calgary, Alberta, Canada, T2N 1N4

The trace metal molybdenum (Mo) is not very abundant in the environment but has found numerous applications in anthropogenic activities. For instance, in the form of Mo sulphide (MoS_2) it is a component of diesel fuel. Mo is used as a catalyst in many engines and is believed to be the most efficient catalyst for the hydrocracking of bitumen [1]. Molybdenum has even been suggested as a fertilizer additive [2] and has also been found in coal-fired power plant emissions [3]. Hence, anthropogenic activities may release Mo in larger amounts to the environment that may affect terrestrial and aquatic ecosystems (e.g. via its coupling with the N cycle). We have therefore investigated the potential of Mo concentration and isotope ratio measurements as a tracer of anthropogenic emissions.

We measured the molybdenum (Mo) isotopic composition of aerosols collected on Teflon air filters [4]. Airborne Mo was collected at selected locations including a residence in the city of Calgary, Canada, the isotope laboratory at the University of Calgary, the University of Calgary weather station, and the City of Calgary Transit bus garage where the city buses start and idle for extended periods. Concentrations ranged from 0.07 ng/m^3 in the laboratory to 19.0 ng/m^3 in the bus garage. The $\delta^{98/95}$Mo values measured for the different urban sampling sites (reported relative to SRM 3134) ranged from –0.18 to +0.94 ‰. The results of this investigation suggest that measurements of Mo concentrations and isotopic compositions have the potential to trace anthropogenic emissions in an urban environment.

Controls on dissolved REE and HFSE in glacial meltwater rivers in southern Iceland

NATHALIE TEPE* AND MICHAEL BAU

Earth and Space Sciences, Jacobs University Bremen, Campus Ring 1, Bremen, Germany, (*correspondence: n.tepe@jacobs-university.de)

The chemical composition of river waters in southern Iceland is strongly affected by geological events such as volcanic eruptions (e.g., the Eyjafjallajökull in 2010), due to the input of nanoparticles and colloids from volcanic ashes.

In this study, water samples from twelve rivers and volcanic ashes were sampled twice in 2010, and once in 2011 and 2012 to characterize the geochemistry of glacial melt waters and to investigate the impact of colloids and nanoparticles from volcanic ashes on their chemistry. The REE and other HFSE (e.g., Th, Zr, Nb and Hf) are characterized by low solubilities and high particle-reactivities. In oxic natural waters, therefore, they are not truly dissolved, but typically associated with particulates. In 0.45 μm-filtered water samples they are often well-below the lower limit of determi-nation by analytical techniques such as ICPMS. Comparison of the trace element distribution of river particulates (i.e. filter residues) and volcanic ash to that of the respective 0.45μm-filtered glacial meltwater (i.e. sum of truly-dissolved trace elements and those that are bound to colloid-/nano-sized particles <0.45 μm) reveals very close similarities.

In 2010, rivers in SW Iceland were affected by the Eyjafjallajökull eruption, while those in the SE were not. La_{CN}/Yb_{CN} ratios of filter residues in the SW are in a similar range as the Eyjafjallajökull ash (EJ-1: 6.16; EJ-2: 6.58 [1]). River waters, which were sampled in August 2010, show a higher variability in the La_{CN}/Yb_{CN} ratio and range between 1.46 and 6.96 in the SW and 1.46 and 5.94 in the SE, but the SW rivers, which were sampled 25 days after the Eyjafjallajökull eruptions, show higher La_{CN}/Yb_{CN} ratios between 7.17 and 9.40. In 2011, an earthquake and a subsequent minor eruption underneath the glacier of Katla volcano caused enhanced glacial flow at the Múlakvísl river, which was accompanied by high trace element concentrations. Its La_{CN}/Yb_{CN} ratio of 13.5 was significant higher in 2011 than in 2010 (2.64) and 2012 (8.73). Moreover, in 2011, the Zr concentration was 222 ppt, which is several orders of magnitudes higher than in 2010 and in 2012.

These results strongly suggests that natural nanoparticles and colloids of a size <0.45 μm control the dissolved REE and HFSE distribution in these rivers.

An improved hot-alkaline DNA extraction method for high cell-lysis efficiency of subseafloor microbial communities

TAKESHI TERADA [1]*, YUKI MORONO [2], TATSUHIKO HOSHINO[2] AND FUMIO INAGAKI[2]

[1]Marine Works Japan Ltd., Oppamahigashi 3-54-1, Yokosuka 237-0063, Japan. (*correspondence: teradat@mwj.co.jp)

[2] Geomicrobiology Group, Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Monobe B200, Nankoku, Kochi 783-8502, Japan.

One of the prerequisite for DNA-based microbial community analysis is the high cell-lysis efficiency –the critical issue has been long ignored or paid very little attention despite of its significance. In fact, using a commonly used DNA extraction kit, ~80% or more of microbial cells in marine sediment are still remained as the intact form (i.e., DNA-stainable cells), indicating that the large DNA fraction of microbial components are initially biased prior to the subsequent molecular analyses.

To address this technical problem, we standardized a new DNA extraction method with alkaline treatment and heating. First, we attempted to destroy all microbial cells in subseafloor sediment samples from different depths by adding 1 M NaOH at 98 ºC for 20 minutes, which treatment disrupted more than 98% of the cells in the examined samples. The DNA integrity test showed, however, that such strong alkaline and heat treatment also destroyed DNA molecules into short fragments, which could not be used for PCR-based molecular analyses. Subsequently, we optimized the alkaline and temperature condition to minimize DNA fragmentation with high cell-lysis efficiency: the best condition we standardized resulted in 50-80% of cell disruption with successfully keeping enough DNA integrity for the amplification of complete 16S rRNA gene (i.e., ~1500 bp). Also, the optimized method yielded higher DNA concentrations than those extracted by a conventional kit-based approach in all tested samples. Consequently, using the newly developed hot-alkaline method, community structure analysis of the extracted DNA assessed by quantitative real-time PCR and pyro-sequencing of 16S rRNA genes showed a clear difference to the result using conventional methods, suggesting the better analytical coverage of subseafloor microbial communities than those by the conventional methods.

Sources and concentrations of Highly Siderophile Elements in VHMS deposits through time

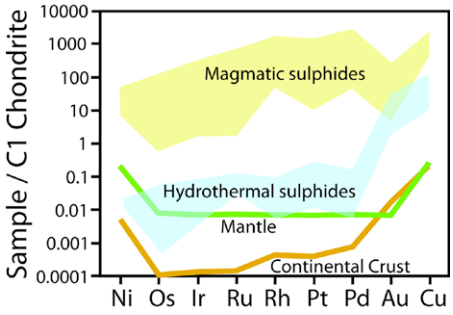
SVETLANA TESSALINA

John de Laeter Centre, Curtin University, Perth, Austarlia

The seafloor hydrothermal acivity is an important mechanism of metals cycling between mantle and continental crust, producing Volcanogenic Hydrothermal Massive Sulphide deposits in various tectonic settings through time.

Concentrations and sources of Highly Siderophile Elemenets (HSE: Ru, Rh, Pd, Re, Os, Ir, Pt Au) were studied in VHMS deposits from Archean to present using new and published Re-Os isotopic data and the HSE concentrations.

In general, concentrations of HSE, as normalised to C1-chondrite, are situated slightly above the mantle values, with the exeption of higher Au contents; and approximately 3 orders of magnitude lower compare to magmatic sulphides.



Remarakably, the Re/(Common Os) ratio significantly increase from Archean deposits in intra-cratonic setting to the Palaeozoic VHMS deposits in island arc setting, reaching the highest values in modern sulphides from MORB setting, with simultaneous decrease in Common Os values. This observations may be related with the change in main metal sources relative to different tectonic settings through time.

Rhenium enrichment in modern VHMS deposits may be also related with higher Re contents in present day seawater, which is along with hydrothermal fluid is one of the main sources of metals in VHMS deposits. Modern seawater is characterised by high Re/Os ratio of ~730, whereas hydrothermal fluid has much lower Re/Os ratio. In general, the Re/Os ratio increases and Os contents decrease by 2 order of manitude from the stockwork toward the seafloor sulphides, reflecting the fluid - seawater mixing. The same pattern has been observed across hydrothermal chimneys, with higher Re/Os ratio and lower Os contents toward the outer part of chimney. This pattern is confirmed by $^{187}Os/^{188}Os$ isotopic mixing between these two end-members, as it was shown for modern and ancient VHMS systems.

Levels and distribution of traffic related metals in Israel; Pb, Zn and platinum group metals (PGM)

N. TEUTSCH*, L. HALICZ AND Y. HARLAVAN

Geological Survey of Israel, 30 Malkhe Israel, Jerusalem, Israel (*correspondence: nadya.teutsch@gsi.gov.il)

Since 1993, automobile exhaust catalysts are compulsory in Israel which obviously lead to a great improvement in the emission of toxic gases to the atmosphere. However, as these convertors contain Rh, Pd and Pt, which belong to the platinum group metals (PGM), their utilization has introduced a new contamination source to the environment.

For characterizing the extent of PGM contamination in Israel, road side soils were examined in four locations adjacent to main roads. In all sites, Pt concentrations in soils were relatively low compared to published values [1] (mostly up to 20 ng/g) and could be detected only in top soils. While Rh concentrations were below limit of detection (10 ng/g), high concentrations of Rh and Pt were found in mixed soil and dust surface samples.

Road dust collected along a half km inclined road with heavy traffic yielded very high concentrations of both Pt and Rh (260 to 1480 ng/g and 80 to 440 ng/g, respectively). Remarkable difference was observed between the uphill and downhill at the same location where oncentrations uphill were 4-fold higher than downhill direction for both metals, indicating significant PGM emission with increased engine activity.

Elevated trace metal concentrations of traffic related metals (Cr, Cu, Ni, Pb and Zn) were noted for the road dust samples. However, only Zn concentrations exhibit a positive correlation with Pt and Rh concentrations and display a distinct 2-fold enrichment in the uphill direction probably due to tire friction. On a plot of $^{208}Pb/^{206}Pb$ vs. $^{206}Pb/^{207}Pb$ along with potential Pb sources, all samples are slightly shifted from a mixing line between the known Pb IC petrol values used in Israel and natural sources. No systematic hill slope pattern was observed.The slight shif of data points from mixing suggests an additional yet undefined, anthropogenic source. Hence, while PGM metals and Zn exhibit current contamination, Pb probably represents re-suspension of dust and soil surfaces that still carry the pre-unleaded petrol signature.

Discovery of a "vital" bacterial effect in the formation of biogenic carbonates

CAROLINE THALER[1]*, MAGALI ADER[1], BÉNÉDICTE MÉNEZ[1] AND FRANÇOIS GUYOT[1]

[1] Institut de Physique du Globe de Paris, Université Paris Diderot, 1, rue Jussieu, 75238 Paris cedex 05, France (*Correspondence: thaler@ipgp.fr , ader@ipgp.fr, menez@ipgp.fr, Francois.Guyot@impmc.jussieu.fr)

Carbon and oxygen stable isotope compositions of carbonates are widely used to provide information on their conditions of precipitation. However, most carbonates result from a biological activity, which in the case of some skeleton-forming eukaryotic organisms has been shown to lead to isotopic characteristics that differ from those expected for isotope equilibrium. The origin of this difference remains poorly understood and is referred to as the “vital effect”. So far, potential microbial vital effects have been overlooked and microbial carbonation is considered from an oxygen isotope perspective as occurring at equilibrium with water. We revisit this assumption by performing an isotope study of carbonates precipitation by the strain *Sporosarcina pasteurii*, a bacterial model of carbonatogen metabolisms. Its ureolytic activity produces ammonia (thus increasing the pH) and dissolved inorganic carbon (DIC) that precipitates as solid carbonates. $\delta^{18}O_{CaCO3}$ results show values up to 20‰ lower than what was expected for carbonate precipitation in equilibrium with water. This demonstrates for the first time that bacteria may precipitate carbonates with a vital effect. The addition of carbonic anhydrase, an enzyme able to equilibrate the oxygen isotopes between DIC and water, yields equilibrium values. This result demonstrates that the vital effect observed in solid carbonates results from disequilibrium between DIC and water, a mechanism also strongly suspected to account for vital effects in skeleton-forming organisms.

X-Ray Spectroscopy and Spectromicroscopy Study of Sulfur Speciation in Urban Soils

J. THIEME[1] AND M. MATHES[2]

[1] NSLS-II, Brookhaven National Laboratory, Building 743, Upton, NY-11973, USA, e-mail:((jthieme@bnl.gov)

[2] Institute for X-Ray Physics, University of Goettingen, Friedrich-Hund-Platz 1, 37077 Goettingen, Germany

This study shows the applicability of sulfur x-ray spectroscopy and spectromicroscopy to analytical problems in urban soils.

A combination of x-ray microscopy, elemental mapping and XANES spectroscopy at the K-absorption edge of sulfur was used to analyze the elemental and particulate composition of an urban soil loaded with debris from WWII, exemplarily from Berlin, Germany. The goal was to specify and analyze the sulfur pool of soils with major anthropogenic impact, i.e. the dumping of war debris. This impact obviously influences soil composition and soil formation processes, but may, due to sulfate leaching, also be a substantial risk to urban water quality. The sulfur load of different debris components was studied and the sulfur content of different soil samples was evaluated and correlated to different parameters, such as position of the respective soil horizon within the soil profile or location of the soil profile in the surrounding terrain. With XANES spectroscopy, the averaged sulfur pool of whole soil horizons as well as of single debris components was studied. With X-ray fluorescence imaging and spectromicroscopy, soil aggregates, debris particles, and soil solution were analyzed on the micrometer and sub-micrometer scale. Different soil and debris constituents could be assigned to elemental distribution patterns within collected fluorescence maps, allowing for a detailed analysis of the sulfur pool and release from war debris in subsequent studies. These measurements show highly heterogeneous sample composition and clear gradients in sulfur speciation and oxidation state within single particles. The weathering of the anthropogenic material is therefore directly observable. A detailed understanding of this sulfur lixiviation is central to preserve urban water quality.

Advances in Mass Independent Isotopic Studies

MARK H. THIEMENS[1]

[1]Departement of Chemistry and Biochemistry 0356 University California, San Diego. La Jolla, CA (mthiemens@ucsd.edu)

Since the first discovery of a chemically produced mass independent isotopic fractionation process by Thiemens and Heidenreich in 1983 the extent of applications of MIF in nature has expanded across a extensive range of applications that encompass much of terrestrial geochemistry, cosmochemistry, atmopsheric science, and climate analysis.Time scales extend from the present to the origin of the solar system, more than 4.5 billion years ago to present. The creation of the INTRAMIF program exemplifies the extent of these investigations.

In the original work on ozone formation, it was shown there is not only a mass independent fractionation that duplicated the pattern oberved in meteorites in oxygen and consequently has application in solar system evolution. A major follow up to that work is determining the actual physical chemical mechanism responsible for the effect, which remains elusive to this day.The role of chemical processes in the early solar system for the source of the anomaly in the early solar system is now agreed upon as compared to nuclear processes. Very recent experimental work has deepend understanding of processes will be presented.

The process of formation of isotopically anomalous ozone in the atmopshere has been used to trace chemical and dynamicaly processes in the atmopshere and has been applied to most major cycles. This includes SOx, NOx, CO_2, CO, N_2O, water, carbonates, chlorates, and O_2. The use of high sensitivity analysis of these species has been demonstrated to provide an analytical tool to decipher chemical reaction pathways which are otherwise identifiable by conventional technique as a consequence of using multiple isotope ratio measurements.

Through polar ice studies these processes have been studied through long time scales (presnt – Holocene). Sulfur isotope measurements have opened a new dimension in tracking the origin and evolution of oxygen in the earths earliest environemnt. Recent work has shown that from Mars meteorite oxygen analysis of bulk silicate, water, and secondary minerals that the processes of Mars formation and evolution is less well understood than previously believed and will be discussed.

Modeling non-equilibrium uptake of Se(IV) upon calcite precipitation

BRUNO THIEN[1], FRANK HEBERLING[2] AND DMITRII A. KULIK[3]

[1]LES, Paul Scherrer Institut, 5232 Villigen, Switzerland (bruno.thien@psi.ch)
[2]INE, Karlsruher Institut für Technologie, 76131 Karlsruhe, Germany (frank.heberling@kit.edu)
[3]LES, Paul Scherrer Institut, 5232 Villigen, Switzerland (dmitrii.kulik@psi.ch)

Selenium is relevant as a nutrient or poison for animal and human life, and as long-lived radionuclide ^{79}Se in the context of nuclear waste management. We investigated time-dependent Se uptake by growing calcite as a possible way of Se immobilization. Calcite precipitation from aqueous solutions in presence of $Se(IV)O_3^{2-}$ was studied under the surface-controlled steady state conditions at low-to-moderate supersaturation in mixed flow reactor (MFR) experiments [1]. We then simulated MFR experiments using the GEM-Selektor v.3 geochemical code [2].

Calcite precipitation rates predicted using [3] were systematically higher than the rates observed in MFR experiments in Se(IV) - containing solutions. This corroborates the inhibiting effect of aqueous Se(IV) on calcite growth reported before [4]. To account for this effect, an inhibition term involving the $Se(IV)O_3^{2-}$ ion activity was added to the rate equation [3].

Measured amounts of Se(IV) incorporated in calcite overgrowths are substantially higher than those predicted by the atomistic calculations for the solid solution- aqueous solution equilibrium [1]. This can be interpreted by invoking an extremely strong surface growth entrapment mechanism, accounted for in our unified uptake kinetics model [5]. This model was able to describe the observed concentrations of Se(IV) in calcite overgrowths by considering a very high Se surface enrichment factor ($1.5 \cdot 10^7$) with a rather low sub-surface diffusivity (10^{-10} nm^2/s). These parameters for Se(IV) oxyanion differ significantly from those typically used in modeling entrapment effects for cations (Sr, Cd, Co) in calcite [5]. Possible reasons for this difference will be discussed.

The PSI/Nagra Chemical Thermodynamic Database 12/07: Present status and future developments

T. THOENEN[1]*, W. HUMMEL[1] AND U. BERNER[1]

[1]Laboratory for Waste Management, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland (*correspondence: tres.thoenen@psi.ch)

The PSI/Nagra TDB has been updated from version 01/01 [1] to version 12/07 to support the ongoing safety assessments for a deep underground repository for radioactive waste in Switzerland. TDB 12/07 contains three types of data: (1) Core data are widely accepted data of high-quality that are mainly based on the CODATA key values. (2) Recommended data are also of high quality, but they originate from rather active fields in the environmental sciences and may be revised over time. They are mainly based on the critical reviews of data for U, Am, Tc, Np, Pu, Ni, Se, Zr, and Th provided by NEA in their "Chemical Thermodynamics" series. (3) Supplemental data are suitable for scoping calculations. Some estimates are made in cases where their omission would lead to obviously erroneous results. TDB 12/07 is provided for use with the geochemical modeling codes GEMS [2] and PHREEQC [3].

Further development of the database will run along the following lines: (1) Data for Sn will be included from the latest NEA review [4] and for Fe and Mo from forthcoming NEA reviews, as well as data from the IUPAC reviews, e.g. [5], on the chemical speciation of environmentally significant metals (at present Hg, Cu, Pb, and Cd). (2) Since a large part of the data included in TDB 12/07 is applicable only at 25°C, estimation methods [6] have to be considered for extending the application range to the higher temperatures expected in the repository environment. (3) Experimental data were reduced to zero ionic strength by NEA and IUPAC using the specific ion interaction theory SIT [6]. SIT coefficients are not known for many aqueous species (especially in NaCl background media). In order to use the SIT in geochemical modeling of natural systems, estimation methods have to be found to fill these gaps.

Biogeochemical cycling of nitrogen on the early Earth

CHRISTOPHE THOMAZO[1], DOMINIC PAPINEAU[2] AND MAGALI ADER[3]

[1]UMR-CNRS 6282 Biogéosciences, Université de Bourgogne, France; (christophe.thomazo@u-bourgogne.fr)

[2]Geophysical Lab, Carnegie Institution of Washington, USA; (dominic.papineau@bc.edu)

[3]Institut de Physique du Globe de Paris, France; ader@ipgp.fr

There has been considerable recent interest in variations of the nitrogen isotope composition of ancient organic matter and associated sediments as they provide clues for the early evolution of Earth's atmosphere-ocean-biosphere system. In particular, large $\delta^{15}N$ isotopic variations recorded from the Mesoarchean to the Paleoproterzoic have been linked to the evolution of the biogeochemical cycle of nitrogen toward its modern –microbially mediated- web of reactions. The biogeochemistry of nitrogen is strongly dependent upon oxidation-reduction reactions, and thus secular variations in $\delta^{15}N$ most probably underline the protracted oxygenation of Earth's oceans and atmosphere, during a period of roughly 700 Ma between 2.7 and 2.0 Ga.

This contribution provides a synthesis of observations made so far from Archean to Mesoproterozoic sedimentary environments. We present an extensive $\delta^{15}N$ database: 874 published $\delta^{15}N$ values measured on various sedimentary lithologies and phases, including kerogen, phyllosilicates, shales, carbonates, cherts, Banded Iron Formations and N_2-bearing fluid inclusions. The compilation spans from 3.8 Ga to 1.4 Ga and we use statistical methods (Gaussian Kernel functions) applied to geochemical times series for its analysis.

Accordingly, we suggest that the anaerobic process of nitrogen fixation and ammonium assimilation evolved early in biological evolution during the Paleoarchean or earlier. Meso- to Neoarchean ^{15}N enrichment of +15‰ in average and up to +50‰ most probably record the initiation of the oxidative part of the nitrogen cycle including nitrification and denitrification. A second positive nitrogen isotope excursion is recorded during the Paleoproterozoic at around 2.0 Ga and might reflect the fluctuation of a redox transition zone where NH_4^+ would be present in the deep anoxic ocean and NO_2^- and NO_3^- would accumulate above the oxic-anoxic interface in response to increasing atmospheric and oceanic oxygen concentrations. A complete nitrogen biogeochemical cycle including its oxidative part might thus be recorded since the Paleoproterozïc, in line with the view that free oxygen had stabilized NO_3^- in the surface oceans by that time. Increasing number of $\delta^{15}N$ measurements through the Precambrain rocks record would help to refine these interpretations.

An experimental investigation of the formation mechanisms of superdeep diamonds

A.R. THOMSON*, M.J. WALTER, S.C. KOHN, G.P. BULANOVA AND C.B. SMITH

School of Earth Sciences, University of Bristol, Bristol, BS8 1RJ (*correspondence: (andrew.thomson@bristol.ac.uk)

The subduction of oceanic crust is not only a fundamental driving force of mantle convection, but also an integral part of the Earth's deep carbon cycle. Subducted material provides almost all of the return flow of carbon to the earth's interior [1]. Seismic tomography suggests that slabs can penetrate into the deep mantle, thus carbon can potentially be delivered into the transition zone and/or lower mantle and react with ambient mantle [2].

Recent studies of superdeep diamonds from the Collier-4 [3] and Juina-5 [4] kimberlite pipes in Brazil have found direct evidence for such processes. The diamonds show complex growth structures, are composed of isotopically light carbon (ranging up to -25‰) and contain mineral inclusions with compositions expected to form from a mafic protolith in the transition zone and/or lower mantle all of which are consistent with a key role of subducted material in their origin. It has also been observed that former calcium silicate perovskite inclusions have extremely enriched trace element abundances, with REE and HFSE up to 20,000 times primitive mantle [5]. Geochemical modelling suggests that inclusions, and their diamond hosts, crystallised from a low degree carbonated melt of subducted basalt in the transition zone upon reaction with ambient mantle [5].

This study aims to test the model of superdeep diamond growth by experimentally investigating the liquidus phase relations and reactions that occur when an oxidized carbonated melt interacts with reducing mantle peridotite. The bulk composition used to determine the appropriate melt composition represents ODP hole 1256D basalt samples containing 2.5wt% CO_2. Initial multi-anvil experiments at 20 GPa show that two immiscible melts, a Na-rich carbonate melt (~16wt% Na_2O) and a Na-bearing 'granite' melt (>70wt% SiO_2) coexist with majorite at 1400-1500°C. We will report on ongoing experiments in which these melt compositions are reacted with reducing peridotite .

Bacterial communities inside soil iron nodules

R.L. THORNE[1]* A.H. KAKSONEN [2] AND R. ANAND[1]

[1] CSIRO Earth Science and Resource Engineering, ARRC, Kensington, WA,6151, Australia (*correspondence: robert.thorne@csiro.au)

[2] CSIRO Land and Water, Underwood Ave, Floreat WA 6014, Australia (anna.kaksonen@csiro.au)

Iron nodules are found in a wide variety of surficial environments across the globe [1, 2] and iron spherules of a similar size and morphology are even found within the sediments of Mars [3].

Iron nodules from soils in Western Australia are homogenous, compound and concentric and dominated by hematite and maghemite. Nodule formation has been attributed to weathering and the mobilisation and migration of Fe^{2+} in response to variations in redox potential and differential drying [1].

Bacterial communities within the soil nodules were investigated using cloning and sequencing of polymerase chain reaction amplified 16S rRNA genes. The results showed that the nodules contain a phylogentically diverse bacterial community dominated by members of *Acidobacteria*, *Actinobacteria* and *Proteobacteria*.

The metabolic potential of uncultivated organisms within the soil nodules can be phylogentically assessed by a comparison with related sequences from environmental clones or cultured bacteria. The results show that some clone sequences closely resemble cultured Fe-oxidising bacteria and clones from environments with high concentrations of iron. The combination of geochemical and bacterial studies can provide new insights into nodule formation and the role bacteria play in the mineralisation process.

Reactive transport modeling of carbon, chlorine, and hydrogen CSIA data to improve monitored natural attenuation for chlorinated ethenes

HÉLOÏSE A.A. THOUEMENT[1]* , MINDY VANDERFORD[2], TOMASZ KUDER[3] , PAUL PHILP[3] AND BORIS M. VAN BREUKELEN[1]

[1]VU Univ. Amsterdam, De Boelelaan 1085, NL-1081 HV Amsterdam, The Netherlands, (*correspondence: h.a.a.thouement@vu.nl)
[2]GSI Environmental, Inc., Houston, Texas, USA
[3]Univ. Oklahoma, Norman, OK 73019 USA

Compound-specific stable isotope analysis (CSIA) has been shown to provide an improved insight into the monitored natural attenuation (MNA) of chlorinated solvents. The work presented here focuses on the simulation of carbon (C), hydrogen (H), and chlorine (Cl) isotopes of chlorinated ethenes with a reactive transport model (RTM) calibrated by CSIA data. Such a model allows for the simulation of variations in concentrations and isotope ratios in aquifer systems as result of various degradation pathways and transport processes. The base RTM model was calibrated for C, H, and Cl isotope fractionation observed during complete reductive dechlorination of TCE in a microcosm experiment. Secondly, the Operational Unit 10 at the Hill Air Force Base site (Utah, USA) was intensively sampled. This intricate site presents two plumes of chlorinated solvents (PCE and TCE), which partly mix. Moreover, based on earlier MNA studies, both reductive dechlorination and aerobic oxidation are likely to occur as the aquifer conditions range from oxic to anoxic. The model aids in drawing a better picture of the fate of those plumes, as each transformation process induces distinctive isotope fractionation patterns for the different elements.

Results/Lessons learned

We present (i) the model background, which includes the highlights provided by the microcosm experiment, discuss (ii) the collection of CSIA data at the complex field site, and illustrate (iii) potential applications of the model, notably for the interpretation of the above-mentioned field data. The use of CSIA data at the field site reveals the complexity of the studied aquifer, where degradation is shown to mostly occur in restricted areas.

Relevance of mass transfer processes for the interpretation of stable isotope fractionation

MARTIN THULLNER[1]*, FLORIAN CENTLER[2], ANKO FISCHER[3], FALK HESSE[4], HANS-H. RICHNOW[5] AND LUKAS Y. WICK[6]

[1] Department of Environmental Microbiology, Helmholtz Centre for Environmental Research – UFZ, Leipzig, Germany; * (correspondence: martin.thullner@ufz.de)
[2] Department of Isotope Biogeochemistry, Helmholtz Centre for Environmental Research – UFZ, Leipzig, Germany
[3] Isodetect – Company for Isotope Monitoring, Leipzig, Germany

In recent years, compound specific stable isotope analysis (CSIA) has become an established tool for assessing (bio)degradation of organic contmainants within aquifers. The fractionation of stable isotopes during degradation leads to observable shifts in stable isotope ratios which can serve as a qualitative indicator for in situ contaminant degradation. However, to use stable isotope data to obtain quantitative information on in situ biodegradation requires among others knowledge on the influence of mass transfer processes on the observed stable isotope fractionation.

Mass transfer processes in aquifers range from macroscopic transport including dispersion driven mixing processes to microscopic transport processes controlling the microbial availabilty of the contaminant. These transfer processes may cause itself an additional fractionation of stable isotopes, but even in the absence of such additional fractionation the mass transfer processes need to be considered for a quantitative anlysis of stable isotope signatures [1,2].

This presentation will introduce theoretical and reactive transport modeling concepts on combining mass transfer processes into a quantitative analysis of stable isotope fractionation and the determinantion of degradation pathways using stable isotope signatures of two different elements. Examples for the verification and application of these concepts will be presented showing the relevance of mass transfer processes at different scales for the interpretation of stable isotope fractionation.

Lithium and oxygen isotope compositions of basaltic glasses from ridge axes and off-axis seamounts in the northern EPR (10-15ºN)

LIYAN TIAN[1]*, STEVEN B. SHIREY[1], ZHENGRONG WANG[2] AND PATERNO R. CASTILLO[3]

[1]Department of Terrestrial Magnetism, Carnegie Institution of Washington, USA (*correspondence: ltian@dtm.ciw.edu)
[2] Department of Geology and Geophysics, Yale University, USA
[3] Scripps Institution of Oceanography, UCSD, USA

Geochemical variations in mid-ocean ridge basalts (MORB) have been attributed to the presence of compositionally distinct mantle components in their source, which may include subduction zone processed oceanic sediment, crust and upper mantle material. The light stable isotopes of lithium and oxygen could be potential tracers of the return of the subducted materials to the surface of the earth via basaltic magmatism since these are strongly fractionated by low-temperature water-rock interactions (e.g., seafloor alteration and subduction processes). We present a study of lithium and oxygen isotopes on a group of well-characterized basaltic glasses from both ridge axes and off-axis seamounts in the northern East Pacific Rise (EPR) between 10°N and 15°N. The samples range from normal-MORB to enriched-MORB in composition.

Our results show that the δ^7Li values of these glasses vary from 3.1 to 5.2‰, which systematically correlate with other geochemical indices of mantle heterogeneity, forming trends toward a more enriched composition. In detail, heavier Li isotopic ratios are associated with higher highly/moderately incompatible element ratios (e.g., K_2O/TiO_2 and Ba/Y), more radiogenic $^{87}Sr/^{86}Sr$ and less radiogenic $^{143}Nd/^{144}Nd$. On the other hand, the oxygen isotope compositions display a fairly narrow range of 5.44 to 5.68‰ (equal or lower than upper mantle whole rock values), do not correlate with other geochemical indices and, thus, could not provide clear information on the nature of mantle heterogeneity. Previous studies have shown that lateral compositional variability exists in the upper mantle beneath the EPR; this lateral compositional variability is reflected by the lithium isotope variability of axial and off-axis seamount volcanism. Moreover, lithium isotopic data seem to record the incorporation of a heavy-Li-enriched component, most likely a recycled subduction-metasomatized mantle [1], into the suboceanic mantle in the eastern Pacific.

Enriched mantle source and petrogenesis of the Miocene ultrapotassic rocks in western Lhasa block, Tibetan Plateau: Lithium isotopic constraints

TIAN SHIHONG[1,2]*, HOU WENJIE[3], HOU ZENGQIAN[4], MO XUANXUE[2], YANG ZHUSEN[1], ZHAO YUE[1], HOU KEJUN[1], ZHU DICHENG[2] AND ZHANG ZHAOQING[2]

[1] Key Laboratory of Metallogeny and Mineral Assessment, MLR, Institute of Mineral Resources, CAGS, Beijing 100037, China (correspondence: s.h.tian@163.com)
[2] School of Earth Science and Mineral Resources, China University of Geosciences, Beijing 10083, China
[3] Geological Survey of Jiangxi Province, Nanchang 330030, China
[4] Institute of Geology, CAGS, Beijing 100037, China

The authors have successfully applied lithium isotope to the typical study of Sailipu, Dangreyongcuo, Xurucuo and Chazi ultrapotassic rocks in southwestern Tibetan Plateau. Lithium concentrations of 33 whole-rock samples show a range from 11.2 ppm to 46.1 ppm. Lithium isotopic compositions exhibit a variable range of δ^7Li values (-3.9 to +3.5 ‰) with an average δ^7Li of 0.1 ‰ that corresponds to the average of upper continental crust (Teng *et al*., 2004). Lithium isotopic compositions of UK from SW Tibet do not show any significant correlations with the degree of magmatic differentiation, as inferred from various compositional parameters (e.g., SiO_2, Li, Rb and Ga). This suggests insignificant Li isotope fractionation during ultrapotassic rock differentiation, reflecting the source characteristics (Teng *et al*., 2009). Lithium isotopic compositions of these samples vary by 7.4 ‰ and do not correlate with radiogenic isotopic compositions or chemical and mineralogical parameters. The Li isotopic heterogeneity therefore likely reflects heterogeneous source rocks (Teng *et al*., 2009). Based on calculation modeling and a comparison with the previous similar results (Agostini *et al*., 2008; Janousek *et al*., 2009), the authors hold that the most probable metasomatic agents were melts or fluids derived from subducted Indian crust instead of from Tethyan crust (including sediments). Therefore, the authors put forward a petrogenetic model of ultrapotassic rocks in southwestern Tibetan Plateau.

On the evolution of the Western Alpine Orogen: U-Pb geochronology and Hf isotopic ratios in zircons from Adamello and Bergell amph-rich mafic and ultramafic rocks

M. TIEPOLO[1], R. TRIBUZIO[2,1], M. LUSTRINO[3] AND F-Y. WU[4]

[1] CNR–IGG–UOS di Pavia, Pavia Italy, (tiepolo@crystal.unipv.it)
[2] DSTA Università di Pavia, Pavia Italy, (tribuzio@crystal.unipv.it)
[3] DST Università La Sapienza, Roma, Italy, (michele.lustrino@uniroma1.it)
[4] IGG, CAS, Beijing, China, (wufuyuan@mail.iggcas.ac.cn)

The orogenic belt intrusive rocks are mostly silica-rich products in which the shallow-depth crustal contamination commonly obscures the original mantle geochemical signal. The rare mafic and ultramafic rocks associated with the major intrusive bodies represent a fundamental petrological tool to track back the evolution of the orogen. The reconstruction of the Cenozoic paleogeography and the tectonic evolution of the Western Alps is still matter of debate, with complex geological models involving multiple oceans (i.e., Ligurian-Piedmontese and Valais oceans) incorporating micro-continents (i.e., Briançonnais domain). Also the origin of the Periadriatic magmatism, developed from ~44 to ~31 Ma along the Alpine belt, and its relationship with tectonic evolution of the Alpine Orogeny remains partly unclear.

We carried out U-Pb geochronology and Hf isotopic ratios on zircons from amphibole-rich mafic and ultramafic rocks of the Adamello batholith and the Bergell pluton, the two largest Cenozoic intrusive bodies of the Alpine Orogen. Results show that the Bergell mafic rocks formed ~10 Ma later than the Adamello analogues. In addition, the Bergell gabbros have a more enriched Hf isotopic signature than the Adamello counterparts. We propose that the formation of the oldest mafic rocks from the Adamello batholith is related to the subduction of the Ligurian-Piedmontese oceanic lithosphere. The mafic rocks from the Bergell pluton most likely record the partial recycling in the source of the continental material. These rocks are presumably related to the younger subduction of the Valais basin, which followed that of the Briançonnais continental block.

Abrupt shifts in Horn of Africa hydroclimate since the Last Glacial Maximum

JESSICA E. TIERNEY[1]* AND PETER B. DEMENOCAL[2]

[1]Woods Hole Oceanographic Institution (*correspondence: tierney@whoi.edu)
[2]Lamont-Doherty Earth Observatory, (peter@ldeo.columbia.edu)

The timing and abruptness with which Africa transitioned into and out of the Early Holocene African Humid Period is a subject of ongoing debate, with direct consequences for our understanding of African climate stability, paleoenvironments, and early human cultural development. Here we present a new proxy record of hydroclimate, based on the hydrogen isotopic composition of leaf waxes, from a marine core in the Gulf of Aden that documents rapid, century-scale transitions into and out of the African Humid Period across the Horn of Africa. Similar and generally synchronous abrupt transitions at other East African sites suggest that rapid shifts in hydroclimate are a regionally coherent feature. In addition, the termination of the African Humid Period in East Africa is synchronous with the termination in West Africa. A probabilistic analysis of the abruptness of the transitions in East Africa suggests that they likely occurred within centuries, underscoring the remarkable sensitivity of Northeast African hydroclimate to external forcings. We speculate that the non-linear behavior of hydroclimate in the Horn of Africa is related to convection thresholds in the western Indian Ocean.

Experimental comparison of abiotic and microbial Fe-mineral transformations to identify pathways of magnetic nanoparticle production during pedogenesis

J.L TILL[1]*, Y. GUYODO[1], F. LAGROIX[2], P. BONVILLE[3], G. ONA-NGUEMA[1], N. MENGUY[1] AND G. MORIN[1]

[1]Institut de Minéralogie et Physique des Milieux Condensés (*correspondance: jessica.till@impmc.upmc.fr)
[2]Institut de Physique du Globe de Paris, 75238 Paris cedex 05, France
[3]SPEC, CEA Saclay, F-91191 Gif sur Yvette Cedex, France

We present results from an on-going interdisciplinary experimental study of possible pathways for producing Fe-oxide nanoparticles during pedogenesis of loess-derived soils. The phenomenon of magnetic enhancement in many soil types has been recognized for several years, but the question of whether the enhancement process is primarily driven by microbial activity or abiotic processes is still unresolved. Bioreduction experiments were carried out using the dissimilatory Fe-reducing bacteria *Shewanella putrefaciens* with synthetic nanoparticle preparations of Fe-oxides and oxyhydroxides including goethite, lepidocrocite, ferrihydrite and maghemite. The products of bioreduction are compared with abiotic alteration experiments to examine heating-induced dehydration and redox reactions. Bacterially-mediated re-mineralization of precursor phases produces characteristic high-purity, highly-crystalline euhedral Fe-oxides. Heating-induced dehydration of nanogoethite and lepidocrocite produces topotactic reactions which form pseudo-morphed hematite and maghemite respectively, with distinctive nanostructures containing high concentrations of crystalline defects. However, reduction-heating of dehydrated nanogoethite produces Fe-oxide with non-unique magnetic signatures and morphology that obscure the inorganic origin of the mineral product. The magnetic properties, microstructure, and morphology of the reaction products were characterized with a combination of low-temperature magnetic remanence and susceptibility, high-resolution TEM microscopy, and x-ray diffraction. This study is working toward the identification of magnetic and non-magnetic biosignatures in Fe-oxides that may help elucidate the origins of magnetic minerals in a number of environments, including soils and terrestrial sediments in addition to other planetary settings.

The nature of pyroxenite xenoliths of mantle wedge beneath the Avacha volcano (Kamchatka, Russia)

T.YU.TIMINA[1]* AND A.A. TOMILENKO[1]

[1]V.S. Sobolev Institute of Geology and Mineralogy SD RAS, Novosibirsk 630090, Russia (*correspondence: timina@igm.nsc.ru)

Bulk-rock composition determined by XRF for peridotite xenoliths of Avacha volcano shows variations in petrogenic components (in wt.%): SiO_2 (40.5-47), TiO_2 (0.01-0.07), Cr_2O_3 (0.25-1.9), Al_2O_3 (0.3-1.8), MgO (42-48.2), FeO (7.6-10.4), MnO (0.11-0.15), NiO (0.25-0.33), CaO (0.35-1.4), Na_2O (0.1-0.15), K_2O (0.02-0.06). Pyroxenite xenoliths are divided into two groups: orthopyroxenites and clinopyroxenites. In comparison with the harzburgite xenoliths clinopyroxenites are characterized by lower of MgO (17-20.3), NiO (~0.02), Cr_2O_3 (0.12-0.3) contents and by higher SiO_2 (48.6-51), TiO_2 (0.2-0.45), Al_2O_3 (2.6-4.9), CaO (17.3-19) and Na_2O (0.4-0.85) (in wt.%). The bulk-rock composition of orthopyroxenite xenoliths (in wt.) is: SiO_2 (49-54.8), Cr_2O_3 (0.3-1.2), TiO_2 (0.03-0.12), Al_2O_3 (1.2-2.8), MgO (26.6-34.5), FeO (4.7-10) and CaO (1.4-8.5), NiO (0.08-0.15), Na_2O (0.1-0.4). The chemical compositions of peridotitic and pyroxenitic minerals and their primary melt and syngenetic fluid inclusions were described in [1-2].

According to ICP-MS data primary peridotite xenoliths are extremly depleted. Metasomatized peridotite xenoliths, which contain newly formed clinopyroxene, amphibole and sometimes interstitial silicate glasses, differ from primary harzburgites by higher REE contents. Orthopyroxenites have smooth patterns with depletion in LREE ($[La/Yb]_n$ – 0.3-0.7). Clinopyroxenites are the most enriched in trace elements compared to other ultramufic xenoliths ($[REE/C_1]_n$ – 2-5). Their patterns are characterized by high MREE/HREE ($[Sm/Yb]_n$ – 1.5-2.1).

Orthopyroxenites can be considered as derivates of the metasomatized harzburgites due to their similar bulk-rock composition and features of changes in the mineral composition. Clinopyroxenite xenoliths were formed probably as a result of metasomatic transformation and melting of mantle lherzolites, but not of harzburgites of mantle wedge beneath Avacha volcano.

Invisible gold in arc volcanic glasses

C. TIMM[1], A. REYES[1], S. GILL[2], D. LAYTON-MATTHEWS[2], M. LEYBOURNE[3], C. DE RONDE[1] AND R. HENLEY[4].

[1] GNS Science, PO Box 30-368, Lower Hutt, New Zealand (c.timm@gns.cri.nz)
[2] Department of Geological Sciences & Geological Engineering, Queen's University, Kingston, Ontario, Canada
[3]ALS Geochemistry, 2103 Dollarton Hwy, BC, Canada
[4]Reserach School of Earth Sciences, ANU, Canberra, ACT 0200, Australia

We present new EMPA major and LA-ICPMS trace element data from submarine basaltic to rhyolitic volcanic glasses recovered from the Kermadec arc volcanic centers Monowai, Brothers, Healy, Cotton, Rumble II West, Rumble III and Clark. During time-integrated analyses, invisible nano-sized nuggets rich in Au, Ag, Mo, Sn, Sb and W—mostly located along microlite or microcrystal-glass boundaries—were identified and then mapped using LA-ICPMS. Field and experimental evidence suggest that hot gases exsolve from magmas and accumulates as bubbles, can act as a carrier for metals, including Au and Ag. Mainly due to changes in temperature, pressure, flow regime and melt characteristics (i.e., viscosity, volatile saturation, and so on) during the ascent of the magma and quenching of the lava during eruption, the bubbles become unstable and may collapse, subsequently depositing metal-rich nano-nuggets in the glass. The localised occurrence of the nano-nuggets indicates a heterogeneity in the metal-contents of the gas phases exsolved from the ascending magma. In addition, imperfections, such as microcrystals, may act as nucleation point for nano-nuggets, which can explain their common occurrence along microcrystal-glass boundaries. Furthermore, these nano-nuggets appear to preferentially occur in basaltic glasses rather than in silica-rich glasses, suggesting there is an influence of magma type on the metal-bearing capabilities of the exsolved gases (bubbles). The formation of nano-nuggets in Kermandec arc glasses most likely represents a syn-eruption metal enrichment, possibly representing an indication of the ore forming capabilities of magmatic sources.

Niobium and Tantalum Mineralization in the Nechalacho REE Deposit, NWT, Canada

ALEXANDER TIMOFEEV[1]* AND A.E. WILLIAMS-JONES[1]

[1] Department of Earth & Planetary Sciences, McGill University, Montreal, Quebec, Canada (*correspondence: alexander.timofeev@mail.mcgill.ca)

The Nechalacho Layered Nepheline-Aegirine Syenite suite at Thor Lake, North West Territories, situated within the alkaline to peralkaline Blachford Lake Complex, contains substantial researves of Rare Earth Element (REE), zirconium, niobium, tantalum, and gallium in two ore zones (Upper and Basal zones). Pervasive hydrothermal alteration, involving replacement of primary magmatic mineral assemblages by an assemblage comprising K-feldspar, biotite, zircon and magnetite, influenced the upper 300 m of the layered suite, including the niobium-tantalum mineralization, which occurs in both ore zones. This was followed by albitization.

Previous studies of niobium and tantalum mineralization have focused on pegmatites, in which they occur as magmatic columbite group minerals that vary compositionally due to crystal fractionation. Unlike most pegmatites, niobium and tantalum at Thor Lake are hosted mainly by secondary minerals, i.e., fergusonite-(Y) and columbite group minerals, and as minor components in zircon. In the Upper ore zone, columbite group minerals occur within the altered cores of zircon crystals and immediately surrounding these crystals. Fergusonite-(Y) displays similar textural relationships with zircon in the Basal ore zone. Primary magmatic columbite group minerals have been identified only within drill core intervals of unusually high bulk iron content.

We propose a model in which niobium and tantalum were concentrated at the magmatic stage in a zirconium-silicate, such as eudialyte in the Basal ore zone or within zircon in the Upper ore zone. The zirconium-silicate, eudialyte, was decomposed by hydrothermal fluids, resulting in the formation of zircon with yttrium-rich cores. Fergusonite-(Y) then crystallized during hydrothermal alteration of these zircon cores in the heavy REE-enriched, Basal ore zone. Simultaneously, alteration of yttrium-poor zircon in the heavy REE-depleted Upper ore zone led to the formation of fine-grained columbite group minerals. Locally, primary columbite group minerals crystallized and were later metasomatically altered within iron rich horizons of the ore zones. As opposed to other niobium and tantalum-bearing intrusions, the minerals in the Nechalacho Layered Suite that host these two metals are predominantly of secondary origin.

WHAM-F_{Tox}: An aquatic cation mixture toxicity model

E.TIPPING[1]*, S.LOFTS[1] AND A.STOCKDALE[2]

[1]Centre for Ecology and Hydrology, Lancaster, LA1 4AP, UK (correspondence: et@ceh.ac.uk; stlo@ceh.ac.uk)
[2]Department of Chemistry, University of Manchester, Manchester M13 9PL, UK (anthony.stockdale@manchester.ac.uk)

An important reason for the development of geochemical models of natural waters is to predict and explain toxic effects towards aquatic organisms. We have extended the WHAM chemical speciation model [1,2] for application in toxicity, by assuming that the binding sites of living organisms can be represented by those of humic acid. The calculated cation accumulation (ν_i mol g^{-1}), or "active body burden", measures the exposure of the organism, and is combined with a cation-specific toxicity coefficient (α_i) to quantify the toxic effect via the combined variable F_{Tox} (= $\Sigma\alpha_i\nu_i$).

The toxic response is set to zero when $F_{Tox} \le F_{Tox,LT}$ (lower threshold) and 100% when $F_{Tox} \ge F_{Tox,UT}$ (upper threshold) with a linear response in between (Figure 1).

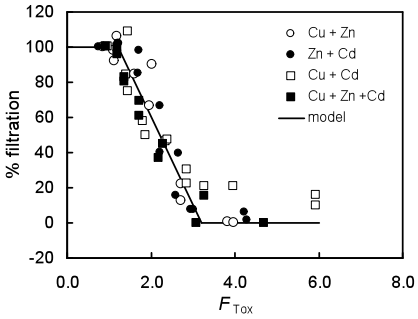

Figure 1: Laboratory toxicity of Cu, Zn and Cd to zebra mussel [3]; data fitted with WHAM-F_{Tox}.

The model has been used to interpret observations of macroinvertebrate species richness in > 400 streams affected by acidification and/or abandoned metal mines [4]. This field application required the use of quantile regression to take into account variations in species numbers due to factors other than the chemical composition of the streamwaters.

[3]Dep. of Science and High Technology, University of Insubria, 22100 Como, Italy
[4]Institute of Geological Sciences, University of Bern, 3012 Bern, Switzerland

The mass transfer from the subducting lithosphere to the overlying mantle wedge is mediated by complex solutions resulting from dehydration and decarbonation processes. Compared to H_2O-only and CO_2-only fluid compositions, experiments dealing with mixed H_2O-CO_2 fluids in equilibrium with high-pressure minerals are limited. In order to investigate the speciation and the solute contents of COH fluids in equilibrium with mantle minerals we performed two sets of experiments at identical P, T and fO_2 conditions using a rocking piston cylinder apparatus. Synthetic forsterite with minor enstatite was used as starting material.

In the first set of experiments we investigate the composition of COH fluids by puncturing the capsule in a gas-tight PTFE vessel at T=80°C. Evolved gases were convoyed toward a quadrupole mass spectrometer through a heated line to avoid the condensation of water. Oxalic acid dihydrate and graphite have been used to generate the COH fluid. Experiments were conducted at fO_2-controlled conditions using NNO, OH (GX, COH) buffer and a double capsule technique. Following thermodynamic modeling we expect in our experiments fluids close to the binary H_2O-CO_2 join.

The second set of experiments was performed to determine the solubility of forsterite in COH fluids. We analyzed the fluid trapped in a diamond layer by the cryogenic laser-ablation inductively coupled plasma-mass spectrometry technique [1]. COH fluids were generated from the addition of graphite, anhydrous oxalic acid and water.

The results will highlight the importance of COH fluids for the mass transport in subduction zones. Comparisons with other experimental systems [2] and with thermodynamic calculations will also be shown.

The distribution of LILE and HFSE in the magmatic hydrothermal systems of mylonites on the example of the detachment-closed metamorphic block (Eastern Trans-Baikalian region, Russia)

TISHIN P.A.[1], BUKHAROVA O.V.[1] AND KREMER I.V.[1]

[1] Tomsk state university, Tomsk, Russia,(tishin_pa@mail.ru)

Among the mylonites of the Borschovochny detachment-related metamorphic block with the Early Cretaceous age, simultaneous sills of andesites and dacites are forming. Their intrusion is accompanied by a hydro-thermal change of mylonites. Three main types of metasomatic associations are defined: K (white mica + chlorite + quartz ± adularia), Na-Fe-Ca (chlorite + albite + hematite + epidote + calcite), and K-Ca (quartz + calcite + ankerite + muscovite ± chlorite).

For unchanged metasediment mylonites, the way LILE and HFSE are enriched cor-responds to the UK standard with only differences in Cs (7-15 ppm) and Rb (92-135 ppm) enrichment, and low content of Sr (24-133 ppm). Geochemical characteristics of andesites and dasites show their similarity to the volcanites from the island arcs and active continental margins.

Metasomatism stimulates the loss of the most LILE and HFSE. At the same time, Ti is added to the Na-Fe-Ca system (up to 0,8 – 2%) with maintaining the Zr, Hf, Nb Ta, and REE concentrations. It is noted that maximum microelements are removed in the K- and K-Ca systems due to Sr enrichment (150-490 ppm) and inert Ti behavior (to 0,1 – 0,9%). It is obviously demonstrated in geochemistry of the frontal and rare zones, where Th decreases from 2,9 to 0,1 ppm, Zr - from 74 to 3, ΣREE from 79 to 13, La/Yb from 6 to 1,5.

A main mechanism for the extraction of REE is assumed to be the monazite decay, which discovers reaction crown composed by xenotime and galenite when contacting with sulfides.

This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.0686, 14.B37.21.1257).

Introducing PT-HPLC

FRANÇOIS L H. TISSOT[1], THOMAS J. IRELAND[1], REIKA YOKOCHI[1,2] AND NICOLAS DAUPHAS[1]

[1]Origins Lab. Department of the Geophysiscal Sciences, The University of Chicago, IL. (ftissot@uchicago.edu)

[2] Department of Earth and Environmental Sciences, University of Illinois at Chciago, Chicago, IL.

High-Performance Liquid Chromatography (HPLC) systems are superior in many respects to gravity-driven open columns commonly used in geochemistry, yet they suffer from several shortcomings that have hampered their adoption in isotope geochemistry (*e.g.* the liquid flow path often contains glass and/or metal parts which are easily corroded/dissolved, electronic controls and housing are often spatially associated with the HPLC unit, shortening the system lifespan [*e.g.* 1])

Here, we present a system developed at the Origins Lab. which addresses many of the shortcomings of commercially available HPLC systems: Pneumatic Teflon-HPLC (PT-HPLC) [2-4]. Development of this sytem was aided by technologic transfers from the semi-conductor industry and the availability of Teflon-manufactured parts. Its key features are:

1) fully automated elution schemes controlled through LabVIEW software interface, which enables for (i) fresh mixing of reagents for each elution step and (ii) gradient/ramp elutions, while removing the human error/non-reproducibility component, 2) temperature control of the system (up to 80°C) for enhanced chemical separations [5], 3) a modular design making the system adaptable to a variety of separation schemes by quick and inexpensive change of the resin type or column length, and 4) pneumatic actuation, allowing for the electronics to be isolated from the HPLC unit, increasing the lifespan of the system.

To test the PT-HPLC we performed a separation of all REE from each other in one column pass with unprecedented resolution. We used a 70 cm long column (ø=0.3 cm) filled with Ln-resin (25-50 μm resin bead size), a constant temperature of 70 ºC, a flow rate of ~0.5 mL/min and a HCl molarity ramp slowly increasing along a convex path from 0.10 M to 10 M HCl. More than 99% of each multi-isotopic REE was separated from its neighbors in one column pass.

This result demonstrates the effectiveness of our system and its great potential to tackle all outstanding geochemical problems that call for demanding separation schemes [6].

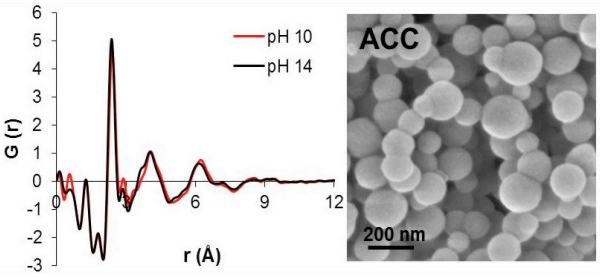
The role of pH and simple organic molecules in amorphous calcium carbonate (ACC) structure

D.J. TOBLER*, K.K. SAND, K. DIDERIKSEN, J.D. RODRIGUEZ-BLANCO, H. O. SØRENSEN AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*dominique.tobler@nano.ku.dk)

$CaCO_3$ crystallization controls a large part of the global carbon cycle through fluid-rock interactions, the formation of biominerals and also industrial processes. The initial steps of $CaCO_3$ crystallization are known to occur via the formation of amorphous calcium carbonate (ACC). The stability of ACC and its crystallization kinetics have been shown to be affected by temperature, pH and (in)organic additives [1]. However, little is known about the effect of these parameters on the structure of ACC at the atomic scale. Obtaining this information would help explain the different stabilities, morphologies, surface properties and formation mechanisms of $CaCO_3$ biominerals.

We carried out atomic pair distribution function (PDF) analysis using synchrotron radiation to determine the ACC structure formed under various conditions of pH and organic compounds. The results were combined with data from X-ray photoelectron spectroscopy, powder X-ray diffraction, infrared spectroscopy (FTIR) and electron microscopy.



PDF results showed that the short range ordering for ACC (<15 Å) was notably affected by increasing the initial pH of the Na_2CO_3 solution from 10 to 14 (figure left). This difference could indicate an association of the hydroxyl ions with ACC at higher pH, possibly affecting the water content. Conversely, ACC structure remains virtually unaffected when it forms in the presence of several organic compounds (e.g., amino acids, polysaccharides). FTIR revealed small changes in the mode of vibration of carbonate bands and also in water content for certain organic compounds (e.g. citric acid) indicating considerable surface interaction between the organic material and ACC.

Spatial distribution of heavy metals in the urban soils of Chisinau city (Republic of Moldova)

E. TOFAN*[1,2], G.O. IANCU[1], GH. JIGAU[2] AND N. BUZGAR[1],

[1]Alexandru Ioan Cuza University, 11, Carol I Bd., 700506, Iasi, Romania (tofanelena@yahoo.com)
[2]Moldova State University, 60, A. Mateevici, MD-2009, Chisinau, Republic of Moldova

The study area comprised the entire area of Chisinau city and has an approximate dimension of 15/15 km^2. Soil samples were collected inside the network of 1km/1km^2, from the depth 0-20 cm. On the grid surface, 120 soil samples have been analyzed. The heavy metal content was analyzed using X-ray Fluorescence Spectrometry (EDXRF Epsilon 5). The analyses for physicochemical parameters were carried out with the following methods: particle size distribution (Kachinsky, 1958), organic matter content (Tiurin, 1965), $CaCO_3$ (Arinuskina, 1970) and the pH was determined using a Corning M-555 pH/Ion Meter. Assessment of anthropogenic contribution in urban soils has been determinate by means of enrichment factor (EF), geoaccumulation index (Igeo) and pollution index (PI) [1].

Correlation matrix for analyzed heavy metals and physicochemical parameters was performed to observe relationship between the analyzed parameters. Results presented the chemical association of heavy metals in the study area. The physicochemical proprieties of urban soils showed a significant positive correlation with each other and with Co, Ni and Cr whose origin is predominantly geogenic. The conclusions highlighted the organic matter has an influence an accumulation of heavy metals. As well is evident that the elements showed a good correlation with each other indicating a common source. The geochemical background range at urban scale has been defined by applying the iterative 2σ technique method. The background geometric mean values for heavy metals (mg/kg) are: Cr (64.2); Co (12.9); Ni (32.7); Cu (28.4); Zn (82.7); Pb (22.8) and As (9.4). The means concentration of analysed chemical elements in Republic of Moldova rocks are Cr (86 mg/kg); Co (11 mg/kg); Ni (38 mg/kg); Cu (22 mg/kg); Zn (83 mg/kg); Pb (17 mg/kg) and As (1.7 mg/kg) [2].

The calculated EF and Igeo results revealed the following order As > Pb > Zn > Cu > Ni > Cr > Co. The PI recorded content from heavily contaminated to uncominated in follwing order Zn > As > Cu > Pb > Co > Ni > Cr.

Fingerprint of last glaciation on ^{2}H and ^{18}O in groundwater of north-east part of Baltic Artesian Basin

TOKAREV I.V.

tokarevigor@gmail.com

In the northern part of Baltic Artesian Basin (BAB) a groundwater of the multilayered hydrogeological system (mainly the Cambrian and Vendian aquifers) is the principal and most plentiful source for the public water supply in Russia and Estonia. But there are problems with the water quality in many sites due to high salinity and/or the specific components abundance. For example, the natural origin radionuclides (mainly Ra and Rn) and microelements (B, F, Fe, Mn etc.) exceed the sanitary limits.

The BAB is characterized by the limited knowledge about the hydraulic boundaries conductivities of aquifers. Taking into account the complex geological history of the Baltic region in the Pleistocene and Holocene, the isotope archive is significant for the groundwater flow and mass-transport understanding.

The stable isotopes (^{2}H and ^{18}O) were studied in the aquifers near north-east margin of BAB from a crystalline basement to Earth surface. The fingerprint of the Baltic ice lake is clearly fixed for Cambrian aquifer in Tallinn (Estonia). The lightest stable isotope composition of groundwater for Europe was found here ($\delta^{2}H$=-160 ‰, $\delta^{18}O$=-21 ‰, Raidla *et al*., 2009). The isotope composition of water is gradually weighted to the east direction and make up $\delta^{2}H$=-125 ‰, $\delta^{18}O$=-17 ‰ near the boundary between Estonia and Russia, and $\delta^{2}H$=-100 ‰, $\delta^{18}O$=-13 ‰ (that is like to modern precipitation) near the Ladoga lake. It seems, a relicts of the Eemian sea water also was obtained in some cases. It is the salty (M=4-6 g/l) and isotopically fractionated water, which have no ^{14}C or have significant ^{14}C age. Isotope composition is weighting, if the water is the thawed permafrost and become lighter, if it is the residual water after sediment freezing.

Clarification of As(V) Sorption Mechanism with ferrihydrite for Quantitative Modelling of Coprecipitation Process in Wastewater Treatment

CHIHARU TOKORO[1]*, DAISUKE HARAGUCHI[2], SAYAKA IZAWA[3] AND SHUJI OWADA[4]

[1] Waseda University, Tokyo, Japan, tokoro@waseda.jp
[2] Waseda University, Tokyo, Japan, d.haraguchi@aoni.waseda.jp
[3] Waseda University, Tokyo, Japan, izasaya@ruri.waseda.jp
[4] Waseda University, Tokyo, Japan, owadas@waseda.jp

Coprecipitation method using ferrihydrite has been commonly applied to remove As(V) in wasteawtaer such as acid mine drainage. Objective of this study is to clarify how coprecipitation of As(V) with ferrihydrite occures in wastewater and quantitative modelling of them.

We investigated the sorption mechanism of dilute As(V) with ferrihydrite using three kinds of experimental studies for an artificial wastewater in which the ion strength was 0.05 and pH was 5 and 7; (i) sorption isotherm formation, (ii) zeta potential mesurment and (iii) XRD analysis. We confirmed that As(V) was formed a simple two-dimentional adsorption onto the surface of ferrihydrite when the initial As/Fe molar ratio was less than 0.4, whereas a surface precipitation of amorphous ferric arsenate was formed when the initial As/Fe molar ratio was more than 0.4 [1].

Furthermore, both of XANES and EXAFS analysis on K-edge of As showed As(V) coprecipitates with ferrihydrite was mixture of As(V) adsorbed ferrihydrite and amorphous ferric arsenate. Estimated weight ratio of amorphous ferric arsenate in As(V) coprecipitates became above 0.5 when the initial molar ratio of As/Fe≥0.5 was used. These results corresponded with results by XRD analysis. EXAFS analysis assuming three kinds of surface complexes for As-Fe bond showed the coordination number for 2.85 Å of As-Fe bond increased and it for 3.24 Å of As-Fe bond decreased with increasing the initial As/Fe molar ratio. All experimental data obtained in this study showed As(V) co-precipitation mechanism shifted gradually from As(V) complexation to the surface of ferrihydrite toward amorphous ferric arsenate. Therefore, we constructed surface precipitation model to evaluate quantitatively the coprecipitation process of As(V) with ferrihydrite. Good agreement between experimental and calculated values was observed.

Selenium coprecipitated with barite as a new redox indicator

KOHEI TOKUNAGA[1]*, YUKA YOKOYAMA[1] AND YOSHIO TAKAHASHI[1]

[1] Hiroshima University, Hiroshima, Japan (*correspondence: ktokunaga@hiroshima-u,ac.jp)

Redox potential (Eh) is an important physico-chemical factor that can affect behaviors of various ions in water. A number of previous studies have suggested that Eh was estimated by the solid-water distribution of redox-sensitive elements based on the effect of change of the oxidation state such as relative enrichment-depletion profiles of particular elements such as iron and manganese. However, the estimation of redox conditions based on these profiles may not be reliable because (i) elemental concentrations are influenced by many factors such as secondary adsorption-desorption reactions and diagenesis and (ii) only the relative evaluation of the redox condition is possible by the depth profile of particular elements. Thus, the aim of this study is to propose a new redox indicator using the oxidation states of redox sensitive element itself in a certain mineral to estimate directly the particular redox condition at the time of the mineral formation. Here, we examined incorporation behavior of selenium (Se) species to barite as a redox indicator for oxic-suboxic condition.

Coprecipitation experiments of Se with barite coupled with determination of Se oxidation state both in barite and water phases were conducted to investigate the influence of the oxidation state on the coprecipitation of Se into barite. The oxidation state of Se in water and barite were determined by HPLC-ICP-MS and X-ray absorption near-edge structure (XANES) at Se K-edge, respectively.

It was found that the Se(VI)/Se(IV) ratio in barite reflects the Se(VI)/Se(IV) ratio in water, which suggests that the oxidization state of Se in barite can work as a redox indicator showing the redox condition at the time of barite formation. Selenium(IV) is incorporated into barite under suboxic condition below the redox boundary of Se(VI)/Se(IV). Selenium(VI), on the other hand, is incorporated under oxic condition above the redox boundary of Se(VI)/Se(IV). Based on the distribution behavior of Se to barite, we conclude that the Se(VI)/Se(IV) ratio in barite can be used as a redox indicator whether barite was precipitated below or above the redox boundary of Se(VI)/Se(IV), the Eh region of which is different from the Fe(III)/Fe(II) and Mn(IV)/Mn(II) boundaries often employed as a signature of redox condition.

Insights into mantle processes from water and trace elements in olivine

P.M.E. TOLLAN[1]*, J. HERMANN[2], R.J. ARCULUS[2], H.ST.C. O'NEILL[2] AND J.P. DAVIDSON[1]

[1]Department of Earth Sciences, Durham University (*p.m.e.tollan@durham.ac.uk)

[2]Research School of Earth Sciences, Australian National University

Olivine continues to be neglected in most trace element studies of mantle rocks. This is in spite of the ablity of modern analytical techniques to measure accurately and precisely a diverse and petrologically useful suite of elements and a burgeoning experimental interpretative framework of partition and diffusion coefficients.

We present the results of a detailed study of water and trace elements in olivine as evidence of their utility. Samples chosen for this study are harzburgite xenoliths dredged from volcanic cones close to Ritter Island in the West Bismarck Arc, Papau New Guinea. From textural observations, these samples are asigned to 'residual' or 'reacted' groups. 'Residual' samples display textures indicating an origin through melt extraction and sub-solidus cooling. Olivines have very low concentrations of all incompatible trace elements and water, consistent with the nominally cpx-free mineralogies. Concentrations of Al (0.5-9.1 ppm), Cr (5.0-19.9 ppm) and V (0.09-0.63 ppm) are exceptionally low due to the exsolution of Cr-spinel plates during cooling to temperatures of ~ 600 °C.

'Reacted' samples display textures consistent with melt-rock reaction. Olivines reflect this in significant water and trace element enrichment and disequilibrium, with over an order of magnitude variation in Y (0.08-23.8 ppb), Ca (22.3-793.0 ppm), Na (0.6-22.8 ppm) and Cr (7.2-252.4 ppm) concentrations among crystals in individual samples on a sub-cm scale. These concentrations overlap with and diverge from those measured in 'residual' olivines.

We interpret this as re-equilibration of olivine during percolation of hydrous mantle-derived melts. The extreme trace element disequilibrium requires that this reaction occurred on a very rapid timescale, shortly before magmatic entrainment. Olivine is the only phase that records this late-stage chemical exchange, due to its high modal abundance and more rapid rates of trace element diffusion. Similar studies on olivine from mantle and magmatic rocks can shed new light on the mechanisms and timescales of melt-rock reaction, transport, differentiation and magma mingling.

Two Noble Families display what happened in their early days

I. TOLSTIKHIN

Geological Institute, Apatity, and Space Research Institute, Moscow, Russian Academy of Sciences, Russia (igor.tolstikhin@gmail.com)

At the first glance there is nothing similar in behaviour of the refractory highly siderophile noble metals (NM) and the highly volatile inert noble gases (NG). However, all these species are extremely under abundant in the Earth's mantle relative to the solar composition, and this common feature allows them to record processes invisible by other chemical / isotopic systematics.

Since long a post-giant-impact late veneer of chondrite-like material (LV) is widely discussed as a plausible explanation of NM elemental and isotopic abundances in the mantle [1, 2, 3]. Less attention has been attracted to the possibility that this same LV could have delivered to the Earth a volatile-rich material, characterised by, e.g., (almost) solar isotope compositions of He and Ne. Moreover, an enhanced density of this material could also stabilize a noble-species-bearing reservoir (DDP [4]), preventing its intense mixing within the convective mantle.

Chemical transport modeling shows that flux of LV materials from DDP into the mantle could be responsible for chondrite-like relative abundances of NM, solar-like light NG, and contribution of early generated radiogenic Xe isotopes [5]. New results of modeling are presented and discussed.

Platinum deposits in hardrock of the Konder massif

NADEZHDA TOLSTYKH

Sobolev Institute of Geology and Mineralogy, SB RAS, pr. Ak. Koptyga, 3, 630090, Novosibirsk, Russia, (correspondence: tolst@igm.nsc.ru)

The problem of finding of promising ore areas in the bedrock of Ural-Alaska type intrusion, which until recently were considered only as source of placer, is now actual. It is necessary to study the regularities of location of platinum mineralization and to find the new search criteria. Alkaline-ultramafic massif Conder (Aldan Shield, Siberia) is now a major source of mined platinum placers. The rocks, that contain the platinum mineralization, were known until now only in chromitite [1]. Chromite schlieren really are most enriched with platinum (Pt-Fe alloys) and other minerals of platinum group elements (PGM), the content of which is about 0.5 kg/t. Our research has shown the possibility of finding of platiniferous zones unrelated to the chromite ores. Dunites with a rare accessory of chromite also contain platinum grains, ranging in size from 80-120 mμ in fine-grained dunites and up to 1 mm – in pegmatoid dunites.

In addition, intensive platinum mineralization was found in the rocks area near a tectonic contact between dunite and clinopyroxenite in the eastern part of the Konder massif. PGMs occur in dunites as well as in clinopyroxenites. A significant part of the Pt-Fe grains are porous. Cooperite amaunt to about 30% of PGM grains. Iridium, osmium, irarsite, hollingworthite, erlichmanite, laurite, braggite, bowieite, kashinite, ferrorhodsite, nickel-rich equivalent of cuproiridsite and Pd-Pb-S unnamed phase were found in Pt-Fe alloys as inclusions. Pt-Fe alloys are sometimes partially replaced by tulameenite and Pt-Cu alloys.

Thus, chromite ore is not the only determining criterion in the search for platinum ores. Localization of platinum ore at the contact of dunite and pyroxenite, the presence of numerous sulphide and sulfoarsenidov of PGE, associated with platinum, as well as post-magmatic transformations and replacement of primary Pt-Fe alloys – all indicate the active involvement of S-, As-containing fluids in the formation of these deposits. Such conditions can be created within the permeable dunite, enabling for the migration of fluids- and PGE-rich residual melt and cristallization the platinum ore near the contact with a less permeable pyroxenites.

Hydrogen isotopic composition of Earth's early ocean estimated from Archean MORB in Barberton Greenstone Belt

FUMIYA TOMIYASU[1]*, YUICHIRO UENO[1,2] AND MAARTEN DEWIT[3]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Meguro, Tokyo, 152-8551, Japan (tomiyasu.f.aa@m.titech.ac.jp)
[2]Earth-Life Science Institute, Tokyo Institute of Technology, Meguro, Tokyo, 152-8551, Japan
[3]AEON-Africa Earth Observatory Network, and Faculty of Science, Nelson Mandela Metropolitan University, Summerstrand, Port Elizabeth, 6031, South Africa

Origin and evolution of Earth's seawater are still poorly understood. Hydrogen isotopic composition is a key to constrain secular change of seawater volume through time. In Barberton Greenstone Belt, South Africa, the past fragment of Archean oceanic crust is well preserved. We have systematically analyzed hydrogen and oxygen isotopic compositions of sub-greenschist facies pillow basalts in upper part of the Hoogenoeg Complex. Based on petrographic observation together with XRD analysis, almost hydrous mineral in the samples are composed mainly of chlorite with minor amounts of epidote and actinolite. Temperature dependence of isotopic fractionation factor between chlorite and water is weak both for hydrogen and oxygen, thus useful to estimate the dD values of co-existing water. The studied basalt show posittive correlation between hydrogen isotopic composition and water content. This relationship is similar to those observed in typical modern basalts hydrated at the seafloor, but systematically offsets to low dD values compared to the modern example. Based on these relationship, we have concluded that the 3.5 Ga seawater and possibly mantle were both depleted in deuterium relative to modern seawater by 24±5‰. These results may suggest that Earth's seawater would have been decreased through time due to hydrogen escape rather than increase by degassing of water from mantle inbalanced against subduction.

Tephra from Ischia: dating eruptions and geochemical changes

E.L. TOMLINSON[1], P.G. ALBERT[2], S. WULF[3], L. CIVETTA[4], R. BROWN[5], V. SMITH[2], J. KELLER[6], G. ORSI AND M.A. MENZIES[7]

[5]Earth Sciences, University of Durham, UK
[6]Institut für Geowissenschaften, University Freiburg, Germany.
[7]Earth Sciences, Royal Holloway University of London, UK

Ischia is an active resurgent caldera. Volcanic activity at Ischia began prior to 150 ka, with the largest eruption being the 55 ka, caldera-forming Monte Epomeo Green Tuff (MEGT). Unravelling eruptive history from proximal deposits can be problematic due to burial, resurgent uplift and erosion. In such cases, distal tephra archives can provide valuable information about eruptive frequencies and about the long-term evolution of the volcanic-magmatic system.

Lago Grande di Monticchio (LGdM) lies 140 km east of Ischia. This anually laminated archive contains 64 Ischia tephra layers spanning 132 to 3 ka. These distal layers indicate that Ischia has experienced approximately one eruption every ca. 2100 years. We present major and trace element data for 20 of the layers and correlate 6 of these with glass data for proximal deposits.

Tephra compositions from the pre-MEGT (>55 ka: UMSA to Porticello) period comprise three compositional groups that occur repeatedly in sucessive eruptions. Tephra from smaller eruptions, e.g. UMSA and Porticello contain just one group, while larger eruptions, e.g. Tisichiello and Olummo record all three compositional groups. Proximal-distal correlations with LGdM indicate these eruptions span the 44 kyrs prior to the MEGT event.

Proximal-distal correlations indicate that the Schiappone eruption occurred 4.5 ka after MEGT. Post-MEGT tephra (<55 ka) record a step to lower FeO and TiO_2 and form compositional groups that overlap with the pre-MEGT but are displaced to lower incompatible element contents.

MEGT tephra spans a wide compositional range, broadly overlapping the three pre-MEGT conpositional groups but displaced to higher Nd and Y and containing an additional less evolved glass population. Confirmed distal equivalents of the MEGT include LGdM TM-19, Ionian Sea Y-7, and PRAD 1870 from the Adriatic Sea and probably C-18 in the Tyrrhenian Sea. Therefore, the MEGT was one of the most widely dispersed late Quaternary tephras to source from the Campanian region.

Microstructural development of in situ deformed and heated polycrystalline halite in depenpendence of silica gel

CATERINA E. TOMMASEO[1]

[1]Technical university Berlin, department of mineralogy, ACK9 13355 Berlin
caterina.e.tommaseo@TU-Berlin.de

Our research focused on the influence of silica gel on the texture development and the mechanical behaviour of predeformed polycrystalline halite. In situ experiments help further our understanding of the fundamental mechanisms of the processes taking place during texture development. With different methods both single grain orientation analyses and the texture development in the bulk were successfully obtained.

The results show the influence of silica gel (amorphous phase) either on the texture development and on the physical properties (as stress/ductility behavior) focusing not only on bulk texture but also on the changes in the single grain orientations. The polycrystalline samples doped with silica gel show an increase in the yield strength and a higher Young's modulus (stiffness). In the texture development a preservation of the starting texture is observed, which correlates well with the mechanical behavior. The amorphous phase probably protects the single grains from deformation, preventing strain accumulation by the introduction of defects and thereby preserving the grain shape.

Heterogeneity and anisotropy in the lithospheric mantle

ANDRÉA TOMMASI[1], VIRGINIE BAPTISTE[1], ERWIN FRETS[1,2], KATHERINE HIGGIE[1], VINCENT SOUSTELLE[1], VÉRONIQUE LE ROUX[1], DAVID MAINPRICE[1], ALAIN VAUCHEZ[1], CARLOS GARRIDO[2] AND JEAN-LOUIS BODINIER[1]

[1] Géosciences Montpellier, CNRS & Université Montpellier 2, France

Despite extensive geophysical investigations and studies of xenoliths and peridotite massifs, the lithospheric mantle, in particular beneath continents, remains a 'mysterious' layer. Seismic anisotropy data point to anisotropic physical properties, and hence structures, coherent at scales of 100s km. Receiver functions, in contrast, imply in lateral and vertical heterogeneity at scales < 10km within the mantle lithosphere, but the physical origin of the reflectors are not clear. We will present constraints on the lithospheric mantle seismic properties based on the analysis of an evergrowing database of naturally deformed peridotites and review recent studies of our group on naturally deformed peridotites. These studies highlight the role of reactive percolation of melts and fluids on the evolution of the lithospheric mantle, focusing on the creation of heterogeneity and the feedbacks between melt percolation and deformation. Based on these data, we will discuss the effect of these processes on evolution of the physical properties of the mantle, in particular the rheology. For instance, analysis of naturally deformed shows that static reactive percolation may significantly change the composition, but does not erase the fabrics and hence the anisotropy of physical properties. The latter, which is inherited from the major deformation episodes that shaped the continental plates, may be preserved for very long time spans, playing a major role on the subsequent evolution of continental plates.

Earthquake-driven noble-gas geochemistry in Lake Van (Turkey)

YAMA TOMONAGA[1], MATTHIAS S. BRENNWALD[1], COLIN MADEN[2], AYŞEGÜL F. MEYDAN[3] AND ROLF KIPFER[12]

[3]Department of Geological Engineering, Yuzuncu Yil University, Van, Turkey

Terrigenic He release and changes in the He isotope ratio in response to tectonic activity is well known [1,2,3]. However, the very local nature of the He release from the solid earth [4,5,6,7] implies that every system considered has to be addressed as a single and unique entity. Only such case-specific assessment allows to infer possible links between geochemistry and seismic events.

Lake Van (Turkey) is one of the largest terminal lakes and the largest soda lake on Earth. The lake basin is situated in a tectonically active region characterized by the presence of major faults and volcanoes and is known to accumulate mantle fluids [7,8,9]. The societal vulnerability of the area to seismic hazards was dramatically documented by the occurrence of the devastating earthquake of magnitude 7.2 close to the city of Van on Oct. 23rd 2011. This unfortunate and tragic event offers a unique opportunity to study the related emission of fluids from the solid earth. Our research in Lake Van during the last two decades [7,8,9,10] sets a solid experimental basis for understanding possible changes in the noble gas isotope composition in the water column induced by such a major earthquake.

In this work we present the noble-gas concentrations of water samples from Lake Van acquired before and after the earthquake. We compare the new data to our previous measurements and we evaluate the potential of noble gas analysis as geochemical proxy for tectonic activity.

[4] Department of Applied Geology, Federal University of Technology, Akure, Nigeria

Surface and subsurface soil from the bitumen environment of Ondo state was characterized for mineralogy, geochemistry and trace element mobility. Physical, mineralogy and geochemical properties of the soil samples was obtained using standard techniques. The soil in the study area is acidic with low cation exchange capacity. The majority of trace elements reside in residue phase. Hence, trace elements are relatively low mobile. They are therefore of little or no risk to ecosystem health. Major oxides are silica, iron oxide and alumina. Quartz, feldspar and kaolinite are dominant mineral constituting more than 99%.

Biomineralization and biomimetic synthesis of magnetite nanoparticles

É. TOMPA[1], I. NYIRŐ-KÓSA[1], R. UEBE[2], D. SCHÜLER[2] AND M. PÓSFAI[1]

[1]Dept. of Earth & Env. Sci., Univ. Pannonia, Veszprém, 8200 Hungary, (*correspondence: mihaly.posfai@gmail.com)
[2]Ludwig-Maximilians-Universität München, Dept. Biol. I, Biozentrum, D-82152 Planegg-Martinsried, Germany

Ferrimagnetic nanoparticles are used in a wide range of environmental, technical and medical applications, including their use for the transformation and degradation of metallic and organic pollutants, as constituents of magnetic fluids, and as contrast agents for magnetic resonance imaging [1]. Most applications require nanoparticles with highly specific physical properties. While magnetotactic bacteria produce magnetosomes (membrane-bound magnetite nanoparticles) with strictly controlled sizes and shapes, the regulation of these properties is typically much less successful in laboratory syntheses. By using the biomineralization process in magnetotactic bacteria as a model system, we performed a series of biomimetic synthesis experiments in order to produce magnetic particles with strictly controlled properties.

First, the possible means of control over nanoparticle shapes were explored in abiotic precipitation experiments, by varying the iron source and/or the concentrations and types of organic additives. Depending on the applied conditions, octahedral, disk-like or elongated magnetite particles formed. We also analyzed magnetosomes from the magnetotactic bacterium *Magnetospirillum gryphiswaldense* and studied the effects of growth conditions and genetic modifications on the sizes, shapes and structures of magnetosome particles. Using the available information on the genetic background of magnetite biomineralization in magnetotactic bacteria [2, 3], we designed a scheme for the bio-assisted synthesis of magnetic filaments. Mutagenized flagellar filaments were produced by inserting part of the gene of the known iron-binding protein Mms6 into the genome of *Salmonella typhimurium*. The mutagenized filaments are being used as stable protein scaffolds for the templated nucleation of magnetite, with the aim of producing magnetic 'nanotubes' [4].

Source Controls on the Metal Contents of Mantle-Derived Magmas

N. TONNELIER[1], C.M. LESHER[2] AND N.T. ARNDT[3]

[1] Department of Geology, University of Johannesburg, Johannesburg, South Africa
[2] Mineral Exploration Research Centre, Laurentian University, Sudbury, Ontario Canada
[3] Institut des sciences de la Terre, Université de Grenoble 1, St. Martin d'Hères 38400 France

Plume-derived magmas are thought to form by melting of mantle peridotite source but recent studies have shown that ferropicrites and Hawaiian basalts have major and trace elements contents that cannot be explained by this model. Geochemical and petrological studies suggest that their compositions are best explained by melting of olivine-free pyroxenite that formed through reaction between peridotite and melts derived from recycled oceanic crust. Pyroxenite with these composition are minor but ubiquitous component in ultramafic massifs and mantle xenolith. Base and precious metals partition into sulfides, silicates and alloys, and their concentrations provide additional constraints on the lithology of their source. To test this hypothesis, we studied the Ni, Cu, Co, Zn, V, Sc and platinum group elements (PGE) contents of tholeiitic basalts and picrites from Hawaii and ferropicrites from Russia, Canada, and Namibia and compared their compositions with those of peridotite-derived magmas. Hawaiian basalts and ferropicrites have relatively low PGE with respect to Ni and Cu, a characteristic that has been previously attributed to a stage of sulfide saturation during magma ascent or the presence of sulfide in the residue of melting of a peridotite source. However, our study shows that Hawaiian basalts and ferropicrites are enriched in Ni-Co-Cu-Zn and depleted in Pd-Pt, but undepleted in Ru-Ir. These features are inconsistent with previous models but consistent with an olivine-free pyroxene-bearing source formed from recycled oceanic crust.

Our study show that a) the base and noble metal contents of mantle pyroxenite from Beni Boussera (Morrocco) is consistent with mixing of eclogite-derived melts and peridotites, and b) the metal content of Hawaiian magmas and ferropicrites can be explained by melting of a mixed peridotite-pyroxenite mantle source. These observations have strong implication on the origin of magmatic ore deposits with mineralization characterized by high Ni-Cu tenors and high Cu/Pd and Ni/Ir ratios (e.g., Voisey's Bay, Canada; Nebo-Babel, Australia; Eagle, USA, Jinchuan, Limahe, Lengshuiqing, Baimazhai, Jinbulake and Kalatongke, China).

Immobilization of long-lived iodine after incorporation into apatite matrice

N. TORAPAVA[1]* AND C. WALTHER[1]

[1]The Institute for Radioecology and Radiation Protection, Leibniz University of Hanover, Herrenhäuser Str. 2, 30419 Hanover, Germany

Iodine-129 being long-lived volatile fission product, among with cesium-135 and technitium-99, represents a challenge for the design of repository-suited matrices [1]. The present study investigates a possibility of iodine incorporation in the forms of iodide and iodate into apatite and hydrotalcite-like matrices. The matrice should meet certain requirements, i.e. being cheap, safe, easy to synthesize, stable and environmental friendly. Optimization of coprecipitation method for synthesis of iodine containing apatite has been done. Obtained matrices will be characterized by SEM and XRD. Stability in the temperature range 100 - 700ºC is studied. Leaching experiments in MQ water and brine will be done as well as radiaton damage (α-, γ-) will be studied before the conference.

[1] Watanabe *et al*. (2009) *Appl. Mater. Interf.* **1**, 1579 – 1584.

The study the granitoid rocks in shear zone in SE-Qorveh (Kurdistan, Iran): With emphasis on geochemical behavior of whole-rock and mineral chemistry of Biotite and Feldspar

TORKIAN ASHRAF[1*] AND REZAIE MOZHGAN[1]

[1]Department of Geology, Faculty of Science, Bu-Ali Sina University, Hamedan, Iran. (a-torkian@basu.ac.ir)
[2]Department of Geology, Faculty of Science, Bu-Ali Sina University, Hamedan, Iran. (rezaiemozhgan@gmail.com)

The studied area is located in NW- Sanandaj-Sirjan belt, between 47° 45' to 48° 00' E-Longitude and 35° 00' to 35° 10' N-Latitude in SE-Qorveh , Iran. The investigation is done on the I-type granitic rocks. Enrichment for LILE & Pb, along with the negative anomaly of HFSE & Ba and low ratios of Nb/Y and Rb/Nb indicate that origin of initial magma is lower continental crust that created in a margin of convergent plate. The deformed granitoid rocks, including protomylonites and mylonites, are investigated in Sangin-Abad, Koh-e-Gazgaz and Poloserkan areas. The deformed rocks show variations in microstructural and mineralogical characterstics. Shear sense indicators (e.g. foliation, lineation, shear folds S-shaped, C-S fabric) suggest dipping slip movement. Petrographic evidence of tectonic activities are including myrmekite, recrystallized and slide alkali feldspars, fractured plagioclases, dynamic quartzes, perthitic orthoclase, and mantled feldspars with $Or_{91.19 - 91.54}$. Comparing geochemical data of deformed rocks and protolith show that there are varieties in abundances of main elements such as increasing of CaO, MnO, TiO_2 & P_2O_5 in protomylointes and mylonites. The pattern of element variations is consistent with activities of hydrothermal fluids and open system in this zone. Due to thses conditions, feldspars in mylonites and protomylonites are sodic-potsic to sodic in composition. Overall, relationship field, microstructural, textural, geochemical and mineral chemistry characteristics confirm role of the shear zone for formation of these features. Many of researchers have approved relationship between forming of microstructures with stress/ strain and hydrothermal fluids. The studied biotite crystals with content of ($\sum$FeO + MnO ≈ 13.4-42.21) are neoform crystals. They may be occurred by post-magmatic fluids of the granitoid and have formed in ~550 to ~750 ºC which corresponds to this deformation temperature.

The vulnerability of subsurface soil organic carbon to *in situ* warming and altered root inputs

MARGARET TORN, CAITLIN HICKS PRIES, BIAO ZHU, JANET JANSSON, EOIN BRODIE, PETER NICO, DON HERMAN, BRYAN CURTIS AND CRISTINA CASTANH[1]

[1]Lawrence Berkeley National Laboratory and UC Berkeley, One Cyclotron Rd, Berkeley, CA, (4720, USA; mstorn@lbl.gov

Subsurface soils (>30 cm) store more than half of global soil organic carbon (SOC) and the processes governing soil C turnover vary with depth. However, most SOC research has focused on surface soil and controls on subsoil dynamics are poorly understood. We are building a whole soil profile (to 1.5 m) warming experiment in an annual grassland to study the effects of warming and root inputs on SOC dynamics throughout the profile. This presentation will describe the experiment prototype and an initiative for an international consortium of replicated experiments. The soil is heated with resistance heaters inserted to heat the profile to 4°C above ambient while maintaining the natural temperature gradient. Highly ^{13}C-enriched *Avena fatua* grass root litter will be added within heated and unheated plots, in a factorial with addition of a DOC mixture to simulate root inputs. A comprehensive suite of measurements—instrumented *in situ* and in the laboratory—will be used to quantify the effect of warming and carbon inputs on soil C and N cycling. To improve predictive understanding and model skill, the experiment is focused on hypotheses concerning: (1) temperature sensitivity of native SOC and new (added root litter or DOC) carbon inputs with depth; (2) the effects of simulated root-input treatments with depth; and (3) interactions between warming and new C inputs. This study is one of the first to study responses of subsurface SOC to global change factors *in situ* and is designed to enhance our understanding of deep SOC stabilization mechanisms and improve predictions of the fate of soil carbon in a changing climate.

Polybaric differenciation within a clinopyroxenite body in the feeder-zone of an ocean island volcano (Fuerteventura, Canary Islands)

TORNARE E.[1]AND BUSSY F.[2]

[12] Institute of Earth Sciences, Anthropole, University of Lausanne, CH-1015 Lausanne, Switzerland 1evelyne.tornare@unil.ch, 2francois.bussy@unil.ch

It is now widely accepted that fractionation processes and magma differentiation or mixing occur during magma ascent to the surface. However, location of these processes remains a subject of controversy, as are the existence and size of shallow-level reservoirs. This question arises particularly in the case of ocean island volcanoes, which are not supported by a thick crust.

Fuerteventura allows access to the root-zone of an alkaline ocean island volcano. The PX1 pluton is a 22 Ma-old vertically layered mafic intrusion emplaced at shallow level. It consists in a heterogeneous clinopyroxenitic body intersected by dykes of various compositions, often gabbroic, and impregnated by more evolved melts. This clinopyroxenitic body does not show any vertical or horizontal layering. Contacts against the host rock are sharp without any development of a marginal facies. In some areas, the clinopyroxenite mass is modally and texturally highly heterogeneous with numerous enclaves and blobs of wehrlite, dunite and olivine-clinopyroxenite. Enclave outlines are often blurred with progressive transition to the matrix. These features are interpreted as evidence of repeated mingling episodes of crystallizing mushes. Other places are rather homogeneous with interstitial plagioclase occurence in olivine-clinopyroxenite. Polybaric crystallization within PX1 is inferred from mineralogical assemblages, typically varying from sp-bearing dunite with high mg# (e.g. ol mg#: 82.2 - 83.2 and cpx mg#: 84.1 - 87.3) to plg-ol-clinopyroxenites or krs-clinopyroxenites with lower mg# (cpx mg#: >75.4). Moreover, whole-rock geochemistry indicate a clear differentiation trend among all clinopyroxenite lithologies. In addition cpx frequently display growth zoning with core composition of Cr-diopside evolving towards Ti-augite rims.

We suggest that the PX1 clinopyroxenite body records at least three levels of crystallization/differentiation, i.e. an upper mantle to lower crustal stage at which formed the spinel-bearing dunitic enclaves, a mid-crustal level recorded by the Cr-diopside cpx cores and a shallow-level final crystallization stage during which residual melts were extracted from the system and erupted as subaerial basaltic flows.

Two sources of water and pre-biotic molecules in the inner solar nebula

C. TORNOW[1]*, P. GAST[1], S. KUPPER[1], I. PELIVAN[1], E. KÜHRT[1] AND U. MOTSCHMANN[1,2]

[1] DLR-Institute of Planetary Research, Rutherfordstr. 2, D-12489 Berlin, Germany, (*correspondence: carmen.tornow@dlr.de, philipp.gast@dlr.de)

[2] Institute of Theoretical Physics, TU Braunschweig, Mendelssohnstr. 2-3, D-38106 Braunschweig, Germany (u.motschmann@tu-bs.de)

Using a multi-stage model of the solar nebula (SN) we derive the chemical abundances and deuterium to hydrogen (D/H) ratios for water and pre-biotic species. The model consists of three consecutive stages described as:

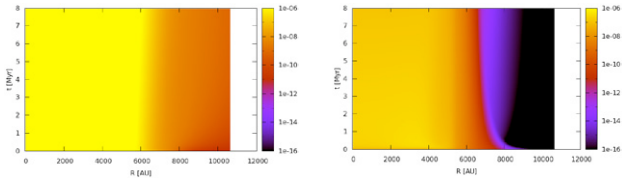
a spherical quasi-stationary core surrounded by the inter-core material of the parental cloud,

a collapsing core forming a proto-stellar source, an extending disk, and a spherical envelope, and

an accreting two-dimensional turbulent disk with gas and dust moving at different velocities

The collapse is simulated by a semi-analytical solution of the magneto-hydrodynamic equations based on a multi-zone mass density. In all stages the same chemical module is used (Semenov & Wiebe [1]).

Large amounts of water and the major pre-biotic molecule H_2CO were produced with relatively high D/H ratios in the dust phase of the first SN stage (source 1, see figure). During the collapse these dust grains flow into the inner nebula being the accretion range of rocky planets. In this range a hot corino forms as a result of the collapse. There, hot neutral gas phase reactions produce H_2O and H_2CO (source 2) along with the equivalent desorbed species but with lower D/H ratios. Thus, this ratio distinguishes molecules originating from different sources (i.e. model stages) of the nebula.



Relative HDO and HDCO abundances w.r.t. total hydrogen.

Metal fluxes at the sediment-water interface in a reservoir affected by AMD

E. TORRES[1], C. AYORA[1], ARIAS, J.L.[2], GARCÍA-ROBLEDO, E.[2], PAPASPYROU, S.[2,3] AND CORZO, A.[2]

[1] GHS, IDAEA-CSIC, Jordi Girona 18-26, 08034, Barcelona, Spain [2] Departamento Biología, Facultad de Ciencias del Mar y Ambientales, Universidad de Cádiz, Pol. Río San Pedro s/n, 11510- Puerto Real, Cádiz, Spain

[3] Unidad Asociada de Oceanografía Interdisciplinar. UCA-Instituto de Ciencias Marinas de Andalucía-CSIC, Pol. Rio San Pedro s/n, 11510 Puerto Real (Cádiz), Spain

Water reservoirs are a main source of water supply, and knowledge of the metal fluxes at the water-sediment interface is essential to predict their ecological quality. Moreover, redox oscillations promoted by turnover events may significantly alter metal cycling, especially if the reservoir is impacted by acid mine drainage (AMD). Under controlled laboratory conditions, several sediment cores were immersed in a tank of reservoir water and subjected to alternating oxic-anoxic conditions. A detailed sequential extraction was then performed on the sediments to speciate the metals into the solid phases, the pore and tank water was systematically analyzed, and a diffusion-reaction model was calibrated using the experimental results to quantify the reaction rates and the sediment-water fluxes.

The results showed that under oxic conditions, protons, Fe, and As decreased in the tank due to schwertmannite precipitation, whereas Al, Zn, Cu, Ni, and Co increased due to Al(OH)3 and sulfide dissolution. The reverse fluxes occurred during hypoxia. The model, extended to the complete year, computed that between 25% and 50% of trace metals and less than 10% of Al precipitated under hypoxic conditions re-dissolved during the oxic period, while only 22% and 9% of the Fe and As precipitated under oxic conditions re-dissolved during hypoxia. Consequently, the sediment showed a total acidity neutralization capacity of 3.34 mol/m2/y, with Al, Fe, and proton removal accounting for 55%, 30%, and 13% of this capacity respectively. Compared with coastal marine environments, metal fluxes were up to two orders of magnitude higher, and the sulfur system was the major redox control, meaning that SO4 was the major oxidant of OM and S(II) was the major O2 consumer, with values near 90% in both cases.

Potential signifigance of sulfide mineral oxidation for the Cenozoic carbon cycle

MARK A. TORRES[1] GAOJUN LI[2] A. AND JOSHUA WEST[1]

[1]Department of Earth Sciences, USC, 3651 Trousdale Parkway, Los Angeles, CA 90089, USA. (marktorr@usc.edu)

[2]MOE Key Laboratory of Surficial Geochemistry, Department of Earth Sciences, Nanjing University, Nanjing 210093, China. (ligaojun@nju.edu.cn)

A climatic control on the rate of CO_2 consumption by silicate weathering is thought to stabilize Earth's climate over geologic timescales. At the same time, the observation that tectonic uplift accelerates weathering rates suggests that mountain building can profoundly affect the carbon cycle and global climate. Extensive uplift of mountain ranges during the Cenozoic is thought to have increased silicate weathering rates as evidenced by the marine isotopic records of Sr, Os, and Li, which all show dramatic changes from ~40 Ma to present. Without a corresponding input of CO_2, increased silicate weathering fluxes would deplete the atmosphere of all CO_2 within a few million years, a clearly unreasonable scenario. While a variety of hypotheses have been put forward in order to balance the Cenozoic C cycle, none of them appear to adequately describe the observations. As such, reconciling this "Cenozoic carbon-weathering paradox" has been a major and as yet unresolved challenge in geochemistry and Earth history. We hypothesize that Cenozoic uplift, in addition to increasing rates of CO_2 drawdown by silicate weathering, increased rates of sulfide oxidation coupled to carbonate dissolution. This provided a transient source of CO_2 that contributed, at least in part, to the relative stability of Cenozoic atmospheric pCO_2. The feasibility of this hypothesis is tested in two ways: (1) a simplified mass balance model that constrains the duration of transient CO_2 release in response to increased rates of sulfide oxidation and (2) an inverse isotope mass balance model that uses the Cenozoic isotope records of Sr and Os to reconstruct changes in silicate weathering and sulfide oxidation rates. Together, these models show that the contrasting residence times of DIC and SO_4^{2-} is sufficient to allow for CO_2 release over 40 Myr timescales and that modeled rates of silicate weathering and sulfide oxidation are consistent with independent proxy records of paleo-pCO_2.

On-site porewater measurements of Lake Baikal sediments

The extraction and analysis of sediment porewater is crucial to investigate the unique early diagenetic processes in Lake Baikal, the worlds largest and deepest freshwater source. Investigation of the intricate sedimentary Fe/Mn layers requires porewater sampling and analysis with high spatial resolution and high yield of chemical parameters. Transporting the sediment samples from the field to the laboratory is logistically laborious, and prone to contamination, temperature changes, outgassing, mixing, diffusion and redox changes. Therefore, on-site methods are to be preferred.

Here we present an on-site application of a high spatial resolution porewater sampling and analysing method. The facility, combining filter tube sampler and a portable capillary electrophoresis instrument, was set up in a container on the shore of Lake Baikal for the immediate porewater sampling and analysis after coring from the ice.

The extraction of one porewater sample and the detection of its major inorganic cations and anions including the nutrients P and N could be accomplished in less than 15 minutes. The disturbance of the sediment was minimal and oxygen-sensitive reduced iron (Fe(II)) was detected within the set of cations, including Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, NH_4^+, and Mn(II) without splitting, acidification or dilution of the sample. The equipment is inexpensive, easy to handle and to transport.

Tungsten isotope Heterogeneities in Archean Komatiites

M. TOUBOUL[1], I. S. PUCHTEL[1] AND R. J. WALKER[1]

[1]Department of Geology, University of Maryland, College Park, MD 20742, mtouboul@umd.edu

Recent studies demonstrated that the short-lived ^{182}Hf-^{182}W isotope system ($t_{1/2}$ ~ 9 Myr) is a valuable tool for exploring key processes in the early evolution of the Earth, such as mantle differentiation by magma ocean crystallization or crustal extraction and late accretion [1, 2, 3]. The 3.8 Ga Isua rocks [1], the 2.8 Ga Kostomuksha komatiites [2] and the Nuvvuaggittuq supracrustal rocks [3] have ~15 ppm ^{182}W excesses, which is similar to the predicted W isotope composition of the mantle prior to late accretion. However, the mantle source of Kostomuksha komatiites has HSE contents similar to that of the PM estimates, which is inconsistent with preservation of a pre-late accretionary mantle reservoir. Instead, their mantle source must contain an old component, which formed by magmatic differentiation or metal-silicate equilibration and, as a result, inherited a high Hf/W ratio during the lifetime of ^{182}Hf.

Here, we present new high-precision W isotope data for 3.3 Ga komatiites from the Weltevreden formation of the Barberton Greenstone belt and 2.4 Ga komatiites from the Vetreny belt. All Vetreny komatiiites show small ^{182}W excesses that average +6.2±4.5 ppm (2σ SD, n = 5). At present, no ^{182}W anomaly can be resolved in the Weltevreden komatiites (μ^{182}W = -4.1±4.7 ppm, n = 2). Similar to 3.5 Ga Komati komatiites [2], the Vetreny and Weltevreden komatiites have W isotope compositions close to that of the modern mantle, consistent with mantle sources having received most of the terrestrial complement of late accreted material, as indicated by the relatively high calculated HSE abundances in their mantle sources (~80% of the PM estimates, [4, 5]). There is therefore no evidence for a gradual increase of late accreted material contribution in the mantle sources of Archean komatiites from 3.5 Ga to 2.4 Ga, in contrast to earlier conclusions [6]. Our new data rather suggest that most late accreted materials were delivered to Earth and homogeneized in the deep mantle prior to 3.5 Ga.

Seasonal and interannual evolution of the monoacids organics in the atmosphere of the humid savanna of Lamto

R. PÊLÈMAYO TOURÉ[1]*, G. KOUADIO[1], V. YOBOUÉ [1] AND C. ROMARIC BEUGRÉ[2]

[1] Laboratoire de physique de l'atmosphère et de mécanique des fluides (LAPA-MF) Université d'Abidjan- Cocody 22BP 231Abidjan22 Côte d'Ivoire [2] Laboratoire de chimie-physique Université d'Abidjan-Cocody 22BP 582Abidjan22 Côte d'Ivoire

*(pelemayo@yahoo.fr)

This work was made within the framework of the network IDAF. It concerns the follow-up of the acidity of the atmosphere of an ecosystem of wet savanna from the organic fraction of the free acidity. It is a question of understanding the major factors which cause the variability of this organic acidity in the interannual and seasonal scales. During ten-year period (1995- 2004) 860 rainy samples were collected in the wet savanna of Lamto. By using Henry's law, we determined the contents in the air of major organic monoacids (HCOOH and CH3COOH) from the concentrations of these acids measured in rains. The annual partial pressure of organic monoacids on the decade is extremely variable. It is 0,675 ± 0,56 ppb and of 0,413 ± 0,14 ppb respectively for the formic acid and for the acetic acid. This strong variability is bound to their various sources which are also very variable from one year to the next. The organic acidity varies from 40 % to 60 % on average and almost stable rest from a season to the other one. The seasonal analysis shows that generally the partial pressures of organic acids are of a factor twice as raised in dry season that in wet season. This difference is not inevitably connected to the quantity of haste registered from a season to the other one. But would more be connected to the biomass burning which contribute from 21 % to 51 % to the formation of organic acids in the wet savanna of Lamto.

Reactivity of natural heterogeneous nanoparticles

RAEWYN M. TOWN[1]

[1]Institure for Physics, Chemistry and Pharmacy, University of Southern Denmark, Campusvej 55, 5230 Odense, Denmark. E-mail:((raewyn.town@sdu.dk

The chemodynamics of metal complexation by humic acid (HA) is not well predicted by molecular concepts. HAs are small permeable particles with radius of a few nm. They carry a significant negative charge at ambient pH and are important complexants of metal ions in the environment. HAs are physically and chemically heterogeneous with distributed thermodynamic and kinetic properties. Recently developed theory for permeable charged nanoparticles [1-3] is applied to interpretation of metal ion binding by HA. Two opposing electric effects are operational with respect to the overall rate of association, namely (i) acceleration of metal ion diffusion from the bulk medium by the negative electrostatic field of the humic particle, and (ii) accumulation of metal ions in the negatively charged particle body by Boltzmann partitioning. The rate-limiting step in the metal-humic complex formation process is identified by comparing theoretical values of the rate constants for outer-sphere and inner-sphere complexation with those derived from measurements of the thermodynamic stability constant (K) and the dissociation rate constant (k_d). The experimentally derived association rate constant, k_a, is found to be practically independent of the degree of metal ion complexation, which confirms previous assumptions that the distribution in K is reflected in that of k_d. For the rapidly dehydrating Cu^{2+}, at an ionic strength of 0.1 mol dm^{-3}, the rate of diffusive supply of metal ions towards the humic particles is comparable to the rate of inner-sphere complex formation, indicating that both processes are significant for the observed overall rate. As the ionic strength decreases, the rate of diffusive supply becomes the predominant rate-limiting process, in contrast with the general assumption made for complexes with small ligands that inner-sphere dehydration is the rate-limiting step. The results are highly significant for interpretation of chemodynamics of metal complexation by HA.

[3]Hokkaido University, Hokkaido, 060-0810, Japan,

Recently, halogens are revealed to be one of the powerful tracers for water cycling in subduction zones [e.g., 1]. In the previous conference, we reported analytical method and some data for Cl, Br and I in kimberlites from South Africa, Greenland, Canada, Brazil, Russia and China, and found that the I/Br ratios of kimberlites are classified into two groups. In this study, additional samples of kimberlites and mantle-derived xenoliths collected from South Africa and Russia were analyzed to investigate the halogen characteristics and their origins in the kimberlite source regions. We analyzed halogens by using the pyrohydrolysis method [2] combined with ICP-MS and ion chromatography.

The kimberlite and xenolith samples from South Africa, Greenland, Canada and Brazil (Group S) showed high I/Br ratios (about 1×10^{-1}). The value is fairly similar to that of CI chondrite (I/Br ratio: about 1×10^{-1} [3]), suggesting these kimberlites preserve the characteristics of primordial halogen in the mantle from which the kimberlite magmas were formed. In contrast, both Chinese and Russian kimberlite and xenolith samples (Group C) showed low I/Br ratios (about 6×10^{-3}). Similarly low I/Br ratios have been observed in fluid inclusions in eclogites derived from seawater-altered oceanic crust [4] and in seawater associated with halite precipitation [5]. This suggests an involvement of seawater-derived halogens having low I/Br ratios in the source regions of the Group C kimberlites. Low I/Br ratios found in xenoliths also indicate possible subduction-related metasomatism on the halogen composition of the subcontinental lithospheric mantle.

Chemical weathering in glacial and proglacial environments

MARTYN TRANTER AND THE BRISTOL GLACIOLOGY GROUP

Bristol Glaciology Centre, School of Geographical Sciences, Univeristy of Bristol BS8 1SS, UK. (M.Tranter@bristol.ac.uk)

Physical weathering in glaciated environments initially produces debris which is fine-grained (predominatly silt-sized) and coated in microparticles. Geochemically reactive phases, such as carbonates and sulphides, are liberated from the interior of silicate mineral masses and so become more readily available for chemical weathering. Chemical weathering in glacial environments is microbially mediated, since ingress of atmospheric gases to glacier beds and water-laden roglacial sediments is oftern limited. Instead, the protons required to push chemical weathering beyound simple hydrolysis reactions are generated from the oxidation of sulphides and organic matter. This is the case beneath smaller glaciers, and appears to be the case beneath ice sheets, from waters sampled either directly or indirectly to date. A fundamental difference between the chemical weathering regimes beneath larger and smaller ice masses is the residence time of water beneath the larger ice masses. It is more likely that low oxygen and anoxic conditons are found beneath ice sheets than beneath smaller glaciers. Hence, it is likely that Fe-rich, anoxic waters will be found beneath sectors of the Antarctic and Greenland Ice Sheets. Such waters have the potential to act as fertilisers of Fe-poor circumpolar seas. Chemical weathering is not limited to the aquatic zones that underlie the ice sheets. Movement of ice over bedrock produces localised pressure melting, and the regelation waters produce micro-chemical weathering environments that allow oxidation of sulphides by oxygen, and the formation of nano-particulate iron oxyhydroxides. The refreezing of these waters back onto the glacier sole traps basal debris, which, following ice berg calving at the ice sheet margin, transport potentially labile Fe further afield into the surrounding sea. Glacial debris is also a source of labile P to aquatic ecosystems. Finally, a spectrum and surface and basal processes result in glacial runoff often containing labile DOC and DON. Hence, glaciers and ice sheets are currently being thought of as biogeochemical reactors that convert relatively bedrock into a cocktail of relatively labile, potentially bioavailable, nutrients.

The chemical weathering of proglacial sediments too has potential to effect global nutrient and geochemical cycles. Recent work of potential impacts on the global P cycle is reviewed.

Technetium Reduction and Permanent Sequestration by Formation of Low-Solubility Sulfide Mineral Phases

P.G. TRATNYEK[1]* AND D. FAN[1]

[1]Oregon Health & Science University, Beaverton, OR, USA (*correspondence: tratnyek@ebs.ogi.edu)

Under anoxic conditions, soluble $^{99}TcO_4^-$ can be reduced to less soluble $TcO_2 \bullet nH_2O$, but the oxide is highly susceptible to reoxidation. One way to minimize the mobility of the Tc^{VII} oxyanion pertechnetate (TcO_4^-) is to effect reduction under sulfidogenic conditions (generated abiotically by Fe^0 or biotically) to form TcS_x, which is significantly slower to oxidize than $Tc^{IV}O_2$. Here we investigate a novel strategy for remediation of Tc-contaminated groundwater whereby sequestration as Tc sulfide is favored by sulfidic conditions stimulated by nano zero-valent iron (nZVI). Fundamental aspects of this hypothesis have been investigated using batch and column experiments under abiotic and biotic conditions.

In the abiotic batch experiments, nZVI was pre-exposed to increasing concentrations of sulfide in simulated Hanford groundwater for 24 h to mimic the onset of aquifer biotic sulfate reduction. Solid-phase characterizations of the sulfidated nZVI confirmed the formation of nanocrystalline FeS phases, but higher S/Fe ratios (> 0.112) did not result in the formation of significantly more FeS. The kinetics of Tc sequestration by these materials showed faster Tc removal rates with increasing S/Fe between S/Fe = 0–0.056, but decreasing Tc removal rates with S/Fe > 0.224. The more favorable Tc removal kinetics at low S/Fe could be due to a higher affinity of TcO_4^- for FeS than iron oxides, and electron microscopy confirmed that the majority of the Tc was associated with FeS phases. X-ray absorption spectroscopy revealed that as S/Fe increased, the pathway for Tc(IV) formation shifted from $TcO_2 \bullet nH_2O$ to TcS_2. The most substantial change of Tc speciation occurred at low S/Fe, coinciding with the rapid increase in Tc removal rate. This agreement further confirms the importance of FeS in Tc sequestration. The inhibition of Tc removal at high S/Fe appears to have been caused by excess HS^-, which, however, is expected to be mitigated under natural conditions due to the abundance of iron oxides that can scavenge sulfide. The reoxidation kinetics of Tc sequestered under sulfidic conditions was significantly slower than that under non-sulfidic conditions, confirming that Tc(IV) sulfide is more resistant to oxidation than Tc(IV) oxide.

Diagenesis, deformation mechanisms and architecture of the fault zones in the extensional Neogene basins of the northeast Iberian Peninsula.

A. TRAVÉ; V.BAQUÉS; I.CANTARERO; E. PLAYÀ, G. ALÍAS, M.MORAGAS; C. MARTÍNEZ; F. PACHECO; C.J. ZAFRA; AND A. PLATA

Departament de Geoquímica, Petrologia i Prospecció Geològica. Facultat de Geologia. Universitat de Barcelona (UB). c/ Martí i Franquès s/n, 08028 Barcelona, Spain. (atrave@ub.edu)

The faults limiting the Vallès and Penedès basins affect Hercynian crystalline rocks, Triassic, Jurassic and Cretaceous carbonates, and Miocene carbonates, evaporites and detrital rocks. These faults generate gouges, cataclasites, breccias and pseudotachylytes. The main cements are calcite, quartz, laumontite, muscovite, chlorite, albite and iron oxides, depending on the PT conditions. We have established four tectonic events that gather different deformation phases.

Applying geothermobarometers in neoformed chlorites and K-white micas, we have established the PT paths from Hercynian to Neogene. We have observed how the faults have controlled the thickness and distribution of sediments during the first Mesozoic rifting.

Dolomitization and karstification are two widespread diagenetic processes that are recurrent through time and are clearly related to faults.

Trace elements together with radiogenic and stable isotopes of the calcite cements in veins have allowed us to constrain the origin and regime of fluids and the fluid pathways through time.

Isotope characterictics of the Bon Accord oxide body, Barberton greenstone belt, South Africa

M TREDOUX[1]*, F ROELOFSE[1] AND A SHUKOLYUKOV[3]

[1]Dept of Geology, Univ of the Free State, Bloemfontein, South Africa (*correspondence: mtredoux@ufs.ac.za)
[2]Scripps Inst of Oceanography, UCSD, La Jolla, USA.

The Bon Accord oxide-silicate body (BAOS) in the the Barberton greenstone terrane is associated with ultramafic igneous rocks. It initially attracted interest because of its extreme whole rock NiO enrichment (>30%) and very unusual mineralogy: In the 1960s, de Waal[1-5] described several new minerals, including the Ni end-members of magnetite (ferroan trevorite) and olivine (liebenbergite). De Waal[6] identified five zones in the semi-circular body, with an increase in hydrous phases from a massive central portion (mainly containing nepouite and trevorite) to the schistose rim. On the grounds of petrographic information, he proposed that the BAOS represents an altered Archean meteorite.

Tredoux and co-workers[7] re-examined samples of the BAOS body (sadly no longer *in situ*) in the 1980s, concentrating on its geochemistry. They rejected the meteorite model in favour of a terrestrial model, because of (a) similarities between chromites in the BAOS and those in the host ultramafite, (b) the possibility that this host rock is potentially associated with the basal part of the Jamestown ophiolite[8] and thus would not have been at surface in the Archean, (c) the high concentrations of platinum-group elements (PGE) which are usually relatively low in Ni-rich irons, and (d) positive (unmeteorite-like) trends of PGE patterns[7] of many of the BOAS samples.

Radiogenic isotope ratios point to extensive, and variable, degrees of disturbance[7], but the U-Pb and Sm-Nd data hint at an Archean (3.5 Ga) age. The Cr isotopes, when normalized to a terrestrial standard, yield a value of 1, within analytical error, which points to a terrestrial source for the material.

Non-Complexing Anions for Raman Microprobes under Hydrothermal Conditions

L.M.S.G.A. APPLEGARTH[1], C. ALCORN[1], K. BISSONETTE[1] AND P.R. TREMAINE[1]*

[1] University of Guelph, Ontario, Canada (tremaine@uoguelph.ca)(* presenting author)

Small scale techniques based on the use of diamond anvil cells (DAC) and capillary cells ("high pressure optical cells", HPOC) are being increasingly employed to study subcritical and supercritical solutions using Raman spectroscopy [1]. Quantitative Raman measurements to determine thermodynamic properties and structural information often require the use of internal reference standards. These must be soluble, non-complexing and stable under hydrothermal conditions. The species used for this purpose at ambient conditions are bisulfate (HSO_4^-), perchlorate (ClO_4^-), perrhenate (ReO_4^-), and triflate ($CF_3SO_3^-$).

This paper reports the thermal stability of these internal standards as a function of pH up to 420 ºC and 30 MPa. Time-dependent reduced isotropic Raman spectra were obtained using a custom-made LabRamHR 800 spectrometer with quartz HPOC capillary cells at 30 MPa. Typical spectra are shown in Figure 1. In neutral solutions, perchlorate, perrhenate and triflatee are stable up to 140 ºC, 200ºC and 400ºC, respectively. Simple rate equations, criteria for selecting reference anions, and measurement practices for quantitative hydrothermal studies in Raman microprobes are presented.

Figure 1. Raman spectra showing 0.1 m $CF_3SO_3^-$ decomposition: a) 350ºC pH 2 and b) 400ºC neutral conditions.

Quantifying the open-system behavior of cosmogenic noble gases in quartz

M.M. TREMBLAY[1,2]*, D.L. SHUSTER[1,2] AND G. BALCO[2]

[1]Department of Earth and Planetary Science, University of California, Berkeley, Berkeley CA 94720 USA (*correspondence: mtremblay@berkeley.edu)

[2] Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley CA 94550 USA

Simultaneous production and diffusion of cosmogenic noble gases in minerals at the Earth's surface offers a potentially powerful tool for reconstructing past Earth surface temperatures. In order to utilize this open-system behavior for paleothermometry, knowledge of both the production rate and diffusion kinetics of a particular cosmogenic nuclide-mineral pair is required. We investigated the diffusion kinetics of ^{3}He and ^{21}Ne in quartz through a series of stepwise heating and degassing experiments. Natural and synthetic quartz samples were irradiated with protons to produce uniform distributions of ^{3}He and ^{21}Ne through similar nuclear transmutations as those induced by cosmic rays. Single grains of irradiated natural quartz exhibit two stages of linear Arrhenius behavior for both He and Ne diffusion: one at low temperatures and for gas release fractions of ~75%, and one at high temperatures for the remaining ~25%. We interpret these two Arrhenian arrays to represent multiple diffusion domain-type behavior in quartz and will discuss the physical meaning of such domains through ongoing experiments on synthetic and natural quartz. Comparison of degassing experiments on vein quartz from the Transantarctic Mountains, conducted using both cosmogenic ^{3}He from a several-hundred grain aliquot and proton-induced ^{3}He from a single grain, demonstrates the following: (i) <6% of the cosmogenic ^{3}He produced within the low retentivity domain is retained at subzero temperatures over several Myr of exposure, while (ii) >90% of ^{3}He is retained within the high retentivity domain. A simple exposure history for this sample using a two-domain diffusion model suggests a maximum effective exposure temperature of -14°C, although ^{10}Be and ^{21}Ne measurements suggest a more complicated history involving both burial and exposure. In contrast, the measured diffusion parameters for Ne from all experiments suggest quantitative retention in quartz over millions of years and at effective exposure temperatures less than 45°C. The ratio of cosmogenic ^{3}He to ^{21}Ne in quartz may therefore be useful for studying the temperatures of surface processes in polar environments.

Impacts of CO_2 perturbation on well composite samples: experiments and numerical simulations

J. TREMOSA[1], S. MITO[2], P. AUDIGANE[1] AND Z. XUE[2]

[1] BRGM, 45060 Orléans, France; (j.tremosa@brgm.fr)
[2] RITE, Kyoto, 619-0292, Japan; (mito@rite.or.jp)

Abandonned wells in the depleted reservoirs envisaged to host CO_2 geological storages are the main possible leakage pathways of CO_2 towards shallow aquifers. Then, for impact assesment, the alteration of well materials with CO_2 in the reservoir conditions requires to be characterized.

Here, the interaction of a composite well sample – formed of steel casing, surrounded by Portland cement, itself surrounded by sandstone – with wet CO_2 and CO_2-saturated brine under pressure and temperature controlled conditions was studied combining a set of batch experiments [1] and reactive transport modeling. In the experiments, lasting up to 8 weeks, noticeable mineralogical changes were observed in the cement, at the interface with the sandstone, leading to a carbonation of the cement. Main mineralogical changes consisted in dissolution of portlandite, replacement of CSH phases rich in Si by Ca-rich CSH phases and precipitation of calcite, amorphous silica and zeolite [1]. Interestingly, no re-dissolution of calcite was observed at the outer boundary of the cement, in relation with the penetration of the carbonation front, as observed in experiments involving only cement and CO_2-saturated brine [2]. For the two other components of the composite well samples, few changes were observed. The steel shown a moderate corrosion with some precipitations of Fe-oxides at its surface. No changes were observed in the sandstone.

These changes in mineralogy were reproduced with the reactive transport model, which highlights the successive dissolution/precipitation reactions. A good agreement was also obtained with the brine composition evolution record during the experiment. It is worth noting that the model suggested slight mineralogical changes in the sandstone consisting in dissolution of carbonates at the boundary of the sample, in direct contact with the CO_2-saturated brine. This observation, in link with the experimental observations in the cement, indicate a buffering effect of the rock on the CO_2 perturbation. This possible buffering was observed by observations at a larger scale on industrial analogue well samples [3] and suggests a preservation of the well integrity.

Benthic nitrogen fixation and Mn/Fe reduction in the Mauritanian oxygen minimum zone: Two overlooked processes?

TREUDE T.[1]*, BERTICS VJ[2], GIER J[3] AND SOMMER S[4]

[1]GEOMAR Helmoltz Centre for Ocean Research Kiel, Wischhofstr. 1-3, 24148 Kiel, Germany, (ttreude@geomar.de)(*presenting author)
[2]Harvard University, Biological Laboratories, 16 Divinity Avenue, Cambridge, MA 02138, USA, (vbertics@fas.harvard.edu)
[3]GEOMAR Helmoltz Centre for Ocean Research Kiel, Wischhofstr. 1-3, 24148 Kiel, Germany, (jgier@geomar.de)
[4]GEOMAR Helmoltz Centre for Ocean Research Kiel, Wischhofstr. 1-3, 24148 Kiel, Germany, (ssommer@geomar.de)

Oxygen minimum zones (OMZ) are currently in the focus of many marine biogeochemical studies, especially since their spreading has been discovered and associated with climate change. Understanding element cycling of OMZ is an important key to predict dynamics of this systems as well as feedbacks to environmental changes. Nitrogen and iron are two central elements in cycling processes of OMZ; however, budgeting and following the fate of these elements still remain challenging. Here we present two benthic processes, microbial N_2 fixation and Mn/Fe reduction, from the Mauritanian OMZ, which were measured at six stations along a depth transect between 50 and 1100 m water depth. N_2 fixation was deduced from nitrogenase activity via the acetylene reduction method. Mn/Fe reduction was measured indirectly via total anaerobic production of dissolved inorganic matter after subtraction of sulfate reduction activity. Highest integrated nitrogenase activity (~360 μmol C_2H_4 m^{-2} d^{-1} down to 20 cmbsf) and Mn/Fe reduction (~29 mmol m^{-2} d^{-1} down to 10 cmbsf) was found within low oxygen zones (45 to 56 μM O_2) beneath water depths of 100-240 m. Both processes generally decreased with greater water depths. The percentage of Fe/Mn reduction in total anaerobic organic matter degradation in the top 10 cm increased from ~65% to over 90% downslope. We are convinced that both processes play an important role for element budgeting of OMZ and should be considered in future studies. Especially in developing OMZ featuring terrestrial dust/iron input to the seafloor, such as the Mauritanian OMZ, iron reduction could play a key role for delaying the buildup of sulfidic conditions during organic matter degradation.

Boninite-derived mafic-ultramafic intrusives from Northern Victoria Land (Antarctica): Implications for mantle source metasomatism

R. TRIBUZIO[1,2]*, F. HENJES-KUNST[3], R. BRAGA[4] AND M. TIEPOLO[2]

[1] Dipartimento di Scienze della Terra e dell'Ambiente, Pavia, Italy.
[2] C.N.R. - Istituto di Geoscienze e Georisorse, Pavia, Italy. (*correspondence: tribuzio@crystal.unipv.it)
[3] Bundesanstalt für Geowissenschaften und Rohstoffe (BGR), Hannover, Germany
[4] University of Bologna, Italy

The Cambrian mafic-ultramafic sequence from Niagara Icefalls area in Northern Victoria Land represents a rare case of boninite-derived intrusive complex. The sequence mostly consists of dunites, orthopyroxenites, melanorites and gabbronorites, locally associated with hornblende granitoids that were most likely emplaced at upper levels of the continental crust. The mafic-ultramafic sequence was interpreted to be formed by boninite-type melts according to the fractional crystallization evolution: olivine → orthopyroxene → orthopyroxene + plagioclase ± clinopyroxene. The concentrations of incompatible trace elements in the whole sequence are extremely low (e.g., TiO_2 ≤0.06 wt%, Y <3 ppm). The whole-rock REE chondrite-normalized patterns vary from slightly depleted to enriched in the LREE (La_N/Sm_N = 3.5-0.5), in agreement with the REE variations observed for the included clinopyroxenes. The initial ε_{Nd} of the mafic-ultramafic sequence spans one order of magnitude, which roughly decrease with increasing La_N/Sm_N. The granitoids associated with the mafic-ultramafic sequence have nearly homogeneous trace and Nd-Sr isotopic compositions. In particular, the granitoids have high REE amounts, with LREE-enriched patterns (La_N/Sm_N = 4.3-3.4), and highly radiogenic initial Nd-Sr values. The highest initial ε_{Nd} and the lowest initial $^{87}Sr/^{86}Sr$ (0.7035) of the mafic-ultramafic sequence document the involvement of isotopically depleted asthenospheric sources. The wide Nd isotopic variations in the mafic-ultramafic sequence could be correlated with the boninite-type parental melts experiencing assimilation of crustal material. However, the most enriched isotopic compositions were found for the most primitive rocks: the dunites and the orthopyroxenites. We thus attribute the enriched isotopic compositions to a mantle source metasomatized by components derived from subducted oceanic metasediments.

High temperature alteration of the gabbroic oceanic crust (Ligurian ophiolites, Italy): Evidence for hydrothermal-magmatic interactions

R. TRIBUZIO[1,2], M.R. RENNA[3], L. DALLAI[4] AND A. ZANETTI[2]

[1] Dipartimento di Scienze della Terra e dell'Ambiente, Università di Pavia, Italy (tribuzio@crystal.unipv.it)
[2] C.N.R. - Istituto di Geoscienze e Georisorse, U. O. di Pavia, Italy
[3] Dipartimento di Fisica e di Scienze della Terra, Università di Messina, Italy
[4] C.N.R. - Istituto di Geoscienze e Georisorse, U.O. di Pisa, Italy

The gabbroic bodies from the Jurassic Ligurian ophiolites are structurally and compositionally similar to the gabbroic sequences from the oceanic core complexes of the Mid Atlantic Ridge. The high temperature cooling evolution the Ligurian gabbros is locally associated with formation of hornblende-bearing felsic dykes and hornblende vein networks. The hornblende veining is correlated with widespread development of hornblende as coronas/pseudomorphs after the igneous clinopyroxene in the host gabbros. We also found hornblende-rich gabbros as dykes/sills within mantle peridotites.

The hornblendes from the felsic dykes and the hornblende gabbros are characterized by low Mg#, CaO and Al_2O_3, negligible Cl, and high TiO_2, K_2O, REE, Y, Zr and Nb. The whole-rock Sm-Nd isotopic compositions of the felsic dykes and the hornblende gabbros define a Jurassic isochron with a MORB-type initial $^{143}Nd/^{144}Nd$ ratio. The $\delta^{18}O$ of the hornblendes and coexisting zircons from these rocks do not decipher the presence of a seawater component in these melts. We propose that the felsic dykes and the hornblende gabbros formed by SiO_2-rich silicate melts derived from high degree fractional crystallization of MOR-type basalts.

The vein and the coronitic/pseudomorphic hornblendes show high Mg# and CaO, significant Cl and low TiO_2 and K_2O. The coronitic/pseudomorphic hornblendes have trace element compositions similar to those of the clinopyroxenes from the gabbros and $\delta^{18}O$ close to that of seawater, thereby documenting an origin by reaction between migrating seawater-derived fluids and the host gabbros. The vein hornblendes commonly show slight LREE enrichment and relatively high values of Nb and $\delta^{18}O$. The crystallization of these hornblendes most likely required the involvement of both seawater and magmatic components.

FASTREACT – Efficient reactive transport modelling for long-term repository safety assessments

P. TRINCHERO[1]*, J. MOLINERO[1], G. ROMÁN-ROSS[1], STEN BERGLUND[2] AND JAN-OLOF SELROOS[3]

[1] Amphos 21 Consulting S.L., Passeig Garcia Faria, 49-51, E-08019, Barcelona, Spain
[2] HydroResearch AB Stora Marknadsvägen 15S SE-18334 Täby Sweden
[3] Swedish Nuclear Fuel and Waste Management Company, Box 250 101 24 Stockholm, Sweden

Reactive transport modelling is commonly used to provide support for repository engineering activities and safety assessment studies [1]. Yet, the very large temporal and spatial scales involved in these types of studies along with the non-linearity of the underlying processes pose formidable computational challenges that usually force modellers to simplify the problem.

In this work, we present a numerical tool, denoted as FASTREACT, for the efficient solution of large-scale reactive transport simulations. The tool, which relies on the theory of Stochastic-Convective models [2], decomposes complex three-dimensional geometries into a set of independent streamlines. Reactive transport processes are then solved over the whole set of streamlines using one single reference simulation that incorporates explicitly all the relevant geochemical processes. FASTREACT has been developed for safety assessment calculations of radionuclide transport in fractured rock and thus provides efficient handling of the coupling between advection, reactions and matrix diffusion processes for large amounts of input and output data.

The methodology is tested against a synthetic case study where a radionuclide transport problem is solved over a set of heterogeneous conductivity fields. The results compare favourably with those obtained using an Eulerian approach whereas the computational performance of FASTREACT is proved to be much more efficient when compared with the "traditional" Eulerian 3D simulations.

High-precision Neodynium isotope analyses by MC-TI-MS

ANNE TRINQUIER[1], CLAUDIA BOUMAN[1] AND JOHANNES SCHWIETERS [1]

[1] Thermo Fisher Scientific, Bremen, Germany, anne.trinquier@thermofisher.com

Resolving Nd isotope anomalies at the ppm level for materials with a wide range of compositions and Nd concentrations is key to unraveling fundamental relations in geochronology, geochemistry, cosmochemistry and environmental sciences. Nd isotope Thermal-Ionization Mass Spectrometry (TIMS) has proven successful in running Nd both as Nd^+ on multiple filament assembly (300-500ng) [1] and NdO^+ on single filament assembly (1-10ng) [2].

The present study on a Thermo Scientific TRITON *Plus* instrument assesses precision and accuracy of Nd analyses adapting the above mentioned protocols on two Nd standards (Merck # 170335 and JNdi [3]) for sample loads ranging from 0.5 µg to the ng range, using 10^{11} Ω amplifiers, automatized mode and shortened analysis time compared to literature. Nd^+ analyses of 500ng and 100ng loads on double Re filament assemblies in static mode with rotation of the amplifier-cup association ("virtual amplifier") yield indistinguishable isotopic ratios. The 1-yr 2RSD reproducibility R_i for $^{i}Nd/^{144}Nd$ ratios expressed in ppm: R_{143} = 5 and $R_{142\text{-}150}$ = 4 to 21 (n=70, 3.6-10V $^{142}Nd^+$, 100 or 500 ng). Notably, analyses with 10V $^{142}Nd^+$ ion beams could be limited to 1hr. NdO^+ analysis of 10ng loads on single Re filament assembly, a different ion-beam setting, in static mode, yields Nd isotopic ratios indistinguishable from those obtained in Nd^+ analyses. This validates the stability of the instrument ion optics, the Faraday cups, and the current amplifier system, as well as accurate oxide interference correction. The 2RSD reproducibility expressed in ppm: R_{143} = 16 (n=13, 1.5V $^{142}Nd^{16}O^+$). Notably, one analysis was limited to 25min.

With acquisition times ≤90min and a reproducibilty on $^{143}Nd/^{144}Nd$ of 5ppm (Nd^+) and 16ppm (NdO^+), this study holds promise for achieving highly reproducible results with ever smaller sample amounts. A TRITON *Plus* Nd^+ study on 100 pg loads using 10^{12} Ω amplifiers reported 2RSD reproducibility of 176 ppm on $^{143}Nd/^{144}Nd$ [4]. Detection limit, precision and accuracy of Nd isotope TIMS analysis are thus expected to be further improved by the combined use of 10^{12} Ω amplifiers and NdO^+ analysis.

Geochemistry and Re-Os age for black shales from the Cambrian-Ordovician boundary, Green Point, western Newfoundland

GYANA R TRIPATHY[1,*], JUDITH L HANNAH[1,2], HOLLY J STEIN[1,2] AND GANG YANG[1]

[1]AIRIE Program, Department of Geosciences, Colorado State University, Fort Collins, CO 80523-1482, USA (*Presenting author: gyana.tripathy@colostate.edu)
[2]CEED Centre of Excellence, University of Oslo, P.O. Box 1048, 0316 Oslo, Norway

Chemical and isotopic signatures for black shales can serve as proxies for reconstruction of paleoenvironmental conditions. Here we bring Rock-Eval, major and trace elements and Re-Os isotopic data together to examine the environmental record at the Cambrian-Ordovician Global Stratotype Section and Point (*GSSP*) at Green Point in western Newfoundland. The Green Point shales are oil mature and contain Type-II organic material of marine origin. A Re-Os isochron for these shales provides the first depositional age for the *GSSP* boundary at 484 ± 16 Ma (2σ; Model 3 age; MSWD = 21; n = 13), with an initial $^{187}Os/^{188}Os$ ratio of 0.74 ± 0.05.

Factor analysis of the geochemical dataset for Green Point shales shows association of most trace elements with TOC and S contents, ensuring an authigenic origin for most elements and hence, their validity for evaluating paleoredox state. Relatively high enrichment factors for redox-sensitive elements (*e.g.*, Re, U and Mo) compared to average shales, but lower enrichment factors relative to modern Black sea sediments, suggest deposition in anoxic waters. Comparison of global Cambrian-Ordovician shale geochemistry datasets leads us to suggest that anoxic conditions and warm oceanic regimes were restricted to the margins of Laurentia and Baltica whereas depositional basins with colder waters (*e.g.* Avalonia and Gondwana) show geochemically less reducing conditions. These outcomes underscore the important role of paleogeography in regulating ocean conditions and marine life.

Supported by NSF award EAR-0844213 to JLH and HJS; thanks to Jörg Maletz and Sven Egenhoff, co-PIs on the NSF award, for guidance in the field and inspiring conversations.

Nanoparticle interactions with lipid bilayers studied by nonlinear optics

J.M. TROIANO, S.R. WALTER, L.L. OLENICK AND F.M. GEIGER*

Department of Chemistry, Northwestern University, 2145 Sheridan Road, Evanston, IL 60208, USA (*correspondence: geigerf@chem.northwestern.edu)

The goal of this work is to understand the fundamental chemistry of how nanoparticles (NPs) interact with biologically relevant interfaces *in situ* at the molecular level. Surface specific nonlinear optical spectroscopies, namely second harmonic (SHG) and sum frequency generation (SFG), are used to investigate the interactions of NPs with lipid bilayers as model cell membranes. Specifically, SHG allows us to probe binding interactions, while SFG allows us to investigate the effect of NPs interactions with the molecular structure of the lipids.

We use resonant and nonresonant SHG to quantify binding constants, adsorption free energies, and interfacial charge densities in real time for gold NPs and quantum dots interacting with bilayers of various lipid compositions. We also examine the relationship between the measured adsorption free energies and the electric double layer interfacial potential to determine the change in the charge state of the NPs during these interactions. Combining this knowledge with the SFG results, detailing molecular structural changes due to the NP-membrane interaction, allows us to predict possible pathways for the molecular level NP-lipid bilayer interactions.

The impact of lipid composition, NP core composition, and capping ligand on the NP-membrane interactions is investigated. Understanding how nanomaterials interact with lipid bilayers at the molecular level is important for predicting and controlling molecular interactions of nanomaterials with living systems as well as designing environmentally and biologically sustainable nanomaterials.

Shallow-level magma-sediment interaction and explosive behaviour at Anak Krakatau

TROLL, V.R.[1,4], JOLIS, E.M.[1], DAHRÉN, B.[1], DEEGAN, F.M [1], BLYTHE, L.S.[1], HARRIS, C.[2], BERG, S. E.[1], HILTON, D.R. [3], FREDA, C.[4] AND SCHWARZKOPF, L.M.[5]

Crustal contamination of ascending arc magmas is generally thought to be a significant process which occurs at lower- to mid-crustal magma storage levels where magmas inherit their chemical and isotopic character by blending, assimilation and differentiation [1]. Anak Krakatau, like many other volcanoes, erupts shallow-level crustal xenoliths [2], indicating a potential role for upper crustal modification and hence late-stage changes to magma rheology and thus potential eruptive behaviour. Distinguishing deep vs. shallow crustal contamination processes at Krakatau, and elsewhere, is therefore crucial to understand and assess pre-eruptive magmatic conditions and their associated hazard potential. Here we report on a multi-disciplinary approach to unravel the crustal plumbing system of the persistently-active and dominantly explosive Anak Krakatau volcano [2, 3], employing rock-, mineral- and gas-isotope geochemistry and link these results with seismic tomography [4]. We show that pyroxene crystals formed at mid- and lower-crustal levels (9-11 km) and carry almost mantle-like isotope signatures (O, Sr, Nd, He), while feldspar crystals formed dominantly at shallow levels (< 5km) and display unequivocal isotopic evidence for late stage contamination (O, Sr, Nd). This obeservation places a significant element of magma-crust interaction into the uppermost, sediment-rich crust beneath the volcano. Magma storage in the uppermost crust can thus offer a possible explanation for the compositional modifications of primitive Krakatau magmas, and likely provides extra impetus to increased explosivity at Anak Krakatau.

Mixing and progressive melting of deep and shallow mantle sources in the NE Atlantic and Arctic

RG TRØNNES[1], V DEBAILLE[2], M ERAMBERT[3], FM STUART[4] AND T WAIGHT[5]

[1] CEED and NHM, Univ. Oslo, r.g.tronnes@nhm.uio.no
[2] Univ. Libre de Bruxelles
[3] Dept. Geosciences, Univ. Oslo
[4] Isotope Geosciences Unit, SUERC, East Kilbride
[5] Inst. Geography Geology, Univ. Copenhagen

NE Atlantic and Arctic MORB and primitive off-rift basalts in Iceland, Jan Mayen and Spitsbergen (late Quaternary alkaline basalts) record variable geochemical interaction between the asthenospheric mantle (AM), material supplied by the Iceland plume and subcontinental lithospheric mantle (SCLM). The SCLM-component was mixed with the local asthenosphere during and shortly after the continental rifting and ocean basin opening. Using combined Sr-Nd-Pb-Os-He-isotope systematics, the Iceland plume can be modelled as a mixture of 70% refractory/primordial lower mantle (LM) and 30% recycled oceanic crust (ROC). Low-degree melts are preferentially from the enriched ROC and SCLM components, before progressive melting gradually consumes more of the the LM and AM components.

The modelled ROC/SCLM-ratio decreases markedly from a maximum of about 2.3 at the Reykjanes Ridge, Reykjanes Peninsula and the Southern Volcanic Flank Zone in Iceland, via 1.2 at the Snæfellsnes peninsula, Western Rift Zone and Mid-Icelandic Belt and 0.7 at Jan Mayen and the Kolbeinsey, Mohns and Knipovich Ridges to less than 0.2 in Spitsbergen and along the Gakkel Ridge. These ratios might be slightly overestimated due to a general background level of ROC (HIMU-component) in an otherwise depleted asthenosphere.

The minor element composition of olivine phenocrysts in primitive off-rift basalts in Iceland and Jan Mayen, sampling preferentially the enriched source components, indicates that the SCLM-lithologies are dominantly peridotitic, in contrast to the ROC-lithologies, recording a higher proportion of eclogites and hybridized pyroxenites. The combined Hf-Nd-isotope systematics also discriminate between these two enriched source components.

The high proportion of the SCLM-component in the asthenosphere along the Kolbeinsey, Mohns, Knipovich and Gakkel Ridges reflects the young, narrow and slow-spreading character of the corresponding oceanic basins. These ridges appear to sample mantle sources with higher proportions of locally derived SCLM-material than other mid-ocean ridges.

Ash-Slag Wastes: the Problem of Recycling

E. TROPNIKOV[1]* AND O. KOTOVA[1]

[1]Institute of Geology Komi SC UB RAS, Syktyvkar (*correspondence: tropnikov.83@mail.ru)

Technogenic materials form separate and the global problem of modern society.They are a special type of raw material from the one hand and an environmental problem from the another. Most urgent part is the recycling of ash and slag.

Coal of Pechora coal-basin (Russia) is characterised with a relatively high ash content. Pechora coal-basin is represented by almost all types of coal, including coke and anthracite at initial stage. Coals are widely used as a fuel, particularly within the bounadaries of the coal-basin (Vorkuta, Inta, etc.). Recycling of solid waste from the combustion of fuel is limited to use as a fertilizer rich in trace elements, as well as export them to the so-called ash field, where the above-mentioned products of combustion are stored for later use.

Ash and slag wastes from thermal power plant (Vorkuta coal deposit) were studied.

The composition of the waste was studied and granular iron ore phase was separated. A hierarchy of its globular structure was made. Iron ore pellets are considered as storage of metals. They can be used after the development of appropriate technologies of extraction and enrichment of [1].

The project was done under the financial support of projects 12-5-6-016-ARKTIKA.

Ce-Monazite and Y-xenotime solubilities in H_2O-NaF at 800°C, 1 GPa: implicatons for REE transport

P. TROPPER[1], D.E. HARLOV[2] J AND C.E. MANNING[3]

[1]Institute of Mineralogy and Petrography, University of Innsbruck, A-6020 Innsbruck, Austria, (peter.tropper@uibk.ac.at)

[2]Helmholtz Zentrum Potsdam, Deutsches GeoForschungs-Zentrum, Telegrafenberg, D-14473 Potsdam, Germany

[3]Department of Earth & Space Sciences, University of California, Los Angeles, CA, 90095-1567, USA

Monazite and xenotime host significant rare earth elements (REE) and are useful for geochronology and geothermometry. There distribution may be impacted by F-bearing fluids, which enhance solubilities of REE and Y in high-grade metamorphism [1]. To assess this we determined the solubility of synthetic $CePO_4$ and YPO_4 in H_2O-NaF fluids at 800°C and 1 GPa. We used hydrothermal piston-cylinder and weight-loss methods. Compared to the low solubilities of $CePO_4$ and YPO_4 in pure H_2O (0.04±0.04 and 0.25±0.04 millimolal, respectively [2]), our results indicate an enormous increase in the solubility of both phosphates with increasing NaF concentration in H_2O: $CePO_4$ solubility reaches 0.97 molal in 20 mol.% NaF, and YPO_4 shows an even stronger solubility enhancement to 0.45 molal in only 10 mol.% NaF. The greatest relative solubility increases occur at the lowest NaF concentration. The solubilities of $CePO_4$ and YPO_4 show similar quadratic dependence on NaF, consistent with possible dissolution reactions of: $CePO_4 + 2NaF = CeF_2^+ + Na_2PO_4^-$ and $YPO_4 + 2NaF = YF_2^+ + Na_2PO_4^-$. Solubilities of both REE phosphates are significantly greater in NaF than in NaCl at equivalent salt concentration [2]. A fluid with 10 mol.% NaCl and multiply saturated with fluorite [3], $CePO_4$, and YPO_4 would contain 1.7 millimolal Ce and 3.3 millimolal Y, values that are respectively 2.1-2.4 times greater than in NaCl-H_2O alone. The results indicate that Y, and by extension heavy rare earth elements (HREE), can be fractionated from LREE in fluorine- bearing saline brines which may accompany granulite-facies metamorphism. The new data support previous indications that REE/Y mobility at these conditions is enhanced by complexing with F in fluids phase associated with metamorphism and subduction [4].

Boron isotope systematics of calcitic gorgonian corals and their response to ocean acidification

J.A. TROTTER[1]*, R. THRESHER[2], P. MONTAGNA[3], M. TAVIANI[3] AND M.T. MCCULLOCH[1,4]

[4] ARC Centre of Excellence in Coral Reef Studies, UWA.

Cold-water corals are thought to be especially susceptible to CO_2-driven climate change and ocean acidification given that many live near the aragonite saturation horizon in the deep oceans. Recently, however, boron isotope analysis of aragonitic (scleractinian) cold-water corals revealed their capacity to modulate internal pH and aragonite saturation state at the site of calcification, which enables these species to maintain higher rates of calcification and potentially escape the effects of ocean acidification [1].

Here we investigate the boron isotopic systematics of a suite of calcitic gorgonian corals from a wide range of environments to determine their potential to modulate the pH of the calcifying fluid, their sensitivity to future climate change scenarios, and their utility as archives of seawater pH. These calcitic corals are lower in boron concentration as well as isotopic composition ($\delta^{11}B$) than aragonitic cold-water corals, with $\delta^{11}B$ values lying along or near the seawater borate equilibrium curve. This shows that, unlike aragonitic corals, these calcitic species have limited if any ability to modify the calcifying fluid and thereby precipitate their calcitic skeletons close to ambient seawater pH. serve as an archive of continuous seawater pH over centennial to millennial timescales, is especially important given the lack of continuous long-term records and the need to understand the natural variability of seawater pH on longer timescales.

Impact of As(V) on abiotic reduction of U(VI) by mackinawite

LYNDSAY D. TROYER[1], JAMES J. STONE[2] AND THOMAS BORCH[1,3]*

[1] Department of Chemistry, Colorado State University, Fort Collins, CO, USA 80523-1170
[2] Department of Civil and Environmental Engineering, South Dakota School of Mines and Technology, Rapid City, SD, USA 57701
[3] Department of Soil and Crop Sciences, Colorado State University, Fort Collins, CO, USA 80523-1170 (*correspondence: borch@colostate.edu)

Arsenic and uranium are commonly found together in areas of historic uranium mining activity because they can be released during the mining of uranium ore. Studying the behavior of these elements together under anoxic conditions is necessary to understand their mobility in natural sediments. Recent studies have shown that mackinawite produced through activity of sulfate reducing bacteria is one of the major reductants of U(VI) in subsurface environments [1]. Although reduction of uranyl species by mackinawite has been shown to occur, the reduction of U(VI)-carbonates or U(VI)-arsenates has not been investigated. U(VI) and As(V) can form uranyl arsenate mineral precipitates or surface precipitates depending on their relative concentrations [2]. This study examines the reducibility of U(VI)-carbonates and U(VI)-arsenates under varying U/carbonate and U/As ratios in the presence of mackinawite.

Anoxic batch experiments were conducted including mackinawite with U(VI) and As(V) at concentrations ranging between 50 to 500 μM, including treatments with 5 mM and 30 mM dissolved carbonate. After 48 hours, mackinawite was collected for analysis by X-ray absorption fine structure (XAFS) spectrosopy to determine speciation and binding environment of U and As. Results showed that the extent of U(VI) reduction was not affected by the formation of U(VI)-carbonato complexes. U(VI) reduction was only shown to be limited by As(V) at concentrations at or above 500 μM, where the formation of uranyl arsenate mineral precipitates is favored. Although little influence of U(VI)-carbonate and U(VI)-arsenate species was observed on U(VI) reduction, As(V) reduction was limited in the presence of all tested U(VI) concentrations due to preferential reduction of U(VI). When remediating natural environments containing both As and U, As(V) does not prevent U(VI) reduction by mackinawite under environmentally relevant concentrations.

Geochemistry and petrogenesis of a nested granite intrusion – the Sedmihoří composite Stock (Bohemian Massif)

J. TRUBAČ[1]*,[2] V. JANOUŠEK[1,2] J. ŽÁK[2] AND A. GERDES[3]

[1] Czech Geological Survey, Klárov 3, 118 21 Prague 1, Czech Republic (*correspondence: jakub.trubac@geology.cz)
[2] Charles University in Prague, Albertov 6, 128 43 Prague 2, Czech Republic
[3] Institut für Geowissenschaften, Altenhöferallee 1, D-60438 Frankfurt am Main, Germany

Better understanding of how zoned plutons are constructed and for how long the upper crustal magma chambers remain active is crucial to constrain a range of lithospheric processes, including igneous petrogenesis, ore formation, crustal rheology/deformation and volcanism.

The shallow-level Sedmihoří Stock in the southwestern Teplá–Barrandian Unit, Bohemian Massif, provides an excellent case example of a zoned post-tectonic granitic intrusion. It is roughly circular in plan-view and formed by nested intrusions of three magma pulses within a single conduit: (i) less evolved outer porphyritic Bt monzogranite (326.2 ± 1.2 Ma (2σ), LA ICP-MS Zrn), (ii) more fractionated inner Bt–Mu monzogranite (326.6 ± 1.2 Ma), and (iii) innermost minor Mu leucogranite with Tur. All the varieties are siliceous (SiO_2 > 71 wt. %) and moderately peraluminous. While major-element contents do not vary greatly, trace elements display significant differences between the pulses (e.g., La_N/Sm_N = 4.24–4.45 outer; 3.38–3.44 inner; 2.95–4.43 innermost). Still, each of them preserves its remarkable homogeneity.

Field observations, fabric patterns and geochemistry suggest that each pulse represents a single batch of magma with its own geochemical characteristics and potentially also petrogenesis. This rules out a shallow-level fractionation or contamination by the country-rock metasediments, and points to processes deeper in crust or differences in source materials.

The trace-element compositions with evolved crust-like Sr–Nd isotopic signatures show that the granite pulses were derived by anatexis of immature metasediments (Neoproterozoic metasediments of the Teplá–Barrandian Unit; shown by the presence of inherited components in Zrn 2 and 0.6 Ga old). The higher proportion of pelite within the source of the inner Bt–Mu monzogranite is shown by higher Rb/Sr ratios (9–15) as well as more evolved Sr ($^{87}Sr/^{86}Sr_{326}$ = 0.7098–0.7154) and less radiogenic Nd (ε^{Nd}_{326} = -3.7) than in the outer facies ($^{87}Sr/^{86}Sr_{326}$ = 0.7067–0.7076; ε^{Nd}_{326} = -2.5 to -2.7). Research funding: Czech Science Foundation (GAČR) P210/11/1168.

Using laser-based technology to quantify carbon-13 ratios and fugitive emission CH_4 flux rates quickly and easily

T. TSAI, C. RELLA, AND E. R. CROSSON[1]

[1]3105 Patrick Henry Dr. Santa Clara, CA 95054 USA

The United States is home to what is estimated to be the largest known shale gas reserves in the world. Often referred to as the "bridge fuel" that will aid in the country's energy transition from coal to renewable sources like wind and solar, natural gas production is growing at the fastest pace in U.S. history. This expansion involves the introduction of hundreds of thousands of new natural gas wells and processing facilities all across the U.S. Of primary concern is the potentially damaging impact of natural gas drilling on human health due to increase pollution exposure.

Picarro has developed a new instrument (plume scanner) which uses laser-based technology to measure natural gas fugitive emission flux rates from natural gas facilities quickly and easily. As the plume scanner vehicle drives through the plume at the speed of traffic, the air is sampled at 4 different heights along the axis of the vehicle. These gas samples are continuously stored in the vehicle along with wind and vehicle velocity information. When a plume is detected, the stored gas samples are redirected into the inlet of a cavity ringdown spectrometer where concentration and or carbon-13 CH_4 ratio measurements are recorded, synchronized, and/or processed to produce an intensity map or a so-called "scanned" plume image. In this way, fugitive emission flux rates and isotopic measurements of highly localized sources such as natural gas facilities can be made quickly and easily providing greater transparency to stakeholders.

Rare earth element behavior in subduction-zone fluids: the effect of T and ligands

ALEXANDRA TSAY[1], ZOLTAN ZAJACZ[1] AND CARMEN SANCHEZ-VALLE[1]

[1]IGP, ETH Zürich, Switzerland (*correspondence: alexandra.tsay@erdw.ethz.ch)

Understanding of rare earth element (*REE*) systematics has a broad application for subduction-zone processes. Particularly, arc-related magmas display a typical trace element abundance spectrum, characterised by the enrichment in light rare-earth element (*LREE: La, Ce, Nd*) and depletion in the heaviest rare earth element (*HREE: Yb, Lu*) relative to *MORB*. This particular geochimical signature may result from the influx of aqueous fluids and/or silicate melts derived from within the slab. Therefore, investigating the behavior of *REE* in fluids at high *P* and *T* conditions is crucial for constraining the composition of slab fluids, as well as for understanding subduction-zone processes in general.

In this study we present new experimental data on *REE* silicate ($REE_2Si_2O_7$) solubility in aqueous quartz-saturated fluids, containing various ligands (F^-, CO_3^{2-}, SO_4^{2-}, Cl^-), and in hydrous haplogranitic melt at conditions relevant for subducting slab (600-800 *°C*, 2.6 *GPa*). The experiments were conducted in an end-loaded piston-cylinder apparatus and the fluids were *in situ* sampled at *P-T* in the form of primary fluid inclusions in quartz. Gold capsules were loaded with a chip of synthetic $(La,Nd,Gd,Dy,Er,Yb)_2Si_2O_7$ – phase, various aqueous solutions (~ 20 *wt.%*) and a piece of natural quartz. In the case of experiments with melt, the capsule was loaded with a piece of $REE_2Si_2O_7$, a synthetic haplogranitic glass and water (~ 15 *wt.%*). Rb and Cs were added to the solutions as internal standards for LA-ICPMS analyses.

The solubility of *REE* in quartz-saturated H_2O, free of additional ligands, increases more than an order of magnitude as temperature is increased from 600 to 800 ºC. Addition of ligands, even in relatively small amounts (0.3-1.5 *m*), promotes *REE* solubility compared to pure H_2O. Each type of ligands leaves a characteristic *REE* pattern, reflecting the preferences of *REE* complexation: *e.g.*, efficient *LREE-Cl* and *HREE-F*, *HREE-*CO_3 complexation. The solubility of *REE* in the melt is moderate, comparable with the solubilities in pure H_2O.

Our results showed that *REE* can be effectively transported by aqueous fluid and the effect of temperature as well as fluid chemistry play an important role in REE mobility and *LREE/HREE* fractionation.

3D shapes of regolith particles: comparison between Itokawa and Moon

[4]AIST/GSJ, Tsukuba, Japan
[5]JARSI/SPring-8, Sayo, Japan
[6]JAXA/ISAS, Sagamihara, Japan

Hayabusa sample analysis elucidated a variety of surface processes on asteroid Itokawa: (1) regolith formation by impact [2], (2) solar wind implantation to uppermost regolith surface [3], (3) space weathering rim formation mainly by solar wind He implantation (~10^3 yr) [4,5], (4) grain abrasion probably by grain motion due to impact-induced seismic waves in a regolith layer (>10^3 yr) [1,2,6], and (5) final escape of particles from the asteroid by impact (<8 Myr) [3].

The grain abrasion was found based on the 3D shapes and surface morphologies of Itokawa samples using x-ray micro-tomography [2] and FE-SEM observation [6]. The 3D shapes of lunar regolith samples were also examine by tomography [7] but not grain-by-grain as performed for the Itokawa samples. In the present study, the 3D shapes of Apollo 16 highland (60501) and Apollo 11 mare (10084) regolith samples were examined by the same method as the Itokawa particles using micro-tomography at SPring-8.

The shape distribution shows that the lunar regolith is more spherical than the impact fragments although lunar regolith is the product of impact on the lunar surface, suggesting that the regolith was abraded. The cause may be grain motion during gardening by impacts. The degree of abrasion is larger than that of the Itokawa particles due to larger scale of impacts and longer regolith residence time.

Influence of aerosols on cloud characteristics over Europe: Study with the meteorology-chemistry-radiation eulerian model.

PAOLO TUCCELLA[1], GABRIELE CURCI[1] AND GUIDO VISCONTI[1]

[1]CETEMPS Centre of Excellence, Dept. Physical and Chemical Sciences, Univ. L'Aquila, L'Aquila, Italy.([1]paolo.tuccella@aquila.infn.it)

Several studies demonstrated that aerosol particles play a crucial role in the climatic system, scattering the incoming radiation (direct effect) and altering cloud properties (indirect effect). Excellent efforts has been done by scientific community to represent the indirect effect in the atmospheric model, but the radiative forcing associated to indirect effect is still very uncertain.

In this study we tried to address the question: how well do the models reproduce the amplitude of aerosol indirect effects? In order to answer to the question, we used WRF/Chem model. A new parameterization for secondary organic aerosol (SOA) yield based on the volatile basis set implemented in WRF/Chem recently, has been coupled with the microphysics of clouds. The effects of this new mechanism is evaluated through the comparison of high resolution simulations on a cloud resolving domain (2 Km of resolution) against the groud-based and aircraft measurements of aerosol chemical composition and particles, and cloud microphysics, issued in the frame of European Integrated project on the Aerosol Cloud Climate and Air Quality Interaction (EUCAARI). The comparison of model results among observations suggest that discrepancies in simulation of chemical fields should be due to errors in simulated meteorological field and uncertainties in horizontal and vertical interpolation of anthropogenic emissions, in their total amount and hourly variations.

The amplitude of indirect has been calculated as $IE=\partial \ln re / \partial \ln N$, where re is the cloud droplet effective radius and N aerosol particle number of each mode of log-normal distribution. Observations attribute the indirect effect to total aerosol particle number with a value of -0.22, very to theoretical value of -0.23. Instead, WRF/Chem reproduces the observed amplitude of IE, but attributes it to the particles of accumulation, while the observations indicate a strong IE due to total particle number.

The reasons of this results are under investigation.

Formation of monazite-(MREE) from paleozoic shales: Role of host rock chemical composition and organic material

JOHANN TUDURI[1], MATTHIEU CHEVILLARD[1], SÉBASTIEN COLIN[1], ERIC GLOAGUEN[1], JÉROME GOUIN[1], SÉBASTIEN POTEL[2] AND OLIVIER POURRET[2]*

[1]BRGM, Orléans, France(j.tuduri@brgm.fr)
[2]LaSalle Beauvais, France
(olivier.pourret@lasalle-beauvais.fr)(* presenting author)

Rare earth element (REE) distributions of stream water, normalized to upper continental crust (UCC), showed, from the source to the catchment outlet, fractionation patterns from heavy REE enriched to more flat and middle REE (MREE) enrichement, together with a progressive disappearance of a negative Ce anomaly. As a consequence, Pourret *et al*. [1] suggest that the continental shelf could be considered as a potential REE trap and thus that shelf sedimentary rocks, similar to metalliferous deep sea sediments, represent a REE potential resource and guide for their exploration. The reassessment of the REE potential of France, led us to discuss the behavior of REEs, from the continental shelf to the basin plain, using authigenic monazite occurences within ordovician shales and black shales from Britanny (France). Monazite grains (up to 2 mm in diameter) are mostly characterized by their grey color, host-rock mineral inclusions, REE_{UCC} distribution patterns enriched in MREE, low Th and U contents, lack of inherited cores, that strongly suggest authigenic crystallization during diagenesis to low grade metamorphism conditions. Chemical composition highlights zoned crystals with MREE enriched cores (up to: 10 wt% Sm_2O_3; 1.3 wt% Eu_2O_3 and 5 wt% Gd_2O_3) and light REE (LREE) enriched rims. Thus grain cores are characterized by negative and low values of $\log[(La/Sm)_{UCC}]$ and high values of Eu whereas rims have slightly negative to positive values of $\log[(La/Sm)_{UCC}]$ with low Eu concentrations. Grey monazite REE_{UCC} patterns also reflect the abundance of these elements in shales and black shales. Indeed, at near neutral to alkaline pH, monazite evidenced MREE enriched patterns directly linked to organic matter (OM) content, whereas at alkaline pH, REE speciation is mainly driven by carbonate complexation, resulting in the formation of the LREE enriched monazite. This latter hypothesis will be further tested and reinforced by analysing OM fractions of shales and black shales. Eventually, such monazites were later concentrated within placers @ 2 kg/t.

Nitrogen isotope biogeochemistry of the South Atlantic

ROBYN E TUERENA[1]*, RAJA S GANESHRAM[1], ANTHONY FALLICK[2], JULIE DOUGANS[2], ANDREW TAIT[2] AND E MALCOLM S WOODWARD[3]

[1]University of Edinburgh, School of Geosciences, UK, (r.e.tuerena@staffmail.ed.ac.uk) (* presenting author)
[2]Scottish Universities Environmental Research Centre, UK
[3]Plymouth Marine Laboratory, Plymouth, UK

The South Atlantic at 40°S is a highly productive region of the open ocean marking the transition between the Sub Antarctic Zone (SAZ) and the South Atlantic gyre. We present a high resolution depth transect of $\delta^{15}N_{NO3}$ from the sub-tropical front to elucidate the contrasting nutrient regimes in water masses of subtropical (Agulhas Current, South Atlantic Central Water (SACW)) and Antarctic origin (Antarctic Intermediate Water (AAIW) and Sub Antarctic Mode Water (SAMW)). The preferential uptake of ^{14}N by biota leaves NO_3 enriched in ^{15}N as it is utilised; therefore, $NO_3/\delta^{15}N$ relationships in combination with nutrient stoichiometry can describe the history of water mass formation at the surface and transformation during transit [1].

The SAMW supplies high nutrient waters to the low latitude Atlantic, fuelling primary productivity [2]. A greater variation in SAMW NO_3 and $\delta^{15}N_{NO3}$ values compared to previous studies [3,4], may result from incorporation of the underlying AAIW and overlying surface waters during transport. At the surface, we estimate isotope fractionation during NO_3 utilization of ε ~9 ‰, which is consistent with previous SAZ estimates [3]. However, this fractionation effect is diluted in most profiles by the influence of the nutrient poor SACW.

Tropical surface waters are identified between 50-53°W, with $\delta^{15}N_{NO3}$ values in the range of 4-6‰. These depleted $\delta^{15}N_{NO3}$ signatures suggest the influence of N-fixation in this water mass. Similarly, the Agulhas leakage into the South Atlantic is characterised by low $\delta^{15}N_{NO3}$ signatures because it is sourced from the combination of tropical and Southern Ocean water masses of the Indian Ocean. These datasets will be modelled in an attempt to quantify the extent of N fixation, NO_3 utilization and water mass mixing that has occurred in these water masses, to address their role in nutrient transport and productivity within the ocean.

Volcanism on Mars controlled by early oxidation of the upper mantle

J. TUFF, J. WADE AND B.J. WOOD[123]

[123]University of Oxford, U.K.,(james.tuff@earth.ox.ac.uk); (jon.wade@earth.ox.ac.uk);(berniew@earth.ox.ac.uk)

We investigated the genetic relationships between Martian meteorites and the surface rocks of the Gusev Crater analysed by MER Spirit. The SNC meteorites, with crystallisation ages mostly in the range 1.4Ga-180 Ma are likely derived from young volcanic regions such as Tharsis Plateau. They are enriched in volatiles and depleted in Ni and other chalcophile elements relative to terrestrial igneous rocks of similar composition[1]. Surface rocks from the Gusev crater are much older (~ 3.7 Ga) and are substantially richer in Ni and S with lower Mn/Fe ratios than the meteorites[2]. These observations lead to doubts that surface rocks and SNC meteorites have similar mantle source regions.

We started with the Dreibus and Wänke (DW) estimate of Martian mantle composition and experimentally-produced partial melts of this mantle at 1.5 GPa ([1,3]). Martian mantle Ni and S contents (up to 3000 ppm) were varied and the Ni and S contents of the melts calculated assuming sulphide saturation at low f_{O2} (FMQ- 2 log units). The melts were allowed to fractionally crystallise the liquidus mantle phases (olivine, orthopyroxene, clinopyroxene spinel and sulphide), using the crystallisation program 'Petrolog'[4]. This yielded the correct SNC trends of Ni-Mg and Mn-Fe for melts and cumulates with mantle Ni content of 1800 ppm. We repeated the procedure at high f_{O2} (FMQ+3 log units), conditions where sulphide is unstable. Partial melts are much richer in Ni and S and reproduce the Ni-Mg trend of the Gusev crater rocks. Furthermore, magnetite, found in the recently described "Gusev-like" meteorite NWA7034[5] becomes the liquidus phase and extracts Mn from the differentiates, consistent with observations of surface rocks. Our results demonstrate that the surface basaltic rocks of the Gusev crater and the igneous SNC meteorites are consistent with partial melting and fractional crystallisation from the same DW-like source but under different fO_2 conditions. The implications are that Mars' surface oxidised early in its history and that oxidised material was recycled into the upper mantle.

[4] Department of Earth, Atmospheric & Planetary Sciences, MIT, E25-633, 45 Carleton Street Cambridge, MA 02139 USA

One of the biggest mass extinctions in Earth's history took place in the Late Devonian. The most well know event occurred at the Frasnian – Famennian boundary, but there were also major biodiversity crises towards the end of the Givetian and Famennian time periods.

Here we present a novel biomarker approach using methyltrimethyltridecylchromans (MTTCs) as indicators of freshwater incursions and terrigenous input to a Late Givetian/Early Frasnian marine palaeoenvironment [1]. The abundance of gammacerane and *Chlorobi* biomarkers furthermore indicated persistent water-column stratification and prevailing photic zone euxinia. MTTCs are isoprenoid substituted aromatic compounds which are established palaeosalinity indicators [2]. Nevertheless, their source and formation pathway remain unknown. Our data would be consistent with an origin from early diagenetic condensation reactions of phytol with alkyl phenols (from higher plant sources) as it has been suggested previously by Li *et al*. [3].

Uranium in groundwaters commonly shows a trend of decreasing concentration with depth due to the chemical reactivity of recharging waters, rich in O_2 and CO_2, which promotes U mobility by oxidising U(IV) to U(VI) and by carbonate complexation. Towards depth, the redox potential drops, U is increasingly reduced to the more insoluble U(IV) form, and U concentrations decrease. However, carbonate complexation may enable dissolved U(VI) to exist to greater depths in even mildly reducing conditions. Such is demonstrated in the crystalline bedrock aquifer of the Forsmark area, where elevated U concentrations (10 to 170 μg/L) are found in several borehole sections at depths down to 600 metres. These concentrations are generally associated with Brackish-type groundwaters which are not oxidising but show Eh > –190 mV and bicarbonate contents >30 mg/L. It can, however, be concluded that this water has not transported U into the bedrock aquifer, but rather has mobilised an easily dissolvable uranium phase present along some of the water conducting fractures. The $^{234}U/^{238}U$ activity ratios (AR) in the groundwaters are within the range 2 to 6 and the samples with the highest U contents tend to show the lowest $^{234}U/^{238}U$ AR ($\leq$ 3). Annual sampling (from 2005 to 2012) in some borehole sections with elevated U, has shown the $^{234}U/^{238}U$ AR to be very stable and unique for each specific fracture groundwater and most probably also for the dissolved phase. Because the suspected source is hosted in the fracture fillings, the water/fracture mineral interaction is also studied using U-series measurements on the mineral phase. The results support a complex pattern of leaching and redeposition of U in many of the studied fractures during the last 1.5 Ma, whereas others show only small or insignificant deviations from equilibrium. Together these results support the very inhomogeneous distribution of flow paths typical for crystalline bedrock and previously interpreted in the Forsmark area.

An understanding of the geologically late (<1.5 Ma) behaviour of U in the groundwater can help to interpret the groundwater circulation and find the most important water pathways during this period. The changes in groundwater composition and redox conditions have caused both mobilisation and deposition of U, and it is possible to trace both processes in one and the same fracture sample.

Volatiles released in subduction zones and their role in sustaining magmatism

SIMONE TUMIATI[1]*

[1]Dipartimento di Scienze della Terra, Università di Milano, 20133 Milan, Italy
(*correspondence: simone.tumiati@unimi.it)

It is widely accepted that the generation of arc magmas is triggered by fluids released from the subducting slab and by their interaction with the overlying mantle wedge [1]. The major lithologies involved in devolatilization are pelites, hydrothermally altered basalts, and serpentinized harzburgites. Thermodynamic calculations and experiments predict that HP fluids are dominated by H_2O. Nevertheless, the importance of carbon species has been highlighted in the last years because of the relevant CO_2 content of arc magmas and the observation of carbon-bearing phases in mantle-wedge peridotites. Experiments have shown that the release of volatiles extends over several tens of km depths and result from a succession of continuous and discontinuous reactions involving hydrous phases in the subducted lithosphere, such as antigorite and chlorite in ultramafics; amphibole, lawsonite, zoisite, and chloritoid in mafic rocks. Phengite and biotite are involved in melting reactions of a variety of bulk compositions whenever K is available. Carbonates once formed are refractory and stable at very high pressures. Therefore, the transport of carbon in the mantle wedge, via solute species in aqueous fluids or via advecting rock masses in buoyant "cold plumes" have been proposed. In the metasomatized mantle wedge, the stability of hydrous phases depends on bulk alkali content, amount of available fluid and possibly the redox state of the system. In COH-bearing systems, the framework of phase relationships is more complex and the position of the solidus is controlled by a number of factors. In fluid-undersaturated COH-systems, the bulk composition (i.e., X_{Ca}, X_{Mg}, alkalies) and the redox state of the Fe-bearing phases are variables that strongly influence the solidus position. Peridotites saturated in a COH-fluid melt at lower temperatures compared to H_2O-free, CO_2-bearing peridotites. However, the increase of bulk CO_2 shifts the solidus, so that fluid-saturated COH peridotite can eventually melt at higher temperatures compared to fluid-undersaturated COH peridotites. Apparent discrepancies concerning solidus position reflect the variety of experimental strategies adopted, which can be applied to a wide range of geodynamic settings.

The formation of elemental sulfur nodules; A modified 'thiosulfate shunt' in unique environments

ALEXANDRA V. TURCHYN[1]*, TOM BISHOP[1] AND ORIT SIVAN[2]

[1]Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK, (avt25@cam.ac.uk) (*presenting author)
[2]Department of Geological and Environmental Sciences, Ben Gurion University, Beer Sheva, Israel

Elemental sulfur, also known as 'native sulfur', has been found in a range of natural environments, including marine and lake sediments, often forming large nodules or veins, millimeter to centimeter in size. What governs the formation of elemental sulphur nodules remains enigmatic. While most of the literature suggests it is formed by partial re-oxidation of hydrogen sulphide, elemental sulfur can also form during incomplete bacterial sulfate reduction, during sulfur disproportionation, or even during gypsum metamorphism.

We present sulfur isotope ($\delta^{34}S$) and major element data from sulfur nodules and surrounding gypsum, from the Lake Lisan formation near the Dead Sea, Israel. The $\delta^{34}S$ in the nodule is constant between -9 and -11‰, 27 to 29‰ lighter than the surrounding gypsum, consistent with their formation in an 'open system'. Iron concentrations in the gypsum increase toward the nodule, while manganese concentrations decrease, suggesting a redox boundary at the nodule-gypsum interface during aqueous phase diagenesis. We suggest that sulfur nodules in the Lake Lisan formation are generated through bacterial sulfate reduction, which terminates at elemental sulfur. Sulfate-saturated pore fluids, coupled with the low electron-donor availability, terminate the trithionate pathway before the terminal two-electron reduction, producing thionites, which disproportionate via a modified thiosulfate shunt to form abundant elemental sulfur.

BTX sorption by surfactant-modified synthetic zeolite

P. TUREK1, B. SZALA1*, J. CZERWIŃSKI2, T. BAJDA1 AND J. MATUSIK1

[1]Department of Geology, Geophysics and Environmental Protection, AGH University of Science and Technology, Krakow, Poland (*bszala@geol.agh.edu.pl)

[2]Environmental Engineering Faculty, Lublin University of Technology, Lublin, Poland

Zeolites are group of aluminosilicate minerals that are distinguishable by their high porosity, high cation exchange capacity and regular cage-like structure. They possess a negative charge that is an effect of heterovalent substitutions of Si^{4+} by Al^{3+} in the thetraedra which are the primary building units of the mineral's framework. Synthetic zeolite was created from fly ash after coal combustion in hydrothermal conditions. Modification of zeolite was conducted with the use of one of the quaternary ammonium salts: hexadecyltrimethylammoniumbromide(HDTMA-Br).
Suspension of synthetic zeolite was mixed with HDTMA solution in high temperature for 24 hours. Surfactant was adsorbed onto a synthetic zeolite in amounts of 1.0 and 2.0 of the external cation exchange capacity (ECEC) in quantities of 24.4 and 48.8 mmol per 100 g of zeolite respectively. Third sample that was used was pure zeolite.

The purpose of this research was to evaluate the difference in sorption of BTX (benzene, toluene, xylenes) on the unmodified zeolite and organo-zeolite modified by HDTMA.

Modification in amount of 2.0 ECEC shows higher sorption of BTX then organo-zeolie 1.0 ECEC. Further still, was the unmodified zeolite. This is caused due to high affinity of apolar BTX to the hydrophobic zone of HDTMA chains. The range of BTX concentrations used in this study was limited by their solubility in water.

Additional objective was to investigate whether FTIR could be used in qualitative and quantitative determination of BTX adsorbed by the zeolite. Our study has provided information on presence of particular spectra that correspond to certain organic compound.

We gratefully acknowledge the support of NCBiR having provided grant PBS1/A2/7/2012.

Three-dimensional distribution of anatectic melt inclusions in garnets by X-ray micro-tomography

TURINA ALICE[1], PARISATTO MATTEO [1], CESARE BERNARDO[1] AND PERUZZO LUCA[2]

[1]Dipartimento di Geoscienze, Università di Padova, via Gradenigo 6, 35137 Padova, Italy

[2]CNR-Istituto di Geoscienze e Georisorse, Padova, via Gradenigo 6, 35137 Padova, Italy

(alice.turina@studenti.unipd.it;) (matteo.parisatto@unipd.it) (bernardo.cesare@unipd.it) (luca.peruzzo@igg.cnr.it)

X-ray micro-tomography (μCT) has been applied to investigate the three-dimensional distribution of primary melt inclusions in garnets from El Hoyazo (Neogene Volcanic Province, Spain). Modeling the distribution density allows a better understanding of the growth and trapping history of peritectic minerals and coexisting fluids and melts during the partial melting of the crust. Glassy inclusions are trapped in nearly all mineral phases in metapelitic enclaves found within El Hoyazo dacites and they have been extensively analyzed. To better investigate their three-dimensional distribution and to understand the relationship between them, other mineral inclusions and the host phase, two garnets have been imaged through μCT. One of the two was then cut to expose a nearly-equatorial plane to SEM analyses. A preliminary classification based on different absorption coefficients was applied to different inclusions in the tomographic images and then verified by SEM chemical maps. We measured the volume and position with respect to garnet barycenter of glassy melt inclusions and of single-phase inclusions such as monazite, zircon and apatite for a comparison. The modeling reveal a clear peak of melt inclusions density at 1/3 radius distance from the garnet center, while mineral phases are more randomly distributed. Moreover, the type and the size of the inclusions are statistically related to their spatial distribution. There is no evidence of a sharp boundary between inclusion-rich cores and inclusion-free rims. This together with the chemical profile of the garnet composition strongly suggests that the garnet grew in one single event in the presence of anatectic melt. After the maximum, the linear decrease in the density of melt inclusions could indicate trapping at a constantly slowing growth rate of the host mineral or a constant decreasing melt supply. The first hypothesis is less convincing, since mineral inclusions are still trapped after the decrease of melt inclusions, and even seem to increase in density.

Recycling of water between the mantle and crust/hydrosphere

MICHAEL TURNER[1] SIMON TURNER[1] TREVOR IRELAND[2] AND JOHN ADAM[1]

[1] Department of Earth and Planetary Sciences, Macquarie University, NSW, Australia
[2] Research School of Earth Sciences, Australian National University, ACT, Australia

Water is added to the mantle via subduction where, due to the break down of hydrous mineral phases, water is released from the subducting slab. Conversely volcanism expels water from the mantle.

To help constrain the water flux of the mantle, we present data from mantle pryoxenes of sub-arc xenoliths and therefore providing estimates of the amount of water recharging the mantle. We have measured the concentration of water within pyroxene phenocrysts from Azores lavas (OIB setting) and the andesitic volcanoes of New Zealand (arc setting).

Preliminary data from pyroxenes of sub-arc metasomatised harzburgite xenoliths reveal varied water concentrations from relatively dry sub-arc mantle regions (Mexico and Kamchatka ~150 ppm) to relatively wet areas (New Ireland and Phillipines >500 ppm). This variation may reflect differences in the petrogenetic history of the xenoliths such as various degrees of metasomatism.

The water content of pyroxenes from Azores lavas vary between 100 and 400 ppm, with the notable exception of relatively hydrous pyroxene cores from Sao Miguel that contain up to 800 ppm.

Preliminary data from pyroxene phenocrysts of Mt Ruapehu and Taranaki (New Zealand) suggest that they also contain a similar variation in water concentrations to that seen within the Azores pyroxenes (between 100 and 450 ppm water). Differences between each andesitic system are also possible with Mt Taranaki (amphibole bearing, back-arc volcanic system) pyroxenes containing relatively low water concentrations (100-250 ppm) compared to the pryoxenes from the volcanic front-arc system of Mt Ruapehu (>300 ppm).

Interestingly pyroxene phenocrysts from OIB and arc magmatism contain a similar range of water contents to pyroxenes from the sub arc mantle.

Extremely young melt infiltration of the continental lithospheric mantle

SIMON TURNER[1]* AND MICHAEL TURNER[1]

[1]Department of Earth and Planetary Sciences, Macquarie University, Sydney 2109, Australia (*simon.turner@mq.edu.au)

It has long been inferred that mantle metasomatism and the incompatible element enrichment of the continents require melts formed by low degree melting of the mantle. Yet establishing the presence of these melts and whether this metasomatism is ongoing and continuous, or spatially and temporally restricted, has proved difficult. Here we report large U-Th-Ra disequilibria in metasomatised, mantle xenoliths from the Newer Volcanics Province in southeastern Australia. The infiltration and passage of carbonatitic ± hydrous silicic melts, combined with crystallization of pargasite can account for the observations. The half-lives of the nuclides indicate that metasomatism was extremely young (≤ 10 kyr) and probably on-going at the time of incorporation in the magmas that transported the xenoliths to the surface. This provides unique evidence for the presence and continuing migration of small melt fractions (~0.02%) in the upper convecting mantle and provides a likely explanation for the seismic low velocity zone. These melts cannot, themselves, be responsible for average continental crust but they could provide an important component for ocean island basalts if returned to the convecting mantle.

Isotopes in vertebrate bioapatite: proxies for climate, pCO_2 and diet

T. TÜTKEN[1]*, P. HELD[2] AND S.J.G. GALER[2]

[1]Steinmann-Institut, Rheinische Friedrich-Wilhelms-Universität Bonn, Poppelsdorfer Schloß, 53115 Bonn, Germany (*correspondence: tuetken@uni-bonn.de)
[2]Max-Planck-Institut für Chemie, Abteilung Biogeochemie, Hahn-Meitner-Weg 1, 55128 Mainz, Germany

Vertebrates integrate bioavailable elements in their skeletal tissues taken up from the environment via air, water and food. Bones and teeth archive isotope signatures of these elements over the timespan of tissue formation and/or remodelling. This enables the reconstruction of diet ($\delta^{13}C$, $\delta^{44/42}Ca$), climate ($\delta^{18}O$), body temperature (Δ_{47}), atmospheric pCO_2 ($\Delta^{17}O$) and habitat ($\delta^{18}O$, $^{87}Sr/^{86}Sr$) from vertebrate fossils. Bioapatite of fossil hard tissues, especially enamel, can preserve original isotope compositions over geological time scales. The isotopes of the two major elements (Ca, $O_{(PO4)}$) in bioapatite are least biased by diagenetic alteration.

$\delta^{18}O_{PO4}$ of terrestrial and aquatic vertebrates is a proxy for meteoric and ambient water $\delta^{18}O$ values, respectively. Enamel $\delta^{18}O_{PO4}$ values of fossil large mammals were used to infer the terrestrial palaeoclimate during the last 35 million years for Central Europe. Reconstructed air temperatures agree well with other climate proxy data. The ^{17}O-anomaly ($\Delta^{17}O$) of air oxygen is a proxy for atmospheric pCO_2. This anomalous $\Delta^{17}O_{air}$ is partially recorded in bioapatite $\Delta^{17}O_{PO4}$ of small mammals (<1kg) with a high metabolic rate and thus O_2 consumption. It is preserved in fossil teeth and $\Delta^{17}O_{PO4}$ can be used as a new proxy for palaeo-pCO_2 reconstructions and to monitor diagenetic alteration of bioapatite $\delta^{18}O_{PO4}$ values.

Calcium isotopes ($\delta^{44/42}Ca$) are a very promising deep time diet proxy for fossil vertebrates with a high preservation potential, even in fossil bones. $\delta^{44/42}Ca$ values enable us to determine the consumption of plant versus animal tissues and decrease systematically with each trophic level along the foodchain. We found a trophic level effect of ~0.4‰ between bones of extant African mammalian herbivores (-0.46±0.14‰) and carnivores (-0.89±0.14‰). Ant/termite-feeding mammals (0.04±0.16‰) have higher $\delta^{44/42}Ca$ values than both herbivores and carnivores. Whether Ca isotopes are indeed a new geochemical proxy for insectivory is currently being investigated. Using Ca isotopes past diets of extinct vertebrates and fossil food webs can be reconstructed to identify apex predators. T-Rex and sympatric herbivorous dinosaurs display a similar trophic level effect as extant mammals. Preliminary $\delta^{44/42}Ca$ data for the Eocene terror bird (*Gastornis*) are more in accordance with a herbivorous diet.

Developing speciation codes and thermodynamic data for non-isothermal and non-isobaric systems: applications to CO_2 sequestration

BENJAMIN M. TUTOLO*[1], ANDREW J. LUHMANN[1], XIANG-ZHAO KONG[1], MARTIN O. SAAR[1], AND WILLIAM E. SEYFRIED, JR.[1]

[1]University of Minnesota Department of Earth Sciences, Minneapolis, MN USA
(*correspondence: tutol001@umn.edu)

Geochemical models typically simulate geochemical processes using thermodynamic data sets of equilibrium constants calculated 0.01-300°C along the steam saturation curve. This approach is sufficient for a broad range of geologic conditions, as long as the data has been calibrated against calorimetric, field, and experimental measurements. However, some commonly utilized data and methods result in unacceptable uncertainties. Notably, longstanding inconsistencies in the aluminum mineral and aqueous species data that are included in many thermodynamic datasets have not been sufficiently resolved. Moreover, simulations of key geologic processes, such as geologic CO_2 sequestration and hydrothermal alteration, are challenging due to the limited T-P range of the data sets.

In this contribution, we correct some of these problems by taking account of recent innovations that enable acquisition of formatted datasets at any T and P within the limits of the thermodynamic equations of state [1]. This is only a short-term measure, however, because modern computers permit development of a new generation of speciation codes that dynamically calculate equilibrium constants at the modeled T-P conditions. These codes will be particularly useful in large-scale, non-isothermal, and non-isobaric reactive transport models. To this end, we develop and use an integrated thermodynamic-speciation code that relies only on standard state thermodynamic properties and equation of state parameters to dynamically calculate mineral-brine-CO_2 interactions. The code incorporates a new, calibrated, internally consistent thermodynamic data set for key aluminum minerals and aqueous species as well as literature data for other minerals and aqueous species. Compared with experiments involving a) thermally-driven dolomite dissolution and precipitation and CO_2 exsolution, and b) arkose alteration under elevated T, P, pCO_2 conditions, the data and integrated speciation code perform well and provide a new opportunity to kinetically evaluate whole-rock dissolution and precipitation reactions.

*correspondence to KatrinaTwing@gmail.com

Serpentinization is a widespread geochemical process involving the alteration of ultramafic rocks in the presence of water, resulting in a high pH (>10), highly reducing environment containing large quantities of dissolved hydrogen and potentially abiogenic organic molecules, which can serve as energy sources for microbes in the subsurface. Habitability models predict that these environments can sustain microbial life, but little work has been done to directly characterize the microbial communities utilizing the energy generated from this process. Furthermore, prior studies of continental serpentinites have sampled surface seeps that represent an interface between end-member fluids and the atmosphere and may not truly represent the extreme conditions encountered deep within the subsurface.

A recent drilling project at the Coast Range Ophiolite Microbial Observatory (CROMO) in northern California has supplied rock cores from up to 40 m below the surface and provided a window into an actively serpentinizing system. Rock cores from two wells, roughly one mile apart, were sampled at various depths and analyzed for microbial community composition via metagenomics and 16S rRNA tag sequencing, allowing for the comparison of communities within and between rock cores. Additionally, fluid samples from both wells have been sequenced, allowing for the identification of rock-specific microbes within the environment. Preliminary data indicate that communities associated with rocks are lower diversity and different composition than those associated with the surrounding fluids.

To test the question of habitability within the serpentinite subsurface, microorganisms have been cultivated *in situ* within the monitoring wells, showing growth over time, and their diversity is being assessed via 16S rRNA tag sequencing. Future experiments include providing environmentally-relevant mineral substrates *in situ* to determine the extent of microbe-mineral interactions within the serpentinite subsurface environment. This work adds to our growing understanding of the role of microorganisms in this extreme environment.

Pilbara greenstones revisited: a multi-proxy geochemical perspective on Archean crust-mantle interaction

JAN F. TYMPEL, JANET M. HERGT, JON D. WOODHEAD, ROLAND MAAS AND ALAN GREIG

School of Earth Sciences, The University of Melbourne, Victoria, Australia

Metabasalt (greenstone) sequences in Archean cratons provide insights into mantle melting and crust formation processes in the Early Earth. The 3.53–3.22 Ga eastern Pilbara Craton, Western Australia, contains large-scale exposures of well-preserved Palaeoarchean supracrustal vol-canic sequences, which can be correlated over considerable distances and are characterised by virtually undisturbed immobile element (REE, HFSE) systematics. Previous studies have aimed to establish a stratigraphic and chronological framework, reconstruct the tectonic setting for greenstone emplacement, and determine the composition of sources that may explain the chemical/isotopic signatures in these rocks. The recent suggestion of involvement of a Hadean crustal component, based on distinctly negative ε_{Nd} values in metabasalts and cherts within the Warrawoona Group [1], has motivated us to revisit these issues.

Here we present new high-precision trace element and isotopic (Nd-Hf) results for tholeiitic and komatiitic rocks of the Warrawoona Group, the lowermost section of the East Pilbara terrane. Trace element patterns in our samples are characterized by comparatively flat HREE distributions but wide variations in LREE abundances, with mantle-normalized ratios of $(La/Sm)_{PM}$ <1 to >4, $(Zr/Y)_{PM}$ <1 to >5, $(La/Yb)_{PM}$ <1 to >20 and $(Nb/Th)_{PM}$ significantly below 1, i.e. from values inferred for mantle-derived melts to values more typical of continental crust. By contrast, HFSE inter-element ratios (Nb/Ta ~ 16.2, Zr/Hf ~ 36.8) and initial Nd-Hf isotope values are homogeneous ($\varepsilon_{Nd} = 1.4 \pm 0.5$; $\varepsilon_{Hf} = 2.2 \pm 0.8$), yielding ~3.45 Ga isochron ages which are consistent with known emplacement ages.

Our Nd (and Hf) isotope results are consistent with those of Jahn *et al*. [2] and Gruau *et al*. [3] and do not appear to support a significant contribution from assimilated enriched Hadean proto-crust to ~3.45 Ga basaltic magmatism. Addit-ional modeling will help to further assess the involvement of potential crustal contaminants.

Linking noble gas and CH_4 concentrations in the sediment porewater of Lake Lungern, Switzerland

L. TYROLLER[1,2], M.S. BRENNWALD[1], C. NDAYISABA[1], Y. TOMONAGA[1] AND R. KIPFER[1,3]

[1] Eawag, Swiss Federal Institute of Aquatic Science and Technology, 8600 Duebendorf, Switzerland (*correspondence: lina.tyroller@eawag.ch)
[2] ETH Zurich, Institute of Biogeochemistry and Pollution Dynamics, 8092 Zurich, Switzerland
[3] ETH Zurich, Institute of Geochemistry and Petrology, 8092 Zurich, Switzerland

Noble gases are powerful tracers for gas transfer processes in lake sediments. They were successfully applied in the sediment of Swiss Lake Sopensee [1] to study CH_4 ebullition in the past. Here, we employed a newly developed method for quantitative sampling of dissolved CH_4 and noble gases [2] to determine both CH_4 and noble gas concentrations in the porewater. In order to asses the depth of active CH_4 production, and to investigate gas transfer processes in the lake sediment we sampled the uppermost metre of the sediments of Lake Lungern, a Swiss hydropower reservoir. This lake is characterised by lake level variations and the formation of CH_4 bubbles in the sediment due to super saturation of dissolved gases in the porewater.

Using the new sampling method, we observed CH_4 concentrations exceeding the in-situ saturation concentration. Compared to the overlying water body, the noble-gas concentration in the sediment porewater showed a depletion of the lighter, more volatile gases relative to the heavier, more soluble gases. This elemental fractionation indicates stripping of noble gases into the CH_4 bubbles released from the sediment. In addition, the absolute noble gas concentrations in the sediment porewater indicate an air excess relative to the concentrations in the overlying water body. We attribute this to the formation of excess air resulting from the dissolution of air bubbles entrapped in the sediment when the lake level falls below the depth of our sampling site. Linking CH_4 and noble gas concentrations in the sediment porewater therefore allows assessing importance of the physical transport processes related to CH_4 emission from the sediments into the water body of the Lake Lungern.

What is hidden in a slag heap?

TYSZKA R.[1], KIERCZAK J.[2], PIETRANIK A.[2], ETTLER V.[3] AND MIHALJEVIČ M.[3]

[1]Wroclaw University of Environmental And Life Sciences, C.K. Norwida 25/27, 50-375 Wroclaw, Poland (rafal.tyszka@up.wroc.pl)
[2]University of Wroclaw, Cybulskiego 30, 50-205 Wroclaw, Poland, anna.pietranik@ing.uni.wroc.pl; jakub.kierczak@ing.uni.wroc.pl)
[3]Charles University in Prague, Albertov 6, 128 43, Prague 2, Czech Republic (ettler@natur.cuni.cz; mihal@natur.cuni.cz)

A slag heap after Zn-Pb ore smelting (Świętochłowice, Upper Silesia, Poland) was disturbed during recent slag removal and the freshly uncovered surfaces are examined in this study. The material forming the interior of the slag heap is fine grained (up to 5 cm) and strongly weathered contrary to the large slag boulders on the slag heap surface (up to 2 m), which are only slightly weathered. It is composed of gypsum and hematite plus a mixture of primary and other secondary phases. The weathered material as whole is chemically more homogenous than unweathered slags and has lower Si and higher Fe, Pb (up to 3 wt. %), Cd (up to 560 mg/kg). The examined surfaces are 3 – 4 meters high and 10 – 30 meters wide suggesting that such an extensive slag weathering may have occurred in larger parts of the slag heap.

The implication is that the slag confined in the interior of the slag heap may have extensively reduced grain size and mineralogy dominated by secondary minerals and may contain more potentially toxic elements than the unweathered slag. As such it poses risk to the environment, especially when the slag heap is disturbed.

Radiation damage evolution in nanocomposites

BLAS PEDRO UBERUAGA

Materials Science and Technology Division, Los Alamos National Laboratory, Los Alamos, NM 87545; correspondence: blas@lanl.gov

As nuclear energy systems are taken to higher levels of radiation damage, there is greater need to develop materials that can withstand that damage. Nanocomposites, nanomaterials comprised of both a high density of internal interfaces and second phases, are one promising avenue for such materials. Most work on nanomaterials has focused on the role of the interfaces as sinks of point defects. Here, motivated by a series of experimental studies on oxide composites, we examine the other component of nanocomposites, the dual phase nature of the material without the interfaces acting as defect sinks. We solve a reaction-diffusion model of defect evolution of simple composites under irradiation which depends on defect properties within each phase with no special behavior accounted for at the interface. We identify three regimes of steady-state defect behavior that depend on the relative thermodynamics and kinetics of the defects in the phases comprising the composite. Importantly, in one regime, defect populations are enhanced on one side of the interface and depleted on the other. Further, transient defect populations can exceed steady-state concentrations. We conclude that the evolution of irradiation-induced defects in one phase of the composite is strongly controlled by the defect properties of the other phase, offering a route to controlling defect evolution in these materials.

Magmatic processes revealed by heterogeneous crystal populations in a lamprophyre system

T. UBIDE[1,2]*, C. GALÉ[1], P. LARREA[1], E. ARRANZ[1], M.LAGO[1] AND J.R. WIJBRANS[2]

[1]Universidad de Zaragoza, Spain (*correspondence: tubide@unizar.es)

[2]VU University Amsterdam, The Netherlands

Minerals respond texturally and compositionally to changing magmatic environments. We have studied a Cretaceous alkaline lamprophyre intrusion cropping out in the Catalonian Coastal Ranges in NE Spain [1] which includes macrocrysts and microcrysts of clinopyroxene and amphibole with complex zoning patterns. Mineral textures, compositional zoning, barometric estimates and geochronology provide insights into the magma plumbing system.

Macrocryst cores show inverse zoning patterns from more evolved to more primitive compositions. Therefore, they are not in equilibrium with the magma that hosts them and cannot be considered true phenocrysts. Rather, they are classified as antecrysts [2] recycled from earlier stages of the magma system. Macrocryst rims and microcrysts, in contrast, define an evolution from more primitive to more evolved compositions that can be related to progressive fractionation of the magma.

According to clinopyroxene barometry [3], macrocryst cores crystallised in a deep magma chamber (500-800 MPa) whereas macrocryst rims and microcrysts crystallised during the ascent and shallow emplacement of the magma below 50 MPa pressure. $^{40}Ar/^{39}Ar$ ages reveal a short timespan between the crystallisation of macrocrysts and microcrysts.

Our results reveal repeated injection and mixing of batches of a more primitive magma with the resident magma in a deep magma chamber, controlling the crystallisation of macrocryst cores (antecrysts). The last recharge event likely triggered the ascent of the magma to the emplacement level, carrying a significant amount of recycled crystals. The melt underwent fractionation during ascent and emplacement, controlling the composition of macrocryst rims and microcrysts.

This investigation highlights the need to carefully evaluate mineral zoning patterns and mineral-melt equilibrium in apparently simple porphyritic rocks.

Sedimentary organic matter variations in the Chukchi Borderland over the last 155 kyr

MASAO UCHIDA[1] AND STEPHAN RELLA[2]

[1]16-2 onogawa tsukuba 305-0044, japan, uchidama@nies.go.jp
[2]16-2 onogawa tsukuba 305-0044, japan, stephanrella@gmail.com

Knowledge on past variability of sedimentary organic carbon in the Arctic Ocean is important to assess natural carbon cycling and transport processes related to global climate changes. However, the late Pleistocene oceanographic history of the Arctic is still poorly understood. In the present study we show sedimentary records of total organic carbon (TOC, δ13C), $CaCO_3$, benthic foraminiferal $\delta^{18}O$, molecular markers (BIT index) and the coarse grain size fraction from a piston core recovered from the northern Northwind Ridge in the far western Arctic Ocean, a region potentially sensitively responding to past variability in surface current regimes and sedimentary processes such as coastal erosion. An age model based on oxygen stratigraphy, radiocarbon dating and lithological constraints suggests that the piston core records paleoenvironmental changes of the last 155 kyr.

TOC shows orbital-scaleincreases and decreases that can be respectively correlated to the waxing and waning of large ice sheets dominating the Eurasian Arctic, suggesting advection of fine suspended matter derived from glacial erosion to the Northwind Ridge

by eastward flowing intermediate water and/or surface water and sea ice during cold episodes of the last two glacia linterglacial cycles. At millennial scales, increases in TOC might correlate to a suite of Dansgaard-Oeschger Stadials between 120 and 45 ka before present (BP) indicating a possible response to abrupt northern hemispheric temperature changes. Between 70 and 45 ka BP, closures and openings of the Bering Strait could have additionally influenced TOC variability. $CaCO_3$ content tends to anti-correlate with TOC on both orbital and millennial time scales, which we interpret in terms of enhanced sediment advection from the carbonate rich Canadian Arctic via an extended Beaufort Gyre during warm periods of the last two glacial-interglacial cycles and increased organic carbon advection from the Siberian Arctic during cold periods when the Beaufort Gyre contracted.

Exploring fractionation models for some martian primary magmas

A. UDRY[1]*, H. Y. MCSWEEN[1] AND J. B. BALTA[1]

[1]Planetary Geosciences Institute, Dept. of Earth and Planetary Sciences, University of Tennessee, Knoxville, TN 37996, USA. (*Correspondence: audry@utk.edu)

The martian surface is mainly composed of tholeiitic basalts [1] as well as some alkaline compositions and sediments derived from basalts. Two hypotheses have been proposed to explain the compositions of martian basalts: 1) melting of martian mantle under various conditions, forming primary magmas with diverse compositions [2], or 2) fractional crystallization of primary magmas, resulting in the various basaltic compositions [3]. On the Earth, the Moon, and the asteroid 4 Vesta, primary magmas are scarce, indicating that most magmas fractionated during ascent. This model should also be applicable for Mars.

We conducted hundreds of fractional crystallization calculations for four different martian primary magmas: 1) Humphrey, 2) Fastball, 3) Yamato-980459, and 4) nakhlite parental melts, using MELTS and pMELTS [4]. Previously, all calculations and experiments have been isobaric. Our results are the first calculations conducted on martian magmas under polybaric conditions. In addition, we investigated isobaric and polybaric calculations at various oxygen fugacities, water contents, and P-T paths for each primary magma. Our study shows that polybaric fractionation of primary magmas (except Y-98) leads to the formation of alkaline compositions if most of the crystallization occurs at high pressures but forms subalkaline compositions if magma undergoes fractionation during rapid ascent.

In addition to examining martian primary magma evolution, we investigated formation of three specific martian alkaline rock compositions: 1) Backstay, 2) Jake Matijevic, and 3) nakhlite intercumulus glass. Backstay and the nakhlite intercumulus glass compositions can be formed through fractional crystallization of tholeiitic primary magmas, with or without water, and with a primary magma held at high pressures. Jake Matijevic [5] likely formed from a metasomatized alkali-rich melt. Our results suggest that alkaline magmas on Mars are formed similarly as on Earth and may be more common than suggested by orbital surveys for alkaline rocks.

Cause of the maximum S-MIF scatter in the late Archean: atmospheric organic sulfur and episodic volcanism

YUICHIRO UENO[1,2]*, SEBASTIAN O. DANIELACHE[3], MASAFUMI SAITO[1], YOSHIAKI ENDO[1] AND MATTHEW JOHNSON[4]

[1]Earth & Planetary Sciences, Tokyo Institute of Technology, Japan. (ueno.y.ac@m.titech.ac.jp)

[3]Faculty of Science & Technology, Sophia University, Japan
[4]Copenhagen Center for Atmospheric Research, Department of Chemistry, University of Copenhagen, Denmark.

Sulfur Mass-Independent Fractionation (S-MIF) has been useful to monitor chemistry of the Earth's early atmosphere. In the latest Archean, from 2.7 to 2.5 Ga, $\Delta^{33}S$ values of sedimentary sulfides exhibit exceptionally large variation compared to older period. The maximum scatter of S-MIF may indicate anomalous chemistry of atmosphere or climatic system of the late Archean Earth, though the primary cause of the large MIF is still poorly understand. We have developed a sulfur isotopic model by improving atmospheric reaction model [1,2]. The improvements to our model includes the addition of hydrocarbon chemistry, chemical formation and deposition of organic sulfur haze, together with newly determined high-accuracy ultraviolet absorption cross sections of SO_2 isotopologues. Our model results suggest that after a volcanic injection of SO_2 into the Archean atmosphere, a significant fraction of the sulfur is converted into organic sulfur and could be accumulated in an atmosphere over a timescale of 10 years, if background atmosphere is reducing enough to yield hydrocarbon haze and volcanic sulfur input is large and episodic. Such model could explain the large $\Delta^{33}S$ preserved in sedimentary rocks. Moreover, isotopically fractionated two reservoirs (i.e. atmosphere and ocean) can be mixed episodically and thus possible to explain the observed small scale heterogeneity of S-MIF even within a hand specimen level. Preservation process of the S-MIF could have been more dynamical than previously thought.

The relation between metasomatism and redox state of the upper mantle below the Massif Central, France

LAURA UENVER-THIELE[1], A. B. WOODLAND[1], H. DOWNES[2] AND R. ALTHERR[3]

[1] Institut für Geowissenschaften, Universität Frankfurt, Frankfurt, Germany (laura.uenver@online.de),
[2] School of Earth Sciences, Birkbeck College, University of London, London WC1E 7HX, UK
[3] Institut für Geowissenschaften, Universität Heidelberg, 69120 Heidelberg, Germany

Several studies have demonstrated the existence of two geochemically and texturally distinct mantle domains lying north and south of 45°30', respectively [1,2]. These two domains are also reflected by differences in their redox state [3] and record different metasomatic overprints. The aim of this study is to combine redox and trace element data to more closely investigate these metasomatic processes at various length scales.

Preliminary trace element data indicate multiple types of enrichment in LREE, MREE and HSFE. These different signatures occur regionally as well as locally, which implies variations in metasomatic style with depth. Most northern domain samples have high La/Nd (>10), but low Sm/Yb (<0.8) and $\log fO_2$ values > FMQ+0.9. The southern domain appears to have been affected by several different types of metasomatic overprints with variable intensity (e.g. high $(Ce/Yb)_N$). Oxidation states are also a function of rock type, with harzburgites having $\log fO_2$ ~FMQ+1.0 and lherzolites lying by ~FMQ+0.5. The harzburgites appear to be more sensitive to changes in oxidation state, presumably due to their generally low spinel contents. The presence of small amounts of amphibole does not correlate with degree of enrichment or the highest fO_2 values. Investigation of how geochemical and redox heterogeneities are influenced by rock type and texture are currently underway.

Detailed history of atmospheric pollution in South America as recorded by trace elements in the Quelccaya ice core

C. UGLIETTI[1], P. GABRIELLI[1,2] AND L.G. THOMPSON[1,2]

[1] Byrd Polar Research Center, 108 Scott Hall, The Ohio State University, 1090 Carmack Road, Columbus, OH 43210, USA (ugliettichiara@gmail.com)

[2] School of Earth Sciences, The Ohio State University, 125 South Oval Mall, Columbus, OH 43210, USA (gabrielli.1@osu.edu)

Reconstructions of past trace-metal deposition are extremely important to address questions linked to changes in land-use, climate, aeolian dust and to identify spatial patterns and temporal trends in global trace-metal associated with anthropogenic activities. The tropical Andes are particularly interesting because they host a long mining history associated with mineral exploitation and environmental impacts. The glacio-chemical record preserved in the ice of the Quelccaya ice cap, located within the southern Peruvian Andes offers a unique opportunity to geochemically constrain the composition of the tropical atmosphere at sub-annual resolution through time. Two ice cores were retrieved from the ice cap in 2003 (Summit Dome core, (QSD; 5670 m asl, 168.68 m) and North Dome core (QND; 5600 m asl, 128.57 m). Determination of twenty trace elements (Ag, Al, As, Bi, Cd, Co, Cr, Cu, Fe, Mn, Mo, Pb, Rb, Sb, Sn, Ti, Tl, U, V, and Zn) was performed by Inductively Coupled Plasma Sector Field Mass Spectrometry (ICP-SFMS, Element 2) over the first 120 m of the QND core, spanning the time period between 1990 AD and 1500 AD. As, Bi, Cd, Cu, Mn, Mo, Pb and Zn show different increases in concentration and crustal enrichment factors over this time period pointing to varying anthropogenic sources.

Geochemistry of urban soils in Karlstad, central Sweden – preliminary results

J. UHLBÄCK[1], A. LADENBERGER[1], M. ANDERSSON[1] AND M. SADEGHI[1]

[1]Geological Survey of Sweden, Box 670, S-751 28 Uppsala, Sweden (*correspondence: anna.ladenberger@sgu.se)

As a part of the European project URGE (Urban Geochemistry), in collaboration with EuroGeoSurveys Geochemistry Expert Group (EGS-GEG), surface soils were surveyed in the urban area of the municipality Karlstad in central Sweden to assess geochemical patterns of potentially toxic metals and other elements that can be considered dangerous at elevated concentrations.

306 surface (<10 cm depth) soil samples were collected from Karlstad town and analysed with aqua regia (AR) digestion by ICP-MS. The results show elevated concentrations of Cd, Cu, Pb, Sb and Zn in industrial parts of the town and in the harbour, while playgrounds, residential districts and recreation areas show lower concentrations. Broadly defined greenfields show more variation in metal concentrations, most likely due to the wider spread of potential sample sites in this category. The results display a mixed and complicated relationship between the geological background and anthropogenic overprint, with elevated concentrations in areas with historical and present industrial activity. The geochemical patterns of Ni, Cr and Co are similar and possibly related to the presence of mafic rocks within the extent of the town (especially in the southern part of Karlstad). Elevated As levels occur randomly in greenfield areas indicating a rather natural origin of these anomalies. Higher concentrations of Pb, Cd and Ni in the city centre can be related to traffic. High Cu and Zn contents in the town's central parts point to the long-term use of copper-zinc construction details in buildings, e.g. gutters and roof elements. Elevated Hg concentrations in several places by the Klara river may indicate the pollution related to sewage and fertilizers and affinity of Hg to bind to organic matter-rich bank sediments.

The results from this study can be further used by the local authorities for future planning of the infrastructure and slum-clearance of contaminated land. Potential health risks for inhabitants who reside and work in contaminated areas can also be assessed, with the aim to specify and inform the public about possible precautionary measures.

Structural-diagenetic evolution of fractures in folds: A TGS example from the Alberta Foothills, Canada

E. UKAR*, P. EICHHUBL AND A. FALL

The University of Texas at Austin, Bureau of Economic Geology, PO Box X, Austin, TX 78713 (*correspondence: esti.ukar@beg.utexas.edu)

The late Jurassic-early Cretaceous Nikanassin formation is generally characterized as a tight gas sandstone formation with submilidarcy values of permeability and porosities typically less than 6% [1]. However, the Nikanassin produces gas at commercial rates where it contains a network of open fractures. But exploration and development outcomes are mixed, underlining the necessity for a better understanding and characterization of the more fractured and potentially more productive regions [2].

A unique combined outcrop and core study of fractures associated with three reservoir-scale anticlines reveals the presence of two main fracture sets in all three mesostructures: fracture set one is perpendicular to the fold axis, whereas fracture set two is parallel. Both sets have an associated conjugate oblique fracture set. Scanline data indicate a higher fracture intensity in the steeply-dipping limbs of the folds than in the shallower-dipping limbs. Cathodoluminescence images of cemented fractures reveal several generations of quartz and ankerite cement that are synkinematic and postkinematic relative to fracture opening. Based on homogenization temperatures of two-phase aqueous inclusions in crack-seal cement, synkinematic fracture opening and cement precipitation occurred at or near maximum burial in core samples (190-210°), and during exhumation in outcrop samples (120-160°).

Structural models constructed using MOVE [3] predict a higher strain accumulation in the steep limb of the Sternie Creek Anticline than in the fold hinge and shallow limb. Models also predict an early opening of fracture set 1, which is in accordance with the general observation that set 2 cross-cuts set 1 in outcrop. Opening of most fractures probably occurred during regional folding at the end of the Laramide orogeny.

Anammox in an ammonium-impacted groundwater aquifer

ANNE ULDAHL[1]*, BO THAMDRUP[2] AND RASMUS JAKOBSEN[3]

[1]DTU Environment, Technical University of Denmark. Miljoevej, Building 113, DK-2800 Kgs. Lyngby. (*correspondence: annu@env.dtu.dk)

[2]NordCEE and Institute of Biology, University of Southern Denmark. Campusvej 55, DK-5230 Odense M.

[3]GEUS, Geological Survey of Demark and Greenland. Oestervoldgade 10, DK-3500 Copenhagen K.

The novel anaerobic ammonium oxidation pathway (anammox) is today recognized as an important sink for reactive N, removing biologically available N in the form of ammonium and nitrite to the gaseous N_2, providing a competition to the dissimilatory nitrite reduction by denitrifiers. Anammox activity and the responsible bacteria are currently demonstrated in a wide range of ecosystems, however; the knowledge about anammox in freshwater systems, like ammonium-impacted groundwater aquifers, is still scarce. With the necessary electron donors and acceptors present in the groundwater system, the activity and abundance of anammox bacteria could be of significant importance since biologically available N, resulting from anthropogenic sources, is a major threat to groundwater quality.

We hypothesize that the anammox process occurs in a contaminated groundwater system, when NO_2^- and NH_4^+ are present under low oxygen conditions. Isotope-based methods were used to quantify anammox activity through the isotope pairing technique: two-meter sediment cores were collected from a groundwater system adjacent to the abandoned landfill site Risby, Denmark; chosen intervals were sectioned and incubated anaerobically as sediment slurries. The production of $^{29}N_2$ and $^{30}N_2$ was monitored over time after addition of labelled N and unlabelled N as: $^{15}NO_3^- + {}^{14}NH_4^+$ for detecting anammox, denitrification (nitrite reduction to N_2) and DNRA (dissimilatory reduction of ammonium) and with $^{15}NH_4^+ + {}^{14}NO_3^-$ for detecting anammox production. Our results show that both anammox and DNRA are active, with denitrification as the dominating pathway.

Preservation potential of δ^7Li values in Mesozoic calcite fossils

C.V. ULLMANN*[1,2], H.J. CAMPBELL[3], R. FREI[1], S.P. HESSELBO[2], P.A.E. POGGE VON STRANDMANN[2] AND C. KORTE[1]

[1]University of Copenhagen, IGN, Øster Voldgade 10, 1350 Copenhagen, Denmark
(*correspondence: c.v.ullmann@gmx.net)
[2]University of Oxford, Department of Earth Sciences, South Parks Road, Oxford OX1 3AN, United Kingdom
[3] GNS Science, 1 Fairway Drive, Avalon 5010, New Zealand

Lithium isotopes of fossil carbonates are a promising proxy for determining the intensity of silicate weathering. Here we use elemental and isotopic trends in diagenetically altered Late Jurassic belemnites (*Belemnopsis* sp. and *Hibolithes* sp.) from New Zealand to see if meaningful δ^7Li values are preserved in fossil calcites over time spans of > 100 m.y.

The parts of the belemnite rostra that are most altered are characterized by low δ^{18}O reaching -12 ‰ and moderate decreases in δ^{13}C (down to -2 ‰), coupled with high Mn/Ca ratios reaching 4.6 mmol/mol. Both, Sr/Ca ratios and ^{87}Sr/^{86}Sr ratios were found to decrease with progressive alteration. The direction and magni-tude of the trends indicate one main diagenetic phase.

Altered materials show variable δ^7Li values between +24 and +40 ‰, while δ^7Li values of the sedimentary matrix are -5 ‰. δ^7Li values of best preserved belemnites are +27 ± 1 ‰ (2 sd, n = 5), pointing to a Late Jurassic seawater δ^7Li of ~29-32 ‰, compatible with the modern value of 31 ‰. Despite burial down to ~4 km, and thus elevated temperatures, uniform δ^7Li values in the well-preserved fossil calcites, and strong isotopic gradients between fossil calcite and sediments have been maintained. This suggests that primary δ^7Li values can be preserved over geological timescales.

Recent views on lamprophyric melilitic rocks (polzenites) of the Bohemian Massif

JAROMÍR ULRYCH[1]* AND LUKÁŠ KRMÍČEK[2]

[1]Institute of Geology v.v.i., Academy of Sciences of the Czech Republic, Rozvojová 269, CZ-165 00 Praha 6, Czech Rep. (*correspondence: Ulrych@gli.cas.cz)
[2]Brno University of Technology, Faculty of Civil Engineering, Veveří 95, CZ-602 00 Brno, Czech Rep.

The easternmost part of the Cenozoic Volcanic Province of western and central Europe includes rare occurrences of Late Cretaceous to Paleocene (70 to 59 Ma) ultramafic melilitic and melilite-bearing rocks. These rock suites, related to the initial stage of rifting of the Bohemian Massif, occur in the shoulder blocks of the Ohře/Eger Rift zone. Here, in the Ploučnice (Polzen) River area, a group of clinopyroxene-free melilitic rocks - polzenites - was defined by K.H. Scheumann in 1913. He recognized three principal petrographic types of polzenite: Vesec, Modlibohov and Luhov type. Inspecting the petrography of the separate types we find that the Vesec type is represented by polzenite s.s. only (olivine + melilite + nepheline + phlogopite + spinels + calcite ± monticellite, hauyne, perovskite, apatite mineral associations), whereas the Modlibohov type is transitional to the Luhov type representing a clinopyroxene-bearing melilitic rock – alnöite, as defined by H. Rosenbusch in 1887.

Regarding the classification of polzenites, there are currently two petrographic approaches. According to the first view polzenites represent only lamprophyric, i.e. volatile-rich, facies [1] of melilite-bearing group of rocks and can be added as a special petrographic type into this group. According to the second view, polzenites belong to an individual group of ultramafic lamprophyres, however they are considered by some scientists as a more felsic variant of alnöite [2]. With respect to the petrography of clinopyroxene-free polzenite (the Vesec type) for which values of Mg# between 74 and 78 are typical, polzenite can be considered a valid end-member of the ultramafic lamprophyre group.

Forceful Carbonation of Serpentine

O. I. ULVEN*, H. AUSTRHEIM AND A. MALTHE-SØRENSSEN

Physics of Geological Processes, University of Oslo, 0316 Oslo, Norway (*Correspondence: o.i.ulven@fys.uio.no)

Mineral carbonation has been suggested as an option for long term sequestration of anthropogenic CO2[1]. It is in this respect critical to know whether the growth of carbonate minerals will clog pore space, and thus limit further transport of CO2 into the rock, or whether the carbonate growth will exert enough stress on the host rock to make it fracture, thus making new fluid pathways.

In this work, we perform a numerical study of natural field examples of growth of carbonate minerals in serpentine, and we use a discrete model to reproduce observed structures.

We achieve an improved understanding of the process of mineral carbonation and the feedback on rock deformation, thus improving our ability to determine whether industrial scale mineral carbonation is a viable option for long term storage of CO2.

Limited releases of U and Tc from Hanford tank residual wastes

WOOYONG UM [1,2,*] AND KIRK J. CANTRELL [1]

[1]Pacific Northwest National Laboratory, Richland, WA, USA
[2]Pohang Univ. of Sci. and Technol., Pohang, South Korea
wooyong.um@pnnl.gov (* presenting author)

Most of the Hanford Tank wastes in Washington, USA are expected to be retrieved, stabilized in an appropriate waste form and then disposed in a repository. Small amounts of residual wastes are expected to remain at the bottom of the tanks in a layer no more than 2.54 cm thick as slurry of solid precipitates. The current final stage of tank closure is planned to consist of the addition of cement or grout to stabilize the remaining wastes and tank structure. In this study, three different chemical treatment methods (lime [$Ca(OH)_2$] addition, an in-situ Ceramicrete based on chemically bonded phosphate ceramics, and a ferrous Iron/Goethite treatment) were tested for their ability to stabilize residual Hanford C-202 tank wastes for reducing contaminant release of Tc and U in particular because they are key groundwater risk drivers.

Leaching tests were conducted using a single-pass flow-through test (SPFT) system with 0.005 M $Ca(OH)_2$ solution for untreated tank sample and C-202 wastes treated with three different chemical treatments. Technetium concentrations in leachates from tank C-202 residual waste treated with the $Ca(OH)_2$, Ceramicrete, and Goethite methods are shown in Fig.1. All three treatments methods effectively reduced the leachable Tc concentrations as well as U to well below untreated waste as a result of formation of insoluble secondary precipitates which can behave like mineral coatings.

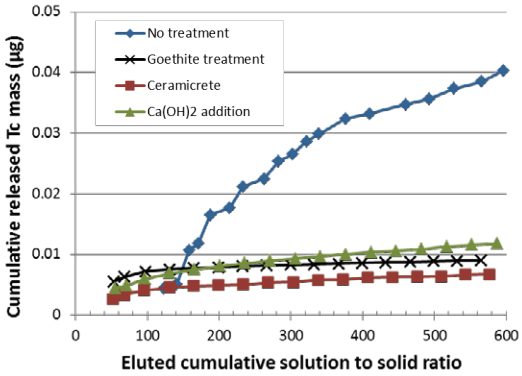

Fig. 1. Released cumulative Tc amounts from the residual wastes.

This innovative approach has the potential to revolutionize Hanford's tank retrieval processes, by allowing larger volumes of residual waste to be left inside tanks while providing an acceptably low level of risk with respect to contaminant release as well as significant cost savings.

Chemical composition of detrital spinel from Eastern Chugoku and Northern kinki of Sangun zone, Southwest Japan.

TOMOYUKI UMEDA[1] AND ICHIRO MATSUMOTO[1]

[1] Faculty of Education, Shimane University, Matsue, Japan, umedatomoyuki@gmail.com (*presenting author) chromim@edu.shimane-u.ac.jp

Geochemical characteristics of chromian spinel from ultramafic rocks and chromitites in Sangun zone of Central chugoku district have become clear gradually by recent many studies [1,2]. Especially, petrogenesis of chromitite formation [3] and explolation for chromitite [4] came to be advanced from these works. However, ultramafic complexes in Sangun zone distribute not only central chugoku district but also from eastern chugoku to northern kinki districts, which are called Wakasa, Sekinomiya, Izushi, Oeyama complexes respectively. Chromitite pods and chromite mines (now closed) also existed in these district. Detailed research of chromian spinel from ultramafic rocks and chromitite in this district is not done sufficiently, and there is the required for a geochemical description for understand origin and petrogenesis of ultramafic rocks and chromitite. However ultramafic rocks in the Sangun zone of these district are also strongly altered and serpentinized. Then we use detrital chromian spinel from the stream sediment, in this study. This is the first report of chemical composition of detrital chromian spinel from ultramafic rocks and chromitite in Sangun zone of from eastern chugoku to northern kinki district.

Cr#(=Cr/Cr+Al) of detrital chromian spinel from Sekinomiya complex varies from 0.43 to 0.56. Cr# of those from Izushi complex varies from 0.36 to 0.56 (mainly 0.43 to 0.50). Cr# of those from Oeyama complex varies from 0.43 to 0.69. That is, Cr# of those from eastern chugoku to northern kinki district overlap with the Cr# (0.4 to 0.6) of detrital spinel from central chugoku district. In addition, We found chromitite boulder in Oeyama complex, and show that Cr# of chromian spinel varies from 0.38 to 0.43, that is the most High-Al podiform chromitite in Japan. This is significant petrological description, indicating involvement of both Al-rich melt and of fertile harzburgite.

Petrological Implications of Temporal and Spatial Variations in Magma Chemistry of the Quaternary Tendurek Shield Volcano, Eastern Anatolian Collision Zone, Turkey

E. UNAL[1]*, M. KESKIN[2], V.A. LEBEDEV[3], ANDREY V. CHUGAEV[3] AND E.V. SHARKOV[3]

[1]YYU, Dept. of Geol. Engineering, Zeve Campus, Van, Turkey (*correspondence: esinunal@yyu.edu.tr)
[2]Istanbul Univ., Dept. of Geol. Engineering, Avcilar, Istanbul, Turkey (keskin@istanbul.edu.tr)
[3]RAS, IGEM, Staromonetny per., 35, Moscow, Russia

The Quaternary Tendürek Volcano is one of the largest eruption centers of the Eastern Anatolia with a summit elevation of 3538 m and a footprint area of 650 km^2. It is a shield volcano consisting of lavas ranging in composition from tephrites through benmoreites/phonolites to trachytes. The young volcanism of the region is thought to be related to the continent-continent collision taken place after the closure of the Neo-Tethys Ocean. The Tendürek volcano is of special importance, because it is one of the rare places in Eastern Anatolia where calc-alkaline and potassic alkaline volcanism coexisted.

Lavas of the Tendürek volcano are classified on the SiO_2 versus K_2O diagram as medium K / high K and shoshonitic series. Results of our FC, AFC and EC-AFC modelings indicate that the Tendürek lavas were influenced by crustal contamination and fractional crystallization. Medium to high potassic basalts, trachy-basalts, tephrites and basaltic-trachyandesites basically follow a partial melting trend on La vs. La/Yb diagram in contrast to the trachy-andesites, phonotephrites, tephriphonolites, phonolites, and trachytes of the shoshonitic series aligning along a fractional crystallization trend. The high-SiO_2 phonolitic lavas have a more pronounced enrichment in incompatible elements, such as Rb, Th, La and Nb, in comparison to those in the other shoshonitic rocks. The aforementioned differences in the chemical compositions of these two groups of shoshonitic rocks may reflect variations in the fractional crystallization process which involved clinopyroxene and plagioclase during the petrogenesis of the potassic rocks.

According to our melting model, primitive magma of the Tendürek lavas were derived from mixing of the spinel and garnet peridotite melts with different melting degrees ranging between 1 - 3%.

Possible link between CO_2 degassing and climate change in SW Turkey

E. ÜNAL-İMER[1]*, I.T. UYSAL[1], J. SHULMEISTER[1] AND J.X. ZHAO[1]

[1]The University of Queensland, Brisbane, QLD, 4072, AUSTRALIA (*correspondence: e.unal@uq.edu.au)

High-pressure CO_2-rich fluids can trigger fault activity by reducing the shear stress [1]. Subsurface meteoric water at crustal depths of 10–15 km, mainly contributed by local rainfall sourced groundwater, may be the major fluid source in large-scale continental extensional areas [2]. Carbonate vein deposits could precipitate from such CO_2-rich, deeply circulated overpressurised meteoric water within intensely-fractured/faulted rocks along active normal fault zones, within a rapidly extending region in SW Turkey [3,4,5] sub-samples of such vein calcites were investigated by advanced U-series dating and O-isotope analyses. The U-series ages show that calcite vein formations occurred largely during lower solar insolation (summer) periods in the Late Pleistocene in this region. These are interpreted as the periods of elevated effective precipitation, which could be responsible for fluid overpressures achieved by either increasing absolute or seasonal precipitation or by reducing evapotranspiration. Although full glacial periods are commonly associated with dry climatic conditions, regional conditions can vary. We suggest that the Eastern Mediterrenean basin including Turkey was relatively wet under low to transitional insolation regimes, specifically, during the Last Glacial Maximum. This is likely a response to southerly-shifted westerly wind flow in the Northern Hemisphere bringing moisture supply over the study area. Further, the trend of $\delta^{18}O$ values plotted against U-series ages of vein calcites demonstrate possible responses to either climate variability or seismicity-related fluid exchange mechanisms on mm scale.

It is possible to correlate fault activity recorded by co-seismic vein calcites as a product of CO_2 degassing and local climate controlling the effective precipitation. This means that seismic hazard can be linked to changing climatic conditions in the region. Consequently, earthquake clusters in SW Turkey may be considered to be climate-related and a function of the increased availability of fluids during cool to cold climate periods.

In the context of geological disposal of radioactive waste in clayey formations, the consequences of a microbial activity are of concern regarding the corrosion of metallic materials. Actually microbial life has been highlighted in argillaceous formations [1]. Sulfate- and iron-reducing bacteria, as well as bacteria able to develop at high temperatures have been detected in Tournemire[1] (Toarcian argillite) [2]. They can grow at the interfaces between steel and argillite in a short period compared with planned durations of disposal. Such bacteria may influence corrosion [3], that may cause a premature loss of containment of metallic barriers. The formation of biofilms may also lead to environmental modifications at the biofilm/metal interface that may further increase corrosion rates [4]. Thus, an experimental setup was designed to understand the conditions favoring the formation of biofilm and the impact of microorganisms on steel corrosion.

A synthetic solution representative of the Tournemire pore water percolated through cells containing steel coupons placed in contact with Tournemire argillite. Various environmental conditions likely to prevail in a repository were tested (anoxic or oxic conditions, 25°C or 50°C). A mix of strains able to form biofilms and sulfate- and iron-reducing bacteria, each present in Tournemire argillite, has been inoculated. Cells were dismantled after 1, 4 and 8 months to establish a chronology of the involved processes. Analyses of outgoing water chemistry provided indications on mechanisms occurring within the cells. Observations of the steel surface were made using Field Emission Scanning Electron Microscopy and Raman spectroscopy. Molecular characterization of the microbial diversity was used to determine which species are responsible for corrosion.

Assesing iron and oxygen isotope homogeneity in garnets

M. UROSEVIC[1], O. NEBEL[1], E.C. PETERSON[2], J.A. PADRÓN-NAVARTA[1,3] AND D. RUBATTO[1]

[1] Research School of Earth Sciences, The Australian National University, Canberra, Australia
[2] Mineralogy, Technology and Innovation, Rio Tinto, Melbourne, Australia
[3] Géosciences Montpellier, Univ. Montpellier 2 & CNRS, 34095 Montpellier, France

Garnet is a key mineral for (i) dating metamorphic processes in the crust, (ii) tracing P-T conditions in the upper mantle, and (iii) understanding porphyry, skarn and epithermal ore systems. All of these geotectonic settings and associated processes are related to mass transfer of elements in fluids or melts. Detailed knowledge of the redox state under which such processes occur (often referred to as fO_2) and/or the source of fluids is crucial for the study of mass transfer in rock forming processes in crust and mantle.

Here we assess three natural garnets for their major, trace and O-Fe isotope budget in search of suitable standards and constraints on processes controlling their isotope systematics. One garnet from Kakanui, New Zealand (KAK) and two from Erongo, Namibia (ERO-R and ERO-G) are analysed. KAK is a xenocryst pyrope-rich garnet ($Alm_{22-23}Prp_{62-63}Grss_{12}And_2Spss_1$) from mantle-derived alkaline melt. ERO-R is an igneous almandine-rich garnet ($Alm_{64-65}Prp_{6-7}Grss_1And_{<1}Spss_{28-29}$) from a migmatitic vein with negligle proportion of Fe^{3+}. ERO-G is a hydrothermal highly zoned andradite-grossular-rich garnet ($Prp_{<1}Grss_{22-65}And_{32-77}Spss_{1-2}$) with all Fe as Fe^{3+}.

KAK is homogeneous in major and trace elements and in oxygen isotopes at the microscale with $\delta^{18}O$~5.3. Its $\delta^{57}Fe_{(IRMM-014)}$=+0.09±0.01 is slightly elevated compared to average depleted mantle. Oxygen and Fe isotopes are homogeneous in ERO-R with $\delta^{18}O$~8.5 and $\delta^{57}Fe$=+0.11±0.06, respectively. ERO-G garnet grains are zoned in oxygen composition with a variation form core to rim between ~13 and ~11 ‰, which coincides with the growth zoning pattern in Grss-Andr observed in BSE images. Accordingly, their heavy $\delta^{57}Fe$ vary from +0.6 to +0.9. Trace elements composition of ERO-G garnet is highly variable.

Based on our preliminary results KAK and ERO-R appear to be suitable standards for coupled Fe-O isotope analysis. Garnet O isotopes are in line with the source of the sample (mantle versus crust). Fe isotopes strongly correspond to Fe^{3+}/Fe^{2+} and may thus be a sensitive redox proxy in garnet.

Discovery of a Triassic magmatic arc source for the Permo-Triassic Karakaya subduction complex, NW Turkey

P. AYDA USTAÖMER[1]*, TIMUR USTAÖMER[2], AXEL GERDES[3], ALASTAIR H.F. ROBERTSON[4] AND GERNOLD ZULAUF[3]

[1]*Yıldız Teknik Üniversitesi, ustaomer@yildiz.edu.tr
[2]Istanbul Üniversitesi, Turkey
[3]Goethe-University, Frankfurt, Germany
[4]University of Edinburgh, U.K.

The Permo-Triassic Karakaya Complex is well explained by northward subduction of Palaeotethys but until now no corresponding magmatic arc has been identified in the region. With the aim of determining the compositions and ages of the source units, ten sandstone samples were collected from the mappably distinct Ortaoba, Hodul, Kendirli and Orhanlar Units. Zircon grains were extracted from these sandstones and >1300 were dated by the U-Pb method and subsequently analysed for the Lu-Hf isotopic compositions by LA-MC-ICP-MS at Goethe University, Frankfurt. The U-Pb-Hf isotope systematics are indicative of two different sediment provenances. The first, represented by the Ortaoba, Hodul and Kendirli Units, is dominated by igneous rocks of Triassic (250-220 Ma), Early Carboniferous-Early Permian (290-340 Ma) and Early to Mid-Devonian (385-400 Ma) ages. The second provenance, represented by the Orhanlar Unit, is indicative of derivation from a peri-Gondwanan terrane. In case of the first provenance, the Devonian and Carboniferous source rocks exibit intermediate εHf(t) values (-11 to -3), consistent with the formation at a continental margin where juvenile mantle-derived magmas mixed with (recycled) old crust having Palaeoproterozoic Hf model ages. In contrast, the Triassic arc magma exhibits higher εHf(t) values (-6 to +6), consistent with the mixing of juvenile mantle-derived melts with (recycled) old crust perhaps somewhat rejuvanated during the Cadomian period. We have therefore identified a Triassic magmatic arc as predicted by the interpretation of the Karakaya Complex as an accretionary complex related to northward subduction (Carboniferous and Devonian granites are already well documented in NW Turkey). Possible explanations for the lack of any outcrop of the source magmatic arc are that it was later subducted or the Karakaya Complex was displaced laterally from its source arc (both post 220 Ma). Strike-slip displacement (driven by oblique subduction?) can also explain the presence of two different sandstone source areas as indicated by the combined U-Pb-Hf isotope and supporting petrographic data.

Multiple fluid events and metal mobility associated with formation of IOCG-type mineralisation in Gawler Craton

Y. UVAROVA[1,2]*, J. CLEVERLEY[1,2] AND R. HOUGH[1]

[1]CSIRO Earth and Resource Engineering, ARRC, Kensington, WA 6151 Australia (*correspondence: Yulia.Uvarova@csiro.au)
[2] Deep Exploration Technologies CRC

The Gawler Craton, in South Australia, is host to the giant Olympic Dam deposit and a number of other economic to subeconomic iron oxide-copper-gold (IOCG) prospects including Prominent Hill, Oak Dam, Wirrda Well, Acropolis, Punt Hill, and Carrapateena. Several genetic models have been proposed for the formation of IOCG mineralisation in the Craton, but little is known about the source of metals and sulfur, and mechanisms of their transport and deposition.

Geologic and petrographic studies on IOCG prospects in the Olympic Dam district (Emmie Bluff, Canegrass, Cocky Swamp and Dromedary Dam) indicate several stages of fluid activity. Subeconomic Cu-Au mineralsiation at these prospects is associated with the hematite-chlorite-sericite alteration with chalcopyrite commonly replacing pre-existing pyrite. With the use of cutting-edge Synchrotron X-ray Fluorescence Microscopy and Field Emission Gun Scanning Electron Microscopy it was shown for the first time that subeconomic IOCG mineralisation in the Gawler Craton was affected by a late fluid event, which resulted in partial dissolution of Cu mineralisation and transport of Cu in the form of chloride complexes. Patchy chlorite associated with the late alteration of chalcopyrite hosts a previously undescribed in IOCG rocks Cu-Cl phase. This Cu-Cl phase is interpreted to be a by-product of chalcopyrite partial dissolution and contains minor Zr, Y and U. The fluids must therefore have been rich in chlorine to mobilise Cu, and probably fluorine, as they were carrying relatively immobile Zr, Y and U which become mobile in the presence of fluoride complexes. This might be an indication of remobilisation and re-deposition of Cu along with other metals elsewhere in the district and could have implications for a possible metal source for the nearby Cu-Au deposits.

Understanding the role of Phanerozoic and active tectonics in generating geothermal resources in central Australia

I. T. UYSAL[1]* , U. RING[2], AND A. W. MIDDLETON[1]

[1]University of Queensland, Queensland 4072, Australia [1]
[2]Stockholm University,Stockholm 106 91, Sweden
(*correspondence: t.uysal@uq.edu.au)

Central Australia has a significant potential for geothermal development. Recent He and C isotope studies of volatiles from artesian waters suggest mantle-derived fluid reservoirs as a source of the geothermal resources [1], rather than radioactive heat production in the basement granitic rocks as widely believed. In conjunction with isotopic data of the volatiles, our structural geological field observations suggest that geothermal systems in central Australia preferentially occur in areas of deformation-enhanced permeability and deep mantle fluid production. To this end, we performed comprehensive isotopic dating studies (Rb–Sr, Ar–Ar and U-series) to understand the role of Phanerozoic and neotectonic deformations in permeability production and stable isotope tracing to determine the source of fluids in the geothermal reservoirs. Isotopic dating results and stable isotope geochemistry of hydrothermal minerals in basement rocks are interpreted as indicating that Cretaceous extensional tectonic events controlled the thermal history of central-eastern Australian basins and distribution of fracture zones allowing recent uprise of hot mantle fluids. Areas affected by Cretaceous tectonics are characterised by significantly high temperatures (>250°C) at 5 km depth [2] and distinctive geophysical anomalies [3]. Our field studies show that pre-existing faults were reactivated neotectonically and controlled the formation of late Quaternary carbonate vein and breccia deposits, which formed as hydro-fractures during CO_2-rich fluid overpressure, analogous to similar deposits in seismically active geothermal systems worldwide [4]. $\delta^{13}C$ values of the carbonates are consistent with CO_2 derived from a mantle source. High precision U-series dating of carbonate veins suggests that the release of the pressurised CO_2 occurred intermittently from 35.9 ± 0.15 ka to 1.2 ± 0.02 ka, possibily in association with mantle degassing in response to seismicity.

Production of The Sodium Sulphate from Acigöl by Solution Mining Method, Denizli, TURKEY

SERENA UZASCI SULTANYAN[1], SALIH BURAK KARABEL[1], DEMET KIRAN YILDIRIM[1], MURAT BUDAKOĞLU[1], MUHITTIN KARAMAN[1] AND MUSTAFA KUMRAL[1]

[1]Istanbul Technical University, Department of Geological Engineering, 34469, Istanbul, TURKEY

Sodium sulphate is used widespread in industry. Common usage areas are paper, glass, detergant, textile, and chemical industries. In this study production of the Na2SO4 from the lakes by solution mining method has been examined. Evaporites and their usage areas, evaporite deposites in nature and types of it and production types of the sodium sulphate and detailed report about the information about the solution mining method and information of the Acıgöl Lake and production examples in it.

Acıgöl is a lake in Turkey's inner Aegean Region, in a closed basin at the junction between Denizli Province, Afyonkarahisar Province and Burdur Province. The lake attracts attention due to its sodium sulfate reserves. Turkey's largest commercial sodium sulfate production operations are based here. Mirabillits and tenardits are common sodium sulphate minerals that are produced from this lakes.

Sodium sulphate from salty or bitter alkali lakes can be produced in natural and artifical methods. This decision is differs by the facilities production area and capacity. Solution mining method of sodium sulphate is examined in detail. Also, room and pillar method is examined briefly.

By comparing these methods, solution mining step forwards with its advantages. But in salt lakes, where the lake area is wide and weather temperature conditions are optimum for the operation method or where by changing of the seasons last product can be collected by freezers from the lakes surface. Therefore any facility for the production is needed and so in this case solution mining method isn't advantageous.

Neoproterozoic accretion along the southeastern margin of the Eastern Dharwar Craton, India: Evidence from zircon U-Pb ages and their Hf isotopic composition

RAVIKANT VADLAMANI[1]*, CHIRANJEEB CHATTERJEE[1], WEI-QIANG JI[2A] AND FU-YUAN WU[2]

[1]Indian Institute of Science Education & Research Kolkata, Mohanpur-741252 (vravikant@iiserkol.ac.in)
[2]State Key Laboratory for Lithospheric Evolution, Chinese Academy of Sciences, Beijing-100090

Late Mesoproterozoic high-grade tectonothermal event due to collision of the Eastern Ghats Belt [1] with the Eastern Dharwar-Bastar Cratons, is not recorded by the Paleoproterozoic Krishna Province rocks [2] south of the Godavari graben [3]. The Vinjamuru domain represents Paleoproterozoic metaigneous rocks of a continental arc accreted to the margin of the Eastern Dharwar Craton [4] and coeval with the UHT granulite-facies event in the easternmost Ongole domain [2]. Here, we report zircon isotopic data from one critical amphibolite-facies metaandesite sample (VL47) from the central Vinjamuru domain.

The U-Pb zircon ages in this metavolcanic rock record a protracted polycyclic evolutionary history (Fig.1). Derivation of youngest zircons from crustal melts are seen in their negative $\varepsilon_{Hf\,(t)}$ values at two clusters: 907-1111 Ma ($\varepsilon_{Hf\,(t)}$ = -5 to -7) and 696-810 Ma ($\varepsilon_{Hf\,(t)}$ = -21 to -9).The most likely interpretation of our data is that the Vinjamuru domain rocks also record latest Neoproterozoic accretion (and coeval metamorphism) of the Ongole domain to the Vinjamuru domain, supporting one interpretation of this Eastern Ghats-craton collision at 820 Ma [5].

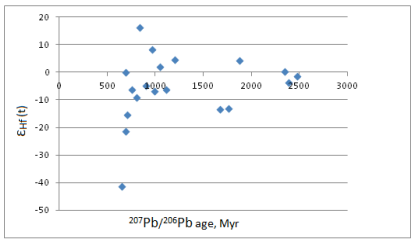

Fig.1. Zircon age vs $\varepsilon_{Hf\,(t)}$ from metaandesite sample VL47

The first data about the REE's contents in new-formed phases (Berezitovoe gold deposit, Priamurye, Russia)

ELENA A.VAKH[1], ALEKSANDR S. VAKH[2,3] AND NATALIA A. KHARITONOVA[2,3]

[1]Far East Geological Institute FEB RAS, Russia, Adasea@mail.ru
[2]Far East Geological Institute FEB RAS, Russia, vakh@fegi.ru
[3]Far Eastern Federal University DVFU, Russia, tchenat@mail.ru

Here we present the first data on contents and geochemistry of REEs in the secondary new-formed phases from weathering zone of Beresitovy gold deposit hostrocks. Also the analysis of fractionation and migration of REE in single geochemical cycle "bedrock - weathering zone - surface and ground water - secondary new-formed phases" are performed.

The Beresitovy gold deposit located in the northeastern Amur gold province in the downstream basin of the Khaikta River. In 2007, two mining companies: Berezitovy Mine Ltd. and High River Gold Mines Ltd., started to mine this deposit. Geologically, the deposit is localized in a southeast part of the North Asian craton, in a zone of its joint with formations of northern frame Tukuringra-Dzhagdinsky terrein Mongolo-Ohotsky zone. Two formations of sediments (granites and ore–metasomatic rocks) occur in the deposit. Main minerals bearing REEs are allanit, monatsit - (Ce), chervandonit - (Ce).

The preliminarily results of investigation showed, that the content and distribution of REEs in the new-formed phases from weathering zone of deposit. Our data indicate that the content of REEs in new-formed phases of Berezitovoe deposit can reach up to 149 ppm and the content of LREEs is at about 93% of total REEs. All types of new-formed phases display of strong negative Ce and Nd amonalies.

Profiles of distribution of REE of new-formed phases are comparable to bedrock profiles, small difference is observed in distribution heavy groups of elements.

Relation between diatom communities and the degree of AMD affection in selected water dams in Iberian Pyrite Belt

T. VALENTE[1,2]*, S. ALMEIDA[3], M.J. RIVERA[1,2], C. DELGADO[3], P. GOMES[1,2], M.L. DE LA TORRE[2], M. SANTISTEBÁN[1,2] AND J.A. GRANDE[2]

[1]CIG-R (PEst-OE/CTE/UI0697/2011) –, Universidade do Minho, Campus de Gualtar, 4710-057 Braga, Portugal (*correspondence: teresav@dct.uminho.pt)
[2]CIPIMS - Universidad de Huelva, 21819 Palos de la Frontera, Huelva, Spain grangil@uhu.es)
[3] Departamento de Biologia e GeoBiotec, Universidade de 3810-193 Aveiro, Portugal

In mining regions the presence of water reservoirs affected by AMD is a common problem. This study is part of a project that characterizes the water dams in the Spanish Iberian Pyrite Belt, in order to achieve a classification based on the effects by AMD. This preliminary work presents data from four selected dams: mining dams (Gossan and Águas Ácidas), for industrial use (Sancho), and for human supply (Andévalo). The main objectives are: i) to describe the water and sediment properties; ii) to characterize diatom communities, and iii) to find possible relations between diatoms and the degree of AMD. Chemical composition of water and sediments was determined by AAS and ICP-MS. XRD was performed for mineralogy (bulk and clay fractions). Diatoms were sampled from sediments. Identification and quantification were performed in slides mounted with Naphrax® . Results indicate that the four dams are subject to the effect of metallic loads from polluted rivers, although with different levels: Águas Ácidas>Gossan>Sancho>Andévalo. In accordance, diatom communities have differences in composition and dominant diatom taxa. *Pinnularia acidophila* and *P. aljustrelica* were found dominant in the most acidic dams (Gossan and Águas Ácidas), *Pinnularia subcapitata* was dominant in Sancho and *Eunotia exigua* in Andévalo.

Zirconology of UHP-ultramafic rocks and eclogites from the Maksyutovo complex (South Urals, Russia)

P.M. VALIZER*[1], A.A. KRASNOBAEV[2], A.I. RUSIN[2] AND E.V. MEDVEDEVA[1]

[1] Ilmeny State Reserve UB RAS, Miass, Russia (*correspondence: valizer@ilmeny.ac.ru)
[2]Institute of Geology and Geochemistry UB RAS, Yekaterinburg, Russia

The U-Pb SHRIMP age of zircons was specified for the UHP-ultramafic rocks (Fo+En+Mgs+Ti-Chu) and jadeite eclogites (Jd+Grs-Alm+Rt±Ph) from the Maksyutovo eclogite-glaucophane schist complex.

The zircon age comprise a range of more than 2 Ga. The most ancient age of 2350±35 Ma corresponds to the primary mantle protolith. The ages of 1644±10, 1492±16 and 1294±64 Ma characterize the different stages of evolution of this mantle protolithe.

The Lower Cambrian age of the most crystals from ultramafic rock and eclogite is similar (545.3±5.8 Ma [1] and 533±4.6, respectively). The validity of this age is confirmed by variations of U (113–332 ppm) and Th (41–281 ppm) contents and U/Th ratio (0.43–0.92) that corresponds to the age of the UHP-metamorphism (P ≥ 4.4 GPa, T ≥ 700 °C). The ultramafic rocks and jadeite eclogites represent the UHP metamorphouzed tectonic mantle-crustal blocks in quarzite-shists of the first unit of the complex.

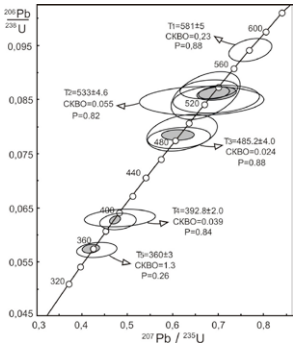

Fig.1 The U-Pb age of zircons from jadeite eclogite.

The Late Devonian (365.3±4.2–360±3 Ma) is the next important stage in the evolution of zircons and rocks. This zircon group is significantly distinct in U content and are characterized by typically magmatic U and Th distribution, which may be interpreted as an index of the progressive stage of HP-metamorphism (P ≥ 1.1–2.2 GPa, T ≥ 450–550 °C). This stage of HP-metamorphism is manifested in all rock associations from the first unit of this complex.

The Early Permian last stage (284.9±7.3 Ma), recording the final transformations of previous generations and appearance of newly formed zircon, was caused by the late shear deformations.

[4]St Olaf College, Northfield, USA.

The Northeast Greenland Ice Stream (NEGIS) is a fast-flowing outlet stream approximately 1000 km in length, with 4 main glaciers terminating in the Greenland Sea. Radar and seismic surveys were conducted in summer 2012, as well as the drilling of a 70 m firn core at the NEGIS site (75 37.61 N, 35 56.49W). DiElectric Profiling (DEP) analysis was conducted in the field, while density and Electrical Conductivity Measurements (ECM) were conducted after the NEGIS core was transported to Copenhagen for analysis. DEP and ECM measurements were consistent and allowed the identification of several volcanic strata commonly found in Greenland shallow cores. Stable water isotopes have been determined, and allow an evaluation of past variability in deposition and temperature at the site. Continuous Flow Analysis (CFA) measurements comprised of dust particle concentrations, electrolytic conductivity, sodium and ammonium concentrations. Annual cycles were observed for all parameters, allowing the establishment of a seasonally resolved chronology covering the past 400 years.

Local-Electrode Atom Probe (LEAP) tomography can identify and determine the position (±0.2nm) of individual atoms in minerals. These data allow 3-D observations at an unprecedented scale, including new insights on thermal history, radiation damage and element mobility in zircon. "Needles" were milled by FIB (~150nm dia. x ~1μm) and analysed by LEAP from the 4374 Ma core of a zircon from the Jack Hills, WA that has a 3400 Ma magmatic rim. In 3-D, Pb & YREE are co-localized and concentrated in ~5nm clusters, spaced ~20-50nm apart. The $^{207}Pb/^{206}Pb$ ratios (7/6) by LEAP average: 1.23±0.11 inside clusters, 0.32±0.10 outside clusters, and 0.52±0.08 for the full volume of 2 needles (0.04μm^3, 6 x10^8 ions detected). Significant ^{204}Pb is not detected. U appears homogeneously distributed. Thus Pb in clusters is radiogenic and unsupported by U. LEAP data for other zircons (Valley *et al*. 2012 AGU) suggest that Pb &YREE were concentrated in clusters by diffusion into nanodomains of α-recoil damage. Diffusion distances of ~20nm for these elements in crystalline zircon require temperatures >700ºC. In the 4374 Ma zircon, 7/6 by SIMS is 0.5476 in the core and 0.2912 in the rim (3400 Ma) in agreement with LEAP. A model age for LEAP 7/6 =1.23 in clusters would be older than Earth; however, diffusion during magmatic heating at 3400 Ma (rim age) could produce unsupported Pb clusters with $(7/6)_{3400Ma}$ of 1.20. Thus, LEAP uniquely explains closed system behavior at the 20-μm-scale of SIMS while documenting Pb mobility at nm-scale. These results refute challenges (based on Pb mobility) to the accuracy of SIMS analyses of age for zircons with similar history and confirm the existence of a population of ~4.4 Ga zircons from the early Earth.

Rhenium-osmium dating of Mississippi-Valley-Type ore deposits: The Robb Lake Pb-Zn deposit, British Columbia

D. VAN ACKEN[1,2], D. HNATYSHIN[1], S. PARADIS[3], AND R.A.CREASER[1]

[1] University of Alberta, Edmonton, Canada (dh10@ualberta.ca, rcreaser@ualberta.ca)
[2] Universität Bonn, Bonn, Germany (vanacken@uni-bonn.de)
[3] Geological Survey of Canada, Sidney, Canada (Suzanne.Paradis@NRCan-RNCan.gc.ca)

Mississippi-Valley-Type (MVT) ore deposits are formed by fluid flow in sedimentary basins and comprise a large portion of global Pb-Zn resources. Dating the formation of MVT deposits has been attempted by dating their host rocks (Sm-Nd, U-Pb), paleomagnetic measurements or Rb-Sr dating of sphalerite, but all of these methods and results remain inconclusive and controversial to some degree. Pyrite as a major phase in MVT deposits can be dated directly using the long-lived Re-Os isotope system, which has been established to date sulfide formation.

The Robb Lake Pb-Zn deposit in northeastern B.C. is hosted by Silurian-Devonian platform carbonates, and forms part of a sequence of MVT deposits in the northern Rocky Mountains. The timing of its formation is still subject to controversy as two groups of ages are commonly cited. On the one hand, sulfide-forming fluid flow is considered to be associated with the Late Devonian - Early Carboniferous Antler orogeny, based on Rb-Sr studies, fluid inclusion composition, stable isotope data, and ages from other western Canadian MVT deposits along the Presqu'ile Barrier (Pine Point, NWT, [1]). On the other hand, Laramide (~65 Ma) ages have been suggested based on numerical modeling of regional fluid flow and paleomagnetism [2].

The Re-Os systematics of pyrite from Robb Lake are quite complex with substantial Re-Os being contained in both the pyrite and the associated dolomite breccia. Leaching of the dolomite using HCl allows for a more reliable age to be calculated from pyrite. A Re-Os isochron for this leached pyrite yields an age of 331 ± 40 (MSWD = 151). Identifying and removing data points that likely still have dolomite contamination produces an age of 351 ± 35 (MSWD = 18). The Re-Os data, although complex, confirm a Carboniferous age for sulfide formation associated with the Antler Orogeny.

Study of the natural iron fertilization off Crozet and Kerguelen Islands (Southern Ocean) using radium isotopes as tracers

PIETER VAN BEEK[1,*], VIRGINIE SANIAL[1], BRUNO LANSARD[1], MARC SOUHAUT[1], ELODIE KESTENARE[1], FRANCESCO D'OVIDIO[2], MENG ZHOU[3] AND STÉPHANE BLAIN[4]

[3]University of Massachusetts, Boston, USA
[4]LOMIC (CNRS/UPMC), Banyuls-sur-Mer, France

The Southern Ocean is known as the largest High-Nutrient, Low-Chlorophyll (HNLC) region of the global ocean. Phytoplankton blooms, however, take place annually off islands and associated plateaus that constitute physical barriers for the Antarctic Circumpolar Current. These phytoplankton blooms were shown to be sustained by natural iron fertilization associated with these topographic features. In the framework of the KEOPS-2 project, we used radium isotopes (Ra) as tracers of iron sources that fuel the phytoplankton blooms around Crozet and Kerguelen Islands, following previous works by [*Charette et al.* , 2007] and [*van Beek et al.* , 2008], respectively. In this work, we report one of the few studies that analyzed all four radium isotopes (^{224}Ra, ^{223}Ra, ^{228}Ra, ^{226}Ra) in Southern Ocean waters. Ra isotopes were used i) to trace the input of iron - and other micronutrients - released by the sediments deposited onto the margins and that sustain phytoplankton blooms, ii) to investigate the pathways of the waters that fuel the phytoplankton bloom north of Crozet Islands and east of Kerguelen Island, and iii) to estimate "apparent ages" for offshore waters. When combined to physical observations and modeling, information provided by our geochemical tracers allows us to assess the rates and timescales of the exchange between the islands and offshore waters and to give information on the origin and mechanism of iron fertilization in these areas.

Ocean ridge magma generation rates at slow-spreading ridges favour Hess-type oceanic crust

PETER VAN CALSTEREN[1]* BRAMLEY MURTON[2] AND ROGER SEARLE[3]

[1] Earth Sciences, The Open University, Milton Keynes MK7 6AA, UK, p.v.calsteren@open.ac.uk
[2] National Oceanography Centre, Southampton SO14 3ZH, UK, bramley.murton@noc.soton.ac.uk
[3] Department of Earth Sciences, Durham University, Durham DH1 3LE, UK, r.c.searle@durham.ac.uk

The widely accepted model for the structure and composition of oceanic crust is based on the 'Steinmann Trinity' or Penrose ophiolite stratigraphy. This has an oceanic crust of mafic rocks: basalt pillow lavas with their feeder dykes (sheeted dyke complex) and gabbro plutons, underlain by the ultramafic, peridotite mantle. However, recent work on slow-spreading ridge systems has revealed significant deviations from this simple layered structure[1,2,3].

The thickness of the oceanic crust is derived from geophysical data interpretations assuming that the crust is wholly mafic but a melange of partly serpentinised mantle peridotite and mafic rocks can equally fit the data. If it is accepted that the crust is not completely mafic, then constraints on the amount of generated mafic magma have to be derived elsewhere. The amount of generated magma is determined by the melt generation rate and time, and by the volume of the melt zone.

We have derived melt generation rates for peridotite melting in the garnet stability zone between depths of the solidus at130Km and 95Km by modelling our U-series data for basaltic glass samples collected by ROV from the Mid Atlantic Ridge slow-spreading centre at 45ºN. Our results can be expanded with published results from thermodynamic modelling to estimate total decompression melt generation. We assume that the volume of the melt zone is given by the width of the active volcanicity in the median valley and the depth to the solidus, with 1Km along strike as the distance over which volcanic and tectonic characteristics can be considered as representative. We argue that in an area of tectonic extension, magma ascends vertically and is not focussed.

The our derived magma flux at 'normal' slow-spreading ridge segments, contributes <50% of the volume of crust, the remainder probably is serpentinised mantle peridotite. These inferences are agreement with the 'Hess' model for oceanic crust.

Soil Respiration – A Wetlands Perspective

PHILIPPE VAN CAPPELLEN

Ecohydrology Research Group, University of Waterloo, Waterloo, Canada (correspondence: pvc@uwaterloo.ca)

Wetlands are an essential part of the Earth's life support system. They provide a wide range of ecosystem services, from food production, via flood protection to pollution abatement. In many parts of the world, however, mounting anthropogenic pressures, for example, water diversion, encroachment, salinization and climate change, are threatening wetlands. Because of their significance, as well as their vulnerability, wetlands are the only class of ecosystems with an international convention dedicated to their protection and sustainable use (the Ramsar Convention). In this presentation I will focus on the biogeochemical functions of wetland soils. As soil biogeochemistry is largely driven by the decomposition of plant-derived organic matter by microorganisms, I will review a number of the physical, biological and geochemical factors that control the turnover of organic matter in wetland soils. Besides the nature of the organic matter itself, key controlling factors include the soil pore network, soil aggregation, water saturation, redox conditions, temperature, and the microbial community structure. I will further discuss the importance of bioenergetic limitations on soil respiration processes. To conclude the presentation, I will highlight a number of areas where I believe geochemists can provide new and timely insights, for example on the effects of redox fluctuations and freeze–thaw cycles on soil organic matter decomposition.

Where Groundwater Meets Surface Water

PHILIPPE VAN CAPPELLEN

Ecohydrology Research Group, University of Waterloo, Waterloo, Canada (correspondence: pvc@uwaterloo.ca)

Biogeochemical processes at transitions between groundwater and surface waters play a major role in the regional biogeochemical cycles of carbon, nutrients and trace elements. These interfaces occur along the entire aquatic continuum, from headwaters to the coastal zone, and include flood plains, seepage areas, riparian soils and the hyporheic zone. However, while the biogeochemical significance of groundwater–surface water interfaces (GSWIs) is generally recognized, the underlying mechanisms and determining properties have yet to be fully unravelled. GSWIs exhibit unique hydrological, geochemical and ecological characteristics, including variable hydraulic gradients, complex flow dynamics, fluctuating redox conditions and diverse, multifunctional biological communities. In this presentation, I will highlight the biogeochemical functions of GSWIs, with a particular emphasis on the biogeochemical implications of the dynamic redox conditions that characterize many GSWI environments. The key take-home message of the presentation is that observations made under stable, "average" environmental conditions may not be sufficient to predict the fate of nutrients and contaminants at GSWIs. Stated otherwise, rate measurements, chemical speciation, microbial abundance, biodiversity, and other experimental data should be obtained under the dynamic conditions representative of GSWIs, both in the laboratory and in the field.

The oceanic cycles of the transition metals and their isotopes

D. VANCE[1]*, V. CAMERON[2], S.H. LITTLE[1,2] AND C. ARCHER[1]

[1]Institute of Geochemistry and Petrology, Department of Earth Sciences, ETH Zürich, Switzerland *Correspondence: derek.vance@erdw.ethz.ch)
[2]School of Earth Sciences, University of Bristol, UK (glxvc@bristol.ac.uk)

The transition metals show variable behaviour in the oceans, from the conservative but redox-dependent behaviour of Mo, through control by scavenging for Cu, to clearly biologically cycled elements like Ni and Zn. Thus, the abundances of these elements in ocean sediments have been used to understand temporal variability in a variety of key parameters for ocean biogeochemistry. Their isotopic systems are also often now available for study, but much remains to be done to understand the important processes fractionating the isotope systems. Here we assess their oceanic mass balance from an elemental and isotopic perspective.

A common feature of all the elements considered here (Mo, Zn, Cu, Ni) is the fact that the dissolved riverine input to the oceans is isotopically heavier than the continental crust, requiring isotopic fractionation during weathering and riverine transport. Moreover, the oceanic dissolved pool is, in all cases, heavier still. For example, the dissolved phase in rivers has δ^{60}Ni ~0.8‰, versus silicate rocks at around +0.1 to +0.2 ‰. The dissolved pool in the oceans has δ^{60}Ni = +1.44±0.15‰. Such isotopic data, for Ni and other metals, impose significant constraints on the marine budgets of these elements. There must, for example, be at least one isotopically light sink that renders seawater heavy.

Our approach to elemental mass balance has been to couple the size of the better-known Mo sinks with their metal/Mo ratios. For Cu and Zn the total known outputs are of the same order as, but slightly smaller than, the dissolved riverine input. However, the same approach with Ni highlights a major problem: the output of Ni to Fe-Mn oxides (isotopically close to seawater [1]) is close to an order of magnitude greater than the dissolved riverine input, a finding that is also made for Mn. This imbalance requires a large input for these two elements that is not significant for Mo. One possibility, given the high Ni/Mo and Mn/Mo ratios of riverine suspended load, is that both these elements are mobilised by reduction of oxide coatings in anoxic sediments in estuaries. But either these coatings are isotopically heavy or such a proposal would make simultaneous balancing of the oceanic elemental and isotopic mass budgets impossible.

The onset of widespread Antarctic glaciation across the Eocene-Oligocene transition (~34 Ma) marks one of the most fundamental climate shifts in recent Earth history representing a major step from the greenhouse world of the Cretaceous and early Cenozoic to the icehouse world of today. State-of-the-art climate models suggest that ice expansion initiated at high elevation nucleation points in response to declining atmospheric carbon dioxide concentrations. While marine oxygen isotope records indicate a very rapid ice growth across the Eocene-Oligocene transition, models differ as to which parts of the continent were actually ice covered during the first extensive pulse of glaciation. Such knowledge however may be crucial for understanding important carbon cycle feedbacks in the Southern Ocean.

Here we investigate the geochemical fingerprint of early Oligocene ice-rafted debris (IRD) layers at two locations off East Antarctica: ODP Site 738 (Kerguelen Plateau) and IODP Site U1356 (Adélie Coast). ^{40}Ar/^{39}Ar ages of ice-rafted hornblende grains (>150 μm) reveal the tectono-metamorphic age of the grains, and hence provide a way to constrain spatial distribution of the initial ice surges. The first peak of IRD on the Kerguelen Plateau is well characterised and shows a clear Pan-African provenance, with ^{40}Ar/^{39}Ar hornblende ages of ~520 Ma, pointing to an origin from the nearby Prydz Bay sector. In contrast, one of the first prominent Oligocene IRD layers offshore the Adélie Coast reveals ^{40}Ar/^{39}Ar hornblende ages of ~1500 Ma. Such ages indicate provenance from the local Mertz Shear Zone. We will discuss details of our new data set in the context of model results on initial ice expansion and potential Southern Ocean feedbacks.

Novel method to reconstruct paleopressure: a combined clumped isotope and fluid inclusion technique

V. VANDEGINSTE[1] AND CÉDRIC JOHN[1]

[1]Department of Earth Science and Egineering and Qatar Carbonate and Carbon Storage Research Centre, Imperial College London SW7 2BP, United Kingdom

Reconstructing the pressure conditions under which diagenetic minerals were precipitated in subsurface can not only enhance our understanding about the burial and diagenetic history of studied rocks, but also bring insight into fundamental processes of mineral precipitation. This novel method is thus relevant for both industrial applications, such as reservoir characterization, as for fundamental research.

We have investigated several carbonate samples from Spain and Oman using both the clumped isotope and the fluid inclusion methods. Clumped isotopes can be used as a paleothermometer, providing a temperature of precipitation of a mineral independent of the stable oxygen isotopic composition of the parent fluid. Hence, both temperature and the stable oxygen isotopic composition of the fluid from which the mineral precipitated are extracted from clumped isotope analysis. The fluid inclusion technique, which is a common technique that has been used for decades, also provides an estimate of the precipitation temperature of a mineral, in addition to information on fluid chemistry and salinity. The estimation of the precipitation temperature of a mineral in this method is based on the temperature of homogenization during cooling-heating experiments. This homogenization temperature is measured at the equilibrium stage between the fluid and the gas bubble. However, at the time of trapping, usually a homogeneous fluid is trapped (and this is a requisite for deriving reliable homogenization temperatures) and a difference between the homogenization and the trapping temperature is expected because of the pressure at trapping conditions and the compressibility of the fluid. Isochores that can be reconstructed based on the density of the fluids, derived from fluid inclusion measurements, can then be combined with the independent temperature data from clumped isotopes, so that both the temperature and pressure conditions during precipitation of the analysed mineral can be reconstructed.

The proposed novel method can thus bring insight into a range of applications, such as prediction of overpressure conditions in the subsurface, fracturing processes, degassing upon pressure drop.

This study is funded jointly by Qatar Petroleum, Shell and the Qatar Science and Technology Park.

Combined Lu-Hf and Sm-Nd garnet-geochronology of lower crustal rocks from Val Strona, Ivrea Zone, Italy

J. VAN DE LÖCHT[1], M. SCHÜNGEL[1], R. KLEINSCHRODT[1], C. MÜNKER[1], M. KIRCHENBAUR[1,2] AND R.O.C. FONSECA 2[123]

[1] Institut für Geologie und Mineralogie, Universität zu Köln, Germany; loechtj@uni-koeln.de

[2] Steinmann-Institut, Universität Bonn, Germany

The Ivrea Zone (IZ, N-Italy) is a key locality to study metamorphic processes in the lower and middle continental crust. The Val Strona section of the IZ is particularly suited to study the timing of metamorphic processes along an increasing temperature gradient, comprising a continuous assemblage of granulite to amphibolite facies rocks. Therefore, three metapelites and one metabasite from the Val Strona section were examined in a combined Lu-Hf and Sm-Nd study, covering both amphibolite-facies and granulite-facies conditions. The samples were also investigated in terms of their petrology and geochemistry, in order to reconstruct the P-T-t path of the IZ rocks. In particular, representative garnets were investigated via electron microprobe (EMP) and LA-ICP-MS, determining their distribution patterns of major and some trace elements (REE, HFSE).

The EMP and LA-ICP-MS profiles in all investigated garnets lack any prograde zonation for 2+ elements (e.g. Mn) and Sm-Nd, whereas for Lu-Hf some growth patterns are preserved. The Lu-Hf ages obtained for the amphibolite-facies metapelites therefore presumably reflect garnet growth (278 ± 3 Ma; MSWD 2.3 and 279 ± 0.9 Ma; MSWD: 0.31). In contrast, the younger Lu-Hf ages obtained for the granulite-facies metapelite (263 ± 0.5 Ma; MSWD 0.9) and for the metabasite (249.6 ± 1.3 Ma; MSWD 2.0) are interpreted to represent cooling ages and document later cooling of the deeper crustal section. All Sm-Nd ages obtained in our study are about 30 Myrs younger than the respective Lu-Hf ages. Hence, the Sm-Nd ages likely represent cooling ages and may indicate retrograde diffusion-controlled re-equilibration processes. In conclusion, the results of this study point to a polyphase metamorphic evolution of the Val Strona section.

Correlation between crystallization patterns and diurnal growth bands in Scleractinian corals

RENÉE VAN DE LOCHT[1]*, ANDREAS VERCH[1], MARTIN SAUNDERS[2], KARINA SAND[3] AND ROLAND KRÖGER[1]

[1]University of York, Heslington, York, YO10 5DD, UK (*correspondence: rvdl500@york.ac.uk)
[2]CMCA (UWA), Perth, Western Australia 6009, Australia
[3]University of Copenhagen, DK-1165 Copenhagen, Denmark

Diurnal growth bands are characteristic features of many scleractinian corals [1, 2] and are thought to be linked to the microstructure of the usually aragonite based mineral forming the coral skeleton. To shed light on this correlation we employed focused ion beam to create large (10 x 30 μm) thin lamellae for transmission electron microscopy enabling the detailed study of crystal morphology and orientation in spherulites of *Porites lobata*.

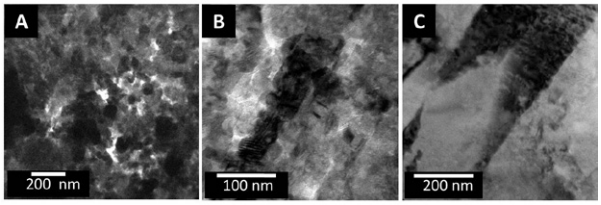

Figure 1: A) Randomly oriented nanocrystals with high porosity. B) Partly oriented nanocrystals with high porosity. C) Large acicular crystals orientated along the [0 0 1] direction (using the Pmcn spacegroup notation).

The investigations show a remarkable sequence of crystal morphology of randomly oriented, partly aligned nanocrystals and acicular crystals (fig 1). Selected area diffraction data shows that the morphology of the partly aligned nanocrystals is polycrystalline at the micrometer scale and no evidence for a non-classical growth mechanism (e.g. self assembly of small units; mesocrystal growth [3]) was found. The overall microstructural sequence is correlated with the observed optical contrast bands associated with a diurnal growth cycle. This is supported by TEM analysis of nanocrystal growth within aragonite needle-like bundels precipitated, using $CaCO_3$ solutions with organics additives.

Experimental Investigation into the Density, Compressibility, and Phase Equilibria of the Northern Volcanic Plains on Mercury

KATHLEEN E. VANDER KAADEN*, FRANCIS M. MCCUBBIN AND CARL B. AGEE[1]

[1]Institute of Meteoritics, 1 University of New Mexico, MSC03-2050, Albuquerque, NM 87131, (kvander@unm.edu)

Knowledge of the density, compressibility, and other physical properties of magmas at high pressure is required in order to understand the differentiation of planetary interiors and secondary crust formation. With the recent estimates of Mercury's surface composition from the X-ray spectrometer and Gamma ray spectrometer onboard the Mercury Surface, Space Environment, GEochemistry and Ranging (MESSENGER) spacecraft, we now have our first opportunity to investigate the physical properties of magmas from the planet Mercury **[1-3].**

The Northern Volcanic Plains on Mercury (NVP) represent, to our knowledge, the most likely example of magmatic liquids that can be compositionally assessed from orbit with relatively high spatial resolution **[1-2].** Although these NVP lavas may not represent primary, unfractionated partial melts of the mercurian mantle, they represent our best candidate to experimentally study magmas from the mercurian interior. Our goal is to determine the density and compressibility for a NVP composition using sink/float experiments in order to assess its eruptability onto the surface of Mercury.

We report the sinking of Fo_{100} spheres at 2.5 GPa, 3.5 GPa, and 5 GPa and temperatures of 1973 K, 2048 K, and 2223 K, respectively. We also report the floating of Fo_{100} spheres at 6 Gpa and 2323 K. With these results we can place tight constraints on the compressibility of this melt at 0.08 g/cm^3/GPa. This is slightly more compressible than a komatiite (0.075 g/cm^3/Gpa) or peridotite (0.065 g/cm^3/Gpa) melt. Phase equilibria experiments are currently underway to determine a possible depth of origin for this melt. However, given its current density curve, the NVP composition is able to erupt at all pressures relevant to Mercury's mantle as a result of buoyancy alone.

Triple oxygen isotope composition of photosynthetic oxygen and dissolved oxygen at saturation

A.E. VAN DER MEER AND J. KAISER

Centre of Ocean and Atmospheric Sciences (COAS), School of Environmental Sciences, University of East Anglia, Norwich, United Kingdom

The measurement of biological production rates is essential for our understanding how marine ecosystems are sustained and how much CO_2 is taken up through aquatic photosynthesis. Traditional techniques to measure marine production are laborious and subject to systematic errors. A new biogeochemical approach based on triple oxygen isotope measurements in dissolved oxygen (O_2) has been developed over the last few years, which allows the derivation of gross productivity integrated over the depth of the mixed layer and the time-scale of O_2 gas exchange [1]. This approach exploits the relative $^{17}O/^{16}O$ and $^{18}O/^{16}O$ isotope ratio differences of dissolved O_2 compared to atmospheric O_2 to work out the rate of biological production. Two parameters are key for this calculation: the isotopic composition of dissolved O_2 in equilibrium with air and the isotopic composition of photosynthetic oxygen. Recently, a controversy has emerged in the literature over these parameters [2] and one of the goals of this research is to provide additional data to resolve this controversy. In order to obtain more information on the isotopic signature of biological oxygen, laboratory experiments will be conducted to determine the isotopic composition of oxygen produced by different phytoplankton species. In addition, the isotopic composition of dissolved oxygen at saturation will be measured under different temperature and salinity conditions.

Constraints on the creation of a HIMU-like isotopic reservoir beneath New Zealand

QUINTEN H.A. VAN DER MEER[1] TOD E. WAIGHT[1] AND JAMES M. SCOTT[2]

[1]Copenhagen University, Department of Geosciences and Natural Resource Management, Øster Voldgade 10, København 1350, Denmark (quinten.vandermeer@geo.ku.dk)

[2]Department of Geology, University of Otago, Dunedin 9054, New Zealand

The New Zealand microcontinent (Zealandia) formed as the active eastern margin of Gondwana. Upon cessation of subduction at ~110 Ma, extension led to opening of the Tasman Sea at 82 Ma, preceded by the formation of metamorphic core complexes, the opening and filling of half-graben structures and the intrusion of mafic dikes (~88 to 68 Ma). Subsequently, Zealandia has been punctuated by volumetrically minor, intermittent yet widespread intraplate magmatism from ~100 Ma through to recent times. This magmatism has typical OIB-like trace element abundances and radiogenic isotope compositions that trend towards a HIMU (high time integrated U/Pb) end member mantle composition. Recent publications have argued that that the intraplate OIB-like magmatism is not related to a mantle plume but is rather formed by delamination of mantle lithosphere, replacement by asthenosphere and associated partial melting. The variably diluted HIMU signature is interpreted to be the result of mixing between depleted mantle bearing a HIMU component with an Enriched Mantle or continental crust component.

New geochemical and isotopic analyses suggest the dike swarms also have an OIB-like chemistry. Initial Pb isotopic compositions of the dikes however are more similar to Pacific MORB. It is possible that the HIMU-like component in Zealandia is a result of trace element enrichment (with high U/Pb and Th/Pb) of a depleted mantle melt region in the Cretaceous. This source has remained stable beneath Zealandia while Pb ingrowth proceeded rapidly in U-Th rich domains. Repeated melt extraction from this source resulted in the intraplate magmatism with HIMU-like Pb isotopes. Isotopic data from peridotite xenoliths in the Cenozoic intraplate volcanoes reveal that the spinel facies lithospheric mantle beneath Zealandia also has high $^{206}Pb/^{204}Pb$ ratios. Lithospheric peridotite mantle is a potential source component for the intraplate basalts, which require an additional garnet rich source component.

Biomass burning as a major source of aerosols

G.R. VAN DER WERF[1] AND B.AOUIZERATS[2]

[1]VU University Amsterdam, grvdwerf@gmail.com
[2]VU University Amsterdam, benjamin.aouizerats@vu.nl

It has been know for decades that biomass burning is a major source of aerosols, but recent advancement in satellite fire detection and biogeochemical modeling enables us better to quantify fire aerosol emissions and resulting concentrations. Here we show recent emissions estimates based on the new version 4 of the Global Fire Emissions Database version (GFED4) modeling framework and explain how climate and humans have shaped spatial and interannual variability in emissions over the past 15 years. We specifically highlight the role of fires not detected by the burned area algorithms but which can be seen in active fire data and occur often close to areas with relatively high population densities. We then focus on Indonesia which has the highest fire emissions density close to populated areas and show the relative importance of secondary aerosol formation on regional air quality.

Assimilation of hydrothermally altered crust at slow spreading ridges

F.M. VAN DER ZWAN[1]*, C.W. DEVEY[1], N. AUGUSTIN[1], A. BASAHAM[2], R.BANTAN[2], J. FIETZKE[1] AND R.R. ALMEEV[3]

[3] Institut für Mineralogy, Universität Hannover, Germany

The process of crustal assimilation at mid-ocean ridges is not always obvious as assimilant and assimilator have similar bulk compositions. Hydrothermal alteration of oceanic crust significantly increases its chlorine (Cl) content, making Cl a potentially sensitive assimilation tracer. Although at fast spreading ridges this process has previously been shown [e.g. 1, 2], the intrinsically lower, more constant Cl values (~50-200 ppm) in basalts from slow spreading ridges make the tracing of crustal assimilation more arduous there.

We performed high precision Cl measurements in basalts from 3 slowly spreading ridges: the Southern Mid Atlantic Ridge (SMAR) at 7-10 °S (~3 cm/yr), the Red Sea at 16.5-26.5 °N (max. 1.6 cm/yr) and the Gakkel Ridge at 6 °W - 85 °E (max. 1.5 cm/yr). Chlorine contents vary from 40 to 400, 700 and 1300 ppm respectively, suggesting assimilation is occurring. Generally our Cl contents are higher than for average slow spreading ridges, although the Cl concentrations are not always elevated relative to elements of similar mantle incompatibility (e.g. K, Nb).

In the Red Sea and partially in SMAR samples we see a clear relation between Cl/K (as indicator of assimilation) and the presence of hydrothermal vents sites or tectonic features associated to these. In contrast, the also hydrothermally active [3] Gakkel Ridge has much lower Cl/K values, suggesting that other factors besides hydrothermalism play a role in the visibility of assimilation. The Cl contents of trace-element-enriched magmas (higher primordial Cl) at Gakkel Ridge are less .sensitive to assimilation. In contrast, highly saline ocean water, brine pools and the presence of evaporites in the Red Sea make assimilation signals stronger there. Other influencing factors are the spreading rate and the type of rifting, i.e. volcanic or tectonically dominated. Through comparison of ridges with similar spreading rates and tectonic setting, we can examine the factors influencing the susceptibility of Cl concentrations to assimilation of altered oceanic crust.

Smart air quality policies for a better climate: a regional analysis

R. VAN DINGENEN[1]*, F. DENTENER[1], G. JANSSENS-MAENHOUT[1], M. MUNTEAN[1], Z. KLIMONT[2], AND L. HOGLUND[2]

[1]European Commission, Joint Research Centre, Institute for Environment and Sustainability, Ispra (VA), Italy (*correspondence: rita.van-dingenen@jrc.ec.europa.eu)
[2]International Institute for Applied Systems Analysis (IIASA), Laxenburg, Austria (klimont@iiasa.ac.at)

Feedbacks of climate policies on air quality (co-benefits as well as trade-offs) are now being recognized and introduced in optimization schemes for air quality policy development. However, also air quality policies can have consequences for climate. Some pollutants are contributing to warming (black carbon (BC), O_3), others are cooling (SO_4, NO_3, organic carbon). Air quality policies are commonly designed without taking into account possible feedbacks on climate, although there is a potential for smart air quality policies that lead to a win-win situation for both climate and air quality.

In this work we evaluate the local and regional benefits of a portfolio of 16 climate-friendly, region-specific air quality measures that were identified in the frame of a recent UNEP-WHO assessment [1] [2]. These measures go beyond the baseline of current legislation and provide a global potential for 0.5K temperature reduction in the coming decades. A first group of measures addresses the reduction of CH_4 emissions (with associated benefits for reduced background ozone), a second group targets BC (with additional benefits for O_3 for those sectors where NOx and NMVOC are co-emitted species). The portfolio of measures was designed in order to yield a maximal climate benefit worldwide, but the measures also generate clear local and regional air quality and crop production benefits which may help to incentivise the implementation. This local and regional aspect was not explored in the UNEP assessments.

In our analysis we apply a global source-receptor model with a relatively high regional resolution (global coverage with 56 regions) to each of the measures. As a result we provide a region-specific ranking of the most relevant measures in terms of local and regional benefits.

Chemical stabilization of soil thallium using Mn(III,IV) oxide birnessite (δ-MnO_2)

ALEŠ VANĚK[1]*, MICHAEL KOMÁREK[2] AND MARTIN MIHALJEVIČ[3]

[1]Department of Soil Science and Soil Protection, Czech University of Life Sciences Prague, Kamýcká 129, 165 21 Praha 6, Czech Republic (* vaneka@af.czu.cz)
[2]Department of Environmental Geosciences, Czech University of Life Sciences Prague, Kamýcká 129, 165 21 Praha 6, Czech Republic
[3]Institute of Geochemistry, Mineralogy and Mineral Resources, Charles University in Prague, Albertov 6, 128 43 Praha 2, Czech Republic

The effect of highly crystalline birnessite (δ-MnO_2) on Tl retention and bioavailability in contaminated soils was investigated. The stabilization/immobilization efficiency of the Mn oxide was evaluated on basis of Tl uptake by white mustard (*Sinapis alba* L.), sequential extraction and sorption experiments.

The obtained data clearly demonstrate that the application of birnessite to Tl-rich soils can effectively transform Tl from the labile (easily mobilizable) fraction to its reducible form, thus lowering Tl bioavailability and subsequent accumulation by plants. Substantial reduction of biological uptake of Tl was identified after the oxide application; the Tl levels in mustard tissues decreased by up to 50%, compared to the control treatment (non-amended soil).

The use of birnessite like soil additive might be an efficient and environment-friendly solution for soil systems contaminated with Tl. Nevertheless, further research focused on the long-term stability of the oxide in soil linked with Mn mobilization and potential toxicity for soil microbiota is needed before any general conclusion will be made.

[3]University of Amsterdam, Amsterdam, Netherlands
[4]Ghent University, Ghent, Belgium

The study of ancient glass is predominantly focused on retrieval of its chemical composition to trace the provenance of raw materials, to unravel fabrication technologies and to investigate degradation phenomena. Techniques such as laser ablation ICP-MS are frequently used for multi-elemental microanalysis of glass in spot or raster mode. This work focuses specifically on the development of laser ablation ICP-MS techniques for lateral (2D) and volume (3D) imaging of glass to enhance the information retrieval. Spatial distribution analysis offers superior insight into the colocalization of elements to elaborate and advance archaeological hypotheses.

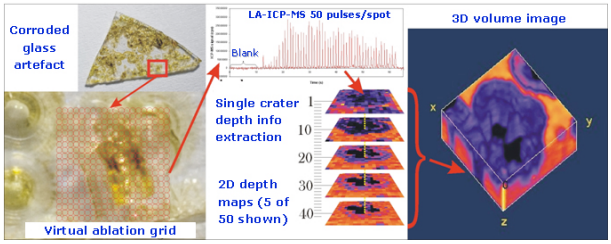

Fig. 1: 3D laser alblation ICP-MS protocol illustrated for imaging of Mg in a corrosion pit of an ancient glass artefact.

Laser ablation ICP-MS imaging techniques will be presented for 2D imaging based on rastering and quantification of the elements in the map using a so-called sum normalization technique which corrects automatically for drift and defocusing issues. Recently an innovative 3D imaging procedure was introduced based on laser drilling on a virtual grid on the surface using a burst of 50 laser pulses on each point of the grid (Fig. 1). After integration of the elemental peak areas, stacks of 50 2D depth maps with a depth resolution of 150 nm were retrieved which could be visualized as volume images. The application of the latter laser ablation ICP-MS imaging procedure will be demonstrated for the study of glass weathering mechanisms involved in the corrosion of some ancient glass artefacts.

Structure of Fe(III) precipitates formed by Fe(0) electrolysis in the presence of groundwater ions

CASE M. VAN GENUCHTEN[1], SUSAN E. AMROSE[1], ASHOK J. GADGIL[1,2] AND JASQUELIN PEÑA[3]

[1]University of California, Berkeley, USA cmvangenuchten@berkekey.edu
[2]Lawrence Berkeley National Laboratory, USA
[3]University of Lausanne, Switzerland

Oxyanions and bivalent cations influence the polymerization and precipitation of Fe(III) (oxyhydr)oxides, thus modifying the mineral structure in terms of local coordination environment of Fe, mineral phase, crystallinity, and oxyanion uptake mechanism. Few studies have investigated the interdependent effects of these ions on the formation of Fe(III) precipitates generated from Fe(II) oxidation, despite the co-occurrence of oxyanions and bivalent cations in natural waters. Such studies are essential to understand oxyanion mobility at both natural and engineered redox boundaries.

We combine wet chemical measurements and complementary synchrotron-based X-ray techniques (high energy X-ray scattering and Fe, As, and Ca K-edge X-ray absorption fine structure (EXAFS) spectroscopy) to investigate the interaction between oxyanions (PO_4^{3-}, AsO_4^{3-}, SiO_4^{4-}) and bivalent cations (Ca^{2+}, Mg^{2+}) , and their subsequent effect on the formation of Fe(III) precipitates. Fe(III) precipitates were produced by the electrolytic dissolution of an Fe(0) electrode in an electrolyte consisting of oxyanion concentrations ranging from 0.05-0.5 mM and the presence or absence of 1 mM Ca^{2+} or Mg^{2+}.

Our results suggest a systematic decrease in the strength of bivalent cation:oxyanion interaction in the order of Ca>Mg and P>As(V)>>Si. We find that 1 mM Ca^{2+} enhances the uptake of As(V) (per mass of Fe) more than 1 mM Mg^{2+}. Whereas Fe(0) electrolysis leads to 2-line ferrihydrite-like material in the presence of 0.05 mM As(V) alone (initial As/Fe = 0.1), the presence of 1mM Ca^{2+} with 0.05 mM As(V) promotes the formation of more crytsalline lepidocrocite-like material. These results are consistent with a strong Ca-As(V) interaction that can modify the extent of As(V) uptake and the resulting Fe(III) precipitate structure. Ca K-edge XAS data in the Ca:As concentration series display features consistent with second-shell As(V) scattering. No discreet As(V)-Ca surface-precipitate is observed. Our results indicate that direct Ca-As(V) interactions must be considered when assessing iron and arsenic biogeochemistry.

Use of LA-ICP-MS and MC-ICP-MS in a biomedical context

FRANK VANHAECKE[1]*, MAITE ARAMENDÍA[2], ANDREI IZMER[1], MARTÍN RESANO[2] AND LANA VAN HEGHE[1]

[1]Ghent University, Krijgslaan 281 - S12, Ghent, Belgium (*correspondence: frank.vanhaecke@ugent.be, andrei.izmer@ugent.be, lana.vanhege@ugent.be)

[2]University of Zaragoza, Pedro Cerbuna 12, Zaragoza, Spain (maiteam@unizar.es, mresano@unizar.es)

Solution nebulization ICP-MS was exploited since its commercial introduction in the 1980s for the analysis of body fluids. Also elemental speciation using a combination of a chromatographic or electrophoretic separation technique and ICP-MS as a very sensitive and element-specific detector was rapidly deployed in a biomedical context. However, for a long while, both direct analysis of solid materials using laser ablation LA-ICP-MS and isotopic analysis of metallic and metalloid elements using MC-ICP-MS largely remained the domain of geochemical applications. More recently however, also the capabilities of these approaches in a biomedical context are being discovered as will be illustrated in this presentation using applications from the UGent lab.

As a result of the laser beam dimensions (typically from < 5 to > 100 μm diameter) and the sub-μm penetration depth per shot, LA-ICP-MS is also suited for spatially resolved analysis of thin sections of entire small animals and/or selected body parts. By scanning such a section line per line, the distribution of a target element can be visualized in a map. It will be shown how this approach can be used for documenting the distribution of a Br-containing anti-tuberculosis drug across the body compartments of rat or the penetration of a Pt-containing chemotherapeutic drug in cancer tissue after intraperitoneal treatment.

MC-ICP-MS was relied on for isotopic analysis of the essential transition metals Fe, Cu and Zn in human whole blood and/or serum. The isotope ratio results obtained for a reference population were evaluated with the aim of revealing the influence of factors such as gender and feeding habits. A link between the Fe isotope ratio results and the parameters used to describe Fe status (among other, ferritin and transferrin levels) was established. Isotope ratio results obtained for blood from patient groups (e.g., hemochromatosis, anemia of chronic disease ACD, Wilson's disease) were compared to those of the reference population with the aim of investigating the potential of isotopic analysis as a diagnostic tool, capable of revealing diseases that otherwise can only be diagnosed at a later stage or via more invasive methods.

Novel particle method for modelling melt generated heterogeneity in spherical mantle convection models

HEIN VAN HECK AND J. HUW DAVIES

Cardiff University, School of Earth and Ocean Sciences, Cardiff, United Kingdom (vanheckhj@cardiff.ac.uk)

Today there are extensive geochemical databases of surface observations but they lack satisfying geodynamical explanations. Working towards this goal we implement a new way to track chemistry in the well developed mantle convection code TERRA.

The bulk composition and trace element abundance (all isotope of He, Ar, U, Th, Pb, K) are tracked via particles. One value on each particle represents bulk composition, which represents the basalt component. Chemical alteration of bulk composition and trace elements happens at self-consistent, evolving, melting zones. We use a composition dependent solidus, therefore the amount of melt generated depends on pressure, temperature and bulk composition. A novel aspect is that we do not move particles that undergo melting; instead the chemical information carried by a particle is transferred to other particles. Melt is instantaneously transported to the surface, thereby increasing the basalt component carried by the near surface particles and decreasing the basalt component in the residue. As melt arrives at the surface, a fraction of its content of trace elements is moved into separate continent/atmosphere reservoirs. For trace elements in the continent, delayed return to the top of the mantle, simulates erosion and recycling back into the mantle.

Results of our implementation will show the evolution of: 1: bulk composition. 2: melt amount. 3: concentration and abundance of trace elements in the atmosphere, continent, melt and surface layer.

The impact of element speciation on apparent partition coefficients

VINCENT VAN HINSBERG[1]* BERNARD WOOD[2] ANTHONY WILLIAMS-JONES[1] AND ARTASHES MIGDISOV[1]

[1]Earth and Planetary Sciences, McGill University, Montreal, Canada. (*correspondence: hinsberg@eps.mcgill.ca)
[2]Earth Sciences, University of Oxford, United Kingdom

Liquids, including aqueous fluids and silicate melts, are strongly underrepresented in the geologic record. This is unfortunate, because fluids and melts play a disproportionately large role in the mobility and cycling of elements, as well as in the rheology of the Earth. To constrain the compositions of these liquids we commonly turn to cogenetic minerals, which are readily available in the geological record, and reconstruct liquid compositions using data on the partitioning of elements among minerals and fluids. Lattice-Strain Theory (LST) provides the reference frame for understanding the systematics of this partitioning, by linking partition coefficients to the extent of charge and/or radius mismatch of an element in the mineral lattice [1]. A large mismatch results in a low partition coefficient and vice versa. This partitioning approach has proven highly successful for silicate melts, and is equally applicable to mineral-aqueous fluid systems [2]. However, partitioning studies are generally mineral-centric and regard the liquid as a passive reservoir from which the mineral selectively incorporates elements depending on their fit. It thereby ignores the variable complexation, or speciation, of elements in melts and fluids.

We have evaluated the impact of speciation on partition coefficients by experimentally determining the trace element partitioning behaviour among minerals and fluids in aqueous solutions with varying ligands. Experimental results, complemented with data from natural systems, show that differences in speciation among the elements change apparent (i.e. measured) partition coefficients by up to 4 orders of magnitude. Speciation exerts control on partitioning by determining the concentrations of the species involved in element uptake [2]. If speciation is known, this effect can be incorporated in LST modelling by correcting concentrations for the proportion of an element present in the species relevant to element uptake.

We conclude that the liquid is not a passive reservoir in element partitioning with minerals. Speciation effects have to be accounted for to accurately reconstruct liquid compositions from minerals. However, if speciation is known, its effects can readily be accommodated in Lattice-Strain Theory.

The distribution of dissolved aluminium (Al) in the ocean is of interest because of the impact of Al on remineralisation of diatom opal and the use of surface ocean Al as a tracer for dust. The main thermocline Al concentration has been simulated reasonably well with only a dust source and scavenging as the removal process [1].

In this study the simulation is significantly improved by the addition of a sediment resuspension source (Fig. 1). This supports the idea that the most significant sources of Al to the ocean are dust deposition and sediment resuspension.

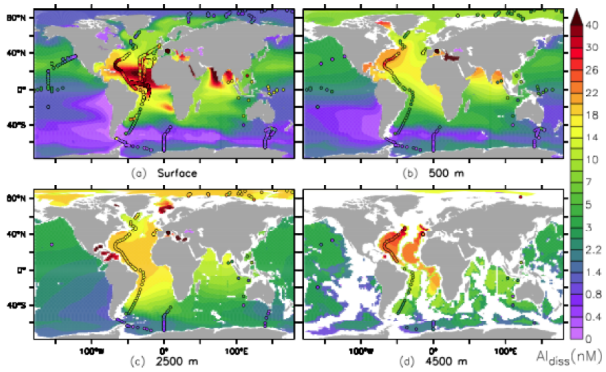

Figure 1: Modelled dissolved aluminium concentration at four depths in the world ocean. Observations as coloured dots. Both simulated and observed concentrations are in nM. Experiments with biological incorporation have been performed as well. These show that this can be an important removal process.

Fluid-rock interaction along plate boundary shear zones: insights from modern and ancient examples

VANNUCCHI P

paola.vannucchi@rhul.ac.uk

Field observations and geophysical investigations on modern and ancient plate boundaries reveal that these shear zones are several 100's to 1000's m thick. Marine geophysicists usually see this zone as a low p-wave velocity horizon that implies high fluid content. Onland, ancient plate boundaries are characterized by evidence for incorporation of unlithified, fluid-rich sediments into the fault zone. A better idealization of this dynamic system should consider rock/sediment and fluid supply to the channel, the heterogeneity of deformation, and the evolution of PT conditions as the deeper parts of the shear zones are reached. The upper and lower boundaries of this system can migrate towards the upper or lower plate, defining the main tectonic processes shaping the margin, but also influencing the processes that are responsible for earthquake nucleation, rupture and propagation. Within the shallow, <15 km deep part of the plate boundary shear zone, a gradual change of physical properties defines three subregions; zone 1 of rapid fluid dewatering, zone 2 of overpressure, and zone 3 with metamorphic fluid release. These implications are that a subduction shear zone is a dynamic feature with along-strike and downdip variations caused by changes in channel material, in trapped fluids, and in interplate boundary geometry.

Release of solid-bound phosphate during the sulfidization of lepidocrocite

K. VAN RIEL[1], T.BEHRENDS[1]*, R. T. BUSH[2] AND E. D. BURTON[2]

[1]Utrecht University, Faculty of Geosciences, NL-3508 TA Utrecht, The Netherlands (t.behrends@uu.nl)

[2]Southern Cross GeoScience, Southern Cross University, Lismore, NSW 2480, Australia

Natural ferric iron (oxyhydr)oxides often carry oxyanions such as phosphate or arsenate either adsorbed onto their surfaces or incorporated inside their structure. As a consequence, reductive dissolution of iron (oxyhydr)oxides can lead to the release of the initially solid-bound oxyanions. This link between iron reduction and the mobility and bioavailability of oxyanions is widely recognized but little is known about the kinetic coupling of oxyanion mobilization and iron reduction as well as the underlying mechanisms. Here, we investigated the release of phosphate from lepidocrocite (γ-FeOOH) during its reaction with dissolved sulfide in flow-through reactor experiments at pH values around 7.5 and 8.5. Two types of lepidocrocite were used: One containing structurally bound phosphate, and a second with only adsorbed phosphate. The release of structurally bound phosphate followed the progress of sulfidization and the rates of sulfide consumption were linearly related to the rate of phosphate release. In general, the reaction with sulfide proceeded faster at pH 7.5 than at pH 8.5 and, in turn, phosphate was mobilized faster at pH 7.5. In experiments with adsorbed phosphate, addition of sulfide to the inflow solution led to a pronounced phosphate pulse in the outflow. This quick release can be attributed to ligand exchange reactions in which dissolved sulfide replaces phosphate in surface complexes. However, not all of the adsorbed phosphate was instantaneously removed from the surface. The mobilization of the remaining adsorbed phosphate followed the progress of lepidocrocite sulfidization similar to the behavior of structurally bound phosphate. Furthermore, the fraction of instantaneously released phosphate was smaller at pH 7.5 than at pH 8.5. We propose, that these phenomena can be explained by the different reactivity of bidentate and monodentate phosphate complexes, whereas the latter are more abundant at pH 8.5. That is, phosphate in monodentate complexes readily undergoes ligand exchange with sulfide while bidentate phosphate complexes are relatively inert towards the attack by sulfide. Our results show that the pH effect on phosphate release in anoxic environments can be oppositional depending on the binding form of phosphate.

Formation of the IIE non magmatic iron meteorites

N. VAN ROOSBROEK*[,1], V. DEBAILLE[1], S. GODERIS[2], J. W. VALLEY[3], M. J. SPICUZZA[3] AND PH. CLAEYS[2]

[1] Lab. G-Time, Université Libre de Bruxelles, 1050 Brussels, Belgium (* nvroosbr@ulb.ac.be, vdebaill@ulb.ac.be)
[2] Earth System Sciences, Vrije Universiteit Brussel, 1050 Brussels, Belgium (stgoderi@vub.ac.be, phclaeys@vub.ac.be)
[3] Dept. of Geoscience, Univ. of Wisconsin-Madison, Madison, WI, 53706, USA (valley@geology.wisc.edu, spicuzza@geology.wisc.edu)

The well preserved ~450 kg fragment of the IIE non-magmatic iron (NMI) Mont Dieu II (MDII) meteorite [1] has been investigated to understand the formation of IIE NMI meteorites that are not directly related to core formation [2]. The present study focuses on the abundant large silicate inclusions of MDII, studied under SEM/EDX, and for which major and trace elements were measured by ICP-OES & ICP-MS. Oxygen isotopes were measured by laser-fluorination.

The silicate inclusions are characterized by coarse-grained granular texture, crossed by metal veins. Round structures (~ 1 mm) composed of ferromagnesian minerals are present, interpreted as relict chondrules. Three well-preserved barred olivine chondrules, a feature so far only described for Netschaëvo NMI IIE [3], and glass have been observed. Low Ca-Px, Ol and albitic Pl are the major mineral phases. FeO-rich glass (interpreted as relict from the impacted body), Chr, Tro, Schr, (chlor)Ap and Fe-Ni metal are found as minor phases. The $\Delta^{17}O$ of MDII is 0.714±0.024 ‰. The Fa and Fs molar contents of the relict chondrules are similar to those observed in H-type OC. The IIE NMI seem also related to OC based on their oxygen isotopic compositions [4], as the $\Delta^{17}O$ of MDII falls within the range defined for H 3-6 OC [4; 5].

Based on these results, an impact formation model is proposed, where a Fe-Ni impactor collided with an H-chondrite parent body. A position near the edge of the asteroid and at a shallow depth of the magma pool is favored for MDII, because fast cooling is necessary to preserve the chondrules and glass. After this first stage of fast cooling, a second phase involving slower cooling is needed to permit the development of the Windmanstätten pattern.

The composition of the lower crust of the Oman Ophiolite

J.A. VANTONGEREN[1] AND P.B. KELEMEN[2]

[1]Yale University, jill.vantongeren@yale.edu
[2]LDEO, Columbia University, peterk@ldeo.columbia.edu

Fundamental questions remain as to where, how, and to what extent chemical fractionation occurs in the oceanic lower crust and upper mantle, prior to eruption of MORB. There is no continuous drill core through oceanic crust *in situ*. Thus, to address these questions, we turn to the Oman ophiolite, where there is a continuous section from residual mantle peridotite to submarine lavas formed at an oceanic spreading ridge.

We present a detailed, stratigraphically-constrained, bulk composition for the lower crust of the Wadi Khafifah section of the Oman ophiolite. Together with sheeted dikes and lavas having trace element contents similar to MORB, the bulk crustal composition meets two fundamental criteria for a mantle-derived melt: (1) It has Mg# in equilibrium with Fo90 mantle olivine; (2) it is multiply saturated in ol+aug+opx±plag/sp at shallow mantle pressures. In addition, clinopyroxene crystallizes early, eliminating the so-called 'pyroxene paradox'. The parent magma – with major element composition indistinguishable from primitive MORB – represents an aggregate produced by polybaric decompression melting of depleted MORB mantle (DMM), which has crystallized approximately 5% olivine – probably by reactive fractionation (Collier & Kelemen, J Petrol 2010) in the crust-mantle transition zone – prior to emplacement within the crust. An additional 40-60% fractional crystallization (ol+aug+ plag) in the lower crust is required to produce the observed sheeted dike and lava compositions. Where data are available for comparison, gabbro compositions reported here are similar to analysed samples from modern fast-spreading mid-ocean ridges. Thus, our results are relevant for understanding modern fast-spreading oceanic crust.

Uranyl on Mg-rich minerals: Polarisation Dependent EXAFS

A. VAN VEELEN[1], R. COPPING[2], G.T.W. LAW[3], A.J. SMITH[1], J.R. BARGAR[4], D.K. SHUH[2] AND R.A. WOGELIUS[1]*

[1]University of Manchester, SEAES, Oxford Road, Manchester, M13 9PL, UK (*correspondence: roy.wogelius@manchester.ac.uk)
[2]Chemical Sciences Division, Lawrence Berkeley National Laboratory, MS70A1150, One Cyclotron Road, Berkeley, CA 94720, USA
[3]University of Manchester, CRR, School of Chemistry, Oxford Road, Manchester, M13 9PL, UK
[4]Stanford Synchrotron Radiation Lightsource, PO Box 4349, Stanford, CA 94309, USA

In the UK, large quantities of intermediate level waste pose complex radiological remediation challenges. Chemical understanding of uranium in these Mg-rich sludges is vital. By applying two EXAFS techniques, we determined: (1) where uranyl (UO22+) is adsorbed, and (2) how uranyl attaches to the mineral surface. Powder experiments with U(VI) were performed with magnesite [MgCO3], brucite [Mg(OH)2], nesquehonite [MgCO3·3H2O] and hydromagnesite [Mg5(CO3)4(OH)2·4H2O] Kd values for the Mg-carbonate powders were comparable to or exceeded published results for Ca-carbonates. A second set of experiments (GIXAFS) used single crystals of magnesite (10.4) and brucite (0001). Single crystals were reacted under ambient and reduced PCO2 ~ -4.5 for 48 hrs. with concentrations of U(VI)-chloride above and below the solubility of schoepite [$UO_2(OH)_2·H_2O$] (ca. 40% U(VI) adsorbed). GIXAFS measurements were made at $\chi = 0^\circ$ and $\chi = 90^\circ$ relative to the synchrotron beam polarisation. GIXAFS results clearly showed polarisation dependence for both ambient and reduced PCO_2. XANES results showed uranyl is oriented with the axial oxygens perpendicular to the mineral surface. The EXAFS structural model corrobates an uranyl-triscarbonate. This implies local rutherfordine-like [$UO_2(CO_3)_3$] regions which may polymerise at high uranyl activities into a thin film. These results are useful for predicting uranium behaviour during disposal and remediation. The development of *in-situ* measurements is currently in progress.

Mass-independent sulfur isotope signature in spherule beds of the 3.4-3.2 Ga Barberton Greenstone Belt, South Africa

M.A VAN ZUILEN[1]*, P. PHILIPPOT[1], M. WHITEHOUSE[2] AND A. LEPLAND[3]

[1]Institut de Physique du Globe de Paris, France (*correspondence: vanzuilen@ipgp.fr)
[2]Swedish Museum of Natural History, Stockholm, Sweden
[3]Norwegian Geological Survey, Trondheim, Norway

Theoretical and experimental studies have shown that atmospheric SO_2 isotopologue self-shielding effects in the 190-220 nm region of the solar spectrum are the likely cause for mass independent fractionation of sulfur isotopes (S-MIF). The main products of this photochemical reaction – SO_3 and S_0 – typically define a compositional array of ca. $\delta^{33}S = 0.6\ \delta^{34}S$. This is at odds with the generally observed trend in Archean sulfides, which broadly defines an array of $\delta^{33}S = 1.4\ \delta^{34}S$. Various explanations have been proposed, including a diminution of $\delta^{34}S$ caused by chemical and biogenic mass-dependent fractionation of sulfur isotopes (S-MDF), mixing with photolytic products produced during felsic volcanic events, or partial blocking of the low-wavelength part of the spectrum due to the presence of reduced atmospheric gases or an organic haze.

Early in Earth's history large meteorite impacts would have ejected dust and gas clouds into the atmosphere that shielded solar radiation and affected global climate. It is thus likely that at certain time intervals of high meteorite flux the atmosphere was significantly perturbed, possibly leaving anomalous sulfur isotopic signatures in the rock record. Here we describe the sulfur-MIF and -MDF signatures in sulfides of spherule beds S2, S3 and S4 of the Barberton Greenstone Belt, South Africa. In particular in spherule bed S3 – and to a lesser extent S4 – a trend of $\delta^{33}S/\delta^{34}S = 0.7$ is observed that closely follows the expected trend for SO_2-photolysis in the 190-220 nm spectral range. This suggests that an impact dust cloud (deposited as spherule beds), which sampled the higher region of the atmosphere, specifically incorporated products of SO_2 photolysis in the 190-220 nm range, and blocked photochemical reactions at higher wavelengths (250-330 nm band). By implication, the generally observed Archaean trend indeed appears to be the result of additional photochemical reactions that took place in the lower part of the atmosphere.

Geochronology of Weathering and Pedogenesis

PAULO M. VASCONCELOS[123]

[1]The University of Queensland, School of Earth Sciences, Brisbane, Qld 4072; paulo@earth.uq.edu.au

The combination of $^{40}Ar/^{39}Ar$, (U-Th)/He, and U-series dating of weathering-product and pedogenic Mn and/or Fe oxyhydroxides permits determining the chronology and rate of chemical reactions in the weathering crust. These methodologies are complementary and suitable for dating processes spanning from Recent to the earliest preserved weathering profiles on Earth. The application of these methods in weathering geochronology reveals that minerals hosted in pedoliths are invariably much younger then minerals preserved in the underlying saproliths, indicating that the pedolith has a much greater propensity to undergo mineral dissolution-reprecipitation than the remainder of the weathering profile. The greater reactivity of the pedolith appears to be controlled by organic activity, mechanical and chemical, which promotes frequent and recurrent mineral dissolution-reprecipitation. In contrast, the underlying saprolith appears to record the influx of weathering solutions during the early stages of evolution of a weathering profile. Once precipitated, saprolith minerals may remain in metastable equilibrium, sometimes for millions or tens-of-millions of years. Saprolith minerals become more prone to dissolve and reprecipitate when the pedolith front advances into the saprolith, But only during drastic changes in weathering conditions do minerals within the saprolith undergo dissolution-reprecipitation. Identifying and dating the multiple generations of supergene minerals in both the pedolith and saprolith reveal a history of weathering that is protracted and episodic, particularly in the case of deep and stratified lateritic weathering profiles. The major challenges in applying these geochronological approaches to the study of weathering and pedogenesis is the difficulty in identifying and physically sampling distinct generations of supergene minerals. This challenge is particularly accute in the pedolith.

Gas discharges for continental Spain: Geochemical and isotopic features

ORLANDO VASELLI[1,2]. BARBARA NISI[3], FRANCO TASSI[1,2], TOM DARRAH[4], JORDI BRUNO[5], JAVIER ELÍO[6], FIDEL GRANDIA[7] AND LUIS PEREZ DEL VILLAR[8]

[1]Department of Earth Sciences, Florence, Italy (*correspondence: orlando.vaselli@unifi.it)
[2]CNR-IGG, Institute of Geoscience & Earth Resources Florence, Italy
[3]CNR-IGG, Institute of Geoscience & Earth Resources Pisa, Italy
[4]Division of Earth & Ocean Sciences, Nicholas School for the Environment, Durham, USA
[5]Amphos21, Barcelona, Spain
[6]Fundación Ciudad de la Energía (CIUDEN), Ponferrada, Spain
[7]CIEMAT, Unidad de Integración de Sistemas Geologicos Madrid, Spain

In this work the results of a geochemical and isotopic survey of 37 gas discharges was carried out in continental Spain are presented and discussed. On the basis of the gas chemical composition, four different areas can be distinguished, as follows: 1) Selva-Emborda (SE) region; 2) Guadalentin Valley (GV); 3) Campo de Calatrava (CC) and 3) the inner part of Spain (IS).

The SE, GV and CC areas are characterized by CO_2-rich gases, while IS has N_2 as main gas compound. The CO_2-rich gases can be distinguished at their turn on the basis on the helium and carbon isotopic composition. The SE and CC areas have a strong mantle signature (up to 3 Ra). Nevertheless, the carbon isotopic composition of CC is within the mantle range and that of SE is slightly more negative (down to -8‰ PDB). The GV gases have a lower mantle signature (≈1 Ra) with respect to SE and CC and more negative carbon isotopes (≈-10‰ PDB). It is worth to mention that the SE, GV and CC areas are related to the youngest volcanic activity in continental Spain, for example the Garrotxa Volcanic Field in Catalonia records the latest event dated at 10,000 years, and the isotopic features, particularly those of helium, are suggesting the presence of magmatic bodies still cooling at depth. The N_2-rich gases, i.e. those from the IS area, has an atmospheric origin, as highlighted by the N_2/Ar ratio that ranges between those of air and ASW (Air Saturated Water). The isotopic composition of carbon is distinctly negative (down to -21‰ PDB) and that of helium is typically crustal (0.02-0.08 Ra), confirming that these gas discharges are related to a relatively shallow source.

The microstructural study of clay minerals - polymer matrix nanocomposites.

A.L.VASILIEV[1,2]* ANTON S.OREKHOV[1,2], ANDREY S.OREKHOV[1,2], S.N.CHVALUN[1] AND S.V.CHERDYNCEVA[1]

[1] NRC Kurchatov institute Moscow, Russia (*correspondence: a.vasiliev56@gmail.com)
[2]Institute of Crystallography RAS Moscow 119454, Russia orekhov.anton@gmail.com

Clay minerals (layered silicates) have been used as reinforcing filler for polymers. Montorillonite (MMT) has well-known 2:1 layered structure where the central octahedral alumina sheet is sandwiched by two tetrahedral silicate sheets with cations such as Na^+ or Ca^{2+}, which are present between layers to compensate the net negative charge. The lateral dimensions of MMT particles vary from tens to hundreds of nm. The interlayer cations can be replaced by organic molecules through a intercalation and further exfoliation. Two processes were crucially important: the ability of MMT particles to intercalation and exfoliation and the dispersion of the clay particles in the polymer matrix. The MMT particles, organomodified particles and 1, 3, 5 и 30 wt% MMT filled polymer (polyimide) were studied by transmission electron microscopy and microanalysis. The interplanar distance in the MMT particles deteremined from the number of high resolution images and electron diffraction pattern was found to be of c=0.99±0.01 nm. The edge type dislocation with projection of burgers vector **b=*c***[001] were observed. The interplanar distance c in the organomodified particles mostly increase to 2.2 – 2.5 nm together with the growth of dislocation density. The study of MMT-polymer nanocomposites demonstrated the enhancement of particles dispersion in the range of 1 to 5 wt% filled polymer with the growth of the exfoliated particles density. Much less exfoliation of the MMT particles were found in 30 wt% filled composite together with formation of high density of pores, observed in these TEM specimens.

The work was supported by grant N 16.253.11.306.

Phase relations of carbonate eclogite during subduction and the effect of redox conditions on diamond – carbonate reactions

PROKOPIY VASILYEV[1]*, GREGORY YAXLEY[1], JOERG HERMANN[1], HUGH O'NEILL[1] AND ANDREW BERRY[1]

[1]Research School of Earth Sciences, The Australian National University, ACT 0200, Australia (*correspondence: prokopiy.vasilyev@anu.edu.au)

High pressure experiments are critical to understanding the recycling of carbon into the deep earth during subduction processes [1,2]. Melting and phase relations of carbonate eclogites (former altered oceanic crust) and the effect of oxygen fugacity on diamond versus carbonate stability along deep subduction geotherms are currently very poorly understood.

To investigate this, a series of piston-cylinder experiments was conducted at P=3.5-6.0 GPa, and T=900-1300ºC. Starting material for the first part of the study models highly carbonated (10% $CaCO_3$) altered oceanic basalt [1]. Experiments at reduced conditions (using Fe capsules) showed the absence of crystalline carbonate and the presence of siliceous near-solidus melts. In high oxygen fugacity experiments, performed using a Re-ReO_2 buffer at 1000-1100ºC, carbon was present as carbonates at high pressure (5.5GPa) and in carbonate-silicate melt at low pressure (3.5 GPa).

The stability of carbon versus carbonate in subducting C-bearing eclogite may be defined by reaction $CaMg(CO_3)_2$ + $2SiO_2$ = $CaMgSi_2O_6$ + 2C + $2O_2$[3]. This reaction is being investigated in a second series of experiments with compositionally variable carbonate eclogites (mixes of synthetic garnet, clinopyroxene, kyanite, coesite, dolomite and Ir metal as a redox sensor) being used to determine P-T-fO_2-X phase relations. Garnet Fe^{3+} contents will be determined using the electron microprobe based flank method [4] and the synchrotron based Fe K-edge XANES method [5].

Petrology of the lamprophyres.

E. VASYUKOV A[1,2]

[1]630090, av. ak. Koptyuga, 3, Novosibirsk, Russia, lenav@inbox.ru
[2]630090, Pirogova st., 2, Novosibirsk, Russia

Chuya complex of mica lamprophyres situated in the southeast part of Gornyi Altai and extends to Mongolia. Dikes of this complex are distributed irregulary and form the belts or the areas accompanying fault zones. Lamprophyres from two largest areas, named south-chuya and yustyd respectively, were characterized in geological, petro- and geochemistry terms. Radiological characteristics give evidence of synchronic formation of the dikes from different areas. Bulk-rock analysis indicates, that the rocks are basic to intermediate, calc-alkaline and ultrapotassic. On the most petrochemical and geochemical binary plots the rocks of dykes from different areas fully or partially overlap. The multi- element and rare-earth diagrams of all investigated rocks are equal in the form, at the position of HFSE minima, have high La/Yb (17-62) and Gd/Yb (4-9,7) relations. Geochemistry characteristics allow us to suggest that all rocks were formed as a result of small degrees partial melting of garnet mantle source. However, in our studies, fundamental differences in the isotopic composition of Nd and Sr and some petrochemical features have been established. For the yustyd area rocks the initial isotopic relations are closes to BSE. And for the lamprophyres from another area εNd varies from (-2.84 - - 4.05) and $^{87}Sr/^{86}Sr>0.70858$. In our work we discuss three hypotheses forming the lateral variability in composition of the lamprophyres of the Chuya complex: 1) heterogeneity of the mantle; 2) contamination the rock forming melt by crust material; 3) liquid immiscibility, accompanied by redistribution of some major and trace elements.

The role of fluoride-silicate liquid immiscibility in REE ore genesis

O.VASYUKOVA AND A.E.WILLIAMS-JONES

Department of Earth and Planetary Sciences, McGill University, 3450 University Street Montreal, Quebec, Canada, H3A 0E8, olga.vasyukova@mcgill.ca

The Mid-Proterozoic peralkaline Strange Lake pluton (Québec-Labrador, Canada) hosts potentially economic concentrations of high field strength elements (HFSE), including the rare earth elements (REE), zirconium and niobium in zoned (Zr-rich borders and Ca-F-REE-rich cores) and unzoned pegmatites. Based on bulk rock geochemistry, mineralogy and fluid inclusion data, HFSE enrichment in the pluton has previously been interpreted to be due to extreme fractional crystallization and late hydrothermal alteration. However, recently collected melt inclusion data suggest that a third process, namely melt immiscibility, may have played an important role in the concentration of the HFSE.

Three types of melt inclusion have been identified in quartz from the Strange Lake granite after heating to 900-950 °C and quenching. Type 1 inclusions are composed of silicate glass and display enrichment in Zr, Nb and Ti with increasing alkalinity. Type 2 inclusions also contain silicate glass and, in addition, a globule of a REE-bearing calcium fluoride glass (up to 14 wt.% REE). Type 3 inclusions contain calcium fluoride glass with multiple silicate globules. Calcium fluoride glass in both Type 2 and 3 inclusions in some cases contains a REE fluoride glass globule (up to 50 wt. % REE).

We propose that fractional crystallization enriched the magma in fluorine, leading to silicate-fluoride liquid immiscibility prior to and during emplacement of the pegmatites. This caused partitioning of Zr, Nb and Ti into the silicate melt and F, Ca and REE into the fluoride melt. Further evolution of the melts occurred separately. Quartz, feldspars and arfvedsonite crystallized from the silicate melt, enriching the latter in Zr, Nb and Ti, and fluorite crystallized from the fluoride melt, enriching its residue in REE. The latter melt eventually exsolved a REE-fluoride melt.

The observed zoning of many pegmatites is interpreted to reflect crystallization of the silicate melt, including formation of zirconosilicates in the outer zone, and migration of exsolving or heterogeneously incorporated (prior exsolution) calcium fluoride melt inwards. This latter melt subsequently exsolved a REE-fluoride melt and the two melts crystallized to form the fluorite- and REE mineral-rich pegmatite cores. To our knowledge, this study provides the first example, in which silicate-fluoride liquid immiscibility has been shown to help concentrate the REE to potentially economic levels.

Volatilization of Hg from HgS minerals mediated by the coupled activity of thiosulfate and a sulfur-oxidizing bacterium

A.I. VAZQUEZ-RODRIGUEZ[1]*, T. ZHANG[2], C.H. LAMBORG[2], C.M. SANTELLI[3], S.C. BROOKS[4], AND C.M. HANSEL[2]

[3]Department of Mineral Sciences, Smithsonian Institution, Washington, DC USA

[4]Environmental Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN USA

Soils and sediments, where mercury (Hg) can exist as the Hg sulfide mineral metacinnabar (β-HgS), represent major Hg reservoirs in aquatic environments. Due to its low solubility, metacinnabar has historically been considered an insignificant source of Hg to the aqueous environment. Our previous work has shown that bacterial colonization of metacinnabar incubated in the shallow sediments of the Hg-contaminated East Fork Poplar Creek (Oak Ridge, TN) is dominated by genera known to use reduced sulfur compounds as electron donors during growth. Based on 16S rRNA pyrosequencing, *Thiobacillus thioparus*, an obligate autotrophic neutrophilic sulfur oxidizer, is among the most abundant colonizers.

Here we show that *T. thioparus* incubated aerobically in the presence of metacinnabar and thiosulfate (0.1-20 mM) results in substantial metacinnabar dissolution and release of Hg. Upon reaction, sulfate concentrations are higher than can be attributed to oxidation of thiosulfate alone, yet aqueous Hg(II) concentrations remain below detection limit. We show that in the presence of live cultures of *T. thioparus* aqueous Hg(II) released following HgS dissolution is rapidly volatilized forming Hg(0). In control incubations (media with thiosulfate and metacinnabar, and no viable cells) thiosulfate concentrations correlate with levels of dissolved Hg(II), suggesting that thiosulfate, a strong Hg-binding ligand, abiotically induces HgS dissolution. *T. thioparus* posseses genes involved in the Mer detoxification pathway, and we are currently investigating *mer* expression in this system.

These findings have important implications for environmental Hg cycling, highlighting the unappreciated potential of Hg release from assumed permanent solid-phase Hg sinks. It further introduces new pathways for solid-phase Hg to enter the global atmospheric mercury pool.

Role of deep carbides in the formation of hydrocarbons?

A VECHT[1] ANDADRIAN P JONES[1]

[1]Department of Earth Sciences, University College London, WC1E 6BT. email: aron@vecht.com,

Whether hydrocarbons in rocks are inorganic or organic in origin might be evaluated by considering carbides as precursors in the formation of deep hydrocarbons and a range of volatile compounds, since carbide may constitute >2 wt% of the Earth's core [1].

Low pressure carbides can be (a) *Interstitial* (Ti, V, Cr, Zr, Nb, Hf, Ta, W) (b) *Covalent* (B, Si): (c) *Intermediate* (Ti, V, Cr, Mn, Fe, Co,Ni): or (d) *Salt-like* (Groups I, II, and III). In the absence of high-P experimental data, groups (a) (b) and (c) should be included as candidates for carbides found in the inner core, because they are stable at high-T; they also react with water and/or oxygen to form hydrocarbons and CO or CO_2 respectively. Carbides can be described as 'reactive minerals' [2] and react with water to yield hydrocarbons. Hydrocarbon pathways from CH_4 at high-P have started to be explored [3].

Siderophile element carbides (Cr, Fe, Ni, V, Mn, Co) hydrolise with water to yield "organic matter"[4]. We propose similar reactions based on carbides of Ca and Al for the formation of methane hydrate. The reactions are expected to be of the general type: $M_xC_y + nH_2O$ where M is the metal = Hydrocarbons such as $CH_4 + M(OH)_2$. In the presence of oxygen such hydrocarbons would react to form CO and ultimately CO_2. Similar reactions could occur with nitrides, sulphides and silicides. These compounds are stable at high-T and would react with water and oxygen at lower temperatures.

Methane hydrates are common in continental shelf sediments and in deep arctic permafrost and occur at depths of around 500m [5]. Methane is found under lakes such as Lake Kivu [6]. It is generally assumed that such deposits are of biological origin. However, no explanation is given as to how complex molecules form organic deposits. Synthesis routes at high-T are well known, but we propose experiments to high-P conditions to test whether deep carbides [7] act as possible precursors in the abiotic synthesis of hydrocarbons and methane hydrates.

Nano and Bulk-Scale Characterization of Biogeochemical Processes: A Case Study

HARISH VEERAMANI[1] AND MICHAEL F. HOCHELLA, JR.[1,2]

[1] Virginia Tech, Blacksburg, VA 24061; harish@vt.edu
[2] Pacific Northwest National Laboratory

Recent advances in nanotechnology and analytic instrumentation allow biogeochemical processes between microbes, metals and minerals to be probed at remarkable levels of complexity, sensitivity, space and time. One of the dominant trends in geomicrobiology is the detailed characterization and application of biogenic minerals whose characteristic features are at the nanometer scale in at least one dimension. It is therefore important to understand – and ultimately exploit – the unique properties and behavior of a wide range of nanoscale biogenic materials. Central to this trend are the development and application of effective analytic techniques for characterizing the structural and chemical properties of biogenic minerals with (sub)nanometer spatial resolution.

Microbes in the subsurface are involved, directly or indirectly, in a plethora of activities such as metal reduction and oxidation, mineral precipitation and dissolution. These innate capacities of subsurface microbes are often exploited for *in situ* remediation of contaminated sites. During subsurface bioremediation of uranium-contaminated sites, indigenous metal and sulfate-reducing bacteria may produce biogenic minerals such as mackinawite (FeS) which could potentially drive abiotic uranium reduction.

In this work, the propensity of well-characterized biogenic mackinawite to abiotically reduce U(VI) was tested using a suite of electron microscopy and synchrotron based spectroscopy techniques. High-resolution electron microscopy confirmed the formation of nanoparticulate uraninite [UO_2] on the surface of biogenic mackinawite, which was further confirmed with bulk X-ray absorption spectroscopy that revealed the molecular coordination environment of uraninite. X-ray photoelectron spectroscopy confirms that U(IV) reduction was coupled to the oxidation of S^{2-} and not structural Fe(II) within the biogenic mackinawite. The combination of rigorous nano- and bulk-scale characterization provides insights into such biogeochemical processes, that occur during subsurface biostimulation, that are not always possible with bulk-scale analyses alone.

Unravelling complex groundwater recharge and transport of contaminants using combined stable and radioactive isotope tracers

T.W. VENNEMANN[1]*, C. REYMOND[1], A. BUFFAT[1], L. DESPOND[1], C. MOREL[1], K. NAUDE[2], J. MILLER[2] AND B. MAPANI[3]

[1]Institute of Earth Sciences, University of Lausanne, Switzerland (*contact: Torsten.Vennemann@unil.ch)
[2]Department of Geology, University of Stellenbosch, South Africa
[3]Geology Department, University of Namibia, Windhoek, Namibia

As part of a project assessing the quality and potential of groundwater, a vital resource in the extremely arid but touristic Namib-Naukluft area, a geochemical study of the surface and groundwaters, plants, soil, and rocks was undertaken. The study indicated excessive nitrate concentrations in about 15% of the 70 groundwaters sampled (several 100's of mg/l). While many of these groundwaters with high NO_3^- also have high $\delta^{15}N$ and $\delta^{18}O$ values and are from boreholes close to settlements, others are not. Furthermore, the vegetation also has elevated $\delta^{15}N$ values, making it difficult to identify anthropogenic or animal watses as contaminants. Mean residence times of groundwaters estimated by ^{14}C measurements of DIC have a wide range (recent as >100% modern carbon to about 14'000 yrs b.p.), and also a wide range of $\delta^{13}C$ values (–4.6 to –12.8‰) related to infiltration across soils of typical C3 (mountains) and C4 (savannah-desert) type of vegetation and limestone-derived soils and aquifers ($\delta^{13}C$ of –3 to +2‰). This variation, in addition to drainage across calcrete soils during brief periods of recharge necessitates substantial corrections to the measured ^{14}C ages, but which can be modelled via the concentrations and stable isotope compositions of DIC. Recharge during decadal "extreme events" is suggested by the H- and O-isotope compositions of the groundwaters with low δ-values compared to normal average annual rainfall. Seasonal variations in H- and O- isotope compositions in combination with modern mean residence times and high high nitrate $\delta^{15}N$ and $\delta^{18}O$ values thus do confirm an anthropogenic/animal-waste origin. The complex recharge of the aquifers across different soils, soil organic matter, can hence be unravelled using a combined isotopic tracing approach. In general, a slow, horizontal flow away from the principal mountain-recharge area, but also with locally important vertical recharge, particularly close to settlements and man-made boreholes, is indicated.

Isotopically light (Solar?) nitrogen associated with the planetary noble gas carrier (Q)

VERCHOVSKY A. B.[1], SEPHTON M. A.[3] AND WRIGHT I. P.[1]

[1]The Open University, Milton Keynes, UK, a.verchovsky@open.ac.uk
[3]Imperial College, London, UK

The nature of the planetary noble gas carrier (Q) has remained an intriguing cosmochemical puzzle for decades. Q can be significantly enriched by dissolving all meteoritic silicate minerals to leave behind only carbonaceous material and oxides. However, even after that, the abundance of Q in the residue is much less than 1%. This is the main reason why Q is so difficult to identify. Therefore, Q is characterised indirectly by its properties, such as its susceptibility to oxidation or its resistance to parent body metamorphism compared to macromolecular materials as well as by the noble gas components it contains. Such observations suggest that Q has been formed very early in the Solar System, or may even predate it formation.

Our analyses of a number of CR meteorites using our multi-element isotope analyser, Finesse, in combination with stepped combustion, has revealed a new property of Q – its separation from most of macromolecular carbon and nitrogen. In CR2 and CR3 petrological groups, but not in CR1s, the Q noble gases, are released in a narrow range at a high temperature (~1100ºC). It appears that Q somehow becomes isolated within the matrix from direct contact with oxygen gas during stepped combustion. Only when the matrix opens up does oxygen react with Q (oxidising it almost instantly). Since almost no macromolecular C and N remains by the time of Q oxidation, the Q nitrogen dominates the release at these temperatures. And, as such, its isotopic composition is revealed. The lowest measured $\delta^{15}N$ associated with the noble gas release at the high temperatures is -140‰. And this is only the upper limit since a certain amounts of other (isotopically heavier) N components are also present along with Q nitrogen. We believe that Q nitrogen is likely to have $\delta^{15}N$ similar to solar composition (-380‰) determined by the Genesis mission. The presence of solar N in Q is also consistent with its He isotopic composition corresponding to pre-deuterium burning era of the early Solar System.

On the importance of ternary alkaline earth carbonate complexes of uranium(VI) in natural waters: a round-robin modeling test

T. VERCOUTER[1]*, P.E. REILLER[1], E. ANSOBORLO[1], L. FEVRIER[2], R. GILBIN[2], C. LOMENECH[3] AND V. PHILIPPINI[3]

[1]CEA, Nuclear Energy Division, France, *correspondence: thomas.vercouter@cea.fr
[2]IRSN, Cadarache, France
[3]University of Nice-Sophia Antipolis, France

The availability of uranium in natural waters is governed by many processes and interactions with chemical compounds. At equilibrium the predominant soluble and solid forms of uranium can be estimated using thermodynamic data and aqueous geochemical speciation codes. The quality of calculations is mainly related to the quality and completeness of the entry data. Within the working group “Speciation” of the CETAMA a round-robin modeling exercize was conducted about the U(VI) speciation in waters of known compositions. The objectives were: i) to test thermodynamic data bases; ii) to compare the modelers’ methods in selecting data; and iii) to evaluate the effect of inorganic species on the U(VI) speciation and solubility.

A recent experimental study on the speciation of uranium in drinking waters have shown that calcium uranium carbonato complexes play an important role [1]. The modeling exercize was build on the basis of water compositions of two of these samples. Other water compositions were derived from these in order to better check U(VI) speciation changes with the bicarbonate content, the saline content and $[Ca^{2+}]$ and $[Mg^{2+}]$. The participants of this exercize were asked to provide the distribution of soluble uranium species and evaluate the uranium solubility-controlling solid phase for each water.

The main outcome is on the importance of alkaline earth carbonato ternary complexes such as $Ca_2UO_2(CO_3)_3(aq)$, $CaUO_2(CO_3)_3^{2-}$, and $MgUO_2(CO_3)_3^{2-}$. These species were reported in recent publications [2], but rarely included in available data bases. As a consequence it emphasizes the necessity of continuous enrichment of data bases with a consistent approach to avoid bias. Moreover, the amount of uranium in solution could be calculated considering various solubility-controlling phases though such estimations definitely requires the expertise of the geochemist.

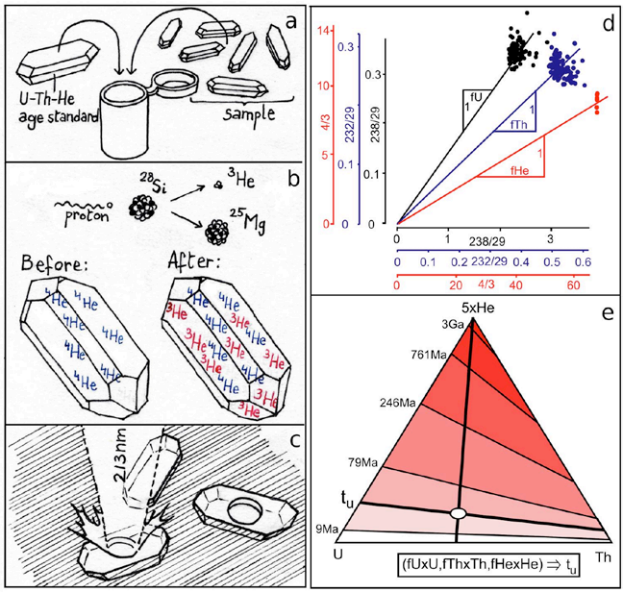
In situ U-Th-He dating by $^{4}He/^{3}He$ laser microprobe analysis

PIETER VERMEESCH AND JAMES SCHWANETHAL[1]

[1]London Geochronology Centre, University College London, p.vermeesch@ucl.ac.uk and j.schwanethal@ucl.ac.uk

We have developed a rapid, flexible and robust method for in-situ U-Th-He dating, in which (a) multiple zircons from the sample are packed together with a standard of known U-Th-He age, (b) these are proton-irradiated to produce spallogenic ^{3}He, (c) the grains are ablated with a UV laser once to measure the $^{4}He/^{3}He$ ratios on a noble gas mass spectrometer, and a second time to measure the $^{232}Th/^{29}Si$ and $^{238}U/^{29}Si$ ratios by ICP-MS. The age of the sample is calculated by comparing the measured isotope ratios of the sample to those of the standard (d), and multiplying the resulting 'scaling factors' (fU, fTh, and fHe) with the normalised (U, Th, He) composition of the standard (e), which can be calculated from the measured U/Th ratio and its age. This method removes the need to know any absolute concentrations or pit volumes and is immune to ICP-MS matrix effects and collateral laser melting.



Thermal history of a Neoproterozoic orogen and A-type leucogranites formation (Yenisey Ridge, Western margin of the Siberian Craton)

A.E. VERNIKOVSKAYA[1], V.A. VERNIKOVSKY[1,2], N.YU. MATUSHKIN[1,2], I.V. ROMANOVA[1,3], I.V. VEYALKO[1], O.P. POLYANSKY[4], YU.M. LAEVSKY[2,5] AND K.V. VORONIN[2,5]

Integrated geochemical, petrological and numerical modeling investigations allowed to understand the sequence of thermal events that took place during the formation of Neoproterozoic A-type leucogranites located in the structure of the Yenisey Ridge orogen, south-western framing of the Siberian craton (Vernikovsky *et al.* , 2011; Vernikovskaya *et al.*, 2013). Two stages of leucogranite formation were distinguished: 1) 750–720 Ma, and 2) 710–630 Ma. The early stage A-type leucogranite plutons are enriched in potassium and were emplaced (≥ 10 km) in the Central Angara terrane during the final phase of its collision with the Siberian craton. This collision was followed by the subsequent accretion of the Yenisey island arc to the Siberian craton in an active continental margin setting during 710–630 Ma. At this time the second stage leucogranite plutons were formed at a shallower emplacement depth (≥ 7 km) within the Tatarka-Ishimba suture zone that was characterized by an elevated heat flow. These leucogranites associate with carbonatites and are characterized by niobium enrichment. The thermal history of the orogen was conditioned by radiogenic heat from the intrusions and their overlapping thermal fields, as well as by elevated heat flow in the suture zone.

Pleistocene and Holocene temperature reconstructions using earthworm-produced calcite

EMMA A. A. VERSTEEGH[1]*, MARK E. HODSON[2], STUART BLACK[3] AND MATTHEW G. CANTI[4]

[1]Department of Geography and Environmental Science, University of Reading, Reading RG6 6DW, UK, e.a.versteegh@reading.ac.uk (*presenting author)

Although not widely appreciated, many earthworm species are true biomineralisers, producing calcium carbonate (predominantly calcite) granules in specialised glands [1,2]. Granule production in European soils is dominated by two earthworm species, *Lumbricus terrestris* and *L. rubellus*. By means of laboratory experiments, using a wide range of temperatures (3–20 °C) and water compositions, we have established an oxygen-isotope ($\delta^{18}O$) palaeothermometer for *L. terrestris*. Granules produced by this species are consistently enriched in ^{18}O by 1.5‰ in comparison to equilibrium [3]. Well-preserved earthworm granules are commonly found in archaeological finds and buried soils up to at least ~2 Ma old. In combination with direct U-Th series dating they offer the potential for accurate temperature reconstructions for specific Quaternary time windows.

A selection of earthworm granule samples have been analysed for $\delta^{18}O$ values and U-Th composition. The samples originate from several interglacials and interstadials (e.g. Weichselian, Hoxnian, Gelasian), as well as Holocene time intervals and well-known archaeological sites (e.g. Silbury Hill, Boxgrove). Temperature reconstructions yield credible values. They show considerable intra-sample variation, which is probably a reflection of seasonal temperature variations. In addition, clear differences can be distinguished between different time intervals. Results will be discussed in context with existing climate reconstructions. We argue that $\delta^{18}O$ values of earthworm-produced calcite granules provide a useful and reliable terrestrial proxy for palaeotemperature reconstructions.

2000 yrs of central Mediterranean change – what do proxies tell us?

G.J.M. VERSTEEGH[1]*, A. LEIDER[1], L. CHEN[1], K.A.F. ZONNEVELD[1], A.-L. GRAUEL[2], S.M. BERNASCONI[2], M.-L. GOUDEAU[3] AND G.J. DE LANGE[3]

[1] MARUM, Bremen Univ., 28334 Bremen Germany (*corrspondence: versteegh@uni-bremen.de)
[2] Geological Inst. ETH, 8092 Zurich, Switzerland (stefano.bernasconi@erdw.ethz.ch)
[3] Geosciences, Utrecht Univ. 3548CD, Netherlands (gdelange@geo.uu.nl).

The Mediterranean is extremely vulnerable to climate warming through decrease of the critical precipitation - evaporation (P-E) balance. Despite its rele-vance for society and environment, the natural dynamics of this balance and the human influence thereupon are poorly understood, especially on decadal to millennial time scales.

To increase this understanding we analysed the coastal sediments of the eastern Gulf of Taranto and the Adriatic Mud Belt. The high sedimentation rates, low bioturbation and excellent tephra, ^{14}C, ^{137}Cs and ^{210}Pb and XRF-core scanning-based regional age model allow reconstruction of terrestrial and marine dynamics with a subdecadal resolution.

We present lipid, dinoflagellate and foraminifera-based environmental reconstructions focusing on temperature, the hydrological cycle and human impact during the last two centuries, the Little Ice Age and the Roman Optimum.

The process of regional proxy calibration appeared challenging, not in the least due to having multiple proxies for the "same" environmental variable such as SST (Fig. 1), terrestrial input or productivity. This forced us to reconsider established proxy-environment relations – their accuracy and what they stand for – strongly improving them as sources of knowledge on past environmental change.

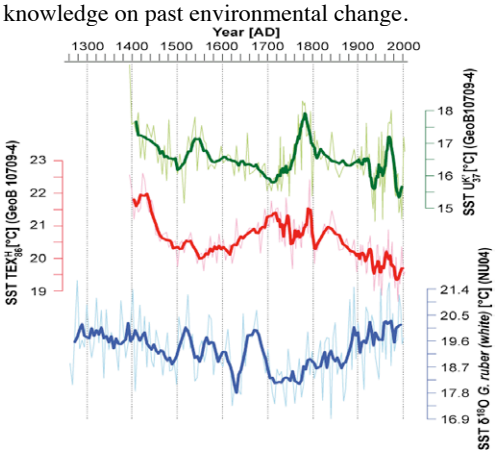

Figure 1: SST: one region, different proxies.

The myth of a highly heterogeneous Hf-Nd Eoarchean mantle and large early crustal volumes

J.D. VERVOORT[1]*, C.M. FISHER[1] AND A.I.S. KEMP[2]

[1]School of the Environment, Washington State University, Pullman, WA, 99163, USA (*correspondence: vervoort@wsu.edu)

[2]School of Earth and Environment, University of Western Australia, Perth, 6009, AUS (tony.kemp@uwa.edu.au)

One of the most fundamental and long-standing problems in Earth Sciences is the question of continental growth. Despite decades of work on this problem there is still no consensus on when the continents formed, what were the mechanisms of their formation, and how they have evolved through time. Resolution between the competing models requires insight into the earliest Earth, but the window into this critical time period is far from clear.

One reason for this uncertainty is the lack of old rocks in the geologic record. Crust older than 3.5 Ga constitutes less than 2% globally and the crust that remains is often a complicated mixture of components with different ages and isotopic compositions. Without an accurate integration of age and isotopic composition, analysis of these complicated rocks can yield meaningless information about Earth evolution.

Our solution is to integrate age and Hf isotope data from zircons of the Earth's oldest rocks. We do this using the laser ablation "split stream" technique whereby the aerosol from the zircon laser ablation is split to two mass spectrometers: one to determine U-Pb ages and the other to determine its corresponding Hf isotopic compositions. In this way we can unambiguously determine age and Hf isotopic composition on the same zircon volume.

Using this approach we find that the isotopic record for rocks older than 3.5 Ga is much less variable than has been recently claimed. Two features stand out from these data. First, there are very few samples with ε_{Hf} values significantly above zero prior to 3.5 Ga, indicating the lack of a widespread depleted mantle before 3.5 Ga. Second, while there are negative ε_{Hf} values for some ancient zircons, consistent with recycling of early-formed crust, the lack of a complementary depleted mantle reservoir from 4.4 to 3.5 Ga indicates that the volume of this early enriched (not necessarily continental) crust was modest. We conclude that widespread continental crust formation did not begin in earnest until ca. 3.5 Ga. This is consistent with both the preserved crystalline rock record and the ages of detrital zircons in the sedimentary record.

Hydrogeochemical study of the multi-aquifer system of the Sibari Plain (Calabria, Southern Italy)

G.VESPASIANO[1,✉], C.APOLLARO[1], A.BLOISE[1], G.CIANFLONE[1], R.DE ROSA[1], R.DOMINICI[1] AND L.MARINI[2]

[1]DiBEST, University of Calabria, I-87036 Arcavacata di Rende (CS), Italy (✉: giovanni.vespasiano@unical.it, apollaro@unical.it, andrea.bloise@unical.it giuseppe.cianflone@unical.it, derosa@unical.it, dominici@unical.it,)

[2] Consultant in Applied Geochemistry, I-55049, Viareggio (LU), Italy (luigimarini@appliedgeochemistry.it)

The groundwaters hosted in the Sibari Plain multi-aquifer system are heavily exploited through a large number of wells drilled for agriculture. Similar to many other coastal areas, this excessive groundwater extraction has led to intrusion of seawater. To understand the extension of this phenomenon and adopt suitable actions, a multidisciplinary approach was applied in this investigation, which is carried out in the framework of a PON project: "*Study for the environmental protection and the mitigation of anthropogenic pollution in the coastal environment of selected areas of Calabria*".

Hydrostratigraphic correlations, water level measurements, field determinations (electrical conductivity, temperature, pH) and laboratory chemical and isotopic analyses were carried out for 100 selected wells. In particular, high conductivity values, even >4 mS/cm, and high chloride contents, up to 1,200 mg/l, were measured in several groundwater samples (Figure 1). Interpretation of geochemical data is complicated by both the dissolution of Miocene evaporite deposits, which generates aqueous solutions with characteristics similar to those dictated by seawater ingression, and the occurrence of other processes, such as bacterial sulfate reduction and ion exchange [1, 2].

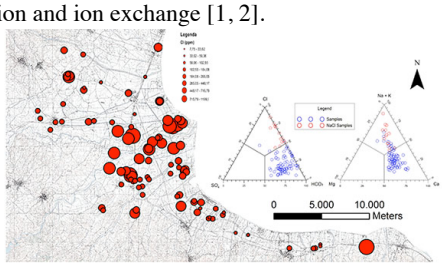

Figure 1. Map of Cl^- concentrations in the wells of the study area and triangular diagrams of major anions and cations.

The role of alkalis in the solubility of H_2O and CO_2 in silicate melts

FRANCESCO VETERE*, HARALD BEHRENS, ROMAN BOTCHARNIKOV, FRANCOIS HOLTZ AND SARA FANARA

Institute for Mineralogy, Leibniz University of Hannover, Callinstr. 3, Hannover, D-30167, Germany

Solubility experiments were performed on phonotephritic compositions in order to investigate the role of alkalies in the behavior of water and CO_2 in magmatic systems The investigated melt compositions are based on natural phonotephrite from Alban Hills (Ab1) with Na_2O/K_2O (in wt %) = 0.26. Two additional compositions with different Na_2O/K_2O ratios, Ab2 (Na_2O/K_2O=0.98) and Ab3 (Na_2O/K_2O=3.82), were synthesized. Experiments were run at 1250°C and 500 MPa in an internally heated gas pressure vessel. The proportions of water and CO_2 in the systems were systematically varied in the range from 0 to 1. For the calibration of carbon-related IR bands, the total carbon content of the synthesized standards was measured by combustion and subsequent IR spectroscopy using an ELTRA CS800 analyzer. Karl Fischer Titration method was used in order to quantify H_2O content in the melts. Absorption spectra were recorded in the mid-infrared (MIR) using a Bruker IFS88 FTIR spectrometer coupled with an IR-ScopeII microscope.

CO_2 is bound in the investigated glasses as CO_3^{2-} exclusively and its concentration was quantified by the peak height of the 1430 cm^{-1} band. A drastic change was observed in the absorption coefficients, ε, with values of 265 ± 27.2, 228 ± 22.4 L/(mol·cm) and 308 ± 26.6, for Ab1, Ab2, and Ab3, respectively, so that the highest ε value is related to the Na-rich composition. There is no detectable effect of the Na/K ratio on the concentrations of dissolved H_2O and CO_2 in the melts. The solubility of CO_2 and H_2O in those melts at 500 MPa is 1.2 wt % and 10.07 wt%, respectively. Results are compared with the existing literature data and models and confirm the very high solubility of CO_2 in phonotephritic melts [1]. Our experimental data indicate that the melt composition in terms of alkali contents influences significantly the extinction coefficient values for CO_2 and that appropriate coefficients must be selected to estimate accurately the amount of dissolved CO_2 in glasses and/or melt inclusions using IR spectroscopy.

[3]Department of Geological Sciences, Pusan National University, Busan, South Korea

*correspondance: eniko.vetlenyi@gmail.com, http://lrg.elte.hu

Primary silicate melt inclusions (SMI) in different host minerals provide a unique possibility to reconstruct the evolution path of the host magma. The 2 million years old Pohang alkaline basalt from South Korea contains such silicate melt inclusions hosted in olivine and spinel phenocrysts.

The Pohang basalt has porphyritic texture and contains forsteritic (mg#=0.84-0.88) olivine, Cr-bearing (cr#=0.15-0.24), high Mg (mg#=67.0-69.0) spinel phenocrysts and anorthite-rich plagioclase. The microphenocrystal groundmass consists of olivine, clinopyroxene, spinel, plagioclase and glass. Olivine and spinel phenocrysts have negative crystal shaped or rounded SMIs in size up to 150 microns in diameter. These magma droplets are identified in zoned clinopyroxene, Al-Mg-rich spinel, K-Na-Si-Al-rich residual glass, Ni-Fe-rich sulfide blebs and bubble(s). In addition, olivine daughter minerals occur in the spinel hosted SMIs.

Based on the results of homogenization experiments (with heating-quenching technique) and the equilibrium temperature calculated from olivine–spinel pairs, the homogenization temperatures are in the range of 1050-1240°C in the SMIs irrespectively their host minerals. The estimated oxygen fugacity values are -1.810 to -0.942 log units below the fayalite-magnetite-quartz buffer indicating SMIs entrapment from a relatively reduced magma. Based on geochemical data, it is suggested that the SMIs in both host minerals were entrapped at the very early stages of the crystallization process and it shows the same crystallization sequence: spinel, olivine, sulfide blebs, clinopyroxene, residual glass and bubbles.

The REE patterns of SMIs are flat or slightly decrease from La to Lu, with (La/Lu)N between 1.6 and 17. The low La/Y and Zr/Nb ratios suggest spinel lherzolite source rock for the Pohang basalt.

Accumulation of trace elements in the Lake Baikal biota

V.A. VETROV

Institute of Global Climate and Ecology, Glebovskaya st., Moscow, 107-150, Russia

The objective of the work was to assess accumulation of chemical elements by different hydrobionts' species and to find out a role of biota in removing trace elements from the lake water. Contents of about 30 trace elements were studied in 1979–1987 in plankton, benthos species (hammaridae, polifera, molluscs), most common food fish and in Baikal seal. The full set of AE-, AA- and NA-analytical techniques was used.

Accumulation factors (AF, the ratio of element concentration in dry tissue to that in water dry residue) for 28 metals (Na, Al, Sc, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Br, Rb, Sr, Mo, Ag, Cd, Sn, Sb, Cs, Ba, La. Ce, Hg, Pb, Th, U) and Br showed that there was no regular rise of a metal concentration in dry biomass when going from an initial producent (phytoplankton) up to ultimate consument (seal). From all 29 considered elements only Rb revealed a tendency to increasing bioavailability from lower trophic levels to upper ones. As a rule, changes in AF's for other elements do not show any certain regularity depending on trophic levels.

The following metals have highest AF: in phytoplankton (AF > 30) – Al, Fe, Pb; in zooplankton (AF > 10) – Al, Fe, Cd, Ce, Hg, Pb; in molluscs (flesh, AF > 100) - Al, Mn, Fe; in seal (flesh, liver, AF > 50) - Al, Fe, Cd. Metal accumulation in fish tissues is relatively low, AF exceeds 5 only for Al, Mn, Fe, Ce.

Estimates of metal flux rates to bottom sediments were calculated on the basis that the input of autochtonic organic matter to sediments was equal to 800.000 ton/year resulting mainly from phytoplankton annual primary produce. These flux rates should be considered as semi-quantitative major estimates which just indicate that uptake of some metals (Na, Cr,u, Zn, Sr, Ag, Cd, Sn, Sb, Hg, Pb, U) by phytoplankton can be a significant route to their removal from the waterbody to the bottom sediments.

Monitoring the stability of scale inhibitors by ATR-FTIR at high pressures and temperatures in synthetic geothermal fluids

ALEXANDRA VETTER[1] AND SIMONA REGENSPURG[1]

[1]Helmholtz Centre Potsdam, German Research Centre for Geosciences (GFZ), International Centre for Geothermal Research (ICGR), Telegrafenberg, D-14473 Potsdam, Germany

Mineral precipitation (scaling) such as sulfates, carbonates, and oxides are well known phenomena in geothermal plants. These precipitations damage plant equipement (e.g. heat exchangers) or reduce the injectivity of the reservoirs and thus the operation liftime of such installations. In this context, the use of environmental friendly inhibitors to avoid the formation of these mineral precipitations become attractive.

In this study, scale inhibitors based on ecologically harmless polycarboxylates are examined with respect to their thermal stability by attenuated total reflection - Fourier transform infrared spectroscopy (ATR-FTIR). The spectroscopical device is equipped with to a high pressure - high temperature reaction cell that allows measurements at up to 200 °C 200 bar. In this study, changes in signal intensity and band position for various inhibitors were monitored dependent on temperature and pressure. Additionally, the behavior of scale inhibitors in synthetic fluids at different ionic strenghtes (up to 5M NaCl) is evaluated as a function of temperature and pressure.

Sulfosalt melts from low-grade metamorphic terrains: The case of the Monte Arsiccio mine (Tuscany, Italy)

S. VEZZONI[1]*, M. D'ORAZIO[1], C. BIAGIONI[1], A. DINI[2] AND P. ORLANDI[1]

[1]Università di Pisa, via Santa Maria, 53, Pisa, Italy (*correspondence: vezzoni@dst.unipi.it)
[2]CNR-IGG Pisa, Via Moruzzi, 1, Pisa, Italy

Sulfosalt melts formed during amphibolite/granulite facies metamorphism of pre-existing orebodies have been well documented (e.g., [1]). However, orebodies containing significant amounts of Low Melting Point Chalcophile Elements (LMCE - Ag, As, Bi, Hg, Se, Sb, Sn, Tl, and Te), could experience sulfosalt/sulfide melting at much lower metamorphic temperatures [2]. Up to date, low temperature LMCE sulfide melts have been documented, as inclusions in quartz, only at Lengenbach, Switzerland [3].

A new interesting case study was provided by the barite-pyrite-iron oxide ore deposit from Monte Arsiccio (Apuane Alps, Tuscany, Italy). The deposit originated during a Palaeozoic-Triassic sedimentary-exhalative metallogenic event and was successively metamorphosed and remobilized during the Alpine orogeny [4] under greenschist facies conditions (P = 0.6-0.8 GPa, T = 350-450°C; [5]).

Within these orebodies we discovered an exceptional Tl-Hg-As-Sb-(Ag, Cu)-Pb sulfosalt assemblage embedded in the barite-pyrite ore and in dolostones. Mineralogy is dominated by LMCE-bearing phases, mainly represented by Tl-Hg-Sb-As sulfosalts. The textural features of these assemblages (tiny veinlets pierced along grain boundaries, drop-like internal textures, low interfacial angles between sulfosalts and matrix mineral grains) is interpreted as the result of the mobilization of low-viscosity sulfosalt melts by percolation through the barite-pyrite crystal matrix, and veining in dolostones. Experimental studies (e.g., [6]) support our hypothesis, showing that thallium-bearing polymetallic sulfide systems have liquid phase fields down to very low temperatures (in the range 200-300°C). The physical (low viscosities and high density) and chemical (up to ~20% wt of Tl) characters of the inferred sulfosalt melts suggest that LMCE melt migration can be an effective mechanism of metal mobility in low-grade metamorphic terrains. The Tl-Hg-As-Sb-(Ag,Cu)-Pb sulfosalt assemblage from Monte Arsiccio likely documents the lowest temperature natural sulfosalt melt ever described.

Magma emplacement and sulfide deposition after skarn formation at Campiglia Marittima, Tuscany

S. VEZZONI[1]*, A. DINI[2] AND S. ROCCHI[1]

[1]Università di Pisa, via Santa Maria 53, Pisa, Italy (*correspondence: vezzoni@dst.unipi.it)
[2]CNR-IGG, via Moruzzi 1, Pisa, Italy

Most economic skarn deposits are related to magmatic intrusions and a general correlation exists between the composition of igneous rocks and skarn ore type [1]. The Cu-Pb-Zn-Ag skarn deposit of Campiglia Marittima (Southern Tuscany, Italy) is the skarn deposit in which a mineralogical zoning of skarn bodies has been first described [2]. It has been considered as a classic example of exoskarn with an outward zoning sequence developed from a main axial dyke of mafic porphyry: magnetite ⇒ ilvaite ⇒ clinopyroxene ⇒ marble [3]. According to this model, the skarn deposit of Campiglia Marittima represents a key example for the understanding of the spatial and temporal evolution of a metasomatic system, from the local source of ore fluids (mafic porphyry) to the final products (skarn and sulfides).

The new field and laboratory data collected for Campiglia Marittima skarn deposit indicate that this classical model is too simplistic. Geological mapping of about 20 km of tunnels/shafts shows that: 1) mafic porphyry does not form a single axial dyke but small dykelets and pods that crosscut the skarn bodies and fill the skarn pockets; 2) the skarn bodies do not show symmetric, outward growing, mineralogical zoning, but they are formed by several metasomatic units displaying distinct mineral parageneses and growing patterns.

The later intrusion of mafic porphyry heated up the skarn bodies, inducing significant prograde back-reactions on skarn minerals: 1) ilvaite in direct contact with mafic porphyry was replaced by magnetite + hedenbergite; 2) pyrrothite, pyrite and chalcopyrite variably replaced ilvaite for several meters from the contacts; 3) hedenbergite crystals suffered overgrowth of Mg-rich rims.

Thus, a direct causality between magma emplacement, fluid release and skarn/ore formation, at a local scale, is not confirmed and must be searched at a larger, crustal scale. The magmatic source of skarn fluids is inferred to be a deeper, mafic intrusion. The shallow level of emplacement of such intrusion controlled the early exsolution of skarn fluids, and the later extraction of magmas that fed the mafic porphyry system, forming the main sulfide ores.

[3]Central Washingotn University, Dept Geol Sci, Ellensburg, WA 98929, USA
[4]Oregon State University, College Earth Ocean Atmoph Sci, Corvallis, OR 97331-5503, USA

Trace element zoning in plagioclase from the historic (pre-1971 AD) and recent (post-1971 AD) activity of Mt. Etna volcano was here used to evidence changes in the feeding system dynamics during the last 250 years. The observed textural characteristics of crystals include both near-equilibrium and disequilibrium textures [1]. The An variation along core-to-rim profiles on selected crystals with different types of textures was evaluated particularly versus the Sr/Ba ratio. At rather comparable average An contents, plagioclase crystals representative of near-equilibrium crystallization from the magma display very distinct Sr/Ba ratios through time (~6 and ~17 in historic and recent lavas respectively). Recent plagioclases also exhibit generally higher potassium contents than the historic ones at the same evolutionary degree. Although contamination due to wall-rock assimilation may have played a role, we suggest here that the features are dominated by input of a K-rich and Ba-poor end-member into the feeding system that becomes evident particularly after the 1971 AD eruption. Magma residence times, which have been calculated through Sr diffusion modeling on plagioclases, are also related to the distinct geochemical signature observed. Calculations give average residence times of ~40 years for crystals of the historic activity and of ~20 years for the post-1971 AD plagioclases. Our estimations strongly agree with geophysical data that highlight an increased E-W directed extension rate within the upper 10 km of the crust before major eruptive events of the last two decades. Differences in the timescales of magma storage observed over the last 250 years can be therefore attributed to the dominant role played by volcano-tectonics on the uppermost part of the feeding system.

Insights into the magmatic processes leading to the Holocene caldera eruption of Rinjani, Indonesia

C. M. VIDAL[1]*, N. METRICH[1], J.-C. KOMOROWSKI[1], I. PRATOMO[2], F. LAVIGNE[3] AND SURONO[4]

[1] IPG-Paris, Sorbonne Paris Cité,Univ. Paris 7, UMR-CNRS 7154, Paris, France (*correspondence: vidal@ipgp.fr)
[2] Museum of Geology, Bandung, Indonesia.
[3] LGP, Univ. Paris 1, UMR CNRS 8591, Paris, France.
[4] CVGHM, Geological Agency, Bandung, Indonesia.

The cataclysmic caldera-forming eruption at Rinjani volcanic complex (Lombok, Indonesia) ranks among the largest explosive eruptions of the Holocene, and is possibly associated to the largest stratospheric release of volcanic sulfur over the past 7 ka [1]. It produced a succession of plinian fallout and pyroclastic flow deposits. Whole-rock analysis of juvenile pumices from plinian fallout units indicates a range of trachyandesitic to trachytic magma batches (61-64 wt% SiO_2). These magmas display variable enrichments in both major and trace elements indicative of a dominant process of crystal fractionation and of the presence of a zoned (or complex) magma chamber. They also share Nb/Th (0.9) and Nb/Zr (0.04) ratios with those of Rinjani high alumina basaltic scoriae, suggesting that they belong to the same suite. As a whole the compositional range of our samples matches that of the Rinjani calc-alkaline suite [2].

The mineral paragenesis consists of plagioclase (An_{41} to An_{80}), clinopyroxene (Mg# 0.75), orthopyroxene (Mg# 0.71), amphibole (pargasitic Hbl/magnesio Hbl) and Fe-Ti oxides. Biotite is rarely found. Apatite shows a wide range of volatile contents: F 1.8-0.25 wt%, Cl 0.9-0.45 wt% and S 1300-<100 ppm. Melt inclusions analyzed in plagioclase handpicked from a basal fallout unit represent the most evolved trachytic term (65-70 wt% SiO_2, on anhydrous basis). They contain 3.3-5.1 wt% of H_2O, 2200-3700 ppm of Cl, 440-600 ppm of F, and <100-490 ppm of S. CO_2 is below FTIR detection limit. The erupted magma was thus rich in H_2O and Cl but relatively depleted in sulfur. The estimated P_{H2O} for this range of water contents is 180-100 MPa [3] that is consistent with prolonged magma ponding at crustal level.

We provide the very first constraints on the pre-eruptive magma conditions and discuss the processes controlling sulfur behavior.

Introduction

Diffuse emissions of several contaminants are linked to water and energy, as the need for these leads to modification of frequency, magnitude and nature of the contribution of water and sediments, mainly due to interventions in the drainage basinsuch as the reservoirs formation. Among these contaminants is mercury (Hg), which offers known health risk [1]. Therefore, this study evaluated the effect of the Funil dam, located in Resende, RJ, SE Brazil, in the level of Hg dissolved in water at three points of the Paraíba do Sul River (RPS) during 1 year.

Results

Sample	ago/10	set/10	out/10	nov/10	dez/10
Upstream	1,38	0,15	0,13	1,60	1,65
Reservoir	0,59	0,08	<0,05	4,58	0,23
Downstream	0,87	0,11	0,16	3,28	1,61
Sample	fev/11	mar/11	abr/11	jun/11	jul/11
Upstream	5,00	2,70	10,12	2,49	1,16
Reservoir	3,02	4,55	4,92	1,11	26,42
Downstream	9,44	1,87	2,64	3,12	0,98

Figure 1: Hg concentrations in Paraiba do Sul river (ng.L^{-1}).

Samples showed concentrations below the maximum allowed by law [2]. Although the basin RPS has compromised quality of water in several parts, this region does not suffer significant contamination by the element studied.

Geological data obtained from boreholes for oil and gas were used for geological mapping of "Jaša Tomić" sheet 1:100.000, in the area of Pannonian basin represents a special geothermal province (M. Milivojević, 1989) and one complex hydrogeothermal conductive system with four mutually separated reservoirs of underground water. A first hydrogeological system includes Upper Pontian sediments about 2 km thick in Northern Banat and a few tenths of meters in peripheral parts of the basin. In deeper parts clayey-marly sand prevail. In shallower parts larger parts presence of sandy-pebbly sediments of lacustrine and river origin are dominant. Sand water-bearing sediments parts presence vary from 1 to 50 m in thickness. The source of mineral water is located nearby structural boreholes Lazarevo (La-1), Topolovac (Tc-1) and borehole for water supply of village Lazarevo.

HCO_3	SO_4	Cl	Na	K	Mg	Ca	Br
569	3655	2744	3076	273	286	118	20
1464	2120	459	1740	1	101	69	5

Table 1: Physical-chemical composition (mg/l) of mineral water in Lazarevo (well) – First raw –data from 1957; second raw – data from 2012

According to results of laboratory researches (2012) water is medium mineralized low alkaline subthermal, Na-Mg-Ca, SO_4-HCO_3-Cl which classifies it as low alkaline saline bitter water.Water which was analysed in the period of 1957 belongs to medium mineralized low alkaline type of water, Na-Mg-Ca, SO_4-Cl-HCO_3 which classifies it as saline-muriatic-bromine-bitter water which is very healing. Variations in chemical composition are obvious, and they depend on the regime of underground water and aquifer type. Reseraches related to this are planned in the following period.

Hf-Nd isotope decoupling in Early Precambrian seawater

S. VIEHMANN[1,3]*, J.E. HOFFMANN[1,2], C. MÜNKER[2] AND M. BAU[3]

[1] Steinmann Institut, Universität Bonn, Germany

* present address, s.viehmann@jacobs-university.de

Banded Iron Formations (BIFs) are Precambrian marine chemical sediments that are archives of the trace element and isotope compositions of ancient seawater. Here we report Hf and Nd isotope data of pure chert and magnetite layers from the ca. 2.7 Ga Temagami BIF (Superior Province, Canada), determined by isotope dilution techniques and MC-ICPMS. Sample aliquots were also analysed for trace element systematics by quadrupole ICP-MS.

Shale-normalised REY patterns of the BIFs are similar to those of modern seawater and other pure Archean seawater precipitates. Enrichment of HREE compared to LREE, positive La and Gd anomalies, and super-chondritic Y/Ho ratios indicate a purely seawater-derived REY composition. Lacking Ce anomalies and strong positive Eu anomalies reveal anoxic conditions (with respect to Ce^{4+}/Ce^{3+}) and REY input into seawater via high-T hydrothermal fluids. Non-chondritic Zr/Hf ratios indicate minor influence of detrital aluminosilicates and a seawater origin of Hf. Samarium-Nd and Lu-Hf isochron ages are within error of the published depositional age of the ~2.7 Ga Temagami IF. Initial $\varepsilon Nd_{2.7Ga}$ values range from +0.2 to +3.0, but six of the nine samples cluster arround +1. In contrast, initial $\varepsilon Hf_{2.7Ga}$ values point towards heterogenous, strongly radiogenic compositions (+6.7 to +24.1). In the εHf-εNd diagram, the Temagami BIFs lie well above the `terrestrial array´ and exhibit significantly different εHf-εNd values than Temagami shale and hinterland tholeiites and adakaites which tapped the Abitibi mantle [1]. Therefore, Temagami seawater Hf was even more radiogenic than ambient mantle, suggesting that selective weathering processes (including the zircon effect) already operated in the Neoarchean, leading to the decoupling of the Hf-Nd isotope systematics, that is well known from modern seawater [2] and Cenozoic FeMn precipitates [3]. This suggests that by 2.7 Ga ago, a significant fraction of evolved continental crust was exposed above sealevel and subject to terrestrial weathering.

Towards a better understanding of Zn transport and storage in the tree-soil-mineral-river system, stable Zn isotope fractionation was studied in main biogeochemical compartments of a pristine larch forest of Central Siberia developed over continuous permafrost basaltic rock lithology.

It appears that Zn isotopes are not fractionated within the soils compared to the basaltic rocks. By contrast Zn isotope fractionation is observed between plants (larch) and soil and within the plant itself. Among the different habitats of the region receiving different amount of solar radiation and nutrients (South- and North-facing slope, peat bog) we observe systematic habitat-specific differences of Zn isotopic composition between whole plant and soil. As there is no apparently different physiological behavior of Zn within the same species within the different habitats we suggest the key role of Zn speciation in the soil solution to explain these differences. We observe a change of Zn isotopic composition in the larch needles within the course of the growing period suggesting a change in the nutrients source. Although the isotopic measurements do not allow distinguishing between mineral and organic source of Zn in natural waters, it can be concluded that, within the climate evolution and the increase of the thickness of thaw layer in peat bog environments, the global value of $\delta^{66}Zn$ in Siberian larch forest will increase.

New constraints on K-Pg boundary environmental changes with Li isotopes

N. VIGIER[1], G. RAVIZZA[2], K. NAGASHIMA[2], R. D. NORRIS[3], S. PETIT[4], D. BEAUFORT[4] AND A-M KARPOFF[5]

[1]CRPG, CNRS, Université de Lorraine, Nancy, France
[2]University of Hawaii at Manoa, Honolulu, USA

[4]IC2MP, CNRS, Université de Poitiers, France
[5]IPGS, CNRS, Université de Strasbourg, France

Climatic and oceanic perturbations associated with the Deccan Traps eruption and with the Chicxulub impact are still strongly debated. Because lithium isotopes significantly fractionate during low temperature processes, the composition of mineral phases formed across the K-Pg boundary can provide quantitative information concerning environmental changes at that time. In this study, we investigate in parallel the Li isotope composition of both marine authigenic smectite and benthic foraminifera over a time window of 3 Ma. Comparing both phases is important because the δ^7Li of foraminifera may be subject to vital effects during calcification, while authigenic clays are not. The objectives are: 1/ To determine the long-term variation of seawater δ^7Li due to changes in continental flux and alteration rate and 2/ To detect short-term variations of the ocean carbon chemistry, recorded by Li isotope fractionation during foraminifera growth.

Li isotopes are measured in clays by MC-ICP-MS, and in benthic foraminifera tests using the ims 1280 ion microprobe, at University of Hawaii. Initial results show a limited variation (<2‰) of clay δ^7Li across the Ir-rich layer, indicating little disturbance of the ocean Li at that time. Compared with 0-6 Ma seawater, K-Pg seawater δ^7Li was 5.5‰ lower, suggesting a lighter input from continents due to more intensive and more congruent continental alteration.

In contast, contemporaneous benthic foraminifera tests vary significantly on time scales much shorter than the oceanic residence time of Li (≈1.5 Ma), too short to attribute to changes in the δ^7Li of the global ocean Also, these variations precede deposition of the Ir-rich layer. These results strongly suggest changes in Li isotope fractionation through time. The δ^7Li of cultured foraminifera indicate a strong dependency on the DIC concentration, but no impact of pH and T on Li isotope fractionation during foraminifera growth. If these data are representative of natural conditions, then our results indicate significant short-term oscillations of ocean DIC before Chicxulub, possibly related to eruption events in the Deccan.

Wild rats as sentinel animals in the assessment of asbestos pollution: a pilot study

R. VIGLIATURO[1]*, M. ARDIZZONE[3], C. VIZIO[4], S. CAPELLA[1] AND E. BELLUSO[1,2]

[4]reg. Bocca 16/a, Cellamonte, Italy; carlottavizio@yahoo.it

Asbestos fibres are potential carcinogens to humans when reach lungs. Animals can be served as sentinels being exposed like humans to contaminants. Recently investigations on the asbestos burden to evaluate the exposure level in the environment has been successfully carried out on cows [1]. To investigate in towns where these animals don't' live, rats as diffused species can be considered. Rats live in colonies in a circumscribed territory. The use of rats as "sentinel animals" would allow to carry out an innovative monitoring method with important practical applications. The aim is to identify the neighbourhoods of the city at risk, by searching for asbestos fibres in the lung tissue of wild rodents captured in specific areas of the Casale Monferrato town. Three kinds of asbestos (crocidolite, chrysotile and asbestos tremolite/actinolite) and five groups of non asbestos fibres (metallic oxides; Al-, Ti-, and vitreous silicates; phyllosilicates) have been detected in the rat lungs by SEM-EDS investigations. These data together with that obtained from positive and negative control rat lungs showed rats are suitable sentinel animals to detect air dispersion hidden sources of asbestos and other inorganic fibres. Regarding the studied area, crocidolite and asbestos tremolite/actinolite are related respectively to anthtropogenic and natural sources. Therefore a complete investigation would allow to identify sites of noxious inorganic phase potential dispersion in order to adopt tools to contain or eliminate it before the general population can be damaged.

Hydrogen mobility in Wadsleyite at low temperatures

E. VIGOUROUX[1], J. INGRIN[1], C. DEPECKER[1], N. BOLFAN-CASANOVA[2] AND D. FROST[3]

[1] UMET - UMR CNRS 8207 - Université Lille 1 – Cité Scientifique, 59655 Villeneuve d'Ascq, France (eric.vigouroux@ed.univ-lille1.fr, jannick.ingrin@univ-lille1.fr, christophe.depecker@univ-lille1.fr)
[2] LMV - UMR CNRS 6524 - Université Blaise Pascal – 5 rue Kessler, 63038 Clermont-Ferrand, France (n.bolfan@opgc.univ-bpclermont.fr)
[3] BGI – Bayreuth University– Universitatsstrasse, 95447 Bayreuth, Germany (dan.frost@uni-bayreuth.de)

Mantle wadsleyite may incorporate large amount of H in its structure (up to several wt % H_2O). A good knowledge of hydrogen diffusion in wadsleyite and its relationship with electrical conductivity is critical to estimate the amount of water present in the transition zone. We present here the results of diffusion experiments realized in deuterium-rich atmosphere at room pressure between 300°C and 450°C. Wadsleyite samples have been synthesized from forsterite powder with a minute amount of water by multi-anvil presses at 16 GPa - 1100°C. The average grain size is less than 5 μm and the water content is around 0.01 wt% H_2O. All samples show major IR peaks at 3372, 3350 and 3322 cm^{-1} with minor peaks at 3726, 3665, 3615, 3523, 3472 and 3208 cm^{-1}.

We observed the same OH extraction behavior in the three slides annealed: extraction kinetics of bands 3726, 3523, 3372 and 3208 cm^{-1} is almost 100 times slower than other bands while deuteration affects all the bands in the same way. We obtain an activation energy of 175 kJ/mol for extraction of the "fast" decreasing bands and an activation energy of 202 kJ/mol for H-D exchange.

Our data extrapolated to high temperatures suggest that hydrogen mobility in Mg-wadsleyite is two orders of magnitude higher than extraction kinetics from Hae *et al*. (2006) ($D=8.3*10^{-11}$ m^2/s at 1000°C) or it implies an activation volume of 11,3 $cm^3.mol^{-1}$. If we neglect the effect of a potential activation volume, we predict a concentration of hydrogen two orders of magnitude smaller.

The IUPAC-IUGS joint Task Group "Isotopes in Geosciences", TGIG, has evaluated the published measurement results for the decay constant (i.e. half life) of ^{87}Rb. A significant part of our evaluation was the effort to follow strict metrological criteria (VIM, 2012) in our assessment of the measurement uncertainties according to GUM (2008).

The ^{87}Rb half life was estimated by three groups using totally independent approaches. Kossert (2003) determined the specific activity of Rb salts by liquid scintillation counting. This approach assumes that inter-sample variations are due to stoichiometry. Nebel et al (2011) compared Rb-Sr and U-Pb ages of cogenetic minerals. This approach assumes that certain natural samples behave "ideally", i.e. all the relevant ages are expected *a priori* to be equal, and relies on control on the samples' petrology. Rotenberg et al (2012) measured the radiogenic ^{87}Sr accumulated in a batch of Sr-free Rb salt over 35 years. This approach relies on having performed precise and accurate measurements of the concentration and isotopic composition of the Sr present in the $RbClO_4$ at the time of crystallisation. The three sets of experiments yield indistinguishable results, which is a good indication that systematic biases were either coincidentally of the same magnitude and direction in three radically different experimental designs, or negligible after accurate correction. The resulting best estimates are $\lambda_{87} = (1.395 \pm 0.002) \times 10^{-11}$ a^{-1} (1s uncertainty), $t_{1/2} = 49.7 \pm 0.1$ Ga.

Observations and modeling of sinking particle speeds in the Twilight Zone using ^{210}Po-^{210}Pb deficit

M. VILLA*[1], F. DE SOTO[2], F. LE MOIGNE[3], S. GIERING[3], R. SANDERS[3] AND R. GARCÍA-TENORIO[1]

[1]Universidad de Sevilla, Dpto. Física Aplicada II, 41012, Sevilla, Spain (*correspondence: mvilla@us.es)
[2]Universidad Pablo de Olavide, Dpto. Sistemas Físicos, Químicos y Naturales, Sevilla, Spain
[3]Department of Ocean Biogeochemistry and Ecosystems. National Oceanographic Centre, Southampton, UK

A one-box model of ^{234}Th uptake and removal in the water column is widely used to calculate downward ^{234}Th and POC flux. The elemental pair of ^{210}Po-^{210}Pb is an alternative method to estimate carbon fluxes which should offer significant advantages due to its different half-life (138 days) and biogeochemical behaviour. Due to its long half-life, a ^{210}Po deficit is maintained below the euphotic zone and penetrates much further into the twilight zone (100-1000 m) than ^{234}Th. Hence ^{210}Po and ^{210}Pb profiles and ^{210}Po deficit could be used to broad our knowledge of the twilight zone.

To address this question several water column profiles were sampled during two expeditions of RSS Discovery on the North Atlantic, PAP site (summer 2009) and Irminger Basin (summer 2010). The most important contribution of this work is that ^{210}Po activity down the water column is modelled using a one-box inverse model. Modelled ^{210}Po activities are in very good agreement with the analysed values and the new approach provides information to understand ^{210}Po and ^{210}Pb concentration profiles on the water column. A key output from the model is average downward sinking velocities. Minimum and maximum values range from 20 m·d^{-1} at 50 m to 150 m·d^{-1} at 400 m. Averaged values at PAP and Irminger areas do not follow a clear geographical pattern; however, an increase with depth is observed. Finally, the contribution of slow sinking particles into the twilight zone and its implication to the carbon storage is discussed.

Adsorption experiments of arsenic and lead onto barite

F. SAMPERIO JIMÉNEZ[1], R. E. VILLANUEVA-ESTRADA[2]*, P. VILLANUEVA-GONZÁLEZ[3], C. CANET[2] AND F. MARTÍN-ROMERO[4]

[1] Facultad de Ingeniería, UNAM
[2] Instituto de Geofísica, UNAM
(*correspondence: ruth@geofisica.unam.mx)
[3] Facultad de Química, UNAM
[4] Instituto de Geología, UNAM

The work consists in the study of the retentions of arsenic and lead onto the barite surface. The barite sample is from a deposit of Múzquiz (Coahuila, México). The batch adsorption experiments using salts of As(III), As(IV), and Pb(II) was according [1]. A measurement of the pHPZC of the barite sample was determined by acid-base titrations.

	As(V)	As(III)	Pb(II)
pH adsorption	8.35	8.55	8.45
$C_{t=0}$ (mg/L)	5.92	9.69	7.07
$C_{t=24\ h}$ (mg/L)	5.08	9.67	< L.D.
Adsorption %	14	0.17	100
R_d (mL/g)	3.6	0.04	2951

Limit of detection (L.D.) for lead is 0.05 mg/L

Table 1. Results of the adsorption experiment. The adsorption was calculated taking account the concentration of the dissolved species. Calculation of the distribution ratio (R_d) between the solutes and barite mineral was calculated as Griffin *et al*. [1].

The determination of the pH_{pzc} of the barite is about 9.8. The present study shows that the barite could be used as adsorbent for Pb(II). Although the adsorption of arsenic is lower, is more effective for As(V) than for As(III). At the pH of adsorption the As(III) the predominant species is not charged (H_3AsO_3), but the As(V) occurs as $HAsO_4^{2-}$ and can be electrostatically attracted to the positive surface of the barite.

Successive geotherms, Granitic production and evolution of the lower crust in a post collisional context

ARNAUD VILLAROS[1], JEAN-FRANÇOIS MOYEN[2] AND MICHEL PICHAVANT[1]

[1]LabEx VOLTAIRE. ISTOrléans, arnaudvillaros@gmail.com
[2]LMV, université Jean Monnet, St Etienne

Post-collisional context is commonly associated with production of large amount of peraluminous granitic magmas produced from the melting of crustal material. The variability of the produced granite commonly varies from leucogranitic to granodioritic and are mostly peraluminous. The South-Eastern French Massif Central (EFMC) region record several evidence for crustal melting revealed by migmatitic and granitic bodies providing ~30 Ma history of peraluminous granite production. Previous thermobarometric studies provides records for two successivves melting event: 1) a biotite stable event at ~314Ma (720°C and 5 kb) 2) a bitotite breakdown melting event constrained at ~301Ma (850°C 4kb) This suggests geotherms evolution from 45 °C/km to 70°C/km in 13Ma.

A thermodynamic modelling approach considering a 20km thick pile of crustal material undergoing successive geotherm evolving from 25°C/km to 70°C/km with starting conditions between 3 and 10 kb. Along this evolution our approach allows successive melt extraction and the monitoring of melt compositional variability, residuum evolution and mineral phases modal and compositional variabities according to depth, geotherm and composition of the source.

Over the 5 crustal sources used as starting composition for the model, 305 individual partial melting reactions are triggered. Melt and peritectic phases produced provide a variability that suggest the importance of source composition in matter of granite production for some element and ratios (K/Na, X_{Mg}). Compared to regional granites (EMCF). Most of the granites produced in the post collisional context of the EFMC can be reproduced by either melt only (leucogranite) or melt in addition to peritectic material produced along with melt (granite to granodiorite). In the same way, the relative-time constrain provided by the approach shows that it is possible to produce simultaneously heterogeneous granitic magmas in respect to source protolith and depth. Identically, the residual crust undergo an very variable evolution depending on protolith leading to an heterogeneous granulitic lower crust.

Phosphorous Speciation in Atmospheric Deposition Samples in the East Mediteranean

KALLIOPI VIOLAKI [1], MARIA KANAKIDOU[1] AND NIKOS MIHALOPOULOS[1]

[1] Environmental Chemistry Processes Laboratory, Department of Chemistry, University of Crete, P.O. Box 2208, 71003 Heraklion, Greece; kviolaki@chemistry.uoc.gr; mariak@chemistry.uoc.gr; mihalo@chemistry.uoc.gr

The interactions between phosphorus-carbon cycles and climate are expected to become an increasingly important determinant of the Earth biogeochemical cycles. The oceans generally act as an important sink of atmospheric CO_2. P limitation of marine primary productivity could play a key-role in this natural process, affecting indirectly the global warming. East Mediterranean Sea (EMS) is P-limited and new knowledge could be arisen by defining the role of organic and inorganic forms of atmospheric P deposition into the marine environment.

This study aims to investigate the sources, the forms and the biogeochemical significance of soluble and insoluble atmospheric P over the EMS. Wet (n=55) and bulk deposition samples (n=76) have been collected during four-year period (2008-2009 and 2011-2012) and analyzed for P speciation. Following the analytical protocol referred in Standard Methods for the Examination of Water and Wastewater (20th Edition), Total Dissolved acid hydrolized Inorganic Phosphorous (TDIP) was determined after mild oxidation of sample. Total Dissolved Phosphorus (TDP) was measured after the acid digestion of samples according to Persulfate Digestion Method. Dissolved organically bound phosphates (DOP) were determined by subtracting TDIP from TDP. Disolved Reactive Phosphorous (DRP) was determined as HPO_4^2 with Ion Chromatography (IC).

To investigate the role of air mass origin in the P speciation in rainwater, rain samples have been classified in two classes (N/NW and S/SW) corresponding to the main wind sectors influencing the area. DOP is associated with S/SW winds that enrich the atmosphere over the EMS with African dust. N/NW winds transport anthropogenic pollution from N/NW Europe and are associated mainly with DRP. In addition, P solubility changes have been observed and are analysed.

Dry deposition of P is found to be higher than the wet one and is dominated by DRP that is so far known as the most bioavailable form of P and thus is expected to have singifiincat impact on the marine ecosystems.

Chemical weathering provides mineral nutrients to the soil solution. The productivity and resistance of the vegetation is dependent to its capacity to find and adsorb these nutrients. The vegetation itself plays an active role in mineral dissolution by the exudation of organic acids. Indirectly, (i) the nutrient uptake can deplete them in the soil solution and (ii) the soil respiration increases the pCO_2. Both indirect processes also favour the chemical weathering. In poor acid soils, the fertility relies mostly on the organic matter recycling and/or atmospheric inputs. But the biological cycle is not closed and looses by the run off are unavoidable. Moreover, in a young growing forest, the initial pool of mineral nutrients has to be built.

For 20 years, the chemical composition of the streamwater *La Robinette*, in the Belgian Ardennes has been monitored. It initially aimed at the estimation of cations losses due to soils acidification and at the understanding of the forest decline. After a large windfall and a clear-cutting in 1995, spruces were replanted and partially replaced by deciduous species. Since 2006, a flux tower records exchange of carbon between this young ecosystem and the atmosphere (*Jalhay* CarboEurope site). The double monitoring on this site gives the unique opportunity to better explore the relationship between mineral nutrients and organic cycle under a temperate forest. A modelling approach allows deciphering the impact of the two indirect processes cited above on weathering fluxes. We use the vegetation model ASPECTS(1) and the geochemical model WITCH(2) to investigate the origin the drastic pH increase observed these last years in the streamwater (from about 4 to more than 5.5).

Chemostratigraphy of Paleoasian ocean's microcontinent covers

IRINA VISHNEVSKAYA

Sobolev Institute of geology and mineralogy SB RAS, Novosibirsk, Russia; e-mail:(vishia@igm.nsc.ru)

After the breakdown of the Rodinia super continent the Siberia for a long time was a continent surrounded by the water (700 Ma [1]). The ocean between Siberia continent and others big continent is called Paleoasian ocean. Thick carbonate deposits have been accumulated on Siberia passive border and on the microcontinents surrounding in Ediacarian time. This study about investigation of Sr and C isotopic composition of Ediacaran and Cambrian carbonate covers of following microcontinents: Tuva-Mongolian, Zavkhan (both in Mongolia now), Batenev and North-Muya (Russia).

Based on petrographic and geochemical analyses we identified the least altered rock samples. These samples are thought to have primary Sr isotope composition reflecting that of the paleocean. The least altered carbonates of the Tuva-Mongolia terrane have Sr isotope values of 0.7073-0.7086 and $\delta^{13}C$ values alter from -1.7 to +5.0‰ [2]. The primary $^{87}Sr/^{86}Sr$ ratio for Zavkhan carbonate are 0.7072-0.7079 for Tsagaan Oloom Fm ($\delta^{13}C$ vary from +3 to +14‰) and 0.7084-0.7086 for Bayan Gol Fm. Carbonate cover of Batenev microcontinent is characterized by $^{87}Sr/^{86}Sr$ rations of 0.7075-0.7085 and $\delta^{13}C$ is -2.5 …+3.7‰ [3]. The $^{87}Sr/^{86}Sr$ ratio from North-Muya microcontinent vary from 0.7085 to 0.7086 and it have $\delta^{13}C$ about 0.

When compared with the $^{87}Sr/^{86}Sr$ ratio variation curve [4] it can be seen that the deposits accumulated asynchronously from the early Ediacaria to middle of Cambrian and cannot be used for lithological correlation of the carbonate successions.

The work was supported by the RFBR (projects nos. 12-05-00569, 12-05-33076).

Global lithium deposits (pegmatites and brines) as indicators of plume-tectonics

A.G. VLADIMIROV[1,2,3]*, V.E. ZAGORSKY[4] AND N.I. VOLKOVA[1]

[1]Institute of Geology and Mineralogy SB RAS, Novosibirsk, 630090, Russia (vladimir@igm.nsc.ru)

[3]Tomsk State University, 634050,Tomsk, Russia
[4]Institute of Geochemistry SB RAS, Irkutsk, Russia

Spodumene pegmatites. Comparative analysis of geotectonic position of Li-bearing pegmatite deposits of Central Asian Folded Belt and their isotopic ages (U-Pb, Rb-Sr, Ar-Ar, Re-Os) suggests the coincidence of time intervals of the pegmatite formation with main age peaks of plume activity (LIP). The origination of deep-seated granite sources of the pegmatite melts with extremely high lithium contents was stipulated by asthenosphere uplift, and their occurrences was connected with strike-slip deformations in continental lithosphere [1-2].

Salt lakes. Comrative analysis of lithium brine deposits of South America and Central Asia allowed us to conclude that lithium contents in lake waters were determined by lithium concentrations in feeding springs and underground waters, their salinity, tectono-volcanic activity of considered regions, arid climate conditions. The formation of lithium brines of salt lakes is usually connected with leaching of acid tiffs, entering in bimodal volcanic series, which are characteristic for marginal and within-plate riftogenesis [3-4].

Siderite Amendment for *in situ* pH Control in Hyperalkaline Environments

DIMITRI VLASSOPOULOS[1], JESSICA GOIN[1] AND MINNA CAREY[1]

[1]Anchor QEA, Portland, OR 97204, USA

Remediation of soils and sediments and restoration of sites contaminated by hyperalkaline wastes associated with legacy industrial facilities (e.g. Solvay and chlor-alkali process wastes) present unique challenges and opportuntities for geochemical engineering solutions. The feasibility and success of in situ treatment strategies such as soil mixing and sediment capping in such settings depends on the use of reactive amendments that can maintian long-term pH neutralization and ultimately lead to establishment of plants and habitat restoration. We present results of extensive experimental and modeling studies carried out to evaluate the reactivity, kinetics, and performance of siderite ($FeCO_3$) for such applications. Porewater pH neutralization and buffering by natural siderite ore concentrates from Texas was investigated in a series of kinetic batch tests using a hyperalkaline (pH 12) Na-Ca-Cl brine porewater from contaminated lake sediments. In all tests, pH was neutralized and consistently buffered to circum-neutral values within timeframes of weeks to months. The reaction rate was inversely dependent on liquid/solid ratio (varied between 2:1 to 50:1) and only weakly dependent on siderite grain size (from 0.1 to 2 mm), the latter due to the aggregate nature of the siderite ore which consists of individual crystallites <<50 μm in size. Calcite and iron oxides/oxyhydroxides were identified as the main reaction products in the batch experiments. Column testing confirmed the effectiveness of siderite for pH neutralization under dynamic flow conditions representative of field situations with groundwater upwelling through contaminated sediments. A reactive transport model of a siderite-amendmed sediment cap, incorporating time-dependent porewater upwelling and consolidation following cap construction, siderite dissolution (pH-dependent transition-state theory rate law) and secondary product precipitaton kinetics, was developed using PHREEQC with reaction rate constants calibrated to the batch experiment data. The model has been used to simulate pH neutraliation under different sediment cap designs, conduct sensitivity analyses to assess potential effects of vertical segregation of amendments during subaqueous cap materials placement, and develop optimal siderite dosing estimates for long-term pH control in support of remedial design for a major sediment remediation project.

Diagenesis affects carbonate $\delta^{53}Cr$: Evidence from the K-Pg boundary section at Stevns Klint (Denmark)

A.R.VOEGELIN[1,2,*], R. FREI[1,2], N. THIBAULT[1], C.V. ULLMANN[1] AND CH. KORTE[1]

[1] Department of Geosciences and Resource Management, University of Copenhagen, DK-1350 Copenhagen, (*correspondance: andrea.voegelin@geo.ku.dk)
[2] Nordic Center for Earth Evolution (NordCEE)

The chromium isotopic composition ($\delta^{53}Cr$) of marine sediments is a valuable tool to detect changes of the redox state of paleoenvironments [1, 2]. Recently, the $\delta^{53}Cr$ of marine carbonates has shown to be a very sensitive tracer of atmospheric O_2, weathering and hydrothermal input [3]. We applied this new tracer to the K-Pg boundary sequence at Stevns Klint (Denmark), comprising non-cemented chalk and bryozoan limestones of the uppermost Maastrichtian to lower Danian. The $\delta^{53}Cr$ data was complemented with other geochemical tracers in order to explore environmental changes before and after the K-Pg extinction event.

We observe a conspicuous 3-step $\delta^{53}Cr$ evolution from strongly positive values at the base of the section (~ +0.7‰) to intermediate values just below the boundary layer (~ +0.3) and finally to mostly negative $\delta^{53}Cr$ values (~ -0.07) after the K-Pg event, reflecting mantle inventory [4]. Several lines of evidence suggest that this distinct trend may not reflect a primary oceanographic signal but is the result of post-depositional alteration. A prominent diagenetic component is implied by the Sr concentration and Sr/Ca data, which match the decreasing Cr trends. Increasing Mn and Fe concentrations as well as Mg/Ca ratios further support this interpretation. In addition, the Cr shifts can be linked to lithological changes, controlled by sea-level fluctuations. Differences in primary sediment composition may thus have led to differential diagenetic alteration of the Cr signal.

We hypothesize that the isotopically most positive $\delta^{53}Cr$ values, preserved in the pure chalks of the lowermost part of the section, reflect a typical marine signal. By contrast, the moderately positive to negative $\delta^{53}Cr$ values of the more coarse grained limestones in the upper part of the section, reflect removal of heavy $\delta^{53}Cr$ in an open-system diagenetic regime.

Arsenic sequestration by fresh and aged Fe oxidation products

A. VOEGELIN*, A.-C. SENN, R. KAEGI AND S.J. HUG

Eawag, Swiss Federal Institute of Aquatic Science and Technology, Überlandstrasse 133, CH-8600 Dübendorf, (*correspondence: andreas.voegelin@eawag.ch)

The oxidation of dissolved Fe(II) by O_2 leads to the formation of amorphous to poorly crystalline Fe(III)-precipitates. Because of their high sorption capacity, Fe oxidation products critically affect the fate and impact of trace elements like As in soils and sediments as well as in Fe-based engineered systems for soil, sediment and water remediation or treatment

Related to studies on As and trace metal dynamics in soils and sediments and As removal from drinking water, we perform laboratory experiments to determine how major dissolved species in near-neutral aqueous solution affect the formation, structure and aging of Fe oxidation products. In continuation of earlier work [1,2], we currently explore the effect of molar P/Fe ratio and dissolved Si and Ca on (i) the structure of fresh Fe(III)-precipitates formed by oxidation of 0.5 mM Fe(II) at pH 7.0 and their counterparts after 30 days of aging at 40°C and (ii) the uptake and solubility of co-transformed arsenate (As(V); 500 μg/L). Both phosphate and silicate interfere with Fe(III) polymerization. The strong interaction of phosphate with Fe(III) reduces As(V) uptake in fresh precipitates above a P/Fe ratio of ~0.55 in the absence and ~0.75 in the presence of Ca. The presence of Si (at molar Si/Fe ratio of 2) does not interfere with initial As(V) uptake but effectively reduces As(V) re-solubilisation during aging by inhibiting precipitate crystallisation.

The mechanistic insight gained from well-constrained laboratory experiments helps to rationalize observations from natural and technical systems, for example related to As and Fe co-sequestration at natural redox interfaces or to Fe-based drinking water treatment for As removal. The results are also relevant with respect to the sequestration of other trace elements by fresh and aged Fe oxidation products, a topic that we will address in future experiments.

Dark production of reactive oxygen species in freshwaters

B.M. VOELKER[1]*, R. MARSICO[1], R. SCHNEIDER[1], C.M. HANSEL[2] AND T. ZHANG[2]

[1]Department of Chemistry and Geochemistry, Colorado School of Mines, Golden, CO 80401, U.S.A. (*correspondance: voelker@mines.edu)

[2]Marine Chemistry and Geochemistry Department, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, U.S.A.

Reactive oxygen species (ROS) superoxide (O_2^-), hydrogen peroxide (H_2O_2) and hydroxyl (OH) can affect metal redox speciation and organic carbon cycling in natural waters. In this study, we focus on hydrogen peroxide, the product of superoxide reduction and the source of strong oxidants including hydroxyl, via Fenton's reaction.

We measured production and decay rates of hydrogen peroxide in dark incubations of freshwater samples from a variety of systems. Dark production was found to be a ubiquitous feature of freshwater environments, and both production and decay rates were generally related to the concentrations of microorganisms in the samples. Production rates ranged from undetectable to greater than 200 nM hr^{-1}, with large temporal fluctuations in two field sites that were sampled repeatedly. Filtering decreased, but did not always eliminate, production of hydrogen peroxide, indicating chemical as well as biological sources of ROS. Our results suggest that metal reactions involving ROS are likely to occur even when photochemical ROS production is minimal.

The dependence of siderophile element partitioning on Pressure, Temperature, fO_2 and S-content

VOGEL, A.K.[1]; RUBIE, D.C.[1]; FROST, D.J.[1], AUDÉTAT A.[1] AND PALME, H.[2]

[1]Bayerisches Geoinstitut, Universität Bayreuth, D-95440 Bayreuth, Germany, antje-kathrin.vogel@uni-bayreuth.de

[2] Forschungsinstitut und Naturmuseum Senkenberg, D-60325 Frankfurt, Germany

The partitioning of siderophile elements between liquid metal and liquid silicate provides information about the conditions that dominated during core formation in the Earth and other terrestrial planets. In particular high pressure – high temperature experiments, performed in a multianvil apparatus, and the quantification of the partitioning behaviour in the form of partition and exchange coefficients yield conclusions about former pressure, temperature and oxygen fugacity conditions.

We have chosen a broad range of elements for our experiments, namely the refractory elements Ni, Co, W and Mo, as well as the moderately volatile elements Ag, As, Au, P, Ge, Cu and Sb and the volatile elements Sn and Pb. We have investigated the partitioning behaviour over the *P-T* range 11-23 GPa and 2200-2800 K respectively. Oxygen fugacities of -2 to -5 log units relative to the iron-wüstite buffer have been determined, enabling us to draw additional conclusions about the valence state of the elements of interest in the silicate melt. In addition, we have investigated the effect of the S content of liquid metal on partitioning because S contents were likely significant, especially during the late stages of accretion.

The most siderophile of the studied elements, gold, exhibits the strongest temperature dependence with exchange coefficients varying over one log unit within a temperature range of 2400-2600 K. Other elements, in particular Pb, show no significant dependence on temperature. The partitioning behaviour of Pb furthermore seems to be unaffected by pressure. With 10 wt% S in the starting material, the exchange coefficient for Sn decreases by 0.5 log units, and converges with the exchange coefficient of Pb, a condition that has to be fulfilled because Pb and Sn are depleted by the same extent in the Earth´s mantle.

The results are being incorporated into an accretion/core formation model in order to understand the timing of volatile element addition to the Earth.

Serpentinization, metasomatism and carbonate precipitation in Jurassic mafic and ultramafic sea-floor

M. VOGEL[1], G. L. FRÜH-GREEN[1], C. BOSCHI[2] AND E. M. SCHWARZENBACH[3]

[1]ETH Zürich, 8092 Zürich, Switzerland (*correspondence: monica.vogel@erdw.ethz.ch)
[2]CNR Pisa, 56124 Pisa, Italy (c.boschi@igg.cnr.it)
[3]Virginia Tech, Blacksburg, VA 24061, USA (esther11@vt.edu)

Several Ligurian ophiolitic units are considered to be fragments of heterogeneous Jurassic lithosphere that record tectono-magmatic and alteration histories similar to those documented along the Mid-Atlantic Ridge, such as at the 15°20'N area and the Atlantis Massif at 30°N. We present a petrological and geochemical study of deformation and fluid-rock interaction in the Bracco-Levanto ophiolite complex (BL), which documents a multiphase history of alteration and hydrothermal activity, similar to present-day hydrothermal processes in oceanic core complexes at slow-spreading ridges. A focus is on investigating mass transfer, fluid flow paths, and fluid fluxes during high and low temperature hydrothermal activity, and on processes leading to hydrothermal carbonate precipitation and the formation of ophicalcites, which are characteristic of the BL sequences.

Bulk rock and mineral compositional data allow us to distinguish (1) a widespread phase of Si-metasomatism during progressive serpentinization, and (2) multiple phases of veining and carbonate precipitation associated with circulation of seawater and high fluid-rock ratios in the shallow, ultramafic-dominated portions of the Jurassic seafloor. In general, the ophicalcites have higher Si, Al and Fe concentrations and lower Mg than the serpentinite basement rocks with minimal or no carbonate veins. We interpret the zones of ophicalcites to reflect paleo-pathways for hydrothermal fluids and Si-metasomatism during uplift and emplacement on the seafloor. Bulk rock major and trace element data and Sr-isotope ratios indicate a seawater source of the hydrothermal fluids, and suggest that these fluids had reacted with rocks of mafic composition. We observe regional variations in Mg, Si and Al, which suggest Si-flux towards stratigraphically higher units. Channelling of Si-rich fluids is also indicated by amphibole and talc growth in shear zones. $\delta^{18}O$-values of the carbonate veins indicate temperatures up to 150°C and document a decrease in temperature with ongoing veining and carbonate precipitation. Continued pulses of Si-rich fluids upon cooling are indicated by the formation of late-stage calcite-talc druses in the ophicalcites.

Noble gas temperature determination in fluid inclusions - method, tests, future applications

N. VOGEL[1,2], M.S. BRENNWALD[1], A. N. MECKLER[3], D. FLEITMANN[4], C. MADEN[2], R. WIELER[2] AND R. KIPFER[1,2]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, Water Resources and Drinking Water, Dübendorf, Switzerland. nadia.vogel@eawag.ch
[2]ETH Zurich, Institute for Geochemistry and Petrology, Zurich, Switzerland
[3]ETH Zurich, Geological Institute, Zurich, Switzerland
[4]University of Reading, Department of Archaeology, Reading RG6 6AB, United Kingdom

Concentrations of dissolved atmospheric noble gases in open water bodies and ground water have successfully been used to reconstruct past climatic and hydraulic conditions [1]. We have developed a combined vacuum crushing and sieving (CVCS) device which allows application of the so-called noble gas thermometer also to samples containing water amounts in the sub-milligram range, such as speleothems [2]. During growth, speleothems trap minute quantities of drip water, whose noble gas concentrations depend on the cave temperature. CVCS enables extraction of this water and the associated dissolved noble gases for analysis without inducing elemental fractionation, and minimizes addition of noble gases from air-filled inclusions. Air-related noble gases do not carry a temperature signal and have hence hampered noble gas temperature (NGT) determination in the past.

CVCS performance has been tested on samples from a stalagmite grown at a known temperature. NGTs deduced from the sieved grain size fractions with the most suitable air/water volume ratios excellently reproduce the expected paleotemperatures [2]. Furthermore, we report NGTs deduced from a stalagmite from Borneo covering two glacial–interglacial cycles (330-460 ka; [3]). These NGTs are compared to a sea surface temperature record from a tropical West Pacific sediment core [4].

We anticipate to apply the CVCS technique also to other fluid-inclusion bearing materials such as organic shells, corals, and consolidated sediments in the future.

Production and certification of Pd and Pt single spikes

JOCHEN VOGL[1]

[1]BAM Federal Institute for Materials Research and Testing, Unter den Eichen 87, 12205 Berlin, Germany

So-called spikes are solutions of isotopically enriched elements, which are used in isotope dilution mass spectrometry (IDMS) for the accurate quantification of element concentrations. Based on its proven records, especially in reference material certification IDMS is considered as one of the most powerful and most accurate methods for determining amounts of substance. [1] Contrary to other calibration approaches, IDMS does not directly suffer from long-time changes or drifts in instrument sensitivity. Moreover, provided isotopic exchange between the sample and spike is ensured, losses of analyte do not affect the analytical result. Both advantages are based on the fact that IDMS only requires isotope ratio measurements and isotope ratios are largely unaffected by instrumental drift, setup or by matrix, unless an isobaric interference is present.

IDMS often is applied for quantification of platinum group elements (PGE), either for reference material characterization or for geochemical research. [2] The main reasons for that are the required accuracy and the low PGE mass fractions in the sample. A crucial point in IDMS is, however, the availability of certified spikes. Unfortunately, no such certified spike solutions are available yet for PGE.

To fill this gap, at least partially, two single PGE spikes, one ^{106}Pd and one ^{194}Pt spike, have been produced and characterized. The selection of the isotopes, the production of the solutions and the ampoulation will be described in this presentation. Details on the characterization of these spike solutions by reverse IDMS using a primary assay for Pd and Pt will be given offering high purity (> 99.9). All relevant data – mass fraction of the spike isotope, isotopic composition and measurement uncertainties – will be presented. Both spike solutions are intended to become certifed reference materials under the ERM® label [3].

Microbial response on siderophores of heavy metal resistant streptomycetes

A. VOIT*, M. GREYER, T. KRAUßE, M. GUBE AND E. KOTHE

Institute of Microbiology – Microbial Communication, Friedrich Schiller Univ., Jena, D 07743, Germany (*correspondence: Annekatrin.Voit@uni-jena.de)

Large soil contamination by mining activities poses a severe environmental problem. The former uranium mining district Ronneburg (Thuringia, Germany) has been mined for more than 40 years until remediation of the area started in the 1990's. Resulting from mining, the banks of the creeks in the area show high concentrations of Ni, Cu, Mn and Zn and microorganisms have to adapt to these conditions. Thus, the area represents a store to screen for heavy metal resistant strains and their resistance mechanisms, such as the excretion of chelating ligands like siderophores. These mobilise, transport and store Fe^{3+} as well as other (heavy) metals in the environment. This causes a modulation of metal availability to other organisms and may influence motile and growing organisms to perform chemotaxis towards or away from a siderophore gradient to get into better living conditions.

Through the application of a new agar-plate method we were able to investigate chemotactic behaviour of different fungal and bacterial isolates to siderophores. A defined content of siderophores in culture supernatants of three different heavy metal resistant *Streptomyces* strains was supplied with Fe-deficient agar media in divided plates. Streptomycetes as well as fungi were inoculated on the non-siderophore containing side of the plate. Their growth was monitored with respect to effects exerted by the added siderophores.

Fungal strains showed faster growth towards the siderophore-free side while there, changes in morphology to fruitbody producing stages with increased development of aerial mycelium. Expecting a shift in the main area of growth for the whole colony, the tested *Streptomyces* strains displayed negative chemotaxis with siderophores while control showed equal growth. The strains *S. acidiscabies* E13 and *S. tendae* F4 showed lacks of substrate mycelium and a different pigment production indicative of a stress reaction.

Our results suggest that siderophores may play an important role in nature, not only in modulating metal availability, but also as signalling molecules.

Complex urban geochemical analysis of attic dust samples in an industrial area, Ajka, Hungary

PÉTER VÖLGYESI[1], GYOZO JORDAN[2], DÓRA ZACHÁRY[2] AND C SABA SZABÓ[1]

[1] Lithosphere Fluid Research Lab, Institute of Geography and Earth Sciences, Eötvös University, Budapest, Hungary, H-1117, Pázmány Péter sétány 1/c

[2] Research Institute for Soil Science and Agrochemistry, Centre for Agricultural Research, Hungarian Academy of Sciences, Budapest, Hungary, H-1022, Herman Ottó út 15

Recent studies suggest that airborne pollutants can be efficiently studied by the means of attic dust analysis. At Ajka region (Hungary), emissions from mining, coal-fired power plants and alumina industry have left the legacy of contamination. The major objective of this research was to study the geochemical behaviour and distribution of toxic elements in attic dust and to identify contamination source using geochemical, statistical and mineralogical methods. The sampling strategy followed a grid-based stratified random sampling design and 30 samples were collected in 27 houses within the 64 km2 project area. The total concentrations of the major and toxic elements (As, Pb, Cd, Cu, Ni and Zn) were measured with ICP-OES and Hg content was analyzed with AAS. Phase analyses of the samples were carried out by the means of scanning electron microscopy (SEM) coupled with energy dispersive spectroscopy (EDS) and X-Ray diffraction (XRD) methods. Results show that the studied attic dust at the Ajka urban area was contaminated mostly by Hg, Pb and Zn with concentrations ranging between 0.1-2 mg/kg, 42.5-881 mg/kg and 90.2-954 mg/kg, respectively. The most frequently identified mineralogical phases were quartz, carbonate, gypsum and Fe- and Al-bearing phases. Based on the SEM and the ICP-OES results, the Power Plant can be considered as the most influential industrial contamination source in the studied urban area.

Halogenated anthropogenic trace gases: The atmospheric imprint and the search for new tracers

MARTIN K. VOLLMER[1], MATTHIAS BRENNWALD[2] AND THE AGAGE TEAM[3]

[3]URL: Advanced Global Atmospheric Gases Experiment: agage.eas.gatech.edu

The atmospheric burden of anthropogenic long-lived trace gases has produced powerful transient tracers of fluid motion and time-dependent processes in aquatic systems (e.g. CFCs, SF6). However, for the CFCs, the Montreal Protocol regulations have lead to reduced emissions and to atmospheric trend reversal. The resulting ambiguity in the transient signals and the eventual disappearance from the atmosphere launches a search for new tracers. Under this view we present records of atmospheric halogenated trace gases, mainly from the Advanced Global Atmospheric Gases Experiment (AGAGE). Quasi-continuous in-situ measure-ments of more than 50 compounds are made at several stations around the globe. The measurements track the global atmospheric back-ground as well as signals of regional pollution such as the Asian out-flow. The records are completed back in time using air archives such as air stored in canisters and polar firn. The measurements include the major ozone-depletion gases, which are regulated by the Montreal Protocol, and their replacements, most of which are powerful greenhouse gases that are regulated within the framework of the Kyoto Protocol. Chlorofluorocarbons (CFCs) have been replaced by hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs). These trends toward the use of less stable substances is advantageous from the climate perspective but poses difficulties when used as aquatic tracers. Perfluorocarbons (PFCs, e.g. CF4), which are extremely stable atmospheric compounds (lifetimes are 1000nds of years) are another group of potential new tracers. In addition to inertness in air and water, there are numerous additional requirements for the usefulness as tracer, such as atmospheric abundance, history and trend, solubility, and sensitivity to current measurement techniques.

The Phanerozoic $\delta^{88/86}Sr$ record of seawater: New constraints on past changes in oceanic carbonate fluxes

HAUKE VOLLSTAEDT[1,*,+] ANTON EISENHAUER[1], KLAUS WALLMANN[1], FLORIAN BÖHM[1], JAN FIETZKE[1], VOLKER LIEBETRAU[1], ANDRÉ KRABBENHÖFT[1], JURAJ FARKAŠ[2,3], ADAM TOMAŠOVÝCH[4], JACEK RADDATZ[1] AND JÁN VEIZER[5]

[+]Present address: Institut für Geologie der Universität Bern

The isotopic composition of Phanerozoic marine sediments provides important information about changes in seawater chemistry. In particular, the established radiogenic Sr isotope system is a powerful tool for constraining plate tectonic processes and their influence on atmospheric CO_2 concentrations. However, the $^{87}Sr/^{86}Sr$ isotope ratio of seawater is not recording temporal changes in the marine Sr output flux, the latter controlled mainly by the burial of $CaCO_3$ on the ocean floor. Here, we present the first stable isotope record of Sr for Phanerozoic seawater ($\delta^{88/86}Sr_{sw}$), which we consider being sensitive to imbalances in the Sr input and output fluxes. This $\delta^{88/86}Sr_{sw}$ record varies from ~0.25‰ to ~0.60‰ with a mean of ~0.37‰. Overall, the Phanerozoic $\delta^{88/86}Sr_{sw}$ record resembles that of the Ca isotope record ($\delta^{44/40}Ca_{sw}$), but differs considerably from the radiogenic Sr isotope record ($(^{87}Sr/^{86}Sr)_{sw}$). This implies different controlling mechanisms for the two Sr isotope systematics in the oceans. A new numerical modeling approach, which considers both $\delta^{88/86}Sr_{sw}$ and $(^{87}Sr/^{86}Sr)_{sw}$, yields improved estimates for Phanerozoic fluxes and concentrations for seawater Sr. During the Phanerozoic, the oceanic net carbonate flux of Sr ($F(Sr)_{carb}$) varied between an output of -4.7×10^{10}mol/Myr and an input of $+2.3 \times 10^{10}$mol/Myr with a mean of -1.6×10^{10}mol/Myr. On time scales in excess of 100Myrs the $F(Sr)_{carb}$ is proposed to have been controlled by the relative importance of $CaCO_3$ precipitates during the "aragonite" and "calcite" sea episodes. On time scales less than 20 Myrs $F(Sr)_{carb}$ is likely controlled by short-term variations in carbonate burial rate (linked to ocean acidification or anoxia) and changes in carbonate weathering and recrystallization on the shelf, leading to transient changes in the oceanic carbonate alkalinity budget.

High-temperature rheology of a megacryst-bearing mugearitic magma from Etna (Italy)

ALESSANDRO VONA[1]*, ANDREA DI PIAZZA[1], EUGENIO NICOTRA[2], CLAUDIA ROMANO[1] AND MARCO VICCARO[2]

[1]Dipartimento di Scienze, Università di Roma Tre, Italy, alessandro.vona@uniroma3.it (*presenting author)
[2]Dipartimento di Scienze Biologiche Geologiche e Ambientali, Università di Catania, Italy

We performed a series of concentric cylinder viscosity measurements at high temperature ($1000 < T < 1400$ °C) and high strain rates ($10^{-2} – 10^{1}$ s^{-1}) to investigate the multiphase rheology of a mugearitic lava from Etna volcano. Natural samples exhibit porphyritic index ranging between 30 and 60 vol%. The mineral assemblage is constituted by megacrystic plagioclase (20–50 vol%), phenocrysts of olivine, augitic clinopyroxenes and Fe-Ti oxides, and a microcrystalline groundmass composed prevalently of plagioclase (75 vol%). The knowledge of the rheological evolution during crystallization is paramount in order to understand completely the dynamics of magma transport from the storage zones up to the surface. We have firstly measured the viscosity of the pure liquid phase on both the bulk rock (i.e. initial crystal-free magma) and the separated groundmass (i.e. residual liquid). The slight compositional variation due to crystallization does not affect substantially the viscosity. The contribution of plagioclase megacrysts to magma rheology has been then evaluated through a set of experiments on partially re-melted samples. We defined a temperature-time window in which groundmass is completely melted and different amounts of megacrysts (20-50 vol%) are preserved. Results confirmed the dependence of rheology on the textural features (crystal content, shape, orientation and size distributions) of the crystal-liquid suspension. The characteristics of these samples allowed us to investigate the viscous flow behavior of medium-high concentrated suspensions at strain rates and temperature pertaining to the natural systems. The results of this study were compared with literature models predicting the rheological behavior of crystal-bearing suspensions and were used to constrain the history of storage and transport of these peculiar magmas.

Plagioclase crystallization kinetics in basalts by high-T viscosity measurements

A. VONA[1] AND C. ROMANO[1]*

[1] Dip. di Scienze, Univ. Roma Tre, Italy,
alessandro.vona@uniroma3.it
claudia.romano@uniroma3.it (*presenting author)

In this study we explore the effect of undercooling and stirring on the crystallization kinetics of remelted basaltic material from Stromboli (pumice from the 15th March 2007 paroxysmal eruption) and Etna (1992 lava flow). Isothermal crystallization experiments were conducted at different degrees of undercooling and different applied strain rate (T=1157-1187 °C and strain rate = 4.26 s^{-1} for Stromboli; T=1131-1182 °C and strain rate = 0.53 s^{-1} for Etna). Melt viscosity increased due to decreasing temperature and increasing crystal content and achieved a steady value after 10^4-10^5 s. The mineralogical assemblage comprises sp + plg (dominant) ± cpx with an overall crystal fraction between 0.06 and 0.27, increasing with undercooling and flow.

Both degree of undercooling and deformation rate deeply affect the kinetic of the crystallization process. Plagioclase nucleation incubation time strongly decreases with increasing ΔT and flow. Plagioclase growth rates G display relative small variation with Stromboli samples (high strain rate) showing higher values ($G=10^{-7.7}$ m s^{-1}) compared to G values from Etna samples (low strain rate; $G=10^{-8.5}$ m s^{-1}).

G values obtained in this study are generally one or two order of magnitude higher compared to those obtained in literature for equivalent undercooling conditions. Stirring of the melt, simulating flow or convective conditions, facilitates nucleation and growth of crystals via mechanical transportation of matter, resulting in the growth rates observed. Any modeling pertaining to magma dynamics in the conduit (e.g. ascent rate) and lava flow emplacement (e.g flow rate, pahoehoe - ‘a‘a transition) should therefore take the effects of dynamic cristallization into account.

Fast hydration of volcanic glass at low temperatures

During volcanic eruptions, magma loses most of its volatiles and cools below the glass transition temperature. However, natural volcanic glass is often oversaturated in water. The water often is distributed inhomogeneously and local increases can be observed around textural features such as bubbles, crystals and cracks. The origin of these heterogeneities can either be redistribution of magmatic water or dissolution of meteoric water. However, the processes of dissolution of water in a solid glass and in a silicate melt at elevated temperatures vary significantly and the quantities, timescales and speciation of water dissolution and diffusion remain poorly constrained.

We present preliminary results of water measurements on naturally hydrated volcanic glass and experimentally hydrated silicate glasses. Water heterogeneities in natural, volcanic rhyolitic glass around cracks, bubbles and spherulitic crystals as well as flow banding show increases of up to ~0.2 wt. % above the general water concentrations of ~0.045 to 0.1 wt. %. Textural and numerical proxies based on bulk water diffusion indicate timescales of hydration from hours to months. We propose to adapt these models to consider water speciation and variation with temperature.

To estimate timescales and quantities of hydration, we rapidly hydrated natural and synthetic (Fe-free) glass in a water vapor saturated Argon atmosphere at temperatures below the glass transition while recording enthalpy and gravimetric changes in a simultaneous thermal analysis. Preliminary data shows that a weight gain of 0.15 wt. % in hydration can be reached over 10 h at 400ºC.

We evaluate the possibility for glass to physically intrude nanopores and chemically diffuse into the structure. Therefore common models of water dissolution, speciation, and distribution in silicate glasses need to be revised for low temperatures and further experimental and analytical work is needed to create reliable quantitative models.

River denudational transport to the sea using the oceans $^{10}Be(meteoric)/^{9}Be$ ratio

F. VON BLANCKENBURG[1] AND J. BOUCHEZ[1]

[1]GFZ Potsdam, Telegrafenberg, Potsdam, Germany (*correspondence: fvb@gfz-potsdam.de)

The ratio of the meteoric cosmogenic nuclide ^{10}Be ($T_{1/2}$ = 1.39 My) to the stable isotope ^{9}Be is a proxy of terrigenous input into the oceans. The system combines a tracer of roughly constant flux to the Earth surface (over time scales characteristic of weathering) with one that depends on its release rate from rock by weathering. Using a mass balance model we previously quantified how the $^{10}Be(meteoric)/^{9}Be$ traces weathering and erosion from the soil to the river scale [1].

Here we take this tracer further by exploring this isotope ratio when river dissolved and sedimentary material is discharged into the ocean, where meteoric ^{10}Be is added by direct precipitation into the oceans. Using river Be data we first find that the fraction of mobile ^{9}Be (meaning unlocked from silicate minerals that is now either dissolved or adsorbed onto sedimentary particles) in rivers is globally 20%. We next find that a measured ocean dissolved $^{10}Be/^{9}Be$ ratio of about 1×10^{-7} [2] is satisfied by the mass balance if only 10% of the mobile river Be is eventually dissolved into the oceans by boundary exchange. This number is obtained using the sum of global solid and dissolved river fluxes [3], an average crustal ^{9}Be concentration of 2.5ppm, and an atmospheric ^{10}Be flux of $1x10^{6}$ atoms $g^{-1}cm^{-2}$.

There is good agreement between modeled and measured ocean $^{10}Be/^{9}Be$ ratios when we perform this mass balance for each ocean basin. Only the southern Atlantic deviates from the predicted value, which can be explained by the dominant external deep and bottom water inputs that affect the measured ratio.

We show that the fraction of mobile ^{9}Be does not change significantly over a large range of global denudation rates. Therefore, the $^{10}Be/^{9}Be$ ratio can serve as a tracer that, unlike radiogenic and stable isotope ratios, truly quantifies past denudation rate and hence terrigenous input into the oceans at a temporal resolution exceeding the residence time of Be in the oceans (ca. 600 years).

Quantification and speciation study of the marine solid-phase iron pool

B.P. VON DER HEYDEN[1]*, A.N. ROYCHOUDHURY[1] AND S.C.B MYNENI[2]

[1]Dept. of Earth Sciences, Stellenbosch University, Stellenbosch 7602, South Africa (*correspondence: bvon@sun.ac.za)

[2]Dept. of Geosciences, Princeton University, Princeton, NJ 08544, USA

Iron chemistry is tightly linked to marine primary productivity, particularly in High Nutrient Low Chlorophyll (HNLC) regions of the world's oceans, where Fe is commonly the limiting nutrient. Only about one third of the total iron present in the upper 200m of the open ocean water column is present in the smallest 'soluble' size fraction; the remainder is bound to colloidal ligands or incorporated into particles and biology greater than the 0.02μm-1000kDa size cut-off. From analyses of a global dataset, colloidal Fe (cFe) behaviour is found to vary between different ocean basins and there is evidence for a seasonal cycle in cFe concentration, associated with depletion during the summer growth season. Controls on distribution and concentration of this (quantitatively more important) larger Fe size class are linked to distance from shore, ambient ligand concentration, and colloid stability and inorganic solubility.

Despite the importance of size-fractionated Fe study, complementary chemical and mineralogical information is required to more fully understand the role of solid phase Fe in the marine system. We have developed a novel Fe L-edge x-ray technique that incorporates both high-resolution (12nm resolution) scanning transmission X-ray microscopy and *in-situ* L_3-edge XANES spectroscopy. Local chemical information derived from the XANES spectra reflect variations in Fe valence state, ligand type and coordination, and the degree of distortion within Fe polyhedra. For use in mineralogical identification of sub-micron sized particles, we present a 2D graphic plot based on variations in the spectral parameters of standard Fe-rich phases. Despite some limitations associated with particle thickness and spectral saturation, this plot has been successfully applied in speciation studies of particles collected from both marine and fluvial systems. A case study is presented highlighting significant chemical differences identified in marine particles (20-700nm in diameter) sampled from the euphotic zone of the different frontal zones of the Southern Ocean. The implications of these differences are discussed in terms of particle solubility and biological availability.

Detection of engineered cerium oxide nanoparticles in the environment

FRANK VON DER KAMMER[1], ELISABETH NEUBAUER[1], ROBERT B. REED[1,2], JAMES F. RANVILLE[2] AND THILO HOFMANN[1]

[1]Department of Environmental Geosciences, University of Vienna, frank.kammer@univie.ac.at

[2]Department of Chemistry and Geochemistry, Colorado School of Mines

Cerium oxide (CeO_2) nanoparticles are increasingly used in products such as diesel fuel combustion catalysts. CeO_2 nanoparticle emission into the environment is of concern due to potential ecotoxicological effects. The detection of engineered CeO_2 nanoparticles in environmental matrices poses a challenge due to predicted concentrations in the part-per-trillion range and the differentiation from nanoparticulate Ce-containing minerals occuring in nature.

Data provided by the Forum of European Geological Surveys (FOREGS) show La:Ce ratios of 0.50 ± 0.05 in bulk topsoils and stream sediments sampled across Europe, while engineered CeO_2 nanoparticles exhibit La:Ce ratios in the range of 0.001 to 0.002. Therefore, deviations from the "natural" La:Ce ratio may potentially be used for the identification of engineered CeO_2 nanoparticles in environmental matrices.

Sediment and preconcentrated water samples from uncontaminated sites were analyzed by flow field-flow fractionation (FFF) coupled to light scattering detection and inductively coupled plasma mass spectrometry (ICPMS) to determine size distributions and elemental composition of the natural nanoparticles. Preliminary results show that La:Ce ratios are constant at about 0.5 across the natural nanoparticles from unpolluted streams.

By addition of engineered CeO_2 nanoparticles at various concentrations to the natural nanoparticle suspensions followed by FFF analysis, we probe the sensitivity of the size-resolved La:Ce ratios as a tool for determination of engineered CeO_2 nanoparticles. FFF size fractions were collected and analyzed by single particle ICPMS, with the aim of differentiating between natural Ce-containing suspended particulate matter and engineered CeO_2. The results were compared to samples from potentally contaminated road runoff samples.

Preliminary findings on the strengths and weaknesses of these methods for the detection of engineered CeO_2 nanoparticles in environmental matrices will be presented.

Hydrological change in the Turkana Basin through the termination of the African Humid Period: The lacustrine Sr-isotope record

H.B. VONHOF[1]*, J. KRAUSE[1], A. JUNGINGER[2], T. JOHNSON[3], J. VAN DER LUBBE[1] AND J. JOORDENS[1]

[1]VU-University Amsterdam, the Netherlands (*correspondence:h.b.vonhof@vu.nl)

[2]Potsdam University, Germany

[3] University of Minnesota Duluth, Duluth USA

At the Termination of the African Humid Period (AHP) important hydrological changes occurred in NE Africa. Lake Turkana in Northern Kenya is one of the larger lakes in the East African Rift Valley and its Holocene history is relatively well studied. The lake dropped by ~ 80 meters at the end of the AHP, presumably caused by a reduced water supply from the Ethiopian highlands, brought to the lake by the Omo River. The Omo River at present supplies more than 80% of the water to Lake Turkana. In the Holocene this situation was different, with significant water supplied to Turkana by two neighbouring Basins: The Chew Bahir Basin to the Northeast and the Suguta Basin to the South.

Here we have analysed the Sr isotope variation of Holocene ostracods and bivalves to identify Holocene changes in water provenance to Lake Turkana. Results show a clear trend in Holocene Sr isotope values. We interpret higher values in the Early Holocene to reflect significantly increased contribution of water from the Chew Bahir Basin. Application of a Sr-isotope mass balance model allowed us to put constraints on the magnitude and rate of hydrological change in Lake Turkana.

The combined signature of Sr- and oxygen isotope variation in Holocene Lake Turkana is in line with a previously postulated increase in rainfall sourced from the Indian Ocean in the Horn of Africa at AHP times.

CA-U-Pb zircon dating obtained by the LA-ICP-MS system: Impact for their interpretations

A. VON QUADT[1]*, D. GALLHOFER[1] , M. WAELLE[1], AND C.A. HEINRICH[1] AND I. PEYTCHEVA[1,2]

[1] ETH Zurich Inst. for Geochemistry und Petrology, Clausiusstrasse 25, 8092 Zürich, Switzerland
[2] BAS Sofia Inst. for Geology, 1113 Sofia, Bulgaria
*vonquadt@erdw.ethz.ch

Laser ablation ICP-MS is a powerful method to determine the age of rocks by measuring U/Th/Pb isotopes. The method is fast, cheap and several applications present precise (< 1% $^{206}Pb/^{238}U$ age errors) and accurate results using corrections and reference materials [1]. For several years U-Pb zircon analyses by TIMS are using the CA [chemical abrasion] technique to avoid domains that have lost Pb parts [2,3]. In this work we apply the same CA technique for LA-ICPMS analyses, using the Excimer 193nm laser system with a constant geometry ablation cell connected to the quadrupole ICP-MS (PerkinElmer, Elan 6100). The selected target material are zircon grains of intrusive rocks with ages of 24 Ma (Miocene) and 80 Ma (Cretaceous) that show no inherited components.

The analyses we include TIMS and LA-ICPMS measurements of U/Pb ratios of CA- and non CA-treated zircons. All non CA-treated zircon measurements show a broader range of their $^{206}Pb/^{238}U$ ages including ratios which refer to recent lead loss or to small inherited Pb components. The CA-treated zircon measurements show a more homogenious age pattern due to the removal of domains with lead loss. In the case of not overlapping concordant ages the cluster with the youngiest ages should be interprated as time of magma crystallization, which is an important advantage of the techniques. Most publications [4] take the 2 sigma error into account for their calculation of $^{206}Pb/^{238}U$ ages; following this procedure we can demonstrate that the non CA-treated U/Pb ages are not overlapping with the CA-treated zircon grains measured by LA-ICP-MS and TIMS techniques. The standard error of this mean has even less geological significance if age variations are real [5]; note that the value of the standard error of the mean would decrease if greater numbers of zircons were measured.

Souring control by six years of nitrate injection into a low temperature oil field

G. VOORDOUW[1]*, A. AGRAWAL[1], HYUNG SOO PARK[1], Y. SHEN[1], T. R. JACK[1], K. MINER[2] AND A. BENKO[3]

[1]Department of Biological Sciences, University of Calgary, Calgary, Alberta, Canada
[2] Baker Hughes, Medicine Hat, Alberta, Canada
[3] Enerplus Corporation, Calgary, Alberta, Canada

Production of oil by water injection can result in souring by sulfate-reducing bacteria (SRB). Souring can be prevented or reversed by inclusion of nitrate in the injection water, which boosts the activity of nitrate-reducing bacteria (NRB). In the Medicine Hat Glauconitic C (MHGC) field, oil production through water injection was started in 2000. Souring, was noted in 2006. Field-wide injection of 2 mM nitrate was adopted as a souring control strategy in 2007. We have monitored the success of this strategy by monthy sampling of producing wells and analyzing the concentrations of sulfate, sulfide, nitrate and nitrite [1], as well as by determining mirobial community composition [2].

Field-wide nitrate injection decreased produced sulfide initially, but this was followed by recovery. Microbial zonation in which NRB grow close to the injection wellbore and SRB deeper in the reservoir was the suggested cause for this. Successful injection of nitrate pulses exceeding the nitrate reduction capacity of the NRB gave credit to this idea [1]. Constant nitrate injection over the past 6 years has given nitrate breakthrough at an increasing number of injection wells. This was associated with removal of sulfide, as well as with breakthrough of sulfate, nitrate and nitrite. Production of oil/water depleted of toluene and other alkylbenzenes and containing increased proportions of the toluene-utilizing NRB *Thauera* were also observed [2].

Long-term injection of nitrate and changes in water management strategy have caused a near complete reversal of souring in the MHGC field. Despite lack of success in the first two years persistence has since paid off.

Geochemistry of uranium in the reduced carbonaceous sediments of small lakes in Baikal Region

YULIA VOSEL[1], VERA STRAKHOVENKO[1] AND IRINA MAKAROVA[1]

[1]Sobolev Institute of Geology and Mineralogy Siberian Branch of Russian Academy of Sciences, vosel@yandex.ru

The most commonly identified pathway to explain the accumulation of authigenic U in reduced sediments is the microbially mediated reduction of U(VI) to less soluble U(IV) [2]. However previous researchers could not acquire the direct evidence of uranium reduction and formation of it's poorly soluble oxides, so the additional investigation of the problem is needed [1]. Our work is aimed at detecting of U reduction process in sediments of two small lakes (fresh and salt) which are located in the Baikal region. To achieve this goal we separated sediments to lithogenic and various authigenic fractions using the method of sequential extraction, which is based on the method of Tessier [3]. According to our research values of activity ratios ($^{234}U/^{238}U$) in the insoluble residue significantly differ from 1 in both lakes. This indicates the presence in the residuals not only the lithogenic fraction, but a noticeable amount of UO_2. Uranium accumulates in lake sediments mainly through chemogenic processes, in different forms (in oxides and hydroxides, organic matter or isomorphic impurities in carbonates). This work was supported by grant RFBR 12-05-31087mol_a

[4] Université Joseph Fourier, Grenoble, 1381 rue de la Piscine, 38400 Saint-Martin d'Hères, France, charlet38@gmail.com

Selenium (Se) is an essential trace element for life. However, it can negatively affect human health due to its narrow range of beneficiary concentration and its unequal distribution in the surface environment. To date, sources, sinks and fluxes in the global Se cycle are poorly understood and quantified. Although methylation and volatilization of Se from terrestrial environments is known to occur (and is studied for e.g. bioremediation purposes), its relevance to the natural global atmospheric Se budget remains unknown.

We applied a novel chemotrapping method in combination with a flow-through chamber system to identify and quantify volatilization of Se, sulfur (S) and arsenic (As) from a minerotrophic peat bog in southern Switzerland. We were able to determine gaseous fluxes of Se (0.11 μg $Se.m^{-2}.d^{-1}$), S (37 μg $S.m^{-2}.d^{-1}$) and As (0.16 μg $As.m^{-2}.d^{-1}$) in the form of non-, mono- and di-methylated species. By comparing these fluxes with total concentrations of these elements in both the peat and surface water, it became evident that Se is approximately 40 to 110 times more efficiently volatilized from the peat bog than As and S, respectively. Furthermore, we observed that elevated temperatures increased volatilization of the investigated elements to a different extent. Our results suggest that Se volatilization from wetlands, and possibly other terrestrial environments, may crucially influence the biogeochemical cycle of Se.

Early Paleozoic intrusives of the Kuznetsk Alatau, Siberia: Isotopic evidence of oceanic lithosphere participation in sources

V.V. VRUBLEVSKII*, I.F. GERTNER AND A.D. KOTELNIKOV

Tomsk State University, Tomsk, Russia (*vasvr@yandex.ru)

Products of the Early Paleozoic intrusive magmatism are represented in the Kuznetsk Alatau (KA) by granitoid, gabbro-syenite, and alkali basite complexes. They were formed during the period of about 510-490 Ma, which is in the Central Asian fold belt [1]. The magmatic activity implies the presence of multi-component melt sources with age that close to the age of the oceanic lithosphere formation. Nd-Sr isotopic signatures discovered for four studied complexes formed in different ways indicate possible participation of Paleo-Asian Ocean (PAO) lithosphere in the processes of magma generation at the Early Paleozoic stage of this ocean's evolution. The oldest complexes (about 510 Ma) are the differentiated series from gabbro to granodiorite as well as alkaline basic complexes. Despite the petrogenetic differences, these complexes have similar isotopic composition of Nd (εNd_T~ +4,8…+5,0). Such values are typical either for magmatic derivatives of moderately depleted mantle, or for mixing products of DMM or PREMA reservoirs with EM-type mantle and continental crust materials. The influence of crust contamination is seen in high ratio of Sr-isotopes in the rocks (εSr_T ~ +1…+28). Granitoids and gabbro–syenite series with the age of about 500-490 Ma don't have significantly different Nd-isotopic compositions (εNd_T ~ +3,5…+4,6). Apparently, it is confirmed by narrow range of these $T(Nd)_{DM}$ values (~ 0,8–0,9 Ga). According to different views [2, 3], the beginning of the Rodinia supercontinent's break-up, and following the PAO opening are estimated to be 970-800 Ma Based on our data, Sm-Nd isotopic age of ultrabasites and gabbroids of the layered series and restite suites varies from 955 to 890 Ma, respectively. Magmatism probably developed under the conditions of plume interacting with active continental margin coupled with MORB+PREMA+EM matter mixing.

This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.0686, 14.B37.21.1257).

Mineralogical and geochemical variations in lower Godavari River sediments, Peninsular India: Implications to source rock weathering

SHILPA VUBA*, SADIA FARNAAZ, NETRAMANI SAGAR AND S. M. AHMAD

CSIR-National Geophysical Research Institute, Uppal Road, Hyderabad – 500 007, India (*correspondence:shilpavuba@gmail.com)

Godavari River is the third largest river in the Indian sub-continent, which originates in the Deccan Traps and drains an area of 3.1 x 10^5 km^2. The river flows in the east and the south-easterly direction for a distance of 1465 km before discharging into the Bay of Bengal. The major, trace and rare earth elements geochemistry and clay mineral compositions in bed sediments from lower reaches of Godavari River suggest that they are derived from weathering of felsic rocks. Trace and rare earth elemental compositions indicate evidence of sedimentary sorting during transportation and deposition. Lower concentrations of transition elements, such as V, Ni and Cr imply enrichment of felsic minerals in these bed sediments. The REE pattern in lower Godavari sediments is influenced by the degree of source rock weathering. The light rare earth elements (LREE) content are indicating greater fractionation compared to the heavy rare earth elements (HREE). A striking relationship is observed between TiO_2 and ∑REE content suggesting a strong control by LREE-enriched titaniferous minerals on REE chemistry. Shale-normalized REE pattern demonstrate a positive Eu anomaly, suggesting weathering of feldspar and their secondary products, which are enriched in Eu. Chondrite-normalised REE pattern is characteristic of felsic volcanic, granites and gnessic source rocks. Trace elemental compositions in sediments located near urban areas suggest influence of anthropogenic contamination. Chemical Index of Alteration (CIA) is high (avg. 65.76), suggesting a moderate chemical weathering environment. X-ray diffraction analysis in clay fraction shows predominance of clay minerals that are formed because of the chemical weathering of felsic rocks.

CO_2 speciation and transport properties of CO_2-bearing silicate melts from First-Principle simulations

R. VUILLEUMIER[1]*, A. SEITSONEN[2], N. SATOR[3] AND B. GUILLOT[3]

[1]UMR 8640 CNRS-ENS-UPMC, Département de chimie de l'ENS, 24, rue Lhomond, 75005 Paris, France. (*correspondence: rodolphe.vuilleumier@ens.fr)

[3] LPTMC, UPMC, UMR CNRS 7600, case courrier 121, 4 place jussieu, 75252 Paris cedex 05, France (sator@lptmc.jussieu.fr,guillot@lptmc.jussieu.fr)

There are growing evidences of the existence of CO_2-rich magmas in the upper mantle [1-3]. So the role of carbon-rich melts at depth is now becoming a credible scenario to explain the extraction of CO_2 from the source region to the surface. During the last three decades many studies have been devoted to measure the solubility of CO_2 in silicate melts of various composition. But due to experimental difficulties these studies were generally restricted to low and moderate pressures (below ~20 kbar). IR spectroscopy has emphasized the importance of CO_2 speciation which may exist either as molecular CO_2 or as carbonate ion (CO_3^{2-}), the molecular form being favored in polymerized (silicic) melts while the carbonate ion is dominant in depolymerized (basic and ultrabasic) melts. However it has been suggested recently [4,5] that the CO_2 speciation observed in quenched glasses by IR spectroscopy may not be representative of that in silicate melts equilibrated at high temperature.

To address this issue we have performed First-Principle Molecular Dynamics of CO_2-saturated basaltic and kimberlitic melts. The molecular form is indeed favored in the more polymerized melt. Furthermore, a new transient species is also identifed. The electrical conductivity of the CO_2-saturated basaltic and kimberlitic melts has also been evaluated and found in good agreement with experiment. These results have also been used to develop an empirical force field for describing CO_2-rich melts by classical MD simulations.

Pyrrhotites (Fe_7S_8) from three different komatiite hosted massive nickel sulphide deposits have been analysed with electron backscatter diffraction analysis (EBSD) and laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) in order to understand how trace elements behave during deformation.

EBSD data reveals strain localisation microstructures in sample from greenschist facies whereas in sample from mid-amphibolite facies, pyrrhotite contains multiple parallel low angle boundaries and crystallographic preferred orientation. A sample from the upper amphibolite facies, is characterised by very large >2cm grains that contains numerous deformation twins. Laser ablation ICP-MS data reveal increased concentrations of Pb, Bi and Ag along low angle subgrain boundaries and twin boundaries. The increased concentrations of Pb, Bi and Ag are explained by diffusion of the trace elements along fast diffusion pathways (low angle and twin boundaries). Trace element variations are developed at the low-temperature stage of the tectonic history of the three deposits. Diffusion of Pb, Bi and Ag is triggered by their low solubility in sulphide phase, pyrrhotite.

Geochemistry and nano-structure of putative filamentous microbes from the 3.24 Ga Sulfur Springs Group, Pilbara, Western Australia

D. WACEY[1,2]*, M. SAUNDERS[2], M.R. KILBURN[2], J.B. CLIFF[2], C. KONG[3], M.E. BARLEY[2] AND D. N. MCLOUGHLIN[1]

[2]University of Western Australia, WA 6009, Australia
[3]University of New South Wales, NSW 2052, Australia

Pyritic filaments from one of Earth's oldest volcanic hosted massive sulfide (VHMS) deposits within the 3.24Ga Sulfur Springs Group, Western Australia, have been interpreted as thermophilic chemotrophic micro-organisms [1]. This interpretation [1] was based upon textural, morphological and inferred behavorial characteristics of the filaments. However, no geochemical evidence for biology has yet been reported, so an alternative explanation as abiotic mineral filaments remains to be discounted.

Here we revisit these putative filamentous micro-organisms, using a suite of high-spatial resolution techniques to investigate their geochemistry and nano-structure.

NanoSIMS elemental mapping reveals occassional enrichments of carbon within some of the pyritic filaments. Similar patterns of carbon enrichment are seen in *bona fide* pyritic filamentous microfossils from the 1.9 Ga Gunflint chert that were also pyritised by hydrothermal fluids.

In situ SIMS multiple sulfur isotope data show small but significant $+\Delta^{33}S$ (and $-\Delta^{36}S$) anomalies, consistent with previous bulk data from this VHMS deposit [2], indicating mixing of a hydrothermal fluid containing sulfur of magmatic origin ($\Delta^{33}S=0$) with circulating seawater containing reduced sulfur derived from atmospheric elemental sulfur ($+\Delta^{33}S$).

The nano-structure of the filaments was investigated in the TEM using focused ion beam (FIB)-milled ultrathin sections, and by 3D FIB-SEM nanotomography. Notable features include circular to elliptical filament cross sections mostly comprising single pyrite crystals, clustering of filaments in pairs and triplets, and a common preferred orientation of many filaments.

These data provide new insights into one of Earth's oldest black-smoker-type environments and potential associated life. The strength of evidence for the biogenicity of the filaments will be discussed.

Clumped isotopes, $\delta^{18}O$, $\delta^{13}C$, $\delta^{11}B$, $^{87}Sr/^{86}Sr$: A multiproxy approach applied to Silurian brachiopod shells

ULRIKE WACKER[1], JENS FIEBIG[1], AXEL GERDES[1], AXEL MUNNECKE[2], MICHAEL M. JOACHIMSKI[2] AND BERND R. SCHÖNE[3]

[1]Department of Geosciences, Goethe University Frankfurt, Germany (U.Wacker@em.uni-frankfurt.de; Jens.Fiebig@em.uni-frankfurt.de; gerdes@em.uni-frankfurt.de)
[2]GeoZentrumNordbayern, FAU Erlangen-Nürnberg, Germany (axel.munnecke@pal.uni-erlangen.de; michael.joachimski@gzn.uni-erlangen.de)
[3]Institute of Earth Sciences, Johannes Gutenberg-University, Mainz, Germany (schoeneb@uni-mainz.de)

The geochemical composition of fossil brachiopod shells reveals information about physical and chemical conditions of the paleo-ocean. We studied different stable isotopic systems on Silurian brachiopod shells from Gotland/Sweden to test their resistance against diagenesis and their use for paleoreconstructions.

In general, preanalyses (CL, SEM and trace element concentrations) of more than 60 shells indicate very good preservation. However, SEM investigations show that partial recrystallization occurred resulting in a patchwork of pristine and altered structures. $\delta^{18}O$ and $\delta^{13}C$, clumped isotope (Δ_{47}), as well as high resolution (LA-(MC)-ICP-MS) $\delta^{11}B$ and $^{87}Sr/^{86}Sr$ data of several brachiopod shells and their inner fillings (mudstones and sparitic cements) were measured. Clumped isotope temperatures range from 30°C to 70°C, indicating, that Δ_{47} values were partly reset during diagenesis. Because highest shell alteration temperatures correspond to those measured for the cements, we propose that ^{13}C-^{18}O clumps were reset during cement formation. Since no correlation between Δ_{47} and $\delta^{18}O$ values is obtained, we conclude that the bulk oxygen isotopic composition was not altered concurrently. Furthermore, $\delta^{11}B$ and $^{87}Sr/^{86}Sr$ values of the brachiopods seem to reflect pristine marine signatures. Therefore we suggest that the alteration of clumped isotope values occurred at low water-rock ratios, not influencing $\delta^{18}O$, $\delta^{13}C$, $\delta^{11}B$ and $^{87}Sr/^{86}Sr$ signals.

B-isotope variations in tourmaline in the Varuträsk rare-element pegmatite: the role of mica

THOMAS WAGNER[1], ROBERT. B. TRUMBULL[2]*, KARIN SIEGEL[3], ERIK JONSSON[4] AND CHRISTOPH A. HEINRICH[5]

[1]Division of Geology, University of Helsinki, Finland
[2]GFZ German Research Centre for Geosciences Potsdam Germany (*presenting: bobby@gfz-potsdam.de)
[3]Earth & Planetary Sciences, McGill University, Canada
[4]Earth Sciences, Uppsala University, Sweden
[5]Earth Sciences, ETH Zürich, Switzerland

The Varuträsk rare-element pegmatite in northern Sweden is a classic and typical example of highly fractionated LCT-type pegmatites, with a well-developed internal zoning pattern composed of border, wall and intermediate zones and a quartz core. Major and trace element fractionation trends of feldspars, micas, tourmaline, and columbite-tantalite correlate well with the internal zoning pattern. This pegmatite therefore forms a good basis for a case study on the use of boron isotopes in tourmaline to record processes of pegmatite internal evolution.

Early and mid-stage tourmalines from Varuträsk show a systematic increase in $\delta^{11}B$ values from -14.6 to -6.2 ‰ during crystallization of the primary pegmatite zones. This trend toward ^{11}B-enrichment in the pegmatite magma is opposite to that expected for fluid exsolution or progressive crystallization of tourmaline, and all geochemical and textural evidence suggests a closed-system crystallization without significant influx of external fluids with heavy B-isotope signature. We suggest that crystallization of abundant muscovite in the Varuträsk wall zone depleted the magma in ^{10}B, driving the residual melt toward higher $\delta^{11}B$ values. Rayleigh fractionation models based on measured B contents of 220 ppm in muscovite and 3.4 wt. % in tourmaline show that the muscovite/tourmaline mass ratio required to explain the observed shift in $\delta^{11}B$ values is about 200:1, which is consistent with the modal composition of the wall zone assemblage.

The assumption is commonly made that in rocks where tourmaline is present, it plays the dominant role in B-isotope evolution. This assumption is likely to be true for most crystalline rocks but our study shows that it may not be the case for assemblages with a high modal abundance of micas, as in many pegmatites and related rocks such as greisens.

Speleothem reconstruction of sea-level at Bermuda over the last climatic cycles

K. WAINER[1]*, G.M. HENDERSON[1], A.J. MASON[1], A.L. THOMAS[1], M. ROWE[2], B. WILLIAMS[3], P. J. VAN HENGSTUM[4] AND R. CHANDLER[4]

[4]Woods Hole Oceanographic Institute, Massachusetts, USA
[5]Bermuda Zoological Society, Bermuda

It is now widely accepted that a sea-level rise is associated with global warming [1]. However, its rate, and the height it might reach by the end of the century remain poorly constrained. This study aims to provide better information and precision on the rates and magnitudes of past sea-level change, for periods when sea-level is close to its modern value, using speleothems from Bermudian caves. Speleothems interrupt their growth when they are submerged by sea-water, so U-Th dating periods of growth in coastal sites allows the reconstruction of past sea-level variation versus absolute time [e.g. 2,3,4]. We will present new MC-ICP-MS U-Th ages from a set of speleothems (stalagmites, stalactites, flowstones) collected from -6 to +12 m versus modern sea level from several caves in this northern Atlantic archipelago.

Relative sea-level (RSL) at Bermuda is of particular interest because it is at a distance from northern hemisphere ice sheets where the isostatic response to ice-unloading is uncertain. RSL reconstruction therefore provides both an indicates of possible rates of sea level change, and a test for glacial-isostatic-adjustment (GIA) models.

Our results provide constraint on sea level over the last climatic cycles, and in particular periods when sea level was equivalent or higher than today, at Bermuda which we place in the context of previous assessments of eustatic change, and of GIA models.

Sulfide Re-Os Dating in Modally Metasomatised Peridotites, Insights from Letlhakane (Botswana)

A.N. WAINWRIGHT,*[1] A. LUGUET[1], R.O.C. FONSECA[1] AND D.G. PEARSON[2]

[1] Steinmann Institut, Universität Bonn, Germany *correspondence: (ashlea.wainwright@uni-bonn.de)

[2]Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada

Mantle xenoliths are a geochemist's window into the chemical and mineralogical make-up of the sub continental lithospheric mantle. However, metasomatism can obscure the primary composition and melt depletion history of the xenoliths. Therefore, whole-rock Re-Os age analysis of peridotite xenoliths may provide only a minimum estimate for the age of the lithospheric mantle, and likely reflects the presence of multiple generations of base metal sulfides (BMS) or platinum group minerals (PGM), which differ in age as well as mineralogy and habit. While metasomatic sulphides and/or PGM are likely to yield 'artificially young' Re-Os ages, refractory PGM such as Os-Ir-Ru alloys and refractory sulphides (e.g. laurite) should preserve older ages as a result of their high Os concentrations and resilience to overprinting and isotopic resetting. Together they provide the perfect target to investigate the Os isotopic heterogeneity in mantle samples.

Peridotite xenoliths found associated with the Letlhakane kimberlite (Magondi Belt, Botswana) provide us with a unique opportunity to study modal metasomatic effects on Re-Os and PGE systematics [1]. Whole rock analysis of xenolith samples from Letlhakane show co-variations of Re-Os T_{RD} ages and highly siderophile element fractionations (e.g. Pd/Ir: 0.1, T_{RD}: 2.7Ga – Pd/Ir 1.69, T_{RD} 1.6Ga), due to variable degrees of metasomatic overprint. Three samples that cover the entire metasomatic range were chosen to measure single grain sulfides for Re-Os via micro-distillation. Preliminary results show a wide range in sulfide T_{RD} ages, from future ages to over 3.0 Ga, even in the most metasomatised sample. The habit and structure of the sulfide seems to be the most important factor. Disseminated sulfides occuring in veinlets have the youngest age and most radiogenic $^{187}Os/^{188}Os$. On the other hand, discrete interstitial sulfides exhibit unradiogenic ^{187}Os and Archean ages. Our preliminary findings stress the micro-scale heterogeneity of Os isotopic signatures, which likely reflects mulitple host mineral generations whose origins are linked to the complex multi-event petrogenetic history of mantle samples.

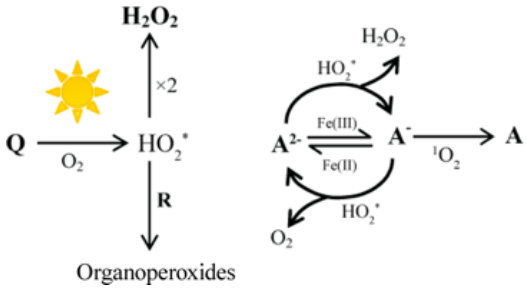
The Role of Reactive Intermediates in Redox Transformations of Iron in Photolyzed Acidic Natural Organic Matter Solutions

T. DAVID WAITE,[1] SHIKA GARG,[1] MARK L. BLIGH[1] AND ANDREW L. ROSE[2]

[1]School of Civil & Environmental Engineering, The University of New South Wales, Sydney; d.waite@unsw.edu.au

[2]Southern Cross Geosciences, Southen Cross University, Lismore; andrew.rose@scu.edu.au

Recent studies of the dark oxidation of Fe(II) in previously photolysed acidic solutions of natural organic matter (NOM) (Garg *et al*. [1]) suggest the superoxide-mediated formation of semiquinone radicals which act as effective oxidants of Fe(II) (Schematic 1).



Schematic 1. Photolysis of NOM generates HO_2* which, in turn, oxidize hydroquinone species (A^{2-}) present in NOM to semiquinone radicals (A^-). These radicals are effective oxidants for low concentrations of Fe(II). After Garg *et al*. [1]

In comparison, on continuous photolysis, light-generated singlet oxygen appears to oxidise A^- to the quinone form (A) with short-lived organoperoxy radicals (ROO*) capable of oxidizing Fe(II) (Garg *et al*. [2]).

Stable isotopic fractionation of Sr and Eu among igneous rocks

S. WAKAKI[123], M. TANIMIZU[1], T. ISHIKAWA[1] AND T. TANAKA[3]

[1]Kochi Institute for Core Sample Research, JAMSTEC, Kochi 783-8502, Japan. (wakaki(at)jamstec.go.jp)
[2]Natural History Sciences, Hokkaido Univ., Japan.
[3]Earth Environmental Sci., Nagoya Univ., Japan.

Sub-permil isotopic variations of Mg, Si, Fe and Sr were observed among igneous rocks, and the possibillity of high temperature isotope fractionation during magmatic processes have been documented (e.g.; Charlier *et al.* , 2012; Savage *et al.* , 2011; Teng *et al.* , 2007; Teng *et al.* , 2008). We report sub-permil to permil order stable isotopic variation of Sr and Eu among igneous rocks with various origins.

28 igneous rocks covering a wide range of chemical compositions (SiO_2 = 46.7 - 78.2 wt.%) were analyzed. Samples were decomposed with a mixture of HF, HNO_3 and $HClO_4$. Granite samples were processed using Teflon bombs. Sr was separated by extraction chromatography using Sr Spec resin (Eichrom). Eu was separated by cation exchange column chromatography using AG 50W-x8 (Bio-Rad) with HCl and α-HIBA. Stable isotopic composition of Sr was analyzed by DS-TIMS technique using ^{84}Sr-^{86}Sr double spike and VG Sector 54-30 at NU. The results are expressed with relative to NBS 987 as $\delta^{88}Sr = [(^{88}Sr/^{86}Sr)_{sample}/(^{88}Sr/^{86}Sr)_{NBS\ 987} - 1] \times 10^3$. The reproducibility of $\delta^{88}Sr$ was ± 0.06. Stable isotopic composition of Eu was analyzed on the Thermo Neptune MC-ICP-MS at JAMSTEC with external normalization using Sm. Potential isobaric interference of BaO was checked and found to be neglegible. The results are expressed with relative to an *Alfa Aesar* Eu_2O_3 reagent as $\varepsilon^{153}Eu = [(^{153}Eu/^{151}Eu)_{sample}/(^{153}Eu/^{151}Eu)_{STD} - 1] \times 10^4$. The reproducibility of $\varepsilon^{153}Eu$ was ± 0.31.

The $\delta^{88}Sr$ and $\varepsilon^{153}Eu$ of the mafic and intermediate samples agreed each other with an average of +0.27 and +0.13, respectively. Felsic samples showed significantly large variations both on $\delta^{88}Sr$ and $\varepsilon^{153}Eu$ ranging from +0.36 to -0.99 and from +0.20 to -5.73, respectively. Our $\delta^{88}Sr$ results for six international reference rocks agree well with the previously reported values. The observed variations of both $\delta^{88}Sr$ and $\varepsilon^{153}Eu$ are correlated with SiO_2 abundances and also with the magnitude of negative Eu anomaly. The correlation between $\delta^{88}Sr$ and $\varepsilon^{153}Eu$ with negative Eu anomaly indicates that the variation of $\delta^{88}Sr$ and $\varepsilon^{153}Eu$ was caused by plagioclase fractionation during magmatic differentiation processes. This observation suggests that the melt-plagioclase isotope fractionation factor (α-1) of Sr and Eu at magmatic temperature is on the order of 10^{-4}.

Anisotropy: A cause of heat flux variation at the CMB?

ANDREW M. WALKER*[1], MICHAEL W. AMMANN[2], STEPHEN STACKHOUSE[3], JAMES WOOKEY[1], JOHN P. BRODHOLT[2] AND DAVID P. DOBSON[2]

[2]Department of Earth Sciences, University College London, Gower Street, London WC1E 6BT, UK
[3]School of Earth and Environment, University of Leeds, Leeds LS2 9JT, UK

We have used atomic scale simulations to determine the thermal conductivity of $MgSiO_3$ perovskite and post-perovskite under D″ conditions and shown that the thermal conductivity of post-perovskite (~12 W/mK) is 50% larger than that of perovskite under the same conditions (~8.5 W/mK). This finding, in agreement with previous studies on analogue materials, means that the high heat flux into cold regions of D″ where post-perovskite is stable is enhanced relative to a simple single-phase case [1]. Furthermore, we have found that the thermal conductivity of post-perovskite is anisotropic, with conductivity along the *a*-axis being 40% higher than conductivity along the *c*-axis. Thus, – similarly to the lithosphere [2] – there is potential for texturing caused by deformation to modify how the mantle is heated from below. We test this idea by coupling our atomic scale results to previous models of texture in D″ [3] and find that anisotropic thermal conductivity may help to stabilise the roots of mantle plumes (Figure 1).

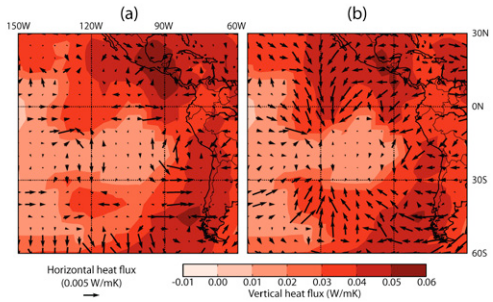

Figure 1: Modelled CMB heat flux at the base of a large plume in the East Pacific. Compared to the isotropic case (a) the horizontal heat flux in the anisotropic textured case (b) feeds heat, and thus boyancy, into the plume.

New Constraints on the Magnitude and Timing of Late Accretion

RICHARD J. WALKER[1]*, MATHIEU TOUBOUL[1], IGOR S. PUCHTEL[1] AND JINGAO LIU[2]

[1]Dept. of Geology, Univ. of Maryland, College Park, MD 20742, USA (correspondence: rjwalker@umd.edu)
[2]Department of Earth & Atmospheric Sciences, Univ. of Alberta, Edmonton, Alberta, Canada

Late accretion is defined as continued planetary growth subsequent to the cessation of core segregation. Late accretion was evidently a common, final step in the formation histories of rocky planetary bodies, regardless of size [1]. Evidence for this comes from estimates of planetary mantle compositions for various bodies, projected to contain raised, and broadly chondritic relative abundances of the highly siderophile elements (HSE). Although a ubiquitous process, the proportions of late accretionary mass additions, relative to planetary mass, may have ranged considerably. For example, current estimates suggest the Earth and Mars received proportionally much more late accreted mass than the Moon, perhaps reflecting stochastic late accretionary processes [2]. The timing of late accretion must also have varied considerably, with late accretion evidently occurring on asteroidal-sized bodies within the first 10 m.y. of solar system formation [1], but also acting on late-formed bodies, such as the Moon.

The nature and timing of late accretion to Earth is a particularly important issue, as this process could have delivered considerable water and organics to the mantle. One possibility is that the putative giant impact that generated the Moon was a major clearinghouse event for HSE, and thus, an event that heralded in a final stage of terrestrial late accretion. The long-term preservation of ^{182}W isotopic heterogeneities in the mantle [3-4], however, likely indicates that the terrestrial mantle was never completely homogenized, and possibly that the cumulative effects of terrestrial late accretion commensed well before the Moon-forming event. The presence of small enrichments in ^{182}W in some early-Earth rocks (Isua [3] and Nuvvuagittuq), coupled with depletions in HSE abundances estimated for their mantle sources, provides some evidence for uneven mixing of late accreted materials into the mantle, although other options to explain the enrichments are also possible. Of note, the magnitudes of ^{182}W enrichments are consistent with the mass addition proportions suggested by HSE abundances [3].

A first principles study of uranyl and neptunyl incorporation into sulfate minerals

S. M. WALKER* AND U. BECKER

Earth and Environmental Sciences, University of Michigan, 2534 CC Little, Ann Arbor, MI 48109, USA (*correspondence: smwalk@umich.edu)

Solid solution formation at the mineral/water interface occurs when an ion in solution replaces an ion in the lattice; however, experimental observations have not fully decoupled the factors that control this process (*e.g*. ionic radius of foreign ion, coordination environment, molecular orbital interactions, charge compensation). In order to examine the thermodynamics of incorporation, the energies of incorporation of uranyl (UO_2^{2+}) into anhydrous sulfate minerals, anglesite ($PbSO_4$), barite ($BaSO_4$), and celestine ($SrSO_4$), are calculated using a quantum mechanical approach. For each mineral, source and sink reference phases are chosen to facilitate the substitution of the uranyl ion with a cation from the host mineral as described by the general equation:

host mineral + *U source* ↔ UO_2^{2+} mineral phase + *sink*
solid UO_3 *solid (Pb,Ba,Sr)O*
UO_2^{2+} (aqueous complex) *$(Pb,Ba,Sr)^{2+}$ (aq. complex)*

Of the three sulfate minerals, the energy of uranyl incorporation into anglesite was the lowest for solid state oxide reference phases (ΔE_{rxn} = 1.57 eV). Anglesite also provided the lowest energy of incorporation of an aqueous species ($UO_2^{2+}{}_{aq}$ with the release of $Pb^{2+}{}_{aq}$). Using aqueous species as source and sink phases but solid incorporation hosts required the combination of periodic and cluster quantum mechanical methods. Incorporation of uranyl was then compared with incorporation of $Np(VI)O_2^{2+}$ and $Np(V)O_2^{+}$ aqueous neptunyl complexes.

Since these static incorporation energies are most closely representative of the enthalpy of incorporation, the free energy was estimated using vibrational entropy values from empirical force field calculations in order to curtail computational expense. These vibrational entropy data tend to make incorporation energy values less energetically uphill. The limits of U- and Np-incorporation were also calculated to predict solid solution behavior.

The geochemisty and mineralogy of responsible mining of rare earths.

FRANCES WALL[1]

[1]Camborne School of Mines, University of Exeter, Cornwall Campus, Penryn, TR10 9EZ, UK. f.wall@exeter.ac.uk

Responsible mining is often regarded as largely a socio-economic issue but although good behaviour and governance are important, the fundamental ore deposit geochemistry and mineralogy also influence many relevant factors. For example, energy use, water use, resource efficiency, financial profitability, potential environmental contamination, and the health, safety and well-being of the work force are all related to the minerals present; to their compositions, sizes, shapes, textural relations, solubilities, amenability to various beneficiation methods, and how strongly thery are held together.

Rare earths, used in many green technologies, are particulary interesting to consider from this point of view. Following the recent supply problems and the designation of rare earths as 'critical' metals, a wide range of rare earth deposits are now under active exploration and development, ranging from fresh and weathered carbonatites and alkaline rocks, to beach sands, ion adsorption clays and even sea floor muds. These divserse deposits have have large differences in the characterisitcs listed above and raise a question about whether some deposits are inherently more environmental-friendly that others.

For example, unconsolidated beach sands, such as those currently mined for monazite in India, do not need comminution and thus can require one third of the energy to process than a hard rock carbonatite deposit. However, the monazite in beach sands is mostly derived from granitic protoliths and contains typically several wt% ThO_2, making it radioactive and problematic to store, ship and process. In contrast, rare earth fluorcarbonates in carbonatite deposits have some of the lowest Th contents of any of the rare earth minerals, and carbonatite monazite is also characteristically low in Th.

In order to make comparisons, metrics are required and it is neccessary to balance the various factors, such as energy use, versus the other environmental impacts. The system of apportionment of these impacts when the REE are by-products also makes a large difference to the outcome. Mineral compositions and associations do vary within each deposit type and it is possible to develop a geometallurgical approach to environmental impact early on in an REE exploration project.

Liquid-liquid separation at the onset of $CaCO_3$ formation

Recent experimental characterizations of the early stages of calcium carbonate crystallization reveal an abundance of nanometer-sized prenucleation clusters that appear prior to formation of an amorphous intermediate phase. The prevailing interpretation of the clusters as thermodynamically stable suggests that the nucleation of calcium carbonate may follow a non-classical pathway.

This research uses replica-exchange molecular dynamics techniques to probe the initial formation and onset of order within hydrated calcium carbonate cluster species and lattice gas simulations to explore the more general behavior of clusters during phase separation. A two-phase thermodynamic model is also used to determine the free energy of the clusters as a function of size and to enable comparison with classical nucleation theory.

The results suggest that a spontaneous liquid-liquid phase separation may occur within the range of concentrations for which pre-nucleation clusters are observed. Coalescence of the nanoscale droplets results in the formation of a phase whose structure is consistent with that of amorphous calcium carbonate. The significance of these results is discussed within the context of classical and emerging non-classical phase-separation theories.

The potential of using a sector field ICP-MS for analysis of fluid inclusions by laser ablation ICP-MS

M. WÄLLE* AND C.A. HEINRICH

ETH Zurich, Inst. of Geochemistry and Petrology, Clausiusstrasse 25, 8092 Zurich, Switzerland, (*correspondence: waelle@erdw.ethz.ch)

Laser ablation inductively coupled plasma mass spectrometry (LA-ICPMS) is a successful technique to measure elemental concentrations in fluid inclusions [1]. Depending on their salinity, inclusions in the size a 10 to several tens of micrometres are needed to determine trace element concentrations reliably. Up to now, quardupole (Q-) ICP-MS have been used for this kind of analyses due to its ability to switch fast (e.g. within one millisecond) from one mass to another over the entire elemental mass range. Short settling times are required to record the fast changing transient signals obtained by LA-ICPMS analyses of fluid inclusions. Sector field (SF-)ICP-MS would provide a higher sensitivity than Q-ICPMS and, therefore, have to potential to measure smaller inclusion, demand a higher settling time than the latter ones due to changing the magnetic field.

A fast scanning SF-ICPMS was used to explore the potential of this instrument for analysing fluid inclusions. An assemblage consisting of fluid inclusions in the range of a few micrometres up to 150 μm and a salinity of 4wt% NaCl was used to (i) check the accuracy of the fast scanning SF-ICPMS system and (ii) compare the performance of a Q-ICPMS (PerkinElemer, Elan 6100 DRC) and a SF-ICPMS (ThermoFisher, Element XR) coupled to the same laser ablation system. The fast scanning SF-ICPMS system was able to analyse fluid inclusions with a 1.8 to 2 times smaller diameter, i.e. 5 to 8 times in mass, with a similar accuracy, e.g. on elements like Pb, Ba, Sb or Mg, than the Q-ICPMS system measuring the same elements.

Magma formation in hot-slab subduction zones: Insights from volatile contents of melt inclusions from the southern Cascade arc

WALOWSKI, K.J.[1], WALLACE, P.J.[1], CLYNNE, M.A.[2], WADA, I.[3] AND RASMUSSEN, D.J.[1]

[1]University of Oregon, Eugene, Oregon 97403, USA (correspondence: walowski@uoregon.edu)
[2]USGS Volcano Science Center, Menlo Park, CA, USA
[3]Tohoku University, IRIDeS, Sendai 980-8579, Japan

Cross-arc geochemical variations can provide insight into dehydration reactions in the subducting slab and magma generation processes in the mantle wedge. In this study, cinder cones were sampled at varying distances from the trench in the Lassen Region, the southern segment of the Cascade Arc, which subducts some of the youngest oceanic crust globally. Olivine-hosted melt inclusions (Fo84-90) from the tephra of 6 calc-alkaline basaltic cinder cones have been analyzed for volatile, major and trace elements.

Using the maximum volatile contents at each cone to represent the undegassed magma, we find values (2.1-3.4 wt% H_2O and 500-1200 ppm CO_2, corrected to be in eq. with Fo90 olivine), slightly higher than primitive melt inclusions from central Oregon [1]. These values from the Cascades overlap with data for other arcs, but are lower on average. We have also analyzed fluid-mobile trace elements to understand the trace element signature of the slab component and the extent of fluid-fluxing across the arc. At the arc axis, $(Sr/P)_N$ values are high, although variable, and they decrease towards the backarc [2]. $(Sr/P)_N$ correlates with other slab-derived fluid tracers such as H_2O/Ce and Cl/Nb, indicating a link between volatile and trace element enrichment of the mantle wedge.

Slab surface temperatures calculated using the H_2O/Ce thermometer [3] range from 740-870±50°C, which is slightly lower than those predicted by new 2D geodynamic models for this region (850-950°C). The similarity of the temperature estimates suggests active fluxing of hydrous material from the slab into the mantle wedge beneath the arc rather than downdragging of hydrous mantle from the forearc region. Both H_2O/Ce and geodynamic model temperatures are at or above the MORB+H_2O solidus [4] suggesting the likelihood of hydrous slab melting beneath the arc. Because high slab temperatures require the slab to largely dehydrate beneath the forearc, our results require either substantial metastability of hydrous phases in altered oceanic crust or serpentinite-derived water from the mantle of the downgoing slab.

World's oldest eclogites? Phase equilibria constraints on 2 Ga metapelitic-hosted eclogites from the Usagaran Orogen, Tanzania

ALEC WALSH*[1], MARTIN HAND[1], ALAN COLLINS[1] AND RACHEL BRICK[1]

[1]Centre for Tectonics Resources and Exploration, School of Earth and Environmental Sciences, University of Adelaide, Adelaide 5005, South Australia, Australia (correspondence: alec.walsh@adelaide.edu.au)

Eclogite-facies rocks preserve a record of deep crustal thickening and exhumation. Orogenic belts that contain eclogites generally mark plate collisions and are considered to represent ancient subduction zones. Eclogites from the Paleoproterozoic Usagaran Orogen, which flanks the eastern margin of the Archean Tanzania Craton, yield ages of 2 Ga and are considered to be the amongst the oldest preserved eclogites in the world.

Phase equilibria constraints indicate that metapelitic rocks, which structurally envelop eclogite-facies mafic rocks [1], developed a peak metamorphic assemblage of gt–ky–amph–mus–bi–ru–q at ~12 kbar and 650ºC; far lower pressures than previously predicted. Prograde chemical zoning preserved in garnet appears to mitigate against exhumation of the metapelites from eclogite facies conditions Rather, the petrological and compositional data suggest a steep up-pressure prograde path. Premlinary data suggests that the mafic eclogites underwent metamorphic reworking at around the conditions recorded by the peak assemblages in the enclosing metapelites. If this is correct is implies that the exhuming eclogites became structually mixed with metasedimetary lithologies located higher in the exhumation channel. Such a scenario is similar to that inferred in modern convergent margin settings, and implies that the Usagaran Orogen is one of the oldest examples of "modern style" plate margin metamorphism.

Diamonds and their inclusions from Dachine, French Guiana: A record of Paleoproterozoic subduction

M.J. WALTER *[1], C.B. SMITH[1], G.P. BULANOVA[1], S. MIKHAIL[2] AND S.C. KOHN[1]

[1]School of Earth Sciences, University of Bristol, Bristol, BS8 1RJ (*correspondence: m.j. walter @bristol.ac.uk)

[2]Geophysical Laboratory, Carnegie Institution of Washington, Washington D.C. 20015, USA

Diamonds and their mineral inclusions provide a record of deep mantle processes. Most diamonds are from the sub-continental mantle lithosphere and record ancient episodes of growth, whereas others form at sub-lithospheric depths and record deep carbon cycling1. We report new data from a unique suite of diamonds and syngenetic inclusions from the Dachine ultramafic, French Guiana. These samples defy categorisation into traditional diamond groups, but show evidence of originating in a subduction zone environment.

The highly altered Dachine host rock (2.1 Ga) is not kimberlitic, but based on textures and chemical characteristics has been identified as a pyroclastic komatiite[2]. Dachine diamonds also have unique characteristics[3] including low N aggregation state (type Ib), a predominance of light C and heavy N isotopes, and complex internal morphologies often showing evidence of deformation. We have located five syngenetic garnet and Cpx inclusions, which are the first reported silicate inclusions in Dachine diamonds. The three garnet inclusions are eclogitic having high Ca and low Cr, and are unusually rich in Mn and Ni but extremely depleted in LIL and LREE. The Cpx inclusions are also extremely depleted in incompatible elements and one is Mn-rich.

The trace element systematics of the silicate inclusions are best matched if the inclusions represent residual phases to either multiple melt/fluid extraction events during subduction, or by a single extraction event involvimg coexisting trace phases such as epidote and rutile. Temperature constraints from N aggregation are inconsistent with a high-temperature komatiite origin for the Dachine host, whereas trace element systematics can be reconciled with a melt generated in a subduction zone environment, an origin which we presume is cold and hydrous. A model integrating all these observation suggests diamond and inclusion growth, and possibly host magma generation, at the interface between a Paleo-proterozoic subducting slab and overlying mantle.

New insights on gas storage and transport in shales

CLIFFORD C. WALTERS[1]

[1]ExxonMobil Research & Engineering, 1545 Rt. 22 E, Annandale, NJ 08801. clifford.c.walters@exxonmobil.com

The rapid development of shale gas and liquids has far outpaced our knowledge of how these systems function. Most of the tools and models used on conventional reservoirs are inadequate to characterize tight rocks. Using new methods and techniques, researchers in industry, academia, and government labs have made considerable progress in revealing the underlying processes involved in gas storage and transport.

Although all shales have some inter- and intra-granular mineral porosity, the majority of the gas in mature, carbon-rich shales is stored in porous organic matter. NMR, small angle neutron scattering (SANS), mercury injection capillary pressure (MICP) and gas sorption experiments suggest that shales possess a broad range of pore sizes with an appreciable volume existing in mesopores having diameters of 2 to 50 nm. Unlike conventional reservoirs where pore throats tend to scale with pore size, the connecting pore throats in shales appear to be small (<20 nm). SEM has been extensively used to image pores in shales**,** but sees only a fraction of the pore network. The Zeiss Helium Ion Microscope has proven to be capable of imaging the nm-scale structures revealing the the true nature of gas storage in shales. Local porosity in kerogen can be extremely highly (>30%) and nm-wide conduits for gas migration can be traces over μm distances. These porous networks form late in the oil window, becomes abundant by the onset of the gas window, and remain relatively unaltered in shales at extremely high maturity.

The nm-scaled features, however, are inadaquet to explain the observed rates of gas transport in producing wells. Using micro X-ray CT and NMR, we have measured gas transport in whole cores under reservoir conditions. Rapid transport occurs in high permeability features sub-parallel to bedding, followed by slower transport into the rock matrix surrounding these features. The high permeability features are physical micro-cracks within the mineral matrix and at mineral-organic boundaries. It is impossible to prove that such features exist in undisturbed subsurface shales; however, we find a correlation with their presence and well productivity.

The work being presented was conducted by Max Deffenbaugh, John Dunsmuir, Aaron Eberle, Hubert King, Chris Kliewer, Pavel Kortunov, and Michael Sansone.

Use of sulfur isotopes to quantify biological and abiotic processes contributing to sulfur cycling in an AMD treatment system

EVAN R. WALTERS[1], CHARLES W. PUGH[2] KELLY S. BENDER[2] AND LILIANA LEFTICARIU[1,*]

[1]Southern Illinois University, Department of Geology, ewalt@siu.edu; lefticar@siu.edu (*presenting author)

[2] Southern Illinois University, Department of Microbiology, cpugh13@gmail.com; bender@micro.siu.edu

Untreated drainages from abandoned coal mines are generally low-pH waters that contain high concentrations of dissolved SO_4^{2-}, Fe, Al, Mn and other elements of environmental concern (e.g., As, Se, Zn, Cd and Ni). In the Illinois Basin this has been a significant and costly problem as extensive mining has been carried out during the last century. Currently, treatment systems of coal-generated AMD include the use of bio-induced stabilization of dissolved SO_4^{2-} and metals in sulfides, as the optimal way for effective, long-term treatment. However as AMD systems evolve, fluctuations in physical (e.g., rain induced-dilution, dynamic AMD flow rates), chemical (e.g., precipitation, sorption, desorption, etc.) and biological processes provoke temporal disequilibra within the system. Therefore, it remains challenging to assess the extent of permanent contaminant sequestration and predict long-term treatment viability.

We present a 1-year study of concentrations and $\delta^{34}S$ values of sulfur compounds in six field-scale column experiments conducted at the Tab-Simco site to constrain the efficiency of various organic substrates in supporting the bio-reduction processes. Our results show: (1) During warm months months (T > 10 °C) high levels in H_2S in the reactors containing limestone and different combinations of *organic amendments indicate the presence of sulfate reducing bacteria (SRB)*. Analysis of initial microbial community and SRB community via the 16S rRNA and dsrAB genes, respectively, suggest the presence of Desulfotomaculum, Desulfomicrobium and Desulfococcus. (2) Sulphur cycling is dynamic and strongly influenced by both biological and abiotic processes. (3) Increasing bacterially-mediated sulfate reduction processes are associated with enrichment of 10-15‰ and precipitation of secondary sulfates is associated with depletion of 1-2‰ in $\delta^{34}S$ in residual SO_4^{2-}. (4) Isotopic mass balance calculations indicate that abiological sequestration was the dominant mechanism during the initial stage of the experiments and the low-temperature months. Our study demonstrates the applicability of the method to assess the rates, progress and environmental fate of pollutants associated with in AMD treatment processes.

Episodic growth of continental crust: A 3-D geodynamic model

UWE WALZER[1]* AND ROLAND HENDEL[2]

[1]Institut für Geowissenschaften, F.-Schiller-Univ., Jena, Germany (*correspondence: u.walzer@uni-jena.de)
[2] Institut für Geowissenschaften, F.-Schiller-Univ., Jena, Germany (roland.hendel@uni-jena.de)

The focus of this paper is the question (1) whether the observed zircon age distribution of continental crust (CC) is produced by real crustal growth episodes or is only an artefact of preservation. Question (2): In connection with the second alternative of (1), it has been proposed that there was little episodicity in the production of new CC and that modeling corroborates this opinion. In answer to (1), we conclude that a combination of the two proposals might be possible. In matters of (2), we ascertain that a dynamic modeling of the convection-differentiation system of the mantle reveals the high probability of magmatic episodes. We solve the full set of balance equations in a 3-D spherical-shell mantle. The heat-producing elements are redistributed by chemical differentiation. A realistic solidus model of mantle peridotite is essential. The solidus depends not only on depth but also on the variable water concentration. Furthermore, we introduced realistic profiles of Grüneisen parameter, viscosity, adiabatic temperature, thermal expansivity and specific heat. Our model automatically produces lithospheric plates and growing continents. Regarding number, size, form, distribution and surface velocity of the continents, no rules have been prescribed. Regions of the input parameter space (Ra, σy, k, f3) which are favorable with respect to geophysical quantities show simultaneously not only episodicity of CC growth but also a reproduction of the observed zircon-age maxima referring to the instants of time. Admittedly, we also obtain Archean events for ages greater than 3000 Ma which are not or scarcely visible in the observed zircon ages. Sinusoidal parts of the evolution curve of qob, Ur and Ekin are found superposed with a monotonous decrease. Tmean, however, decreases smoothly and slowly, nearly without pronounced variations. Therefore, we can dismiss catastrophic mechanisms which simultaneously incorporate the whole mantle.

Role of exopolymeric substances in dolomite biomineralization by coastal sabkha sulfate-reducing bacteria: an *ex situ* study of microbial community-mineral interactions using solid-support imaging

*WAN ABDUL-MATIIN[1], BILAL MANSOOR[2], AND FARRUKH AHMAD[1]

[1]Bio-Energy and Environmental Laboratory (BEEL), Water and Environmental Engineering, Masdar Institute of Science and Technology, PO Box 54225, Abu Dhabi, United Arab Emirates. *wabdulmatiin@masdar.ac.ae
[2]Advanced Materials and Manufacturing Laboratory, Materials Science and Engineering, Masdar Institute of Science and Technology, PO Box 54225, Abu Dhabi, United Arab Emirates. bmansoor@masdar.ac.ae

While the microbial-mediation model has advanced current understanding of modern dolomite genesis, the exact mechanism remains speculative, especially in the context of microbial community architecture. Here we investigate the biofilm aspect of natural SRB growth within a dolomitizing culture via analysis of media chemistry and surface formations. SRB from a coastal sabkha (western Abu Dhabi) were studied vis-à-vis different quantities of exopolymeric substance (EPS), under simulated sabkha pore water conditions, and using inert solid support materials to capture biofilm/biomineral growth. The experimental reactor with the highest EPS content presented the most significant areal distribution of Mg-rich carbonate phases against reactors of lower/no EPS content (mean Mg/Ca molar ratio of 44.1% vs. 27.9%). More detailed microanalyses of major formations also revealed greater incorporation of Mg^{2+} in saturated, partially degraded EPS aggregates (Mg/Ca molar ratio up to 91.2%) compared to a growing biofilm matrix (Mg/Ca molar ratio up to 41.4%). Furthermore, a variety of mineral morphologies with varying levels of Mg incorporation were observed in inoculated reactors supplemented with EPS, hinting at gradual dolomitization. Strategic nucleating sites for Ca-Mg carbonates appeared to be provided by aged EPS, while actively secreted and extensively growing biofilm EPS instead would initially inhibit mineralization through cation binding. Ca-Mg carbonate biomineralization might hence depend on the dynamic interplay of various physical, chemical and physiological conditions of local EPS that would constitute an optimal nucleating microenvironment.

Thermal evolution of surface silanols and nanopores in silica particles

QUAN WAN*, SHANSHAN LI, ZONGHUA QIN AND YI XIAO

Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, 550002, P.R. China
(* Correspondence: wanquan@vip.gyig.ac.cn)

Nanoporous structures have been commonly found in rocks, soils, minerals, and organic matters. It is believed that nanopores are closely related to a range of vital geo-processes and geo-engineering applications, including rock weathering, elemental enrichment and bioavailability, shale gas exploration, carbon cycling and sequestration, etc [1]. Yet knowledge gaps still exist toward understanding fundamental structures and properties of nanopores. Difficulties and inaccuracies in determining nanopore structure and its evolution easily lead to misinterpretation and contradiction of experimental observation [2]. In this study, we used monodisperse, submicron-sized silica particle (synthesized through Stöber process) as our model system, which was subject to dehydration (2hr at 200°C), dehydroxylation (2hr at 400~800 °C) and rehydroxylation (overnight boiling in water). The thermally treated silica particles were subsequently characterized by thermogravimetry (TGA), differential scanning calorimetry (DSC), TGA-IR, pycnometry, elemental analysis and scanning electron microscopy (SEM), etc [3]. Our experimental findings indicated that thermal evolution of surface silanols for Stöber silica (~500nm diameter) accurately fits with the Zhuravlev model for surface chemistry of amorphous silicas [4]. For example, heating at 400°C quantitatively removed all vicinal silanol groups resulting a weight loss (200~1000°C) of ~48.3% (*i.e.*,1.728/3.574 from TGA data), which was nearly identical to the calculated result using theoretical silanol densities (*i.e.*, 4.6, 2.35, and 0.25 groups/nm^2 at 200°C, 400°C and 1000°C, respectively; (2.35-0.25)/(4.6-0.25)=48.3%). Our results also indicated a fully reversible recovery of silanol density through boiling in water and a specific surface area (SSA) of ~550 m^2/g for silica treated ≤400°C. The large SSA apparently supports a nanoporous structure, which was observed to undergo irreversible pore collapse when heating at above 600°C. This nanopore structure evolution is consistent with the results from density measurements.

Late Triassic adakitic rocks formed by partial melting of ancient mafic lower crust in the North China Craton

CHAO WANG[1] AND SHUGUANG SONG[1]*

[1]School of Earth and Space Sciences, Peking University, Beijing 100871, China
(*correspondence: sgsong@pku.edu.cn)

Adakites were originally defined as partial melts of young subducting oceanic crust [1]. However, based on investigations of adakitic rocks in various settings, several other genetic mechanisms have also been proposed, including partial melting of slab-melt modified mantle wedge [2], assimilation and fractional crystallization of basaltic magmas [3], mixing between felsic and basaltic magmas [4], partial melting of thickened lower crust [5] and partial melting of delaminated lower crust [6].

Here we report the Late Triassic adakitic rocks in the eastern part of the North China Craton. They are granitic gneisses with high SiO_2 (68.87-70.15 %), Sr/Y (118-176) and $(La/Yb)_N$ (54-66) and low MgO (1.30-1.47 %), which are similar to adakitic rocks formed by partial melting of thickened lower crust. In-situ zircon LA-ICP-MS U-Pb dating reveals that they were emplaced in the Late Trassic (218-229 Ma). In-situ Hf isotope data for zircons show that they are characterized by the evolved $\varepsilon_{Hf}(t)$ of -17.4 to -14.6 and T_{DM2} ages of 2.18-2.36 Ga, implying their source materials were extracted from the depleted mantle in the Paleoproterozoic. Trace element modeling suggests that they might be produced by 20-30 % partial melting of the Paleoproterozoic mafic lower crust materials equlibrated with eclogite residues (Grt/Cpx = 30/70).

Based on the above lines of evidence, plus the post-collisional extensional enviroment in the Late Triaasic, we propose that these adakitic rocks in the NCC were produced through melting of the thickened ancient Paleoproterozoic mafic lower crust triggered by upwelling of basaltic magmas. Futhermore, they might be the result of the onset of lithospheric thinning of the NCC initiated in the Late Triassic.

Biomarker evidence for the Neoproterozoic marine redox condition in South China

CHUNJIANG WANG*, XIAOFENG XIONG, HAIFENG GAI, YUE LIU, BAOGANG LI, XUAN ZHOU AND BO XU

State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing 102249, China, wchj333@126.com (*presenting author)

An important increase in atmospheric oxygen appears to have taken place during the late Neoproterozoic period [1, 2]. This increase may have stimulated the evolution of macroscopic multicellular animals [1, 3] and may have led to oxygenation of the deep ocean [4].

In order to understand more about the ocean oxygenation process during the Neoproterozoic period, a core spanning 450m of stratigraphic section across Cryogenian Datangpo Fm. and Nantuo Fm., Edicarian Doushantuo Fm. and Dengying Fm., and early Cambrian Niutitang Fm. (ca. 663–518 Ma), was drilled at Xiushan in South China. The paleogeographic reconstruction suggests that Xiushan region was located at the outershelf margin to slope in the central Yangtze platform of South China [5]. Here we report a secular change in biomarker and C_{org}- and C_{carb}-isotopic compositions based on this drillcore section, which aims to reveal the difference in organic matter sedimentation and marine redox condition between the interglacial Datangpo Fm. and postglacial Doushantuo Fm., and the difference between the outershelf-slope facies Doushantuo Fm. at Xiushan region and the innershelf basin facies at the Jiulongwan section.

Organic geochemical evidence shows that the Datangpo Member I and II could deposit in dysoxic and oxic condition, respectively. It means that the Datangpo Member I black shale was likely not deposited in an anoxic or euxinic condition as suggested before [6]. Obvious difference in Doushantuo biomarker assembly occurs between Xiushan region (outershelf–slope) and the Jiulongwan section (innershelf basin), which may have been caused by differential redox conditions or depositing processes of organic matters. Our data support the idea that the reconstruction of the redox condition in Cryogenian and Edicaran oceans should be based on approaches from various facies ranging from shallow marine shelf to deep marine basin [5, 7].

Interaction of Bioavailability of Soil Heavy Metals in Black Soil Region of Central Jilin Province

D.Y.WANG*, Y.F.LI, Y. Y.YANG AND X.L.YANG

Jilin University, College of Earth Sciences, Changchun, China (wang_dy@jlu.edu.cn*, yuefenyoud@163.com, yangyuan52415241@163.com, 33390016@qq.com)

Heavy metal, which endangers ecological environment directly and brings indirect harm by affecting the bioavailability of soil nutrients, is an important substance resulting in soil pollution and degradation. Correspondently, nutrient elements in soil also affect the eco-environmental impacts of heavy metals. Thus, the interaction between heavy metals and nutrient elements, as a new aspect of pollution ecology of heavy metals, is important for maintaining ecological balance.

In present study, it is analyzed that the total and bioavailability contents of heavy metals (Cr, Cd, Cu, Zn, Ni, As) and the contents of major nutrient elements (P, K, Ca, Mg, Fe, B) for 61 surface soil samples in black soil region of central Jilin province, NE China. The bioavailability characteristics of heavy metals are recognized according to the effective coefficients of soil elements (available contents of elements in soil accounting for total amounts). And the effective coefficient correlations for different heavy metal as well as the heavy metals and nutrient elements are calculated by SPSS (Ver. 13.0).

The obtained results indicate that all the following effective coefficient correlations are obvious positive, (1) Cd and Zn with the other heavy metals, (2) Cr with As, Cd, Zn and Ni, (3) Ni with Cr, Cd and Zn, (4) As with the Cr, Cd, Cu and Zn. These findings indicate that the bioavailability conversion of heavy metals have promoting effect to each other in study area.

Remarkably, the effective coefficients of six heavy metals show obvious positive correlations with P, which is consistent with the major standpoint about the interaction between P and heavy metals in soil, implying that the effective content of P plays a role in promoting the activation of heavy metals. Additionally, these results indicate that the following effective coefficient correlations also exhibit obvious positive, (1) micronutrient element B and Fe with As, Cu and Zn, (2) between Fe and Cr, (3) Mg with Cr, Ni and Zn. However, the effective coefficient of Ca has obvious positive correlations with heavy metals except Cu. And the correlations between the effective coefficients of K and As exhibits obviously negative.

In short, study on interaction of bioavailability of elements provides insights to understand the black soil degradation mechanism, prevent heavy metal pollution, balance the nutrients, and strengthen management of the black soil resource.

Petrology, geochemistry and metamorphic evolution of metamorphic rocks in Diancang Shan-Ailao Shan metamorphic complex belt, Southeastern Tibetan Plateau

FANG WANG, FULAI LIU , PINGHUA LIU, JIANRONG SHI AND JIA CAI

Institute of Geology, Chinese Academy of Geological Sciences , Beijing 100037, China (wangfang_mr@yahoo.cn)

Combined study of petrology, geochemistry and metamorphism of meta-sedimentary rocks and meta-basic rocks, provide clear evidence of metamorphic evolution of Diancang Shan-Ailao Shan metamorphic complex belt. Detailed geochemical analysis in the meta-sedimentary rocks and amphibolites suggest the protoliths of claystone, siltstone, graywacke and island-arc basaltic rock, respectively. Microprobe and mineral inclusions analysis reveals that garnet porphyroblasts in meta-sedimentary rock bear a chemical composition zonation from core to rim. On the basis of paragenesis, mineral transformation and chemical composition zonation of garnets, four metamorphic stages have been recognized, i.e. early prograde metamorphic stage (M_1), peak amphibolite-granulite facies metamorphic stage (M_2), near isothermal decompression retrogression metamorphic stage (M_3), and late amphibolite facies retrograde stage (M_4). The paragenesis of Grt + Pl + Ms + St ± Ky ± Bt ± Kfs + Qz (meta-sedimentary rocks), which formed at 560 ~ 590°C and 5.5 ~ 6.3 kb, is regarded as the M_1 stage mineral assemblage. The typical mineral assemblage of M_2 stage, which constrains *P-T* condition of 720 ~ 760°C and 8.0 ~ 9.3 kb, contains Grt + Bt + Ky/Sil + Pl + Qz or Grt + Bt ± Sil + Pl ± Kfs + Qz (meta-sedimentary rocks) and Grt + Cpx + Pl (meta-basic rocks). The paragenesis of Grt + Bt + Sil + Pl + Qz (meta-sedimentary rocks) and Hbl + Pl ± Cpx ± Bt ± Qz (meta-basic rocks) defines M_3 stage mineral assemblage, occurring at *P-T* condition of 650 ~760°C and 5.0 ~ 7.3 kb. Newly formed intersectional biotite and muscovite, together with the rim of garnet, define the M_4 stage mineral assemblage of Bt + Ms + Pl ± Kfs ± Grt + Qz (meta-sedimentary rocks), inferred at 553 ~ 613°C. The metamorphic complex, record a clockwise metamorphic *P-T* trajectory characterized by near isothermal decompression. The integrated clockwise *P-T* path established for metamorphic complex in Diancang Shan-Ailao Shan metamorphic complex belt is a potential record of geodynamic process related to subduction-collision-exhumation between Indian and Eurasian plate.

This study was financially supported by the Nation Natural Science Foundation of China (Grant no. 40921001 and 40725007) and by a Chinese Geological Survey Bureau project (Grant no. 1212011121276)

Zircon U-Pb-Hf-O isotopes and REE constrains on the origin of Mesozoic ore-bearing high Mg# adakitic rocks from Ningzhen area of east China: Petrogenesis and tectonic implications

FANGYUE WANG [1]*, SHUGUANG LIA,[2]*, SHENG-AO LIU[2] AND SHEMIN AKHTARA[1]

[1]CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China

[2] State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing 100083, China

Cu-Mo-Fe mineralized high Mg# adakitic porphyries intruded in the eastern Lower Yangtze River Belt (LYRB), but the timing and petrogenesis of these adakites are not well constrained. In this study, five samples were collected from the ore-bearing adakites (Anjishan Cu deposit, Tongshan Cu-Mo deposit and Xiangshan Fe deposit) of Ningzhen region, in order to precisely constrain their formation ages, petrogenesis and tectonic settings. Zircon U-Pb ages dated by LA-ICP-MS show that ore-bearing adakite in Ningzhen region are about 110-118 Ma, obviously younger than ore-bearing adakites (140±5Ma), bimodal volcanic rocks with A-type granites (126-131Ma) along the LYRB. Magmatic zircon Ce^{4+}/Ce^{3+} of adakites ranges from 4-1615, compatible to those from the older adakites in LYRB. Zircon Hf and O isotopes from Ningzhen adakites show a wide range from -10.58 - -23.35 and 5.74-7.03‰, respectively, fall between those of the LYRB and South Tan-Lu fault zone (STLF). Zircon Ti-thermometry of Ningzhen adakites range from 550-700 ºC, averaged at 650 ºC, similar to those from the LYRB too. Zircon O-Hf-Ce^{4+}/Ce^{3+} and Ti-thermometry from the Ningzhen ore-bearing porphyries show their magma source may from an oxidized water-rich sources with continental crust involvement. Genesis of adakites in Ningzhen region is best explained by assimilation between metasomatised mantle and lower continental crust and followed by fractional crystallization. Combined with published ages data of ore-bearing adakites from the LYRB, Mesozoic magmatic activities from LYRB show a younging trend from inland to outland. A slab flat subducting and rolling back evolution model of the LYRB is proposed in this study.

Hydrocarbon Mobility Prediction for lacustrine shale oil plays

WANG, FEIYU[1], WEIPING FENG[1] AND ZHIYONG HE[2]

[1]China University of Petroleum, Beijing,102249)
[2] Zetaware Inc., Sugar Land, TX. 77479 USA

Lacustrine shale oil plays or tight oil systems have become the important exploration and development target in China, a great amount residual hydrocarbon exist in the mature organic matter rich lacustrine shale plays, For a shale play to work, it has to have enough original oil in-place volumes and producible, The occurrence and mobility of residual hydrocarbon are key to assessment of shale oil plays.

Residual hydrocarbon can be splited into two parts, free oil and adsorbed oil, the former occur in the organic matter rich source rocks intervals and interbedded various scale tight reservoir layers within the shale plays, the latter are mainly located in organic matters in the shale plays. The amount of adsorbed oil for lacustrine shale range from 80 mg/gTOC to 100 mg/gTOC, which will be decreased with maturation increase.The most of adsorbed oil in a shale play are immobile and hard to produce. The free oil appear when residual oil is higher than the adsorbed oil threshold. the more free oil amount correspond to the higher mobility for shale oil. Viscosity is very important to hydrocarbon mobility, but less predictable quantitatively, As maturity or transformation ratio increases, GOR increases four orders of magnitude and viscosity decreases three orders of magnitude in the oil window,.The kinetic model of GOR,API and viscosity have been established for the organic rich lacustrine source rock, If maturity or transformation ratio of source rocks can be measured ith much greater precision, the viscosity and hydrocarbon mobility will be predicted in reasonable resolution. Vitrinite reflectance data are often problematic for lacustrine shale play when used for the maturity or thermal calibration,a better approach is calibrated with the residual HI of high TOC source rocks. Higher maturity means lower viscosity, maturity map will provide the hydrocarbon mobility trending in the area.

Case studies from the Hataoyan Formation of Biyang basin and Upper Triassic Chang 7 Shale in Ordos basin have been shown the approaches of hydrocarbon mobility prediction in the lake basins. these case studies indicate that the best oil production seems to be from late oil window with vitrinite reflectance equivalent of 0.9 to 1.2 (%Ro).

Neoproterozoic terranes in the NE China and its tectonic implications

FENG WANG, WENLIANG XU*, FUHONG GAO, JIE TANG, AND WENLI HAO

College of Earth Sciences, Jilin University, Changchun 130061, (jlu-wangfeng@sohu.com, * xuwl@jlu.edu.cn)

NE China is located in the eastern section of the Central Asian Orogenic Belt (CAOB), in a region that consists of a collage of several microcontinental massifs (including, from northwest to southest, the Erguna, Xing'an, Songnen-Zhangguangcai Range, Jiamusi, and Khanka massifs). It has been a controversial issue whether did the Precambrian terranes occur within these microcontinents of NE China, although the geochronolical data of the detrital zircons from the Paleozoic strata in NE China display a lot of the information the Precambrian ages. Additionally, the tectonic attribution of these microcontinents is also an unsolved issue.

The Neoproterozoic magmatisms, corresponding to the breakup of the Rodinia supercontinent, have been widely identified in the Erguna Massif [1]. By comparison, no igneous rocks of this age have been identified in the Xing'an, Songnen–Zhangguangcai Range, and Khanka massifs. However, the LA-ICP-MS detrital zricon U-Pb dating for Dongfengshan and Tadong groups indicate that a suite of Neoproterozoic terranes is present along the eastern margin of the Songnen–Zhangguangcai Range Massif (~821–752 Ma, ~752–560 Ma, and ~750–516 Ma)[2]. And Neoproterozoic magmatic zircons (0.75–0.92 Ga) are the most common zircons identified in the Dongfengshan and Tadong groups, suggesting that a Neoproterozoic magmatic event occurred within the Songnen-Zhangguangcai Range Massif. The detrital zircons with similar ages (0.76–0.97 Ga, our unpublished data) have been also identified in the Huangsong Group along the western margin of the Khanka Massif. Additionally, increasing evidence suggests that Neoproterozoic magmatic zircons are present in Paleozoic sedimentary rocks in the Xing'an Massif [3].

The above findings suggest that the Precambrian terranes did occur within the Erguna, Xing'an, Songnen-Zhangguangcai Range, and Khanka massifs, and that these microcontinents have an affinity to the Siberia craton. This research was financially supported by the National Science Foundation of China (Grant 41272075 and 41072038).

Understanding the sub-surface metabolic activity and pathways of microbial mediated C/N cycling in North Pond, western flank of Mid-Atlantic Ridge

FENGPING WANG[1]*, XINXU ZHANG[2], YUEHENG ZHOU[1,2], AND THE IODP EXP336 SCIENCE PARTY,

[1]State Key Laboratory of Microbial Metabolism and State Key Laboratory of Ocean Engineering, Shanghai JiaoTong University, Shanghai, 200240, People's Republic of China
*Correspondence: fengpingw@sjtu.edu.cn

This project tries to reveal the microbial mediated C/N cycling in the sediments and rocks of North Pond, western flank of Mid-Atlantic Ridge, which represents an ideal model system for studying the biologically mediated oxidative basement alteration. A series of incubations with ^{13}C and ^{15}N labeled substrates including sodium carbonate, acetate, methane, ammonium chloride and sodium nitrate, have been set up onboard. Significant cell growths were observed only when nitrogen substances were supplemented, either alone, or in combination with carbonate or acetate. This data suggests that nitrogen is the limiting nutrient source for cell growth in the North Pond crust biosphere. The microorganisms and their utilized pathways in the assimilation and transformation of C, N are under investigation. In addition, enrichment and isolation of microbial groups involved in iron transformation will also be performed. These integrated studies would give clear clues to understand the underwater microbial activities, key metabolic pathways and their roles in ocean crust weathering.

Seasonal patterns of CO_2 emission from a subtropical reservoir

FUSHUN WANG[1] BAOLI WANG[2] AND CHENCHEN YAO[1]

[1] School of Environmental and Chemical Engineering, Shanghai University, Shanghai 200433, China. fswang@shu.edu.cn

The XinAnJiang River, is the mainstream of Qiantang River, the largest river in Zhejiang Provence, China. The XinAnJiang Reservoir, located in Chun'an County, Zhejiang Province, was accomplished in 1959, also known as the Qiandao Lake. Five cruises were carried out along the XinAnJiang Reservoir and its river reach in April, June, August, November 2010 and January 2011, in order to understand the CO_2 emission from this subtropical reservoir. pCO_2 of surface water was determined using a continuous measurement system (equilibrator-NDIR system), besides that sampling and analysis of the outflow water and the water column in front of the dam were also conducted in each cruise. The results showed that, pCO_2 in the surface water strongly varied during the whole year, ranging from 5μatm to 1,300μatm at the inflow reach, from 2μatm to 1,000μatm at the central reservoir area, and from 1400μatm to 3,800μatm at the outflow water, respectively. In the inflow river reach and central reservoir, the highest values of surface water pCO_2 appeared in winter, and the lowest in summer. While the outflow water, has the highest surface pCO_2 in summer, and the lowest in spring. Along the water column in central reservoir, pCO_2 increased downwardly. In summer, the difference between pCO_2 in surface water and bottom water reached to 5,900μatm, and in spring this difference was only 50μatm. The annual average pCO_2 in inflow waters, reservoir surface and outflow waters were all higher than that of air(380μatm), and the annual average diffusion flux of CO_2 at water-air interface in these area were 11.37, -0.02 and 345.93 $mmol \cdot m^{-2} \cdot d^{-1}$, respectively, which indicated that the Xin'AnJiang reservoir should be a CO_2 source to the atmosphere. However our result also showed that central reservoir indeed has a role in mitigating the CO_2 emission in this case.

Organic carbon proxies in black shales: strontium

H.J. WANG[1], X.M. WANG[1] AND S.C. ZHANG[1]*

[1]Research Institute of Petroleum Exploration & Development, CNPC, Beijing 100083, China (wanghuajian@petrochina.com.cn, wxm01@petrochina.com.cn, *correspondence: sczhang@petrochina.com.cn)

Isotopic and elemental proxies are used to discern the original compositions of ancient sediments, which are subject to later diagenetic/thermal alteration, etc[1]. Recent work about the Mesoproterozoic (1.36 Ga) black shales in the North China Craton showed a high correlation between total organic carbon (TOC) content and the enrichment factors of Sr normalized to upper crust (Sr EF = $(Sr/Al)_{sample}/(Sr/Al)_{upper\ crust}$). No matter which paleoredox conditions is, the relatively low Sr EF (< 1.0) and good positive correlation with TOC (Figure 1), means the uptake of Sr is mainly controlled by the availability of organic substrates, not the solubility at the redox boundary. Besides the isotopic compositions of Sr can reflect the evolution of paleocean[2], thus jointly estimates of original TOC with the content and isotopic composition of Sr in samples spanning the geologic record, should be useful in estimating the of primary productivity of ancient oceans and the distribution of potential source rocks of petroleum.

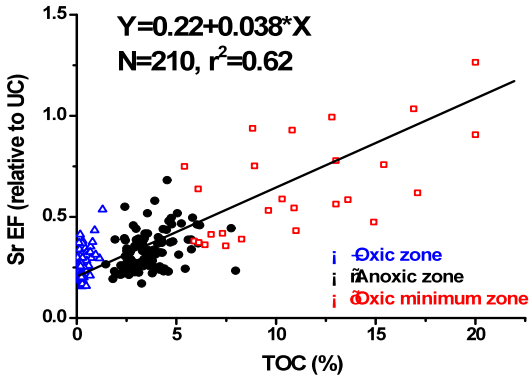

Figure 1: Enrichment factors of Sr (relative to upper crust) versus TOC in Mesoproterozoic sediments.

Simultaneous measurements of C and N Isotopic composition and N abundance in diamonds by NanoSIMS

JIANHUA WANG *, STEVEN B. SHIREY AND ERIK H. HAURI

Department of Terrestrial Magnetism, Carnegie Institution of Washington, 5241 Broad Branch Rd. NW, Washington DC 20015, USA (*correspondence: jwang@ciw.edu)

Diamond, one of the three native carbon minerals on Earth, has been intensively studied for more than 40 years to provide extraordinary information on the cycling of carbon in the Earth's interior. Diamonds are found at the Earth's surface in ultra-high pressure metamorphic terranes, meteorite impact sites, and volcanic eruptions of kimberlite magma or their weathering products. It is the kimberlitic diamonds that provide the largest and deepest specimens - from 150 km to 800 km depth in the mantle. Multi-stage growth patterns are commonly seen in the cathodoluminescence (CL) imaging of diamonds, including those that are large, transparent monocrystals. The SIMS method has been developed to study zonation of carbon and nitrogen isotopic composition and nitrogen abundance in diamonds [1] and is the method of choice for study in the context of the zoning patterns. Separate analytical sessions are require to measure carbon and nitrogen isotopes and nitrogen abundance in the previous method on the Cameca 6f [1] because a single detector must be used at different mass resolution for C and N. We have developed a method to measure both carbon and nitrogen isotopes and nitrogen abundance simultaneously on the same spot using multicollection on the Carnegie NanoSIMS 50L. The NanoSIMS method has a better special resolution (15μm) with better precisions ($\delta^{13}C$: 2s of ±0.5‰ and $\delta^{15}N$: 2σ of ±2.2‰) and much better transmission of nitrogen ($^{12}C^{14}N$: 1600cts/ppm/nA). We will discuss the details of the NanoSIMS method comparing with the previous method.

Palot *et al.* reported lowest $\delta^{15}N$ values (up to -39.4‰) of terrestrial sample in Kankan (Guinea) diamonds [2]. They interpreted this low N isotopic composition as the primordial heterogeneity preserved in an imperfectly mixed convective mantle [2]. We measured $\delta^{15}N$ value of -29‰ in a peroditic diamond from Liaoning, China. In situ and simultaneous measurements of C and N isotopic compositon and N abundance in zoned Liaoning diamonds reveal their complicated growth history and N isotope geochemistry in the deep Earth.

Multi-scale simulation of structural heterogeneity of swift-heavy ion tracks in complex oxides

JIANWEI WANG*, MAIK LANG, RODNEY C. EWING AND UDO BECKER

Department of Earth and Environmetnal Sceinces, University of Michigan, Ann Arbor, Michigan 48109 USA (*correspondence: jwwang@umich.edu)

Understanding and prediction of the phase behavior of materials under extreme environments provide a great challenge in the materials' design and engineering in various applications. Swift heavy ion have been used to probe the effect of the high-energy radiation on a wide variety of materials and to explore the complex far-from-equilibrium behavior of the materials under extreme conditions. In this study (J. Phys.: Condens. Matter,25,135001), track formation caused by a swift-heavy ion irradiation, 2.2 GeV Au, of isometric $Gd_2Ti_2O_7$ pyrochlore and orthorhombic Gd_2TiO_5 phase was modeled using thermal-spike model combined with a subsequent molecular-dynamics simulation. The thermal-spike model was used to calculate the energy dissipation over time and space. Using the time, space, and energy profile generated from the thermal-spike calculation, the molecular-dynamics simulation was performed to model the atomic-scale evolution of the track. The advantage of combining these two methods, that is using the output from the continuum model as an input for the atomistic model, is that it provides a means of simulating the coupling of the electronic and lattice subsystems and at the same time providing atomic-scale details of the track structure and morphology.

The simulated internal structure of the track consists of an amorphous core and a shell of disordered, but still crystalline, domains. For $Gd_2Ti_2O_7$, the shell region has a disordered pyrochlore with a defect fluorite structure and is relatively thick and heterogeneous with different degrees of disordering. For Gd_2TiO_5, the disordered region is relatively small as compared with $Gd_2Ti_2O_7$. In the simulation, "facets", that is surfaces with a definite crystallographic orientation, are apparent around the amorphous core and were more evident in Gd_2TiO_5 along the [010] than [001], suggesting an orientationally dependent radiation response of this structure. These results show that track formation is controlled by the coupling of several complex processes, involving different degrees of amorphization, disordering, and dynamic annealing. Each of the processes depends on the mass and energy of the energetic ion, the properties of the material, and its crystallographic orientation with respect to the incident ion beam.

Gallionella-like microorganisms involved in iron oxide formation in groundwater wells across a broad pH range

JUANJUAN WANG[1], MAREN SICKINGER[2] AND KIRSTEN KÜSEL[3]

[1]Friedrich-Schiller-University of Jena, Dornburgerstr.10 07743 Jena,(juanjuan.wang@uni-jena.de
[2]maren.sickinger@uni-jena.de
[3]kirsten.kuesel@uni-jena.de)

Clogging caused by iron ochre incrustations has been a challenge for the functioning of groundwater wells, especially technical wells in mining areas. The formation and dissolution of iron oxides can be mediated by iron-oxidizing and -reducing microorganisms. In this project we studied the potential role of these microbes in the clogging process at three locations in an open-cast mine, comparing a total of 16 wells. The groundwater had pH ranging from acidic (4.5) to neutral (7.5) and relatively high contents of Fe(II) (0.5~7 mM) and DOC (1.4~12.6 mgL^{-1}) at an average oxygen concentration of 3.8 mg $L^{-}1$. The mineral composition of ochres differed with ferrihydrite being common in circumneutral wells and schwertmannite dominating in the slightly acidic wells. 454 pyrosequencing revealed a high diversity of bacteria in the ochres with a large fraction of *Gallionella*-related sequences. Quantitative PCR suggested that *Gallionella*-related organisms on average accounted for 44 % of the total bacteria. Surprisingly, their abundance was not correlated to any geochemical parameter. *Gallionella*-related organisms were also present in the ground water ranging from 8.4×10^6 to 2.0×10^8 16S rRNA gene copies per L water. Iron reducing bacteria such as *Geobacter*, *Geothrix*, *Rhodoferax*, were only detected at low abundance, in agreement with a low iron reduction potential. However, the iron reduction potential could be stimulated by the addition of lactate. In conclusion, *Gallionella*-related iron oxidizers dominated ochres and groundwater irrespective of pH, suggesting a major role of these organisms in the formation of ochres across a broad range of geochemical conditions. Deeper insight into the microbiology of the ochre formation process may help to develop strategies for relieving clogging problems in technical wells.

Geochemical fingerprints in Siberian mantle xenoliths reveal progressive erosion of an Archean lithospheric root

KUO-LUNG WANG[1]*, Y.-H. CHIEN[1], M. I. KUZMIN[2], SUZANNE.Y. O'REILLY[3], W.L. GRIFFIN[3], A. VORONTSOV[2] AND N.J. PEARSON[3]

[1]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan (*correpsondence: kwang@earth.sinica.edu.tw)
[2]Institute of Geochemistry, SB RAS, Irkutsk, Russia
[3]CCFS/GEMOC, Macquarie University, Sydney, Australia

Mantle xenoliths from a picrobasalt quarry in Miocene (14 Ma) and Holocene (~0.65 Ma) basalts of the Bulykhta Riverside and Kandidushka volcanoes in the Vitim volcanic plateau, SE Siberia, are dominantly spinel-, garnet-, or garnet–spinel-bearing lherzolites with minor pyroxenites. Equilibrium temperatures and pressures of garnet-bearing lherzolites in the Miocene basalts range from 1110 to 1250 °C and 22 to 28 kbar, whereas those in Holocene basalts have similar temperatures (1110–1180 °C) but lower pressures (20 - 21 kbar). The latter thus yield a hotter geotherm than the former. The Fo contents of olivine in these lherzolites range from 89.1 to 90.6, with most from 89.8 to 90.2. Trace-element patterns of clinopyroxenes (cpx) in the lherzolites can be divided into three types: depleted, enriched and intermediate. The depleted patterns are typical of unmetasomatised, refractory lithospheric mantle. The enriched and intermediate ones provide fingerprints of different metasomatic episodes. Some lherzolites contain amphibole and/or apatite as evidence of modal metasomatism. Whole-rock and cpx Sr–Nd isotopic ratios of lherzolites in Miocene basalts are more radiogenic ($^{87}Sr/^{86}Sr$=0.70225-0.70561 and $^{143}Nd/^{144}Nd$=0.51288-0.51303) than those in Holocene basalts ($^{87}Sr/^{86}Sr$=0.70244-0.70374 and $^{143}Nd/^{144}Nd$=0.51300-0.51329). It indicates the material sampled from the SCLM beneath the Vitim region in Holocene time is more depleted than that sampled in the Miocene. Os isotope compositions of sulfides display simiar temporal variation; the lherzolites in the younger basalts have more radiogenic ratios ($^{187}Os/^{188}Os$=0.1066-0.1318) than those in the older basalts ($^{187}Os/^{188}Os$=0.1168-0.1350). Both T_{MA} ages from the least-disturbed sulfides ($^{187}Re/^{188}Os$<0.07) and T_{RD} ages from higher-Re/Os sulfides yield model ages ranging from 0.5 to 3.2 Ga, with peaks around 1.4, 1.1, 0.9 and 0.5 Ga. The Miocene basalts sampled a deeper, more refertilised part of the Archean root, compared to the shallower part sampled by the Holocene basalts.

Compositional variation in apatites from carbonatites and associated alkaline silicate rocks: A case study of the Kaiserstuhl complex, Germany

[3]Faculty of Earth Sciences, China University of Geosciences, 430074 Wuhan, China

In the present study, we investigate textural and chemical signatures of apatites from a series of carbonatites, related alkaline silicate rocks, an unusual carbonate-bearing melilitic dyke rock (bergalite) and a diatreme breccia of the Miocene Kaiserstuhl Volcanic Complex, South Germany.

Significant chemical differences between apatite from carbonatites and associated alkaline silicate rocks exist for Sr, Fe, Mn, Th, U, Nb, Si, S, As, Cl and Br. These differences can be attributed to different partition coefficients, melt compositions, substitution mechanisms and redox conditions.

A systematic and sharp core-mantle-rim zonation is present in apatites from the bergalite sample. The core and mantle zones are compositionally similar to apatites from silicate rocks, whereas the rim compositions correspond to that of carbonatitic apatites. These observations imply that bergalititic apatites initially nucleated in a siliate melt and continued crystallizing from a melt with carbonatitic affinity during later stages. This late-stage carbonatitic melt was interpreted as the protracted fractionation product of the carbonate-bearing nephelinitic melt [1].

Apatites from a diatreme breccia (containing carbonatitic and silicate rock components) comprise three textural and compositional populations: (1) similar to apatites from silicate rocks, (2) similar to apatites from carbonatites, and (3) resembling apatite population (1) partially replaced by population (2). We infer that apatite population (1) derived from silicate rock fragments and apatites (2) crystallized from the later intruding carbonatitic melt causing the formation of the breccia. During ascend of the carbonatitic melt, metasomatic overprint caused the observed replacement textures in apatite population (3).

Research on the phase compostion , expansion property and heavy metals absorption capacity of vermiculite from Yuli Xinjiang Province

L.J. WANG, L.B. LIAO* AND X.X. HUO

School of Material Sciences and Technology, China University of Geosciences, Beijing 100083, China (*correspondence: lbliao@cugb.edu.cn)

Vermiculite is a kind of natural, non-toxic clay, which was formed from mica weathering or alteration. The Qeganbulak vermiculite ore in Yuli, Xinjiang province is one of the largest vermiculite deposits discovered in China, which is about 90% of the vermiculite reserves in China. Because of its layer ions exchangeability, vermiculites have strong cation exchange capacity, which can be used to remove heavy metals in wastewater.

Under the investigation of X-ray diffraction(XRD), thermogravimetric–differential thermal analysis(TG-DTA), infrared spectroscopy(IR), and chemical analysis etc., vermiculite from Yuli Xinjiang was approved to a mixture of vermiculite, mica, calcite and two kinds of vermiculite-mica mixed-layer minerals Hy-a (vermiculite/mica mole ratio of 6:4), Hy-b (vermiculite/mica ratio of 4:6). Phlogopite was identified as the major type of mica in mica layer in mixed-layer minerals. A small amount of biotite cannot be expelled. Vermiculite are Mg type vermiculite and Na type vermiculite.

Results show that expansion capacity of vermiculite majorly comes from mixing layer minerals(Hy-a, Hy-b), in which Hy-a affect its expansion ability most. The expansion ratio of vermiculite increases with the increase of temperature when the temperature is less than 700 °C, after then it's becoming stable. The expansion ratio of vermiculite reduces with the increase of particle size. The expansion ratio of vermiculite is the highest when its particle size ranges from 1 to 2 mm. When particles are bigger than 2mm, its expansion ratio decreases with the increase of particle size.

Before reaching the absorption/desorption balance of vermiculite towards heavy metal ions like Cd,Cu,Cr etc., the absorption capacity is positive to absorption time, however, after reaching this balance, absorption time won't increase absorption capacity obviously . In addition, the absorption capacity of vermiculite towards heavy metals increases with the increase of concentration of heavy metals. The vermiculite's absorption capacity towards heavy metals can also be phenomenally affected by pH, normally, higher pH can cause higher absorption capacity.

Petrogenesis of Late Permian picritic porphyries associated with Pingchuan iron ores, Emeishan Large Igneous Province, southwest China

MENGWANG[1] AND ZHAO-CHONG ZHANG[1]

[1] State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China (houtong08@gmail.com)

The Pingchuan iron oxide deposit is spatially and temporally associated with the Late Permian picritic porphyries in the Emeishan Large Igneous Province, southwest China. The estimated ore reserve for the Pingchuan deposit is 40Mt at ~60 wt.% Fe. The iron ore bodies are intimately associated with the intrusive masses of picritic porphyry, occurring mainly along the contact zone between the picritic porphyries and the sedimentary country rocks, i.e. limestone. The most important ore types are massive and brecciated ores which together make up 90 vol. % of the deposit. The massive type generally occurs as dykes and large veins consisting predominantly of magnetite with minor calcite and apatite. The picritic porphyries are characterized by a marked range of SiO_2 (37.12-47.39 wt. %) and MgO (19.22-29.08 wt. %), but show a minor variation in Na_2O+K_2O (0.12-1.58 wt. %) and TiO_2 (0.64-1.44 wt. %). The total concentration of rare earth elements (REE) is relatively low (21-83 ppm), and show moderate enrichment in light rare earth element (LREE; $[La/Yb]_N$=3.01-3.63). The primitive-mantle-normalized patterns of the rocks are comparable to those of ocean island basalt, plausibly indicating a plume source. Petrographic observation suggests the Pingchuan picritic porphyries are virtually cumulus product, and possibly experienced fractional crystallization of Cr-spinel + olivine + clinopyroxene during the magma chamber process. Moreover, the estimated primitive magma composition is picritic which is possibly produced by partial melting of the garnet-facies asthenospheric mantle peridotite. In combination with the available information including field observation and geochemical studies, e.g. fluid inclusions and stable isotope data, we infer that the deposit is hydrothermal in origin and the ore-forming fluids are predominantly primary magma-derived fluids which had been released during the post-magmatic period and mixed with fluids from country rocks.

Carbonate reservoir features and its main control factors in South Slope of Northern Tarim, China

RUIJU WANG, ZHENG HONGJU, JIANG HUA, CHUNMING ZHANG, SUYUN HU, ZECHENG WANG

(PetroChina Research Institute of Petroleum Exploration & Development, Beijing 100083, China)

Good exploration prospects have been shown in carbonate of lower Ordovician, which's depth is larger than 6500m, in south slope of Northern Tarim, but carbonate reservoir features and its attributions have not been completely known. In this research, cores, glass slides, logs, 3-d high resolution seismic,and so on, are used. And researching methods such as tectonic evolution analyzing, reservoir feature depicture, and so on, are applied. Types,periods,distribution and overlapping method of karst were studying in this area. It was recognized that different karsts played the various parts in different areas. North area of Tumuxiuke pinch-out developed potential karst, while most areas on the south side developed alonging-karst. It was particular that Yingmai area developed vertical karst. Complexity of karst reservoir was decided by attribution of high -energy facies and history of tectonic evolution. Research on superimposing pattern of karst and different features was going to help the exploration in the research area.

Geochemical characteristics of sediment of Pearl river estuary and its palaeoenvironmental evolution

WANG SHANSHAN[1] * CAO ZHIMIN[2] AND LAN DONGZHAO[2,3]

[1] Zhejiang Institute of Hydraulics & Estuary, Hangzhou, 310020, China(correspondence:shanshwang@gmail.com)

[2] College of Marine Geosciences, Ocean University of China, Qingdao, 266003,China

[3] Third Institute of Oceanography, SOA, Xiamen 361005, China

Data and method

The concentration of metal elements(Co, Cu, Zn, Ni, Cr, Zr, Sr, Ba), total content of organic matter and average grain size were determined from 16 sediment samples in different depth of 3.5m core in Pearl River estuary of China. Three important factors were identified from 160 data, using principal component analysis method.

Discussion of Results

The variance contribution(Tab1) shown the effect for chemical composition of sediment, and after further analysis, We found that, the three factors represented catchment erosion (F1), biogenic deposit (F)and marine dominated condition(F3)(Tab1) respectively. The factor score curves(Fig1) represented the changes of humidity and temperature and the hydrodynamics in different depth(times).

Factors	Variables and factor loading	Variance contribution %
F1	Co0.873,Cu0.906,Ni0.925,Zn0.807, Cr0.628, Average grain size 0.710	42.06
F2	Sr 0.885, Ba 0.949	21.95
F3	Zr 0.748, TOC* -0.937	21.58

*TOC:total organic carbon

Table1: Result of factor analysis

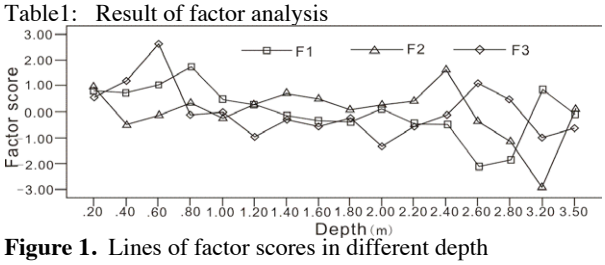

Figure 1. Lines of factor scores in different depth

The study provided an effective approach for palaeoenviroment reconstruction of Pearl river delta. It revealed that the basic palaeoclimate succession in the region of Pear river delta is cool-humid, cool-dry, warm-dry, warm-dry , warm-humid and warm-dry successively.

[3]Centre for Environmental and Marine Studies (CESAM) and Geosciences Department, University of Aveiro, Aveiro 3810-193, Portugal
[4]Institut für Mineralogie, Universität Münster, Corrensstr, 24, 48149 Münster, Germany

The mineral and geochemical studies are carried out on a profile through a diagenetic methane-derived authigenic carbonate sample which was collected from southwestern Dongsha area of the northern South China Sea. The five samples located in the cross-sectional middle mainly consists of dolomite and quartz, and two samples close to surface show small amounts of Mg-calcite. The $\delta^{13}C$, $\delta^{18}O$ and $\delta^{44/40}Ca$ values of the samples range -30.59‰~-0.30‰ VPDB, 3.07‰~3.59‰ VPDB and 1.35‰~1.47‰ SRM915a, respectively, indicating a clear contribution of methane oxidation to the carbon pool from which the authigenic carbonates precipitated from. From the isotope signals alone it can not be distinguished if the carbon source is rather thermogenic gas or a mixture of biogenic methane and marine dissolved inorganic carbon (DIC). The $\delta^{18}O$ values are in general consistent with dolomite precipitation from a fluid similar to present seawater. The observed small variability might be related to fluid oxygen isotope composition. The relative small range in calcium isotope values indicates relatively constant growth conditions and precipitation from seawater like fluid. The central part of the carbonate nodule formed under the strong influence of methane seepage, and the external part is less influenced by methane, either due to reduced methane flux to the surface or caused by erosional exhumation of the carbonate nodule from greater depth to the sediment surface.

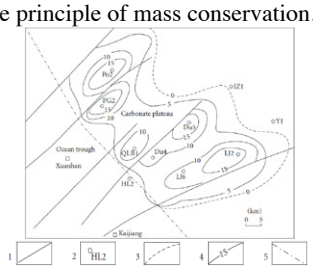
A Prediction Model of Oil Cracked Gas Resources and Its Application in NE Sichuan Basin, SW China

T.S.WANG*, S.Y. HU AND X. LI

PetroChina Research Institute of Petroleum Exploration & Development,Beijing,China(*correspondence:wts2007@petrochina.com.cn)

The prediction of oil cracked gas resources is necessary and urgent in the gas exploration of these basins at high to over stage in China. A marine crude oil sample was pyrolyzed using sealed gold tubes systemin our study. The pyrolysates including gas, liquid, and solid were quantitatively analyzed. Based on the pyrolysis data and kinetic calculation, the yield correlativity among gas, liquid, and solid products was regressed with high correlative coefficients to establish a prediction model suitable for the resource estimation of oil cracked gas. The verification formula for this model was also established on the principle of mass conservation.



1. Fault 2. Well 3. Boundary of sedimentary facies
4. Content contour of solid bitumen in reservoir (%)
5. Distribution area of solid bitumen in reservoir

Fig1.Content contour of solid bitumen in reservoir in NE Sichuan Basin

The affecting factors and the application preconditions of this model were discussed. Finally the model was extrapolated to the prediction of oil cracked gas resources of Feixianguan formation in NE Sichuan basin, SW China[1]. The prediction value of oil cracked resources is about $6.84\times10^{12}m^3$, and generation intensity of oil cracked gas is about 97.5×10^8 m^3/km^2, and the paleo-oil reserves is about 97×10^8t. The verifying value for this prediction is approximately equal to 1, indicating the model is reliable in the resource estimation of oil cracked gas.

It is the first attempt to evaluate oil cracked gas resources through analyzing the increase or decrease of gas, liquid, and solid products in crude oil pyrolysis and the correlativity among the three yields.

Some new ideas are provided for the estimation of natural gas resources and the restoration of paleo-oil accumulations in the areas with high and overmature marine source rocks in south China. It is significant for the decision-making of natural gas exploration in China.

Geochemistry and isotope geochemistry of Upper Cretaceous chalk as equivalent for reservoir chalk of the North sea Basin for EOR

W. WANG[1], M. V. MADLAND[1], U. ZIMMERMANN[1], S.A.R. BERTOLINO[2], T. HILDEBRAND-HABEL[3] AND R. I. KORSNES[1]

[1]Univ. i Stavanger, IPT, Norway, udo.zimmermann@uis.no
[2]CONICET-FAMAF, Cd. Universitaria, Córdoba, Argentina
[3]IRIS, P.O. Box 8046, 4068 Stavanger, Norway

Upper Cretaceous chalk from five exposures (Kansas, USA; Liège and Mons, Belgium; Aalborg and Stevns Klint, Denmark) have been sampled for comparison with reservoir chalk of the North Sea Basin (Tor and Hod Formations at Ekofisk, Brynhild, Enoch, Sleipnir and Jotun fields) of similar porosity in order to understand its reaction in flooding experiments for enhanced oil recovery (EOR). Chalks from Stevns Klint and Mons are very pure and contain like samples from Aalborg only few amounts of clastic material. The latter has abundant diagenetic chert. Liège and Kansas chalk contain the highest amount of clastics. Kansas chalk is particular, as it has reached the highest diagenetic grade, has higher concentrations in trace metals like Fe, Ni, Pb, Zn, Cu than all other chalk types and shows disturbed O-isotopes. This can be explained by abundant secondary micritic and sparitic cement in foraminifer shells. In contrast, C-O isotope values for all other on-shore chalk samples reflect primary seawater composition. This cannot be found in reservoir chalk. Here, O-isotopes are disturbed and similar to samples from Kansas. In some fields (Sleipnir and Jotun fields) trace metal compositions are also enriched and the chalk contains slightly higher amounts of clastic materials (Zr & Rb concentrations 2-5% of typical upper continental crust) and generally higher ΣREE concentrations with lower Y/Ho ratios (29-44) than in all on-shore samples. A post-depositional process affected the reservoir chalk, hence, in disturbing the O-isotope signature and affecting slightly the REE pattern, which is not related to clastic input. Chalk from Kansas shows a higher diagenetic overprint which explains the re-setting of the O-isotopes, but for the re-setting of the O-isotopes in reservoir chalk a reason have still to be found.

Provenance of Eolian Deposits in Desert-Loess Transition, North China by using Nd-Sr isotopic tracers

WANG XIAO*, AND RAO WENBO[2],

Institue of Isotope Hydrology, School of Earth Sciences and Engineers, Hohai University, Nanjing, 210098, China
(* correspondence:jswangxiao@126.com)

The desert-loess transition of China is very sensititive to climate change. Many studies on desert evolution and loess formation have been carried out in recent years[1]. However, the provenance of late Quaternary deposits in the desert-loess transition is not yet known. Here, we present Nd-Sr isotopic data of coarse-grained sands in the Dishaogouwan (DSGW) profile in the transition between Ordos deserts and Chinese Loess Plateau to identify the source of eolian deposits during the past 20ka.

The DSGW profile mainly consists of Dishaogouwan (DSGW), Dagouwan (DGW), Chengchuan (CC), Salawusu (SW) and Lishi (LS) Formations. The Salawusu Formation was aqueous but other formations were predominantly of eolian origin. $\varepsilon_{Nd}(0)$ values and $^{87}Sr/^{86}Sr$ ratios of coarse-grained fractions vary from -8.4 to -12.5 and from 0.7169 to 0.7199 in DSGW and DGW, from -9.1 to -11.5 and from 0.7179 to 0.7192 in the CC, from -10 to -12 and from 0.7188 to 0.7206 in SW and from -10.5 to -12.7 and from 0.7183 to 0.7190 in LS, respectively.

80% ~ 90% of the eolian deposits developed in different periods were coarse-grained fractions. $\varepsilon_{Nd}(0)$ values and $^{87}Sr/^{86}Sr$ ratios of coarse-grained in the Formations which were dominated by eolian deposits vary within a narrow range, implicate for a similar source. Furthermore, the coarse-grained fractions merely sprang and rolled on the earth's surface by the wind[2]. So, eolian deposits in these Formations might be fed by sediment blowing of adjact highland or mechanical weathering of the sandstones in Ordos. Contrastly, the aqueous deposits of SW was dominated by fine-grained fractions, and water erosion of underlying depoists probably dominated coarse aqeous deposits of sw. $\varepsilon_{Nd}(0)$ values and $^{87}Sr/^{86}Sr$ ratios of coarse-grained in SW don't have a obvious difference with the values of eolian deposits. However, there are rarely coare-grained fractions in Loess plateau from where salawusu valley originated. So underlying eolian deposits with abundant coarse-grained fractions could supply the aqueous deposits with coarse-grained fractions.

In-situ observations of liquid-liquid immiscibility in the system $MgSO_4$-H_2O (D_2O)

XIAOLIN WANG [1,2] AND WENXUAN HU [1,2]

[1]School of Earth Sciences and Engineering, Nanjing University, Nanjing, 210093, P.R. China
[2]Institute of Energy Sciences, Nanjing University, Nanjing, 210093, P.R. China

Liquid-liquid immiscibility has been documented in aqueous UO_2SO_4 solutions at temperatures up to 468 ºC [1]. Recently, we reported our observations on the liquid-liquid phase separation in vapor-saturated aqueous $MgSO_4$ solutions at temperatures up to 350 ºC [2]. Under these conditions, we observed that $MgSO_4$-rich droplets were separated from the original aqueous $MgSO_4$ solutions during heating, and these two coexisting liquid phases homogenized during cooling. It has been found that the phase separation temperature decreases from 304.5 ºC to 259.5 ºC as $MgSO_4$ concentration increases from 1.19 % to 19.36%. The newly discovered liquid-liquid phase separation in $MgSO_4$ solutions was characterized by a lower critical solution temperature phenomenon, which was considered to be a macro-scale chemical property of polymeric mixtures.

To further characterize the properties of the immiscible fluids in the system $MgSO_4$-H_2O, we documented in-situ Raman spectroscopic investigations and observed a distinctly new $\nu_1(SO_4^{2-})$ mode at ~1020 cm^{-1} in the $MgSO_4$-rich droplets; the new $\nu_1(SO_4^{2-})$ mode was predicted to be present in $MgSO_4$ polymer(s) in aqueous solutions. As mentioned above, both the phase behavior and relevant Raman spectra indicate the existence of polymer(s) in $MgSO_4$ solutions.

We compared the new $\nu_1(SO_4^{2-})$ mode with that of $MgSO_4$-rich droplets in the system D_2O-$MgSO_4$. We found that there was also an $\nu_1(SO_4^{2-})$ mode at ~1020 cm^{-1}. This observation suggests that the polymer(s) in aqueous $MgSO_4$ solutions is not bonded through H_2O and is probably contact ion pair chain(s), although the exact structure of the polymer(s) is still unknown. In addition, we investigated the hydrogen-bonds in the immiscible fluids. We found that the $MgSO_4$-rich fluids has higher potential for the preservation of hydrogen bonds compared with that in the $MgSO_4$-poor fluid at the same temperature. This can be ascribed to the formation of hydrogen bonds between SO_4^{2-} and water molecules because the probability of collision of H_2O with SO_4^{2-} in $MgSO_4$-rich fluid is higher than that in the $MgSO_4$-poor fluid.

The distribution of DBT and DBF in Mesoproterozoic (1.36 Ga) sediments

X.M. WANG[1], H.J. WANG[1] AND S.C. ZHANG[1]*

[1]Research Insttitute of Petroleum Exploration & Development, CNPC, Beijing 100083, China (wxm01@petrochina.com.cn, wanghuajian@petrochina.com.cn, *correspondence: sczhang@petrochina.com.cn)

Previous studies of polycyclic aromatic hydrocarbons considered dibenzofuran (DBF) and dibenzothiophene (DBT) to be derived from phenolic compounds of lignin from woody plants, thus their occurrence was attributed to terrestrial organic matter input[1]. However, in our recent works in North China Craton, high contents of DBF and DBT were both detected in the Mesoproterozoic (1.36 Ga) low mature mudstones and shales. No matter how high of the total organic carbon contents in the shales, the distribution of DBF and DBT were more likely to be controlled by the paleoredox conditions (Figure 1). DBT had a peak abundance in the anoxic zone, while DBF was enriched in the oxic minimum zone, the transition zone from oxic to anoxic. When the redox conditions changed to oxic, a dramatic decrease was happened in the abundances of DBF and DBT. Thus, we speculated that the abundance and distribution of DBT and DBF in ancient sediments may be controlled by the dynamic sulfic-oxic conditions.

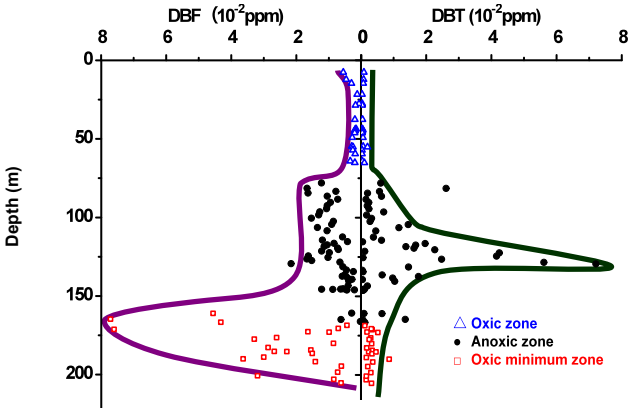

Figure 1: The distribution of DBF and DBF in Mesoproterozoic low mature mudstones and shales.

Age, geochemistry, and origin of Proterozoic rapakivi granites in the North Qaidam Orogen, NW China

XIAOXIA WANG[1], NENGGAO HU[2] AND TAO WANG[3]

[1] Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing 100037, China
[2] Chang'an University, Xi'an 710054, China
[3] Institute of Geology, Chinese Academy of Geological Sciences, Beijing 100037, China

Proterozoic rapakivi granites are mainly distributed within craton in the Northern Hemisphere. However, Proterozoic (ca.1770Ma) rapakivi granites have been recognized from the North Qaidam Orogen, the west segment of the Central Orogenic Systems of China. These granites exhibit typical rapakivi texture. They are A-type granite characterized by high FeOt/(FeOt + MgO) and Ga/Al ratios, and SiO_2, Na_2O + K_2O and rare earth element (except Eu) contents. Their whole-rock $\varepsilon_{Nd}(t)$ (–6.09 to –5.74) and zircon $\varepsilon_{Hf}(t)$ (–9.4 to –2.8) values, similar to those of the Proterozoic rapakivi granites in North China Craton (NCC), indicate they were derived from old continental crust. These granites contain magmatic microgranular enclaves and are intruded by diabases. The enclaves (more felsic) and granites show a uniform decrease in TiO_2, CaO, Na_2O, K_2O, FeO, and MgO with increasing SiO_2, and similar trace element patterns but different whole-rock $\varepsilon_{Nd}(t)$ values. The diabases and other enclaves (more basic) deviate from the trend and have high whole-rock $\varepsilon_{Nd}(t)$ values (ca. +4), suggesting their derivation from mantle. All these features indicate that the granites are almost the same as the Proterozoic (ca. 1700 Ma) rapakivi granites in NCC and belong to the Proterozoic rapakivi granite suit in the Northern Hemisphere. They were involved in the Paleozoic North Qaidam orogen. It is first time to recognize Proterozoic rapakivi granites in Phanerozoic orogens. This also reveals that Precambrian craton in North China were strongly destructed and reworked during Phanerozoic.

Rare earth elements in hydrothermal fluids from Kueishantao, off northeastern Taiwan

XIAOYUAN WANG[1] AND ZHIGANG ZENG[1]

[1] Key Laboratory of Marine Geology and Environment, Institute of Oceanology, Chinese Academy of Sciences, Qingdao, 266071, China
(*correspondence:wangxiaoyuan@qdio.ac.cn)

The ΣREE concentrations of Kueishantao hydrothermal fluids are 813-1212 ng/L, 1-2 orders of magnitude higher than those of seawater (ΣREE of shallow seawater is 92 ng/L; ΣREE of deep seawater is 14 ng/L), but are lower than they are in most deep-sea hydrothermal fluids [1] and acidic hot waters in continental geothermal fields [2-4]. The difference may be caused by the low leaching efficiency under the seafloor due to the short duration of fluid-andesite interaction in the Kueishantao hydrothermal field [5].

The REE_N distribution patterns of the yellowish fluids (108℃, pH≈2.6, the flux is 35 m^3/h) show a slight enrichment of LREE and a slight convex-downward curvature at Eu. The whitish fluids (51℃, pH≈4.9, the flux is 19 m^3/h) have REE_N distribution patterns that exhibit a higher enrichment of LREE than those of the yellowish fluids and without Eu anomalies. The REE_N distribution patterns of Kueishantao fluids are different from those of shallow seawater (generally flat with a negative Ce anomaly), deep-sea acid-sulfate fluids, the acid-sulfate fluids in Taiwan Tatun volcanic area and other acid-sulfate hot waters in continental geothermal fields. The Eu anomalies of Kueishantao hydrothermal fluids are controlled mainly by the lower temperature and relative oxidizing conditions. The fractionation between LREE and HREE of the yellowish fluids is influenced mainly by the very low pH and the precipitation of native sulfur. In contrast, the LREE/HREE ratios of the whitish fluids may be related to the adsorption by small sulfur particles.

Nitrogen isotopes of coral skeleton-bound organic matter: Proxy evalution at Bermuda

XINGCHEN T. WANG[1]*, ANNE L. COHEN[2] AND DANIEL M. SIGMAN[1]

[1]Department of Geosciences, Princeton University, Princeton NJ 08540, USA xingchen@princeton.edu (*presenting author); sigman@princeton.edu

[2]Department of Marine Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA, 02543, USA acohen@whoi.edu

Nitrogen isotopes of organic matter bound in coral skeleton (hereafter, skeletal $\delta^{15}N$) have the potential to be a high-resolution proxy for the marine nitrogen cycle. By adapting a previously developed foraminifera-bound $\delta^{15}N$ method, we have developed a sensitive method for measuring coral skeletal $\delta^{15}N$, requiring 5 mg of skeleton powder and yielding a precision of ~0.2‰. We evaluated the natural variability of this proxy in Bermudan brain corals. Ten live coral colonies (*Diploria labyrinthiformis*) from four locations around Bermuda were collected in 2005 and analyzed for skeletal $\delta^{15}N$ (Fig. 1). Skeletal $\delta^{15}N$ showed good reproducibility (< 0.5‰) among different colonies at the same location, suggesting coral skeletal $\delta^{15}N$ is a reliable proxy for the local nitrogen cycle. Among the four sampling sites, skeletal $\delta^{15}N$ decreased with distance from the island, from ~6.8‰ (inshore, Tynes Bay) to ~3.8‰ (offshore, HOG Reef). The annual calcification rate of each colony was estimated from image analysis of 3-D CT scans. Skeletal $\delta^{15}N$ at each site exhibits a strong, negative correlation with annual calcification rate (R^2>0.9). We propose that the efficiency of nutrient recycling between the symbionts and coral host is reduced when nutrient concentrations of reef seawater are elevated, resulting in higher skeletal $\delta^{15}N$ and lower calcification rates at our inshore sites.

[3]Seoul National University, National Instrumentation Center for Environmental Management, Seoul, South Korea

Portable X-ray fluorescence spectrometry (P-XRF) is currently used as a cost-effective and rapid analytical tool for assessing the heavy metal pollution of soil. However, the *in-situ* measured data are frequently unreliable due to soil heterogeneity, which may result in a difficulty to accurately interpret the spatial patttern of pollution status. This study is purposed to evaluate the feasibility of P-XRF to obtain a reliable auxiliary dataset for the cokriging interpolation of soil heavy metal data. For this study, we used analytical results of arsenic concentrations in soil samples (n=156) from a metal-polluted site, which were obtained by the conventional chemical leaching method and P-XRF. The both arsenic levels showed a good correlation (R^2 = 0.72). The true As pollution map was initially established by an ordinary kriging of 156 data. Then, one third of the total samples (i.e., 52 P-XRF data) were randomly chosen to presume the virtual soil investigation, and two kinds of pollution maps were constructed using the ordinary kriging and cokriging methods. Comparison of the estimated As levels with the true data at total sampling points (n=156) showed that the cokriging map is more reliable (R^2 = 0.89) than the ordinary kriging map (R^2 = 0.40). This study shows the advantage of the cokriging interpretation of P-XRF data to evaluate the spatial distribution of heavy metal pollution of soil.

Study on uranium speciation in the water of a river near phosphate mining area

XIN-YU WANG[1,2], ZE-MING SHI[1,2] AND SHI-JUN NI[1,2,*]

[1]Department of Geochemistry, Chengdu University of Technology, Chengdu, 610059, China;
[2]Key laboratory of Nuclear Techniques in Geosciences, Chengdu 610059, China (E-mail: wangxinyucdut@gmail.com; shizm@cdut.edu.cn; nsj@cdut.edu.cn.)

Uranium is a toxic and radioactive element for human health. Previous research has revealed that those people who lived in the phosphate mining affected zone, had higher concentration of uranium in blood than those who lived in urban area. Based on the investigation of uranium concentration in a river which flowed through phosphate mining affected zone, the speciation of uranium in the water was discussed in detail.

In this paper, the potential, temperature and pH value were in situ analysed. The concentrations of uranium, other cations and anions were respectively determined by ICP-MS, ICP-OES and IC. According to the above experimental data, the uranium speciation model was constructed. The results show that:

In nearly-neutral pH value range, the uranium speciation distribution in water was mainly controlled by the phosphate concentration of the water. The MUS (major uranium speciation) of the river near the phosphate mining affected zone was $UO_2(HPO_4)_2^{2-}$, while the MUS were $UO_2(CO_3)_2^{2-}$and $UO_2(CO_3)_3^{4-}$in water which near the cement factories. When the river flowed through a farmland where the phosphate fertilizer was being used, the MUS in the water was $UO_2(HPO_4)_2^{2-}$. But after that site, the MUS of the river changed into $UO_2(CO_3)_2^{2-}$ and $UO_2(CO_3)_3^{4-}$ because of the increase of pH value and phosphate concentration. In this process, We found the use of phosphate fertilizer would lead to a significant increase of the phosphate concentration in the river. Moreover, the increasing of the phosphate concentration resulted in the hydrolysis of the anion and led to the raise of pH value of the river. Some studies about the relationship between the uranium toxicity and its speciation revealed that, because of the biological preference of element Phosphorus, the speciation of uranyl phosphate had stronger cytotoxicity (bioavailability) than the common speciation of uranyl carbonate.

Holocene changes in fire frequency in the Daihai Lake region (north-central China): Indications and implications for an important role of human activity

XU WANG[1], LINLIN CUI[1], JULE XIAO[1] AND ZHONGLI DING[1]

[1]Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O. Box 9825, Beijing, 100029, China; (xuking@mail.iggcas.ac.cn)

Black carbon (BC) content in a sediment core from Daihai Lake, Inner Mongolia, was analyzed to reconstruct a high-resolution history of fires occurring in northern China during the Holocene and to examine the impacts of natural changes and human activities on the fire regime. The black carbon mass sedimentation rate (BCMSR) was disintegrated into two components: the background BCMSR and the BCMSR peak, with the BCMSR peak representing the frequency of fire episodes. Both the background BCMSR and the magnitude of the BCMSR peak display a close relation with the percentage of tree pollen from the same sediment core, suggesting that regional vegetation type would be a factor controlling the intensity of fires. The inferred fire-episode frequency for the Holocene exhibits two phases of obvious increases, i.e., the first increase from <5 to ~10 episodes/1000 yrs occurring at 8200 cal. yrs BP when the vegetation of the lake basin shifted from grasses to forests and the climate changed from warm/dry to warm/humid condition, and the further increase to a maximum frequency of 13 episodes/1000 yrs occurring at 2800 cal. yrs BP when herbs and shrubs replaced the forests in the lake basin and the climate became cool/dry. Both increases in the fire frequency contradict the previous interpretation that fires occurred frequently in the monsoon region of northern China when steppe developed under the cold/dry climate. We thus suggest that human activities would be responsible for the increased frequencies of fires in the Daihai Lake region in terms that the appearance of early agriculture and the expansion of human land use were considered to take place in northern China at ca 8000 and 3000 cal. yrs BP, respectively.

Early Archean ultra-depleted mantle: Evidence from newly discovered ~3.8 Ga trondhjemite in North China

YAFEI WANG[1]*, XIANHUA LI[1], WEI JIN[2] AND JIAHUI ZHANG[2]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China (*correspondence: pengfei4783@163.com; lixh@gig.ac.cn)

[2]College of Earth Sciences, Jilin University, 130021, China

The scale and degree of early mantle depletion and continental crust growth are poorly constrained because isotopic systems of ancient rocks are susceptible to later disturbances and most reliable Hadean to Archean zircons exhibit enriched isotopic characteristics.

Detailed field and zircon isotopic studies show that our newly discovered ~3.81 Ga trondhjemite was enclosed by ~3.36 Ga migmatite complex, and variable younger ages due to various degree of ancient radiogenic Pb loss, intrusion of leucosome, and a possible new ~3.31 Ga crustal growth event.

The concordant (disc.<5%) ~3.8 Ga zircons with simple oscillatory zonings preserve the primary isotopic signatures, ranging in ε_{Hf} values from -1.9 ± 0.9 to 6.2 ± 0.7 and $\delta^{18}O$ from 5.3 ± 0.3 to 7.0 ± 0.3‰. The extremely positive ε_{Hf} values exceed values of previously reported contemporaneous zircons and existing depleted mantle Hf isotopic evolutionary models at ~3.8 Ga, providing robust isotopic evidence for the existence of an ultra-depleted mantle source corresponding to significant crustal growth at least 3.8 Gyr ago.

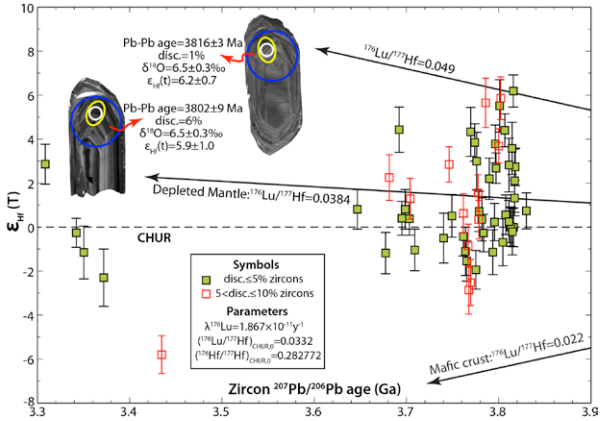

Figure 1: Plot of $\varepsilon_{Hf}(T)$ versus age of disc.<10% zircons in ~3.81 Ga unit with putative reservoirs differentiated at 4.5 Ga and details of two highest ε_{Hf} zircons. The highest ε_{Hf} value requires a reservior with $^{176}Lu/^{177}Hf$ ratio of 0.049, significantly higher than present-day depleted mantle value of 0.0384, differentiated at 4.5 Ga. The blue circle is ~60μm in diameter.

Silicate melts under high pressure

YANBIN WANG[1], TATSUYA SAKAMAKI[1,*], LAWRIE SKINNER[2], GUOYIN SHEN[3], TONY YU[1], YOSHIO KONO[3], ZHICHENG JING[1] AND CHANGYONG PARK[3]

[1]Cnter for Advanced Radiation Sources, the University of Chicago, Chicago, IL, USA

[2]Stony Brook University, Stony Brook, NY, USA

[3]HPCAT, Carnegie Institution of Washington, Argonne, IL, USA

We present our recent data on structural evolution of silicate melts and glasses at high pressures, along with measurements of density, elasticity, and viscosity. High-pressure melt structure studies were conducted using a Paris-Edinburgh Press at the HPCAT beamline 16-BM-B. Acoustic velocities were also measured on silicate glasses. A DIA apparatus was used for melt density measurements based on x-ray absorption at GSECARS beamline 13-BM-D. Structures of polymerized (jadeite – $NaAlSi_2O_6$) and depolymerized (diopside, $CaMgSi_2O_6$) melts show distinct responses to pressure. In jadeite melt, T-O (T denotes tetrahedrally coordinated Al and Si) bond length, T-T bond length, and T-O-T angle all exhibit rapid and non-linear decrease with increasing pressure to ~3 GPa. In diopside melt, these parameters vary linearly with pressure and change very little. A large viscosity dataset from the literature shows that, with increasing pressure, viscosities of polymerized liquids (including jadeite) first decrease and reach a minimum at around 3 GPa before turning over. On the other hand, viscosities of depolymerized melts (including diopsite) increase monotonically with pressure. Molecular dynamics calculations, constrained by the x-ray structural data, were employed to examine details of structural evolution in the two types of liquids. A model will be presented to link structural evolutions to changes in melt properties, such as density and viscosity, with pressure.

Oxygen isotope compositions of Al-rich chondrules from carbonaceous chondrites

Y. WANG[1]*, W. HSU[1], X. LI[2], AND Q. LI[2]

[1]Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing 210008, China (*correspondence: y_wang@pmo.ac.cn)

[2]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China

Al-rich chondrules (ARCs) are rare objects with >10 wt% bulk Al_2O_3 content. They have petrological, chemical, and oxygen isotopic characteristics intermediate between Ca,Al-rich inclusions (CAIs) and ferromagnesian chondrules (FMCs) [1]. ARCs are an unique window to study the orgins of CAIs and chondrules and their genetic relationship.

Eleven ARCs and representative CAIs and FMCs from three CV3 (NWA 2140, NWA 2697, and NWA 989) and Ningqiang chondrites were studied. Olivine, pyroxene, plagioclase, spinel, and Si,Al-rich glasses were analyzed with the Cameca ims-1280 ion microprobe, housed at IGG, Beijing. The oxygen isotope compositions of ARCs form a mixing line with a slope of 0.86±0.04 (Figure 1), close to the CCAM line (slope=0.94) [2]. ARCs have $\Delta^{17}O$ values (0.3~-17.9 ‰) intermediate between CAIs (-1.4~-27 ‰) and FMCs (2.4~-9.8 ‰), indicating that the precursors of ARCs might be mixtures of CAIs and FMCs. Minerals in individual ARCs are heterogeneous in oxygen isotope compositions, with the biggest $\Delta^{17}O$ variation of 15.4 ‰. This imples that during the formation of ARCs, oxygen isotopic exchange with nebular gases might have occurred.

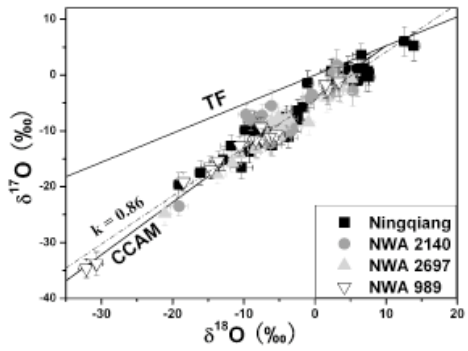

Figure 1: Oxygen isotope compositions of ARCs from Ningqiang and three CV3 chondrites.

Geochemical characteristics of different type reservoirs from the Sinian Dengying Formation in Southeastern Sichuan Basin, China

WANG YONG AND SHI ZEJIN[2]

[1] Department of Geochemistry, Chengdu University of Technology, Chengdu 610059, China; e-mail: wangyong10@cdut.cn

[2] State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Chengdu University of Technology, Chengdu 610059 , China; e-mail: szj@cdut.edu.cn

Reservoirs in Sinian Dengying Formation can be divided into three categories according to genesis, that is, paleo-karst reservoirs related to tectonic uplift, buried dissolution reservoirs due to burial and dissolution and hydrothermal dolomite reservoirs. Compared with surrounding rocks in Dengying Formation, paleo-karst reservoirs had the characteristics of low Na, high Mn, high Fe, low Sr, low carbon isotope and high $^{87}Sr/^{86}Sr$ value, generally reflecting the fact that the formation of paleo-karst reservoirs was closely related to fresh water. Buried dissolution reservoirs had the characteristics of high Mn, low Fe and low carbon isotopes. The characteristics of high Mn indicated that buried dissolution reservoirs experienced stronger diagenesis modification in the burial environment, while low Fe and low carbon isotopes were related to dissolution effects of organic acids during burial. Hydrothermal dolomite reservoirs had very low contents of Fe and Sr element, significantly partial negative oxygen isotope, and very high $^{87}Sr/^{86}Sr$ value. The formation of these characteristics was related to hydrothermal physical and chemical properties. Three major types of reservoirs in Dengying Formation had significant geochemical response characteristics, which could be taken as geochemical indicators to identify different types of reservoirs.

Lawsonite as a potential repository of Th and REE in subduction zones: Blueschists from Tavşanlı (Turkey)

Y. WANG[1], D. PRELEVIĆ[1], S. FOLEY[1,2], S. BUHRE[1], T. JOHNSON[1] AND T. HÄGER[1]

[1]Uni Mainz, Mainz, Germany (wangyu@uni-mainz.de)
[2]CCFS, Dept. Earth and Planetary Sciences, Macquarie University, North Ryde, NSW 2109, Australia

Constraining the processes by which crust is recycled back through the mantle wedge and into volcanic arcs is one of the most challenging issues in modern geochemistry. Discussion is mostly centered around the dichotomy of fluid vs melt transport and subsolidus dehydration vs melting, in which the mobility of Th and REE has particular significance. In this context, production of fluid or melt by breakdown of hydrous minerals such as lawsonite, and the consequences for trace element mobilization remain largely unconstrained.

Here we combine EMP, LAM-ICP-MS and confocal microRaman spectroscopy with THERMOCALC modelling of four samples of lawsonite and garnet bearing blueschist from the Tavşanlı Zone, Turkey, a melange metamorphosed under blueschist to lawsonite-eclogite facies conditions. Our aim was to monitor trace element redistribution during high-pressure–low-temperature metamorphism. Two samples have low concentrations of Th, REE and K, suggesting an essentially oceanic crust protolith, while the other two samples are enriched in K (up to 2.89% K_2O), Th and REE, implying the presence of a continent-derived terrigenous component.

Equilibrium assemblages are lawsonite + glaucophane + chlorite + phengite + titanite + apatite +/- garnet +/- quartz and iron oxides. Garnet is the major host for HREE, phengite contains most LILE and titanite and zircon are the dominant carriers for Nb, Ta and Zr, Hf, respectively. Lawsonite and apatite carry almost all Sr and a significant proportion of the REE. In Th rich samples, lawsonite is extremely enriched (up to 100 ppm) in Th, giving rise to high Th/La ratios up to 1.0, at relatively low Sm/La (down to 0.4).

The high Th/La ratios observed in lawsonite are significantly higher than in average crust and normal arc volcanics, but similar to those in Mediterranean lamproites, rare ultrapotasic orogenic lavas occurring within Alpine-Hymalayan belt. This “fingerprint” may result from the incorporation of lawsonite-bearing blueschists into their melting source, and subsequent melting. High Th/La can be liberated only by direct melting, ruling out prograde recrystallization into new mineral phases, which redistribute trace elements differently.

Mercury biogeochemistry and its biomagnification in the fish food web in Three Gorges Reservoir after 175m impoundment

YUCHUN WANG[1] MEI MA[2 A] AND YANG YU[1]

[1]Department of Water Environment, China Institute of Water Resources and Hydropower Research, Beijing 100038, China. wangyc@iwhr.com; yuyangle@126.com
[2]State Key Laboratory of Environmental Chemistry and Ecotoxicology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing 100038, China. mamei@rcees.ac

Three Gorges Reservoir (TGR) is a giant canyon-shaped reservoir located in the lower section of the upper reaches of the Yangtze River. Concern about human consumption of fish contaminated with MeHg had been raised even before the construction of TGR. This study tried to investigate the total mercury concentrations in fish and biomagnification characters of mercury along food chains in TGR after 175m impoundment. We collected eleven fish species from three main stem sections and seven typical tributaries of TGR from 2011 to 2012. Result showed that mercury concentrations in fishes from TGR had not obviously increased after impoundment. But spatial difference was found among different sections of main stem. Due to the enhanced sediment deposition along reservoir, there was a decreasing trend of mercury concentration in fish from upper stream to lower stream within TGR. Mercury concentrations in the fishes from Luoqi in up area of reservoir (88.0μg/kg, average) was significantly higher than those from Wushan in middle area of reservoir (43.1μg/kg, average) and tributaries (57.1μg/kg, average). The mercury concentrations in fish from tributaries were comparable to those from main stem, and there were no significant difference among most tributaries. While Log-transformed mercury contents were consistently correlated with $\delta^{15}N$ values for the fish food web in all sampling sites, the slope of the relationship with $\delta^{15}N$ (biomagnification power value) was significant higher in Shennong River than that in Wanzhou and Wushan section. This indicated that biomagnification power of mercury is greater in tributary than in main stem of TGR. Data of $\delta^{15}N$ and $\delta^{13}C$ showed that fishes in tributary rely more on pelagic primary production while those in main stem tend to take allochthonous materials carried by runoff. In conclusion, the difference between body type of tributary and main stem after impoundment may be an important reason of different mercury bioaccumulation within TGR.

[3]Helmholtz Center Dresden Rossendorf (HZDR), Institute of Resource Ecology, Dresden, Germany

Uranium is known to accumulate in wetlands through its association with organic-rich soils. The precipitation of relatively insoluble U(IV) minerals under reducing conditions is considered as a means to immobilize U in constructed wetland systems [1]. A wetland in the Limousin region in France, located adjacent to a former U mine was impacted by mining activity for several decades and contains U hotspots (~4,000 ppm) [2]. The concentration of U steadily increases as a function of distance in a stream flowing through the wetland, suggesting U release from the wetland into the stream. We collected soil and porewater samples under anoxic conditions from two selected U hotspots in the wetland as a function of depth and season to assess the geochemical conditions leading to this release. High porewater Fe(II) concentrations suggest that metal-reducing conditions prevail in the wetland soil. Using laser fluorescence spectroscopy (LFS) and X-ray absorption spectroscopy (XAS), we concluded that the predominant U redox state in both porewater and soil was tetravalent. A near constant U(IV) concentration is observed throughout the porewater profile while soil U(IV) is restricted to the top 30 cm. Evidence for U association with colloidal $Fe(OH)_2$-organic matter assemblages provided a ready explanation for the mobility of porewater U. Furthermore, U in the soil occurs primarily as a non-crystalline U(IV) species corresponding to U(IV) adsorbed onto amorphous Fe-Al-P-Si aggregates. Hence, U(IV) species in the porewater are distinct from those present in the soil. These results show that the form of U(IV) in soil is labile and releases U(IV) to form mobile colloids that ultimately result in the release of U into the stream. The surprising mobility of U(IV) in this system brings into question the often assumed immobilization of U through reduction, particularly in high organic matter environments such as wetlands.

Nano pore evolutions of shale and coal during petroleum generation process using SANS and pyrolysis

YUNPENG WANG[1] MEI DING[2 A] AND LINGLING LIAO[1]

[1] SKLOG, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China

[2] EES-14, LANL, Los Alamos, NM 87545, USA

This study aims to examine the changes of nano- to microscaled pores of shale (marine and lacustrine) and coal with petroleum generation, retaining and cracking. Pyrolysis was used to define oil and gas window, as well as study the compositions of expulsed and retained oil while small-angle neutron scattering (SANS) was used to characterize nano- to microscaled pores of residual source rocks. Oil windows are defined as 0.6-1.3%Ro for shale and 0.5-1.2%Ro for coal; wet gas window are 0.9-3.0% Ro for shale and 0.8-3.0% Ro for coal; dry gas windows are 1.3-3.6%Ro for both shale and coal. In oil window, marine shale oil shows mainly saturated and aromatic fractions, resins and less asphaltene. In gas window, higher saturated fractions is due to its higher stability. Coal oil shows dominant asphaltene fraction with higher aromatic HC, resin, asphaltene and rare saturated HC.

Pore features corresponding to oil and gas windows by SANS show that shale and coal have unique pore features at the scale between 1 to 100 nm. Results also show that pore features change more significantly in coal relative to shale rock during hydrocarbon generation and expulsion from source rocks, presumably due to the much higher organic carbon content of the coal and unique HC fractional compositions (Fig. 1).

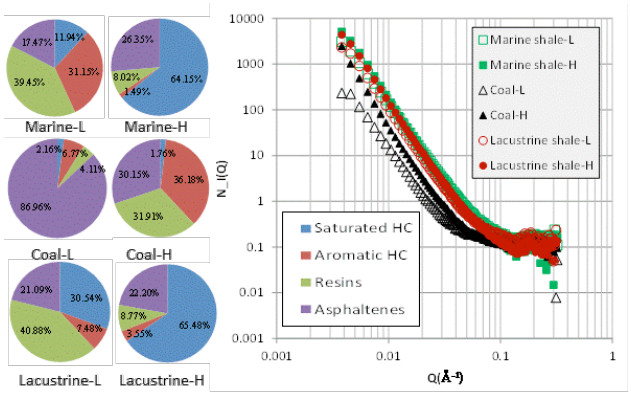

Figure 1 SANS plot of shale and coal in early oil window(L, 0.4%Ro) and post gas window(H,3.8%Ro) as well as the corresponding hydrocarbon(HC) fractional compositions

Accretion of a volatile rich late veneer recorded by CI chondrite-like S/Se and Se/Te in the Earth's mantle

ZAICONG WANG* AND HARRY BECKER

Freie Universität Berlin, Malteserstrasse 74-100, 12249 Berlin, Germany (*contact: zaicongwang@gmail.com)

The history of delivery of volatile elements is of fundamental importance for understanding planetary evolution (Albered, 2009). The detailed origin and history of moderately volatile and atmophile elements in the Earth remains uncertain. The excess of highly siderophile elements (HSE) and chondritic ratios of most HSE in the bulk silicate Earth (BSE) may reflect accretion of a chondritic late veneer of about 0.5 % of Earth's mass after core formation[1,2]. The proportion of volatiles delivered by the late veneer is a key constraint for the budget and the origin of the volatiles in the Earth. At high pressure-temperature conditions, the moderately volatile chalcogen elements S, Se and Te with rather low 50 % condensation temperatures near 700 K are moderately to highly siderophile, thus, if depleted by core formation, their mantle abundances should reflect the composition of the late veneer[3]. Here we determined ratios and abundances of S, Se and Te in the mantle based on new isotope dilution data for post-Archean mantle peridotites with negligible low-temperature alteration. Infiltration and trapping of silicate melt in peridotites have very similar effects on abundances of S, Se and Te as partitioning during open system melting[4,5]. The mean S/Se (2690±700, 1σ) and Se/Te (7.9±1.6, 1σ) of mantle lherzolites overlap with CI chondrite values[6]. In contrast, Se/Te of ordinary and enstatite chondrites are significantly different (11-30)[7]. The chalcogen/HSE ratio of the BSE is similar to CM group carbonaceous chondrites, consistent with the view that the HSE signature of the BSE reflects a mixture of slightly volatile depleted carbonaceous chondrite and minor non-chondritic material[8]. Depending on the estimates for the abundances of water and carbon in the BSE (Marty 2012), the late veneer may have supplied a significant proportion of the budget of hydrogen and carbon in the BSE.

Origin of deep gas and oil cracking gas potential in Tarim Basin, China

ZHAOYUN WANG[1], YONGXIN LI[2], AND HONGJU ZHENG[3]

[1] Research Institute of Petroleum Exploration and Development, Petrochina, Beijing, China, wzy@petrochina.com.cn
[2] Research Institute of Petroleum Exploration and Development, Petrochina, Beijing, China, lyxin@petrochina.com.cn
[3] Research Institute of Petroleum Exploration and Development, Petrochina, Beijing, China, hjzheng@petrochina.com.cn

The marine strata in China is of old age and in high evolution period, and the potential of gas generated from high-overmature source rocks is limited, but the gas exploration of this marine strata in Tarim basin has greatly effective with large gas fields constantly discovered.

This paper brings up the successive gas generation machanism for the origin of deep marine gas, including three meanings of transformation of gas generation matter, replacement of gas generation time,and change of gas source kitchen. The gas source kitchen of dispersive liquid hydrocarbon inside of source rocks inherits the characteristics of original gas source kitchen, but the gas source kitchen of dispersive & concentrated liquid hydrocarbon outside of source rocks has occurred the spacial change comparing with original gas source kitchen. The above three liquid hydrocarbon can be cracked into gas at high-over mature stage, but the latter is embeded flatter and its time of cracking and gas generation is later than the former, which makes for the late gas accumulations.

This paper creates expulsion oil rate plates of different organic matter abundance through simulation experiments of hydrcarbon generation and expulsion of different organic matter abundance and different lithology source rocks, providing the basis for the reasearch of allocation proportion and quantity of dispersive liquid hydrocarbon inside & outside of source rocks.

This paper demonstrates the quantity, distribution and cracking degree of dispersive soluble organic materials of palaeozoic strata in Tarim basin from the evaluating indicator S_1 of hydrocarbon generating potential, heat-origin asphalt and the fluorescence characteristic of reserviors, and makes sure of the reality of successive gas generation of organic matter of palaeozoic marine source rocks in Tarim basin, and also calculates the cracking gas quantity of dispersive soluble organic matter in middle and lower Cambrian of Tarim basin. The application of successive gas generation mechanism of organic matter can greatly increase the gas exploration potential and hopeness of palaeozoic strata in Tarim basin,China.

Novel calcite-aragonite sea transition in the terminal Proterozoic

ZHENGRONG WANG[1] JUSTIN AND RIES[2] CHAO LIU[1]

[1]Department of Geology and Geophysics, Yale University, New Haven, CT, USA, Zhengrong.wang@yale.edu
[2]Department of Marine Sciences, University of North Carolina, Chapel Hill, NC, USA, riesjustin@gmail.com

Tectonically driven fluctuations in seawater Mg/Ca are thought to have caused changes in the polymorph mineralogy of platform carbonates throughout Phanerozoic time (Mg/Ca<2 = calcite seas; Mg/Ca>2 = aragonite seas) [1]. Previously published elemental analyses of micritic limstones from the terminal Proterozoic Nama Group (552-544 Ma), southern Namibia, show a threshold increase in Sr/Ca (by a factor of 6-7) from 549 to 547 Ma and a decrease in Mg/Ca ratio (by a factor of 5) from 552 to 544, which are both consistent with a transition from primary calcite limestones (Sr-depleted, Mg-enriched) to primary aragonite limestones (Sr-enriched, Mg-depleted) across this interval [2].

To further investigate this potentially novel calcite-aragonite sea transition, we measured the Sr and Mg isotope compositions of the Nama Group carbonates (552 – 544 Ma) at Yale University. $^{87}Sr/^{86}Sr$ ratios are elevated from 0.7090 to 0.7105 between 552 and 549 Ma, and then decline to a relatively stable value of 0.7086 between 549 and 544 Ma.. The bulk $\delta^{26}Mg_{DSM3}$ values of the carbonates increase steadily from ~ -2.5 to -1.2‰ between 552 and 544 Ma, with a brief excursion down to -3.5‰ at ca. 549 Ma, which coincides with peaks in $^{87}Sr/^{86}Sr$ and Mg/Ca ratios.

Theoretical work and empirical observations of modern carbonates show that ^{26}Mg is enriched in the following order: low Mg calcite < high-Mg calcite < dolomite < aragonite [3]. Thus, the increase in $\delta^{26}Mg$ from 552 to 542 Ma is consistent with an increase in the proportion of primary aragonite with time. Likewise, the decline in $^{87}Sr/^{86}Sr$ across the interval is consistent with a transition from a lower-Mg/Ca calcite sea characterized by increased hydrothermal flux of radiogenic Sr (higher $^{87/86}Sr$), to a higher-Mg/Ca aragonitic sea characterized by decreased hydrothermal flux of radiogenic Sr (lower $^{87/86}Sr$). High-frequency incremental leaching of a set of limestone samples also suggests that the anomalous peaks in $^{87/86}Sr$ and Mg/Ca around 549 Ma may have resulted from localized diagenetic alteration.

Oxygen isotope equilibrium between sulfite and water

SCOTT D. WANKEL*[1,2], ALEXANDER S. BRADLEY[1,3], DANIEL L ELDRIDGE[4] AND DAVID T. JOHNSTON*[1]

[1]Dept. of Earth and Planetary Science, Harvard University, Cambridge, MA 02138 (johnston@eps.harvard.edu)
[2]Dept. of Marine Chemistry and Geochemistry, WHOI, Woods Hole, MA 02540 (sdwankel@whoi.edu)
[3]Dept. of Earth and Planetary Science, Washington University, St. Louis, MO 63130
[4]Dept of Geology, Univ of Maryland, College Park, MD 20742

Application of the oxygen isotopic composition of sulfate ($\delta^{18}O_{SO4}$) is complicated by rapid equilibration between sulfoxyanions and water. Specifically, the apparent relationship that develops between $\delta^{18}O_{SO4}$ and $\delta^{18}O_{water}$ during microbial sulfate reduction is thought to result from rapid equilibrium between water and aqueous intracellular sulfite (SO_3^{2-}) – a reactive intermediate in the sulfate reduction network. Here, we describe the oxygen isotope equilibrium effect between SO_3^{2-} and water, based on experiments conducted over a range of pH (4.5 to 9.8) and temperature (2 to 90˚C). Experimental results are consistent with predicted values based on *ab initio* estimates of oxygen isotope equilibrium values among S(IV) species and water and changes in speciation. We find that $\varepsilon_{sulfite\text{-}water}$ = 13.61 – 0.299*pH – 0.081*T˚C such that at a pH (7.0) and temperature (25˚C) typifying common experimental conditions of sulfate reducing bacterial cultures, SO_3^{2-} is enriched in ^{18}O by 9.5‰ (± 0.8‰) relative to ambient water. By evaluating previously published data within an updated sulfate reduction network, results prove consistent with high enzyme reversibility in the sulfate reduction biochemical network. We show that intracellular SO_3^{-2} exchanges with water up to 3 orders of magnitude faster than internal recycling and that kinetic isotope effects upstream of SO_3^{2-} are required to explain previous laboratory and environmental studies of $\delta^{18}O_{SO4}$ resulting as a consequence of sulfate reduction.

Seawater δ^7Li: A tracer for global CO_2 consumption by continental silicate weathering?

CHRISTOPH WANNER* AND ERIC L. SONNENTHAL

Lawrence Berkeley National Laboratory, Berkeley, CA, USA, (*correspondence: cwanner@lbl.gov)

Lithium isotope fractionation has been used as a proxy for silicate weathering and as a tracer in geothermal systems [1,2]. Misra & Froelich [1] recently presented the first record of Cenozoic seawater δ^7Li showing an increase of 9‰ over the last 60 Ma. This increase was attributed to increasing riverine δ^7Li values caused by a general change in continental silicate weathering behaviour.

Reactive transport modelling was performed using TOUGHREACT [3] to gain insight into the geochemical and isotopic effects of the changing weathering pattern. Simulations considered a granitic aquifer feeding a major river system. Li isotope fractionation was assumed to solely occur during Li incorporation into precipitating secondary minerals, computed using a solid solution approach [4]. Different weathering patterns were simulated by varying the contribution from weathering of unaltered granitic mineral phases (quartz, feldspars, micas), including the precipitation and dissolution of secondary minerals (kaolinite, chlorite) using a dual continuum approach.

Simulated δ^7Li values increased with an increasing contribution from weathering of primary granitic mineral phases suggesting that today's heavy riverine and seawater δ^7Li values are the result of a "weathering-limited" weathering pattern such as proposed by Misra and Froelich [1]. In contrast, our simulations suggest that low δ^7Li values inferred for the Paleocene-Eocene boundary [1] were largely inherited from weathering of previously formed secondary mineral phases associated with little or no Li isotope fractionation. Moreover, total simulated CO_2 consumption by silicate weathering reactions are positively correlated with δ^7Li values suggesting that global riverine and seawater δ^7Li values are directly linked to the total amount of global CO_2 consumption by continental silicate weathering. For a quantitative correlation, however, more experimental work is needed to better understand Li isotope fractionation processes including identifying key minerals involved and determining corresponding Li isotope fractionation factors.

Noble gas partitioning in CO_2 environments: a supercritical assessment of current assumptions

O. WARR[1]*, A. MASTERS[2], C. ROCHELLE[3] AND C.J. BALLENTINE[1]

[1]SEAES, University of Manchester, M13 9PL, UK (*correspondence: oliver.warr@manchester.ac.uk)
[2]CEAS, University of Manchester, M13 9PL, UK
[3] British Geological Survey, Nottingham, NG12 5GG, UK

Noble gases are powerful inert tracers which can yield key information about physical processes occurring within geological systems. Currently all modelling involving binary phase noble gas partitioning are based on the determinations by Crovetto *et al.* 1982 [1] under conditions that did not require consideration of phase composition, supercriticality nor the effect of non ideality on solute noble gases. Subsequent studies have not investigated these factors; the validity of all current interpretations is based on the assumption that these variables have no effect on noble gas partitioning. However, no published study exists which substantiates this supposition. Assessing the effects these variables have on partitioning will give us a much warranted greater insight and understanding into geological systems that operate under significantly different PVTX conditions.

We present noble gas partitioning results from a supercritical CO_2–H_2O binary phase system at elevated temperatures and pressures (50-100°C & 90-140 bar). This system was chosen due to a strong current interest in underground storage of anthropogenic CO_2 and their natural analogues for which noble gases have already proven invaluable [2,3]. Partitioning is determined using a combined experimental and numerical simulation-based approach to generate partitioning values which forms the basis of a robust model for predicting partitioning over a wide range of PT conditions. We present our methodology and results which we compare and contrast with values derived from the Crovetto *et al.* dataset. Preliminary findings suggest noble gas partitioning is demonstrably different for a supercritical CO_2–H_2O system; overall water phase solubility is significantly reduced, especially for the heavier noble gases by up to 60%. This observed disparity appears greatest at higher pressures and lower temperatures although an observable difference is noted across the studied PT range.

Global Abyssal Peridotite Constraints on the Upper Mantle

JESSICA M. WARREN[1]

[1]Stanford University, 450 Serra Mall, Stanford, CA 93405; warrenj@stanford.edu

Abyssal peridotites are the residues of adiabatic decompression melting beneath ridges. A broad sampling of abyssal peridotites from all major ocean ridges reveals variations in composition that reflect both ridge processes (melting, refertilization) and pre-existing heterogeneity. I present a compilation of geochemical data for abyssal peridotites from 59 localities on 6 major ridge systems (EPR, MAR, SWIR, CIR, AAR, and Gakkel). While the majority of peridotites have been sampled at transform faults, sampling at slow and ultra-slow ridges in the past decade has recovered large suites of on-axis peridotites. Compositional data has now been published for ~1500 peridotites, permitting a detailed look at global variations in the oceanic upper mantle.

I classify peridotites into residual peridotites and four types of veined peridotite: (1) gabbro-veined & plagioclase-bearing peridotite, (2) pyroxenite-veined peridotite, (3) dunite, and (4) cryptically metasomatized peridotite. The veins are generally interpreted to represent incompletely extracted melt or melt-related features retained in peridotite after adiabatic decompression melting. Veined peridotites represent >30% of the dataset. The abundance of veined peridotite indicates that oceanic lithospheric mantle is less depleted than commonly assumed, resulting in recycling of relatively more enriched material at subduction zones.

Residual peridotites provide the best representation of mantle composition following melt depletion and extraction. However, these unveined, residual peridotites define a surprisingly large compositional range, particularly at some individual localities. Modal Cpx varies from 0 to 15%, while spinel Cr/[Cr+Al] varies from 0.1 to 0.6. Individual trace elements vary by one to three orders of magnitude, which corresponds to ~0-12% degree of nonmodal fractional melting. Such variation is at odds with theory, which predicts that the degree of melting beneath ridges should be relatively uniform, except at ultra-slow spreading rates. In addition, some sections of ridge contain highly depleted peridotite associated with thin or absent basaltic crust. Some local-scale variability can be explained by incipient melt-rock reaction to produce dunite, but the pervasive variability at all length-scales indicates that regions of the upper mantle must contain pre-existing heterogeneities. This agrees with isotopic data (available for <100 abyssal peridotites), which require long-term depletions and enrichments in the mantle.

Long-term CO_2 induced reactivity, observations on natural CO_2 analogues and geochemical model predictions

LAURA J. WASCH[1], MARIELLE KOENEN[1] AND SUSANNE NELSKAMP[1]

TNO, Princetonlaan 6, P.O. Box 80015, 3508 TA Utrecht, the Netherlands. Laura.wasch@tno.nl

Predicting CO_2 trapping and containment over extended timescales asks for accurate models and well constrained input parameters. CO_2 natural analogues provide good opportunities to study the actual long-term effect of CO_2 on reservoir and caprock. This will provide valuable insight in long-term geochemical processes concerning CO_2 storage. Moreover, natural analogues can help calibrate simulations of the long-term chemical effects of CO_2 storage. Accurate simulations are essential for confirming whether the observed and modelled behaviour of injected CO_2 are in agreement, as required for EU regulations, thereby facilitating succesful implementation of CCUS.

We present an integrated approach of petography, basin modelling and geochemical modelling. Our study is focussed on the Werkendam natural analogue, a Dutch gas field containing > 70% CO_2. The CO_2 was trapped milions of years ago and hence the reservoir has been reacting with CO_2 for prolonged periods of time. In addition to CO_2 induced reactions, reactions related to 'ordinary' diagenesis are expected to have occurred. To distinguish the effect of CO_2 from diagenesis, the Waalwijk methane field was selected as a CO_2 free reference of the same formation. Basin modelling showed that this field has a comparable burial history as Werkendam. Samples from both reservoirs are studied with SEM to assess the differences in the mineral relations. Comparison of the reactions observed in the CO_2 and the CH_4 fields points to differences in mineral dissolution and secondary carbonate formation. The presence of CO_2 appears to enhance feldspar dissolution while facilitating (additional) formation of carbonates such as siderite, dolomite and ankerite. Geochemical modelling with PHREEQC is performed to assess if these reactions associated with CO_2 correspond to the predicted mineral changes. Calibration of the model indicates that the selection of primary mineralogy, especially the minor iron-bearing minerals, has a large effect on predicted CO_2 mineralization.

Detailed mineralogical input and assessment of the burial history is required to calibrate geochemical models which will increase our knowledge on long-term geochemical processes considering CCUS.

Bioweathering of chrysotile asbestos

KIRSTIN E. WASHINGTON* [1], JANE K. WILLENBRING[1] AND BRENDA CASPER[2]

[1]University of Pennsylvania, Department of Earth and Environmental Sciences, Philadelphia, PA 19104, USA
[2]University of Pennsylvania, Department of Biology, Philadelphia, PA 19104, USA
*kirstin.e.washington@gmail.com

The serpentine mineral, chrysotile, is the most common asbestiform mineral at asbestos-contaminated sites. Similar in mechanism to other asbestos minerals, its toxicity is related to the presence of iron, which induces oxidative stress, and the fiber's shape, which can lead to piercing of lung alveoli and induces inflammation.

Previous research has developed the idea that fungi endemic to serpentine substrates (*Fusarium oxysporum* and *Verticillium leptobactrum*) can remove atoms of key elements from asbestos particles, rendering them less toxic[1]. In this study, we investigate natural mechanisms of removal of impurity elements (Fe) and structural cations (Mg, Si) from the chrysotile asbestos fibers. We ran greenhouse experiments using heavy metal accumulating plant species, *Brassica juncea, Helianthus annuus*, and *Thlaspi caerulescens*. We also planted the native serpentine grassland species, *Sorghastrum nutans*, whose roots form mutualist relationships with arbuscular mycorrhizal fungi (AMF). We also evaluated the use of fungal exudates to remove iron from asbestiform chrysotile through cultured fungal experiments for different species of *Fusarium*.

We analyzed the iron content of plant tissue, fungal tissue, and iron in solution in fungal growth media and organic acid solutions over time via ICP-OES. We imaged the chrysotile fibers and fungi mycelium using an ESEM to determine the change in mineral structure and aspect ratio over time, and we assessed the change in mineral composition of untreated and treated asbestos samples via XRD. Preliminary data demonstrate that *Brassica juncea* was able to remove an average of 300ppm Fe per gram of plant tissue from the surface of chrysotile asbestos, and there was no difference in plant biomass when compared to plants grown with the addition of fertilizer containing iron. Preliminary results from the fungi treatments show that fungi take up iron but do not liberate the iron into the broth solution.

Cd isotope fractionation during sorption to Mn oxide at low and high ionic strength

LAURA E. WASYLENKI[1] AND JARED W. SWIHART[1]

[1]Department of Geological Sciences, Indiana University, Bloomington, Indiana USA 47405 (lauraw@indiana.edu)

Two potential applications of Cd isotopes motivate this study:

First, some diatoms have evolved to use Cd instead of Zn in their carbonic anhydrase enzyme [1]. Because these diatoms strongly fractionate Cd isotopes [2], marine sediments may preserve isotopic records of Cd utilization and diatom productivity in the past. A recent study [3] indicated that ferromanganese crusts in particular might preserve a straightforward record of global deepwater Cd isotopes.

Second, for freshwater or groundwater contaminated with Cd, sorption to Mn oxyhydroxide particles can be the dominant process retarding mobility of this toxic heavy metal (except in sulfide-rich conditions). If sorption drives a distinctive isotope effect, then determining the extent to which sorption reactions are attenuating flow of Cd may be possible by tracking Cd isotope signatures in soils or water.

To lay groundwork for these potential applications and to investigate fractionation mechanisms for Cd, we conducted sorption experiments using particles of the Mn oxyhydroxide birnessite, both in pure water and in synthetic seawater. Suspensions of synthetic birnessite particles were doped with Cd and allowed to react for 24 hours (*p*H adjusted to 8-8.5). Dissolved and sorbed Cd pools were separated by filtration, purified by ion exchange chromatography, and analyzed by MC-ICP-MS.

At low ionic strength we observed a constant offset of +0.15‰ ($\Delta^{114/112}$Cd) between dissolved and sorbed Cd (sorbed is lighter), regardless of proportion sorbed. This is consistent with reversible sorption driving an equilibrium isotope effect. At high ionic strength, the magnitude of fractionation increased with the proportion of Cd adsorbed, suggesting a kinetic or Rayleigh effect. The difference between low and high ionic strength results is likely driven by solution speciation; *chloro-* complexes dominate Cd speciation in synthetic seawater. We hypothesize that the difference in bonding environment between Cd^{2+} and an inner-sphere sorbed complex drives the equilibrium effect at low ionic strength, while fractionation in solution between various *chloro-* complexes becomes important at high ionic strength.

Hayabusa-2 – sample return from a near-Earth C-type asteroid (2014-2020): Current status

S. WATANABE*, M. ABE, M. ARAKAWA, M. FUJIMOTO, M. ISHIGURO, K. KITAZATO, N. KOBAYASHI, N. NAMIKI, T. OKADA, S. SUGITA, S. TACHIBANA, S. TANAKA, M. YOSHIKAWA, H. KUNINAKA AND HAYABUSA-2 PROJECT TEAM

*Nagoya U., Nagoya 464-8601. seicoro@eps.nagoya-u.ac.jp

Hayabusa-2 is an asteroid exploration mission to return surface samples of a near-Earth C-type asteroid 1999 JU_3. Because asteroids are the evolved remnants of planetesimals that were the building blocks of planets, detailed observation by a spacecraft and analyses of return samples will provide direct evidence of planet formation and dynamical evolution of the solar system. Moreover, C-type asteroids are expected to preserve the most pristine materials in the solar system, an interacted mixture of minerals, ice, and organic matter. Space missions are the only way to obtain such pristine materials with geologic context and without terrestrial contamination. In order to understand the dynamical and chemical evolution of the solar system by investigating and sampling 1999 JU_3, Hayabusa-2 sets the following scientific objectives: (1) Thermal evolution from planetesimal to near-Earth asteroid, (2) Destruction and accumulation of rubble pile body, (3) Diversification of organics through interactions with minerals and water on planetesimal, and (4) Material circulation in the early solar system. The basic design of the spacecraft is the same as in the original Hayabusa, but many improvements will be made and new technology will be adopted. The on-board instruments necessary for the fulfillment of the scientific objectives are a laser altimeter (LIDAR), a multi-band camera (ONC-T), a near-infrared spectrometer (NIRS3), a thermal infrared imager (TIR) and a wide-angle camera (ONC-W). A small impactor (SCI) will also be aboard for an asteroid-scale impact experiment, which will make a crater of several meters in diameter. The sampler, of which concept and design are also the same as the original Hayabusa, has three projectiles for impact sampling and the sample container has three separate rooms inside for sampling at three different locations, one of which could be ejecta from the artificial impact to sample sub-surface materials.

Hayabusa-2 will be launched in late 2014, arrive on 1999 JU_3 in mid-2018, and fully investigate and sample the asteroid during its 18-month stay. The spacecraft will return to Earth with samples in December 2020. Preliminary integration tests of the spacecraft are now being made, and the current mission status will be presented at the meeting.

Geochemical discrimination of tsunami sediments in Tohoku and Shizuoka area, Japan

T. WATANABE[1]*, N. TSUCHIYA[1], C. INOUE[1], A. KITAMURA[2], T. KOMAI[3], S. YAMASAKI[1], R. YAMADA[1], N. HIRANO[1], A. OKAMOTO[1], F.W. NARA[1] AND TOHOKU AND TSUNAMI SEDIMENT RESEARCH GROUP

Tsunami sediments from the stricken area

Geochemical studies of modern and past-tsunami sediments were performed to detect a tsunami invasion proxy. In this study, the modern tsunami sediments from the Pacific coast of Tohoku area, Japan (March.11th, 2011), have been analyzed by EDXRF and ICP-MS. In addition, past-tsunami sediments were also taken from the coastal area of Japan (Jogan, ca. 1100 BP; Yayoi, ca. 2000 BP; Sizuoka, ca. 3000 BP) in order to establish a novel method for the geochemical discrimination of invisible tsunami layers, such as mud and thin sand layers.

Na/Ti atomic ratios of tsunami sediment

Na/Ti and Si/Al atomic ratios in the tsunami sediments varied from 2.7 to 22.4 and from 1.7 to 13.6, respectively (Fig. 1). The Na/Ti ratios markedly increased up to ca. 7-22 in the tsunami layers from the northeast (Tohoku area) and middle Japan (Shizuoka prefecture). Our results show that the Na/Ti values are useful indicator of past-tsunami sediment layers.

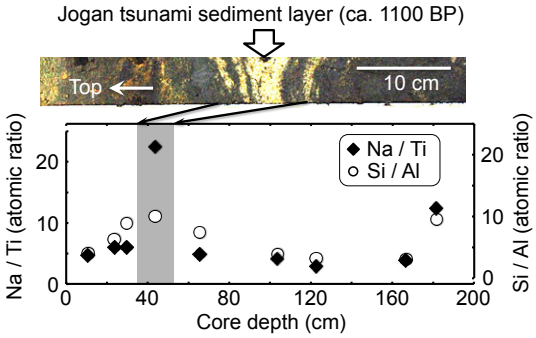

Figure 1: Na/Ti and Si/Al atomic ratios of tsunami sediments (Jogan, ca. 1100 BP) from Sendai plain in Tohoku area, Japan.

[4]Grad. Sch. of Science, Kyushu Univ. Fukuoka 812-8581 JAPAN (kiyokawa@geo.kyushu-u.ac.jp)

Coral cores from massive corals could record marine environmental and ecological changes in their annual bands with monthly temporal resolution in the present and/or the past. We discovered large massive Porites corals living at active volcanic island of Satsuma Io-Jima, located 50 km south from Kyushu area, southern part of Japan. Satsuma Io-Jima provides a unique opportunity to observe marine organism living under extreme environments of volcanic gases emission and different types of hydrothermal activities from sea flower. We collected eleven coral cores from four different conditions around the island to test if corals could record volcanic and hydrothermal activities and how corals could survive in extreme environments such as very low pH condition with CO2 gasses emission. Coral extension rate for the site near hydrothermal vent was significantly small (1-2mm/year) relative to that for general condition of Porites corals (ca. 10-20 mm/year), suggesting that coral growth was influenced by hydrothermal activity. We will demonstrate our preliminary results of geochemical approaches of δ18O, δ13C, Sr/Ca, Mg/Ca, Ba/Ca, and F/Ca in coral skeletons and in surrounding seawater and discuss the possibility for reconstructing the past hydrothermal events and relationship between marine ecosystem and extreme environments at volcanic activity as the analogues for coral adaptation to future ocean acidification.

Applications of neutron beam analysis to study the origins of carboneceous matter in terrestrial and planetary rocks: A new approach

Y. WATANABE[1]*, Y. FURUKAWA[2], T. KAKEGAWA[2] AND H. OHMOTO[3]

[1]J-PARC, Ibaraki 319-1195, Japan (*correspondence: yumiko.watanabe@j-parc.jp)
[2]Tohoku University, Sendai, Miyagi 980-8578, Japan (furukawa@m.tohoku.ac.jp, kakegawa@m.tohoku.ac.jp)
[3]PSARC and Penn State University, College Park, PA 16802, USA (hqo@psu.edu)

Some of the most fundamental and and important questions in the fields of Earth Sciences, Biology and Astrobiology are when, where and how life originated and different species evolved from the common ancestor during the 4.5 billion years history of the Earth. For exmple, we do not know whether carbonaceous matter in a particular Archean sedimentary rock represents a product of inorganic processes (e.g., Fisher Trophsch reactions) or a remnants of organisms. Similarly, the origins of carbonacerous matter in meteorites, Mars, and other planetary rocks have been debated.

The origins of carbonaceous matter in terrestrial and planetary materials have been investigated primarily from its chemical, isotopic, and physical characteristics, such as the H/C/N/P ratios, H, C, N, and S isotope ratios, crystal structure, and crystalinity. Here we introduce a new method, an application of neutron beam analysis, to determine the chemical composition and crystal structure of solid carbonacerous matter. Compared to the other techniques using x-ray, such as XRD, an advantage of neturon beam analysis is that it will identify the positions of light elements, particularly hydrogen, in the structure.

We will present the results of our preliminary investigations using neutron scatter analysis, XRD, and Raman spectroscopy on simple organic compounds (e.g., glycin steroid), micro-organism (e.g., cyanobacteria), and kerogens of various geologic age.

Influence of kinetics on the oxygen isotope composition of calcite

J. WATKINS[1]*, L.C. NIELSEN[2], F.J. RYERSON[3] AND D.J. DEPAOLO[4],

[1]University of Oregon, Eugene, OR 97403, USA (*correspondence: watkins4@uoregon.edu)
[2]Stanford University, Palo Alto, CA 94305, USA
[3]Lawrence Livermore National Laboratory, Livermore, CA 94550, USA
[4]Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA

Paleotemperature reconstructions rely on knowledge of the equilibrium fractionation of oxygen isotopes between aqueous solution and calcium carbonate. Although oxygen isotope separation is expected on theoretical grounds, the temperature-dependence remains uncertain because other factors, such as slow exchange of isotopes between dissolved CO_2-species and water, can obscure the temperature signal. This is problematic for crystal growth experiments on laboratory timescales and for interpreting the oxygen isotope composition of crystals formed in natural settings.

We present results from experiments in which inorganic calcite is precipitated in the presence of 0.25 μM dissolved bovine carbonic anhydrase (CA). The presence of dissolved CA accelerates oxygen isotope equilibration between the dissolved carbon species CO_2, H_2CO_3, HCO_3^-, CO_3^{2-} and water, thereby eliminating this source of isotopic disequilibrium during calcite growth. The experimental results allow us to isolate kinetic oxygen isotope effects occurring at the calcite-water interface during mineral growth.

The oxygen isotope composition of precipitated calcite is lighter than dissolved HCO_3^- yet heavier than CO_3^{2-} at pH = 8.3. ^{18}O uptake into calcite varies with precipitation rate, but the observed rate-dependence is lower than in previous studies where calcite is not precipitated in the presence of dissolved CA. These non-equilibrium effects can be explained in terms of isotopologue-specific reaction rate coefficients. We present a framework of ion-by-ion growth of calcite that reconciles our new measurements with measurements of natural cave calcites that are the best candidate for having precipitated under near- equilibrium conditions. Our findings suggest that isotopic equilibrium between calcite and water is unlikely to have been established in laboratory experiments or in many natural settings. The use of CA in carbonate precipitation experiments offers new opportunities to refine oxygen isotope-based geothermometers and to interrogate environmental variables other than temperature that influence calcite growth rates.

First melt inclusion study of the Sudbury Igneous Complex (Ontario, Canada): Evidence for two-liquid immiscibility and constraints on trace element distribution

KATHLEEN WATTS[1]*, JACOB J. HANLEY[1], DANIEL KONTAK[2] AND DOREEN AMES[3]

[1]Saint Mary's University, Halifax, NS, Canada (*correspondence: kathleen.margot@gmail.com)
[2]MERC, Laurentian University, Sudbury, ON, Canada
[3]Geological Survey of Canada, Ottawa, ON, Canada

The 1.85 Ga Sudbury Igneous Complex (SIC), Ontario, Canada, is an intrusive complex representing a crystallized melt sheet formed during a bolide impact. The SIC has been extensively studied due to its rich endowment in magmatic sulfide ores (Ni-Cu-PGEs). In this study, primary melt inclusions hosted in cumulus apatite within three mafic units of the SIC (gabbro, norite and sublayer quartz diorite) are used to decipher the physical and chemical characteristics of the evolving melt sheet as it crystallized.

The compositions of coeval melt inclusions show 2 distict types: (1) SiO_2-rich, ranging from tonalitic to granodioritic in composition (60-70 wt% SiO_2, up to 11 wt% FeO); and (2) Fe-rich with syenogabbroic to essexitic to alkali gabbroic compositions (27-49 wt% SiO2, 16-44 wt% FeO). The liquids are interpreted to represent the products of immiscibility (*c.f.* Skaergaard Intrusion [1]).

$D^{\text{Fe-rich melt/Si-rich melt}}$ values range between ~0.7 and ~2 with the exception of V and Co that partition more strongly into the Fe-rich melt ($D > 4$). Microthermometry shows that complete melting of the inclusion contents occurs at ~1100°C, with homogenization (i.e., minimum trapping T; by bubble contraction) between ~1230 and 1300°C, confiming that apatite is an early liquidus phase in melt and trapped melt over a range of temperatures. Preliminary melt inclusion analyses suggest that the earliest melt phase of the SIC, as represented by sublayer quartz diorite, was enriched in Ni and Cu, up to an order of magnitude higher than those liquids trapped in the units stratigraphically higher in the SIC, and may reflect loss of these metals to early sulfide liquids.

The results of this study may lead to the development of parameters that enhance exploration success in mafic-ultramafic systems where post-magmatic processes have severely limited the application of bulk rock chemistry in understanding their petrogenesis.

Effect of magma oxidation state on iron isotope composition of magmatic-hydrothermal minerals

CHRISTINE WAWRYK* AND JOHN D. FODEN

Centre for Tectonics, Research and Exploration, University of Adelaide, South Australia, 5005
(*correspondence: christine.wawryk@adelaide.edu.au)

Do ore minerals precipitated from magmatic-hydrothermal solutions reflect the isotopic composition of the parent magma? We present new stable iron isotope compositions of sulfides from two deposits associated with fractionated, reduced magmas. The Renison tin deposit is associated with magmatic fluids exsolved from an S-type magma [1]. The Hillside deposit is an IOCG skarn associated with an A-type granite of the Hiltaba Suite [2]. Figure 1 compares isotopic composition of host intrusions, pyrite and chalcopyrite from Renison with published data from Grasberg [3] and Xinqiao [4].

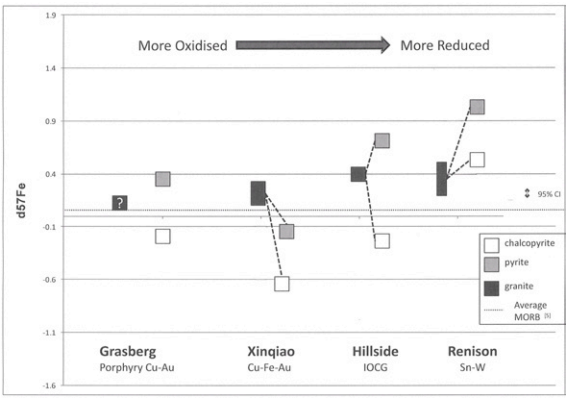

Figure 1. Comparison of δ57Fe composition of host intrusions, pyrite and chalcopyrite.

Our results demonstrate that sulfides associated with the reduced Hillside and Renison Granites have, on average, heavier iron isotopic compositions than ore minerals associated with the oxidised GIC, and the Jitou Stock hosting Xinqiao. Our modelling of magma/fluid evolution considers variables such as fO2, pressure and temperature.

Amino acid binding on oxide surfaces: Results from CTR and surface x-ray anomalous scattering

GLENN WAYCHUNAS[1], JOANNE STUBBS[2] AND PETER ENG[2]

[1]Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, CA, USA
[2]University of Chicago, Consortium for Advanced Radiation Sources, Argonne, IL, USA

The interaction and binding of organic species and amino acids with mineral surfaces is a large frontier in geochemistry. As opposed to inorganic sorbates, which interact with a surface by forming covalent and hydrogen bonds, organic structures may have partial or dominant hydrophobic interactions and reduced interaction with waters, multiple charges on a single molecule such as a zwitterion, and very complex multi-site interactions with surface functional groups. These considerations have limited the utility of many studies in the past, with the vast majority involving measurement of uptake concentrations without information on the actual binding geometry or mechanisms. We are developing a program to couple sum-frequency vibrational spectroscopy (SFVS), surface x-ray scattering methods, and computer simulations to characterize organic species topologic interactions with well-known mineral surfaces. Initial investigations examined ethanol as a single monolayer, and as a bulk liquid, on the corundum R-plane (1-102) surface using SFVS. Subsequent studies examining selenomethionine and other heavy atom-substituted amino acids are in progress. This approach enables x-ray surface scattering and anomalous scattering measurements to be correlated with SFVS vibrational information. The complexities and advantages of this approach will be described, as well as most recent results.

Probing quartz for P-T-D paths

LAURA E. WEBB[1], PATRICK G. DYESS[1], KYLE T. ASHLEY[2], FRANK S. SPEAR[3] AND JAY B. THOMAS[3]

[1]University of Vermont, Department of Geology, Burlington, VT, USA, lewebb@uvm.edu, patrick.dyess@gmail.com

[2] Department of Geosciences, Virginia Tech, Blacksburg, VA, USA, ktashley@vt.edu

[3] Earth and Environmental Sciences, Renssaelaer Polytechnic Institute, Troy, NY, USA, spearf@rpi.edu, thomaj2@rpi.edu

TitaniQ (Ti-in-quartz) thermobarometery of chlorite–staurolite grade metapelites reveals that quartz grains in different fabric domains may record distinct stages of the P-T-D path and, in some cases, preserve detrital [Ti] signatures. Our findings are based on integrated microstructural and petrologic analyses, cathodoluminscence (CL) imaging, and secondary ion mass spectrometry (SIMS) of samples with known tectonic histories collected along an E–W transect across central Vermont, spanning rocks of the Rowe–Hawley Belt (RHB) and the Connecticut Valley–Gaspe Trough (CVG). Rocks of the RHB record crenulation cleavage development during both the Taconic and Acadian orogenies; CVG rocks record similar processes during the Acadian orogeny only. CL and SIMS analyses were conducted on quartz in different microstructural contexts such as in fold hinges, quartz-feldspar cleavage domains, inclusion suites defining internal foliations in garnet, and pressure shadows. Both suites of metapelites lack evidence for significant dynamic recrystallization of quartz; quartz grains predominately display polygonal textures. The dominant CL zoning pattern of quartz is darker rounded–anhedral cores and brighter polygonal rims, indicating an increase in [Ti] from core to rim. In some cases grains record bright cores with dark rims (RHB), or dark cores, bright mantles, and dark rims (CVG). RHB chlorite–garnet grade metapelites yield [Ti] from 0.4–157 ppm; a small fraction of analyses yield [Ti] greater than that predicted for peak metamorphic conditions. Analyses of garnet–staurolite grade CVG metapelites yielded [Ti] of 2.2–9.8 ppm. In both suites, dark cores with low [Ti] are interpreted as quartz growth during burial metamorphism and cleavage development via strain-induced solution transfer. Brighter mantles and rims with increasing [Ti] relative to cores result from quartz-producing metamorphic reactions and continued solution transfer to low strain and quartz-feldspar domains. [Ti]>50 ppm in RHB rocks are interpreted to be inherited detrital signatures and thus likely provide information on sedimentary provenance of the protoliths. These studies highlight the importance that both structural and metamorphic processes play in the cycling of quartz in metapelites and its ability to record P-T-D paths.

Micro-scale complexity in iron-sulfide phases in Precambrian sedimentary rocks determined by coupled spectroscopic, isotopic, and magnetic techniques

SAMUEL M. WEBB[1]*, JENA E. JOHNSON[2], SARAH P. SLOTZNICK[2], JOSEPH L. KIRSCHVINK[2] AND WOODWARD W. FISCHER[2]

[1]Stanford Synchrotron Radiation Lightsource, Menlo Park, CA 94025, USA (*correspondence: samwebb@slac.stanford.edu)

[2]California Insitute of Technology, Pasadena, CA 91125, USA

The record of sedimentary pyrite forms the foundation for most isotope records working to define the coupled evolution and behavior of the ancient iron and sulfur cycles. In order to assess the strengths and limitations of records derived from pyrite-rich rocks (e.g. iron speciation, sulfur isotope ratios), we need to understand more about the processes that form and alter sedimentary pyrite.

From samples of the Archean/early Proterozoic Transvaal and middle Proterozoic Belt Supergroups, petrography reveals that what might operationally be called sedimentary pyrite has complex textures that hint at a rich process history of sulfur mineralization. A common limitation of virtually all proxy measurements employed to date is that they operate on 'bulk' samples, typically gram-sized or larger pieces. As such, they lose the ability to relate geochemistry to petrography at the scale of mineral grains. Many of the sedimentary pyrites in the Transvaal Supergroup exhibit complex redox and electronic structures of S and Fe, with crystals of pyrite, pyrrhotite, and sulfate-bearing minerals throughout.

Parallel application of multiple techniques on the same samples across micron bases spatial scales, provide an opportunity to diagnose issues resulting from post-depositional alteration of sedimentary rocks. We have integrated light and electron microscopy for petrography, electron microprobe and synchrotron XRF for elemental composition, synchrotron X-ray spectroscopy for redox and chemical state, SQUID microscopy for remnant magnetism, and secondary ion mass spectrometry (SIMS) for isotopic composition. The coupling of these tools allows in essence "images" of the proxy data at the micrometer scale, giving a wide array of textural and mineralogical information designed to inform and untangle the complicated histories of these early Precambrian rocks.

Large ^{34}S depletions of reduced sedimentary sulfides at low sulfate concentrations in an iron-rich lake dominated by anaerobic methane oxidation

WEBER H.S.*, THAMDRUP B. AND HABICHT K.S.

Nordic Center for Earth Evolution and Institute of Biology, University of Southern Denmark, Campusvej 55, 5230, Odense M, Denmark (*correspondence: hannah@biology.sdu.dk)

The sediment of Lake Ørn (Denmark) is characterized by a high reactive iron content and a strong methane consumption in the deep sulfate-containing zone reaching ~15 cm depth. Radiotracer studies (^{14}C-methane and ^{35}S-sulfate) confirmed anaerobic oxidation of methane (AOM) and microbial sulfate reduction (SR) and demonstrated the highest AOM rates (up to 40 nmol cm^{-3} day^{-1}) at 10-15 cm depth with very low sulfate concentrations (5-10 μmol L^{-1}). We further used stable sulfur isotope analysis and incubation experiments to investigate the interactions of iron, sulfur and methane with particular focus on a hypothetical cryptic sulfur cycle. Isotope analyses revealed substantial ^{34}S depletion in reduced sulfur species with $\delta^{34}S$ values of down to -15‰ for acid volatile sulfides (H_2S and FeS) and -25‰ for chromium reducible sulfides (S^0 and FeS_2) accumulating in the AOM zone. Anoxic slurry incubations demonstrated $\delta^{34}S$ values of up to 40‰ in sulfate in the incubations with methane and S^0 respectively, indicating that large sulfur isotope fractionations can be established by a combination of sulfate reduction, sulfide oxidation, AOM and microbial sulfur disproportionation. RNA stable isotope probing was applied to identify key players of the cryptic sulfur cycle.

The cycling and transport of glacially derived iron in Arctic fjord sediments

L.M. WEHRMANN[1]*, M.J. FORMOLO[2], J.D. OWENS[1], T. G. FERDELMAN[3], R. RAISWELL[4] AND T.W. LYONS[1]

[4]University of Leeds, Leeds, UK, r.w.raiswell@leeds.ac.uk

Iron is an essential nutrient for primary production and is strongly connected to glacial-interglacial variations in atmospheric CO_2 concentrations. Glacial runoff rapidly delivers large volumes of potentially bioavailable Fe, produced by mechanical and microbially enhanced chemical weathering in glacial environments, to high latitude oceans. Little is known about the fate of this Fe pool in adjacent coastal marine waters, particularly fjord systems. We investigated the concentration and speciation of Fe in the sediments of three Western Svalbard fjords with the aim of quantifying and understanding the biogeochemical processes of the sedimentary Fe cycle. Results of porewater and solid-phase analyses show that the input of glacially derived Fe plays an important role in the biogeochemical processes in fjord sediments by controlling sulfur and manganese cycling and by providing a large Fe-oxide pool for dissimilatory iron reducers (DIR). Extreme sedimentation rates in the fjords result in elevated Fe accumulation but dilution of the organic carbon pool. From this combination, the sediments show a strong signature of DIR, leading to high dissolved Fe concentrations of up to 800 μM in the porewaters of Kongsfjorden and Van Keulenfjorden and correspondingly enhanced benthic Fe flux from the sediment to the water column. Our data point to extensive benthic Fe cycling in Svalbard fjord sediments likely promoted by bioturbation and physical disturbance via iceberg calving. Thus, recycling of iron in fjord sediments may facilitate the transport of this important micronutrient across the fjords while maintaining its bioavailability for fertilization of primary productivity on the adjacent continental shelf. This work complements recent studies on the bioavailability and concentration of Fe in glacial runoff and contributes to the emerging picture that glacially derived Fe may constitute an important component of the global Fe cycle, particularly in high-latitude ocean regions.

Using radium isotopes to determine the residence time of circulated seawater in coastal sediments

WEINSTEIN Y.[1], SHALEM Y.[1], BRINBERG B.[1] AND NOIMEIR Y.[1]

[1] Bar-Ilan University, Ramat-Gan 52900, Israel (*correspondence: weinsty@biu.ac.il)

The circulation of seawater in seafloor sediments and the resultant fluxes of water to the water column are highly important to oceanic mass balances of certain elements and to coastal water quality. The residence time of this water in the sediments is critical to the kinetics, therefore the effectiveness of water-rock interaction, which further affects the delivery of chemicals from the sub-seafloor to the ocean.

We used radium isotopes to decipher about the residence time of circulated seawater in coastal sediments. Seawater is radium-poor, with the activity of ^{226}Ra (half time of 1605 yrs) on the order 0.1 dpm/L, and those of the short-lived isotopes, ^{224}Ra and ^{223}Ra (half lives of days), being close to zero. On the other hand, activities in pore water of both short and the long-lived isotopes may be 2-3 orders of magnitude higher. Another important consideration is that while the pore water activities of the long-lived ^{226}Ra are pretty much controlled by desorption, those of the short lived isotopes are mainly controlled by recoil during the disintegration of their thorium radioactive parents. Gonnea *et al.* (2008) have shown that pore water attains secular equilibrium for ^{226}Ra within a few hours, may be less. On the other hand, since ^{224}Ra in pore water is enriched by recoil due to the disintegration of sediments' ^{228}Th, the activity of this nuclide may be built-up during a period of up to several weeks, which could be more relevant to the proces of seawater circulation (hours to years).

We pumped pore water using mini piezometers from depths of 0.5-2 m in the granular sediments (quartz sands) of Dor Bay (eastern Mediterranean, northern Israel). Water salinities were between 30-39 (eastern Mediterranean water salinity is ~40, psu scale). ^{226}Ra activities were mostly 2-2.5 dpm/l, though in a few shallow cases (0.5 m), activites dropped to <1 dpm/l. Experiments showed similar ^{226}Ra ctivities of 2-3 dpm/l, which suggests that the residence times of pore water are longer than a few hours. Activities of ^{224}Ra varied between 1.5-6.5 dpm/l, with the deeper water (1.5-2 m) significantly more enriched than the shallow ones (0.5-1 m). In chromatography experiments with the same sediments and coastal seawater, ^{224}Ra increased from <0.5 to 4 dpm/l at residence times of 1 and 24 hrs, respectively. Assuming uniform sediment characteristics. this suggests that the average age of pore water at 1-2 m depth is about 0.5-2 days.

Low-T hydrothermal fluid evolution

C. G. WEINZIERL[1]*, W. BACH[2], F. BÖHM[3] M. REGELOUS AND K.M. HAASE[1]

[1]GeoZentrum Nordbayern, Univ. Erlangen-Nuernberg, Schlossgarten 5, 91054 Erlangen, Germany (*correspondence: christoph.weinzierl@fau.de)

[2]Geoscience Department, Bremen Univ., Klagenfurter Str., 28359 Bremen, Germany

[3]GEOMAR Helmholtz Centre for Ocean Research Kiel, Wischhofstr. 1-3, 24148 Kiel, Germany

The chemical and isotopic composition of calcium carbonate veins precipitated within the oceanic crust can be used to infer the composition of their parent fluid [1], and trends of fluid compositions with temperature [2] can be extrapolated to estimate ancient ocean water compositions [3, 4]. Previous studies focused on carbonates from drillcores in ancient oceanic crust, but ophiolites could be used to extend the record of ocean water chemistry further back in time. We evaluated the potential of ophiolites as paleoseawater archives by analysing carbonates from the Cretaceous Troodos Ophiolite of Cyprus.

Variations of fluid Sr/Ca, Mg/Ca, ^{87}Sr/^{86}Sr and ^{44}Ca/^{40}Ca with temperature (δ^{18}O) in the volcanic section of the Troodos Ophiolite display similar trends to data for fluids [2] and carbonates [3, 4] from drilled oceanic crust, indicating that similar processes acted upon the fluids. In accordance with experimental results [5] we found that the formation of saponite and palagonite, and the subsequent precipitation of anhydrite, are responsible for modifying the composition of seawater as it percolates downwards through the oceanic crust. Our data and thermodynamic calculations indicate that anhydrite may form at much lower temperatures (ϑ < 70°C) than previously thought [6], if seawater interacts with basalt.

Our results allow not only to identify fluid evolution pathways affected by mixing of seawater with a more evolved fluid (e.g. Juan de Fuca), but also to show that ophiolites can be used to determine past seawater compositions, and to study the chemical evolution of fluids in greater detail than is possible using samples drilled from oceanic crust, where recovery of interstitial carbonates is less complete.

"Tuning the Torch" of the Nu Plasma II-ES MC-ICP-MS

D. WEIS[1]*, K. GORDON[1], L. XING[1], A. BURROWS[2], R. COHEN[2] AND P. FREEDMAN[2]

[1]Pacific Centre for Isotopic and Geochemical Research, Department of Earth, Ocean and Atmospheric Sciences, University of British Columbia, 2207 Main Mall, Vancouver BC, V6T 1Z4, Canada. *dweis@eos.ubc.ca
[2]Nu Instruments Ltd, 74 Clywedog Road South, Wrexham Industrial Estate, Wrexham LL13 9XS, United Kingdom

Since the development in the early 1990s of the first multi-collector inductively coupled plasma mass spectrometer, there has been an unprecedented broadening of isotopic analysis applications in geochemistry, mostly because the ICP source effectively ionizes virtually all elements in the periodic table. The Nu Plasma II-ES is Nu Instruments Ltd.'s latest generation plasma source multi-collector mass spectrometer. The NP II at UBC is equipped with a newly designed ES interface system that increases the overall sensitivity of the instrument. Additionally, the instrument is equipped with an enhanced detector system that includes large dynamic range 55 volt Faraday amplifiers coupled to 16 Faraday detectors plus 5 full-size discrete dynode ion counters. Sensitivity tests across the mass range, from Li to U, reveal a significant increase compared to the previous generation interface. We tested the instrument for stability of mass bias and accuracy of isotopic ratios while measuring oxide production, interface pressure, and other key parameters.

This work demonstrates that the enhanced sensitivity can be achieved with no compromise in either mass bias stability or isotope ratio accuracy. Small sample concentrations of Nd, Hf and Pb are now analyzed to precisions previously attainable only with great analytical effort or by pooling samples. Larger samples show much improved external reproducibility that previously required longer analysis times. The improved ion interface and detector systems on the NP II-ES increase the overall productivity and analytical capability of multi-collector ICP-MS, which is especially advantageous in a multi-disciplinary laboratory.

These improvements open up new avenues in geochemical research with analyses of samples down to sub-ppm levels or with transient signals. They will allow further understanding of the timing and processes, and fingerprinting of sources, in Earth, planetary, biological and medical science.

Matrix-independent calibration of LA-ICP-MS using femtosecond-UV-lasers?

U. WEIS[1]*, K.P. JOCHUM[1], B. STOLL[1], D. JACOB[2], R. MERTZ-KRAUS[2] AND M.O. ANDREAE[1]

[1]Max Planck Institute for Chemistry, Mainz, Germany (*correspondence: ulrike.weis@mpic.de)
[2]University of Mainz, Germany

The major limitations regarding accuracy and precision of LA-ICP-MS trace element analysis are elemental fractionation [1] and mass-load-dependent matrix effects [2]. Reducing the pulse width of the laser from the ns to the fs range leads to an improvement of the analytical results, in particular for in-situ isotope ratio measurements [3], where matrix related mass fractionation is considerably reduced. To test matrix-related effects in trace element analysis, we determined the fractionation factors (FF) and element/Ca ratios in reference materials with different matrices (silicate, basalt, phosphate, carbonate) by a Ti-sapphire based fs-UV-LA-ICP-MS. Measurements were performed with different spot sizes (10 – 55 μm), pulse repetition rates (PRR) (10 – 250 Hz) using spot and line scan mode. For comparison, similar experiments were made using 213 nm and 193 nm Nd:YAG lasers and a 193 nm ArF excimer laser.

Our measurements demonstrate that in each case the fs data are more reproducible and less matrix-dependent with respect to FF and mass-load induced matrix effects than the results obtained using the other lasers. The FF are independent of the measuring conditions and of the matrix within about 0.3 - 1 % and 0.5 - 3 % for line scan and spot analysis, respectively. The line scan mode yields unity FF, whereas in the spot analysis mode small, but significantly lower values for the volatile elements Zn (0.88) and Pb (0.93) were observed. The ratios of the lithophile elements Sr, Ba, Rb to Ca are identical for all spot sizes, PRR and materials within about 5%, for both line scan and spot analyses. An extreme dependency of the element ratio with spot size (up to 50%) was found for Pb/Ca and Zn/Ca using spot analysis; however, it is similar for all matrices. This is in contrast to measurements done with the 213 nm Nd:YAG laser, where high spot sizes may lead to different element/Ca ratios compared to low spot sizes. Consequently, the use of fs-UV lasers improves not only high-precision isotope ratio measurements but also trace element analysis. Calibration can be performed reliably for quite different matrices with certified reference materials, e.g. those from NIST [4].

Bacterial mineral-metaloid redox transformations in anearobic environments

CHRISTOPHER WEISENER[1]*, RACHEL FRANZBLAU[1] AND NADINE LOICK[1,2]

[11]Great Lakes Environmental Institute for Research, University of Windsor, Windsor, Canada, franzbl@uwindsor.ca*
[2]Rothamsted Research Institute, NorthWyke, UK

Jarosite minerals are of environmental importance as trace metal scavengers and are involved in metal cycling. A number of metal species can be incorporated into the jarosite structure, including selenium (Se). Se is a trace nutrient, but is toxic in relatively low doses to humans, microbes, and other fauna[1]. Se is present in aqueous systems in its two oxyanion forms; selenate and selenite (SeO_4^{2-} & SeO_3^{2-}). The sulfate group can be completely substituted for selenate in jarosite minerals ($NaFe_3(SO_4)_X(SeO_4)_{2-X}(OH)_6$). Under certain environmental conditions (e.g. pH, ionic strength, anaerobic environment), bacteria use these metals as potetnial electron acceptors mobilization and reduction from iron hydroxy sulfate minerals. Several species of bacteria have been observed to reduce Se oxyanions to nanoparticulate elemental Se, which is insoluable under most conditions. This pathway potentially poses a vector for mobilization and transport at Se-contaminated sites. The mechanisms pertaining to this research along with toxicity thresholds to model organisms will be discussed.

Diamond-forming fluids: The trace-element perspective

Y. WEISS[1,3]*, W. L. GRIFFIN[2] AND O. NAVON[1]

[1]The Institute of Earth Sciences, The Hebrew University of Jerusalem, Edmund J. Safra Campus, Israel
[2]CCFS and GEMOC, Dept. of Earth andPlanetary Sciences, Macquarie University, NSW, Australia
[3]Lamont-Doherty Earth Observatory, Columbia University, 61 Rt. 9W, Palisades, NY 10964-1000, USA
(*correspondence: yweiss@ldeo.columbia.edu)

Diamond-forming high-density fluids (HDFs) of different major-element composition share similar incompatible-element characteristics, regardless of their host diamond provenance. All have fractionated REE patterns and variable, mostly negative, anomalies (PM normalized) in K, Rb, Cs, Ti, Zr, Hf, Nb, Ta, Sr and Y relative to Ba, Th, U and REEs of similar compatibility. Two principal patterns, "Planed" and "Ribbed", are characterized by differences in the highly incompatible elements from Ce–Pr. The two patterns are best distinguished using co-variation diagrams of (La, Ce)/(Nb, Rb) vs (U, Th)/(Nb, Rb).

Similarities of canonical ratios, Nb/(Th, U, La) and K/U, between MORB and OIB samples and HDFs with "Planed" patterns suggest that an asthenospheric source for these HDFs is plausible. This idea is strengthened by calculating the composition of sources in equilibrium with "Planed"patterns of silicic HDFs which range between the DMM and more fertile parts of the convecting mantle. The direct production of HDFs with "Planed" patterns by melting the asthenosphere with no need for a pre-metasomatized source, avoids the circular "chicken and egg" reasoning that has plagued diamond and kimberlite genesis. Such asthenosphere-derived enriched fluids can metasomatize the lithosphere to produce the old and new enriched sources that are needed to explain the formation of kimberlites and metasomatized xenoliths.

We suggest that the "Ribbed" incompatible-element pattern in HDFs evolved during percolation of HDFs with "Planed" patterns through a previously metasomatised lithosphere that carries accessory phlogopite, ilmenite and rutile. HDFs that are trapped in growing diamonds very soon after entry retain their "Planed" trace-element characteristics. If they percolate and interact with the accessory minerals, they acquire the "Ribbed" pattern before they are sealed in microinclusions in diamonds. This model explains the decoupling between major- and trace elements in HDFs and the resemblance of incompatible-element patterns of HDFs from different mantle localities; the averaging of large volumes of mantle rocks smooths the effect of small-scale heterogeneities in the subcontinental lithosphere.

Methylated hopanoid biosynthesis and function in modern bacteria

PAULA V. WELANDER*[1], JESSICA N. RICCI[2], DIANNE K. NEWMAN[2] AND ROGER E. SUMMONS[3]

[1]Dept. EESS, Stanford University, Stanford, CA 94305 (*correspondence: welander@stanford.edu)
[2]Divs. Biology and GPS California Inst. Technology, Pasadena, CA 91125 USA
[3]Dept. EAPS, MIT, Cambridge, MA 02139 USA

The majority of life's history has been dominated by microbes whose metabolic inventions have significantly altered the Earth's surface environment and, in turn, impacted the evolution of life on Earth. Because unicellular microorganisms do not readily leave diagnostic morphological fossils, alternative strategies are necessary for studying microbial communities in the context of the Earth's distant past. One predominant strategy is to correlate organic compounds deposited by ancient microbes and preserved in sedimentary rock with lipid molecules produced by extant microorganisms. One such class of biomarkers are the hopanes, pentacyclic triterpenoid lipids that are clearly the diagenetic products of modern day hopanoids. Hopanoids are produced by a diverse set of bacteria and as a result most sedimentary hopanes do not provide any taxonomic specificity below the domain level. However, hopanoids methylated at the C-2 or C-3 position are produced by a limited number of bacterial taxa and thus have the potential to function as robust biomarkers. Traditionally, 2-methyl and 3-methylhopanoids have been utilized as proxies for cyanobacteria and aerobic methanotrophs, respectively. However, our discovery of the two proteins necessary to methylate at the C-2 (HpnP) and C-3 (HpnR) position revealed that the diversity of bacteria capable of producing methylhopanoids was underestimated. Subsequent ecological studies of the C-2 methylase have shown that alphaproteobacterial copies of the *hpnP* gene are found in diverse modern environments while cyanobacterial *hpnP* genes are rarer. Further, physiological studies of a C-3 methylase deletion mutant have demonstrated a potential role for 3-methylhopanoids in survival under nutrient limited conditions. Taken together, these studies illustrate that a proper interpretation of methylhopanes in the rock record requires us to look beyond simple taxonomic classification of methylhopanoid producers. In addition to understanding which organisms produce methylated hopanoids, a deeper knowledge of the physiological function and environmental factors that induce their expression in modern cells is needed.

Changes of the GWP due to shifts from flooded to upland rice cultivation

S. WELLER [1]*, K. BUTTERBACH-BAHL [1] AND R. KIESE[1]

[1]Karlsruher Intitute of Technology, IKM-IFU, 82467 Garmisch-Partenkirchen, Germany (*correspondence: sebastian.weller@kit.edu, ralf.kiese@kit.edu, klaus.butterbach-bahl@kit.edu)

Changes in climate and water distribution resulting in physical or economic water scarcity may have severe effects on rice production systems. Shifting to rotations with non-flooded crops entails pronounced implications in terms of C and N element cycling and associated greenhouse gas (GHG) emissions (CH_4, N_2O, CO_2). Higher soil aeration in upland systems might decrease CH_4 emissions, but increase N_2O emissions ("pollution swapping") and cause losses in soil organic carbon that translate into CO_2 emissions [1, 2].

An automated GHG measuring system was set up at the IRRI farm, Philippines to investigate changes in the total GHGs balance when shifting from flooded to upland rice cultivation in the dry season under consideration of different fertilizer regimes (zero, conventional, improved). The system consists of two analytical sampling units (valve steering and GCs) connected to a total of 18 chambers (2 treatments, 3 fertilizer regimes; 3 replicates).

The highest global-warming potential (GWP) (kg CO_2eq ha^{-1} $season^{-1}$) was found for flooded rice without N fertilization. Higher N application in irrigated plots resulted in lower CH_4 emissions. This finding supports theories that ammonium based fertilizers can decrease CH_4 emissions [3, 4]. Total GWPs (CH_4, N_2O) were about 70-80% lower in the upland systems due to lower CH_4 emissions but were offset by lower yields.

Upland rice cultivation using high yield varieties could help to mitigate GHG emissions and reduce water-use in rice production systems while further research of N fertilization-impacts on CH_4 emissions seems necessary.

Integrated analysis of hydrogeologic and biogeochemical processes controlling Technetium mobility at the Hanford site, Washington State, USA

DAWN M. WELLMAN, M. HOPE LEE AND DANIELLE P. JANSIK[1]

[1]902 Battelle Blvd, P.O. Box 999, MS K3-62, Richland, WA, USA 99354; dawn.wellman@pnnl.gov; hope.lee@pnnl.gov, danielle.jansik@pnnl.gov

Historic nuclear power and weapons operations resulted in an enduring legacy of approximately six billion cubic meters of radionuclide-contaminated soil and groundwater. Technetium (^{99}Tc) is one of the primary risk-driving contaminants and of the most problematic in the environment. At the Hanford Site, over 500 Ci of ^{99}Tc was released to the vadose zone as part of past site operations. However, the complex hydrogeology of the subsurface and associated biogeochemical cycles result in a variety of technical, scientific and financial challenges for ^{99}Tc remediation efforts.

The mobility of ^{99}Tc in the geologic medium is mainly a result of redox chemistry. Long believed to exist as the pertechnatate anion (TcO_4^-) and predicted to be highly mobile in the predominantly oxidizing groundwaters, with eventual discharge to the Columbia River, ^{99}Tc is one of the site's major risk-drivers for remediation.However, recent results have demonstrated the fractionation and persistance of ^{99}Tc through the existance of three different species. There are two primary means by which ^{99}Tc can be immobilized in subsurface environments: (1) indirect (abiotic) and (2) direct (biotic). Although much has been learned about the physiology and metabolic potential of single microbial species (pure cultures) that immobilize ^{99}Tc, major gaps exist in our understanding of the functioning of these and other microorganisms in natural and contaminated ecosystems. To this end , we will present results of an on-going multidsicplinary investigation that provides an integrated, comprehensive understanding of the hydrogeologic, and biogeochemical processes controlling ^{99}Tc behavior and fate in complex subsurface system. This information is further being used to develop tools that integrate the chemical and biological reaction network influencing the mobility of ^{99}Tc in the subsurface.

Gas geochemistry and soil CO_2 flux in active volcanic areas, China

HSIN-YI WEN[1], TSANYAO FRANK YANG[1], ZHENGFU GUO[2], CHING-CHOU FU[1], AI-TI CHEN[1] AND MAOLIANG ZHANG[2]

[1] Department of Geosciences, National Taiwan University (*correspondence: d99224009@ntu.edu.tw)

[2] Institute of Geology and Geophysics, Chinese Academy of Sciences

Changbaishan intra-plate volcano and Tengchong hydrothermal area are two of the active volcanic areas in China. In order to better understand current status of magma/hydrothermal activities of the Changbaishan intra-plate volcano and Tengchong hydrothermal area, we have conducted the soil gas survey and bubbling gas sampling from hot springs around the Tianchi crater lake and Rehai geothermal area.

In Changbaishan volcano, the results show that CO_2 is the major component gas for most samples. The maximum value of helium isotopic ratio of 5.8 R_A (where $R_A = {}^3He/{}^4He$ in air) implies more than 60% of helium is contributed by mantle component, while carbon isotope values fall in the range of -5.8 to -2.0‰ (vs. PDB), indicating magmatic source signatures as well. Nitrogen dominated samples, 18Dawgo, have helium isotopic ratio of 0.7 R_A and carbon isotope value of -11.4‰, implying the gas source might be associated with regional crustal components beneath 18Dawgo. The first-time systematic soil CO_2 flux measurements indicate the flux is ca. 22.8 g m^{-2} day^{-1} and 6.8 g m^{-2} day^{-1} at the western and southern flank of Changbaishan, which is at the same level as the background value in the Tatun Volcano Group (24.6 g m^{-2} day^{-1}), implying that Changbaishan may not be as active as TVG.

In Tengchong hydrothermal area, the preliminary results show that CO_2 is the major component gas for most samples. The helium and carbon isotopic ratio fall in the range of 0.5 R_A to 3.5 R_A and -4.7 to -1.6 ‰ (vs. PDB), respectively. We also analyzed the hot springs water. The δD and $\delta^{18}O$ values fall in the range from -59.8 to 84.6 ‰ and -6.20 to -12.38 ‰ (vs. SMOW), respectively. Rehai has the highest helium isotopic ratio of 3.5 R_A, which implies ca. 40% of helium is mantle-derived. The δD and $\delta^{18}O$ results implied the water in this area was affect by primary magmatic water. Nevertheless, samples from Banglazhang and Shihchiang hydrothermal areas show much lower helium isotopic ratio of 0.8 R_A and 0.5 R_A, respectively. It suggests that the local tectonic setting plays an important role for the gas degassing in this area.

Geochemical characterization of tire-wear particles

M. WENZEL[1]*, V. DIETZE[2], P. STILLE[3] AND R. GIERÉ[1]

[1]Institut für Geo- und Umweltnaturwissenschaften, Albert-Ludwigs-Universität, 79104 Freiburg, Germany, (*correspondence: melanie.wenzel@minpet.uni-freiburg.de)

[2]Deutscher Wetterdienst, Zentrum für Medizin-Meteorologische Forschung, Referat Lufthygiene, 79104 Freiburg, Germany, (Volker.Dietze@dwd.de)

[3]Laboratoire d'Hydrologie et de Géochimie de Strasbourg, Université de Strasbourg, UMR 7517 CNRS, 67084 Strasbourg, France, (pstille@unistra.fr)

Tire-wear particles are a basic component of common road dust present in urban environments, and their annual emissions to the environment in Germany are reported to be 60 x 10^6 kg [1]. The knowledge of their basic characteristics can be useful to trace tire material in environmental dust samples and for the evaluation of possible health effects related to the inhalation of tire-wear particles. For this study, we analyzed particles generated in a closed indoor tire test rig at the Bundesanstalt für Straßentechnik (BAST) from three car tires as well as particles generated by cryogenic milling of shredded waste tires.

Particles ranging in size from 0.2 μm to 25 μm were characterized with a scanning electron microscope (SEM). All samples contained particles with diameters <0.6 μm. According to their morphological and chemical features the particles were divided into characteristic groups. The bulk chemical composition of each sample was distinct, with the total carbon content varying between 28.73 and 83.75 wt%. Inductively coupled plasma mass spectrometry (ICP-MS) data revealed significant variability in the contents of various trace elements (e.g. Pb 3.4 ppm - 437.2 ppm). Characteristic among all samples was a very high Zn content (> 1100 ppm). In addition, the ratios of ^{87}Sr/ ^{86}Sr, which varied from 0.7089 to 0.7094, and of ^{204}Pb/ ^{206}Pb, with values between 0.0560 and 0.0570, were found to be characteristic for the tire-wear particles, but differed from the ratios measured for the shredded tires. Comparison of the Pb isotope ratios with literature data [2, 3] from road-related dust samples (e.g. pavement particles or brake-wear) and traffic-related lead sources (e.g. batteries or gasoline) showed that Pb isotope ratios could be used as a tracer for the tire-wear contribution to road dust.

Mojave Crater, Mars: One meteorite source crater

S.C. WERNER[1], A. ODY[2] AND F. POULET[2]

[1]Centre for Earth Evolution and Dunamics, University Of Oslo, Norway (stephanie.werner@fys.uio.no)

[2] Institut d'Astrophysique Spatiale, Université Paris-Sud, 91405 Orsay cedex, France.

The Mojave Crater on Mars has a diameter of about 55 km; it is situated at 7.5˚N and 33.0˚W at the joint of Simud and Tiu Valles in Xanthe Terra. It attracted attention for its well preserved landforms resembling the morphology of alluvial fans in arid environments, and suggesting a very young formation age. However, because of its large size, speculations on the age range from late Hesperian to late Amazonian age.

From crater count statistics technique, we here demonstrate that Mojave formed only 2-4 Ma ago. Such a young age makes it a prime candidate for being the ejection source of seveal groups of martian meteorites. Additional potential links (site mineralogy and presence of an extended ejecta ray pattern) between this crater and the SNCs will be discussed.

Because Mojave formed on old Noachian terrain, it questions the original crystallization age of shergottites. A 4.1 Gyrs old was inferred by debated Pb-Pb isotope ratios (*Bouvier et al. , 2008, EPSL 266, 105-124; Bouvier et al. , 2013, LPSC No. 1719*), whereas some apparently young crystallization ages (173-596 Ma, *Mars Meteorite Compendium, JSC Pub. No. 27672*, the latter is Tissint, which is the oldest, *Brennecka et al. , 2012, 75th Met Soc abstract No 5157*) are more commonly accepted. We will attempt to reconcile our observations with the debate about the age of shergottites.

Interaction of corroding iron with bentonite at repository conditions

P. WERSIN[1]*, A. JENNI[1] AND U.K. MÄDER[1]

[1]Insitute of Geological Sciences, University of Bern, 3012 Bern, Switzerland (*paul.wersin@geo.unibe.ch)

Iron canisters containing high-level nuclear waste surrounded by swelling bentonite backfill are foreseen to be emplaced in geologic formations. Corrosion will release Fe(II) species which will interact with the bentonite. This may induce cementation and clay mineral transformations. The details of this process are still poorly understood. In an in-situ experiment (ABM-1) at the Äspö Hard Rock Laboratory (Sweden), compacted bentonite materials in contact with steel were exposed to temperatures up to 140°C for 2 years. After overcoring, clay samples in contact with the Fe were sampled and analysed with microscopic techniques and μ-Raman spectroscopy. Both sides of an Fe metal structure, the Fe-water and the Fe-clay interfaces were studied.

The Fe-water side reveals a 100-200 μm thick corrosion layer conposed of magnetite, siderite, hematite, hydrous ferric oxide. The Fe-clay side exhibts a web-shaped ~100 μm thick layer of iron corrosion products (bright) and clay (dark). Siderite and Fe oxyhydroxides could be identified. The clay matrix is somewhat enriched in Fe and partly also in Mg, but no change in A/Si ratio was noted. At a distance of about 1 mm from the metal formation of $CaSO_4$ is observed. The front enriched in Fe exends 1-2 mm into the clay. Overall, the data suggest an intimate association of iron corrosion product and montmorillonite, but no formation of Fe silicates.

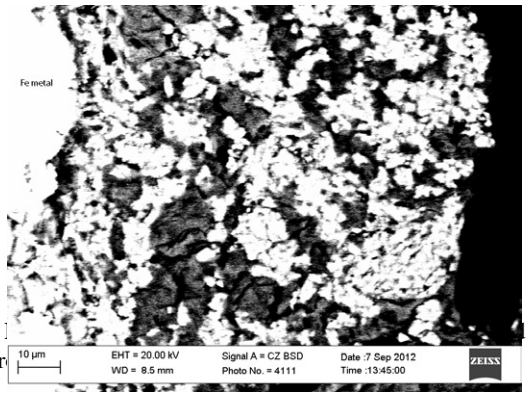

Figure 1: Interface between iron corr

Insights into U-series weathering chronometers from size fraction distribution of U and Th nuclides in Himalayan soils and sediments

A. JOSHUA WEST[1]

[1]University of Southern California, Department of Earth Sciences, 3651 Trousdale Parkway-ZHS 117, Los Angeles, CA 90089 UNITED STATES; (joshwest@usc.edu)

As a result of varying mobility between different nuclides, disequilibria within the U-series decay chain potentially provides valuable constraints on the timescales of Earth surface processes. Models describing the evolution of both ($^{234}U/^{238}U$) and ($^{230}Th/^{238}U$) activity ratios during leaching are increasingly used to determine the duration of weathering and sediment transport. However, important assumptions in these models remain untested. While the basic mechanisms driving observed disequilibria during weathering are well-established (e.g. alpha recoil and preferential leaching), the picture remains somewhat fuzzy in terms of how bulk rocks, soils, and sediments, and the complementary dissolved phase, actually acquire their U and Th signature. Important puzzles, such as the reason for ^{234}U enrichment of some bulk solid phases despite the expected more rapid leaching of this nuclide, have yet to be completely resolved.

This study focuses on measurements of the U and Th nuclide abundance in a suite of samples (rocks, soils, sediments, and stream water) from the Middle Hills of Nepal, where solid products of weathering show distinct depletion in soluble elements (e.g. Ca, Na). Bulk soils and sediments have ($^{234}U/^{238}U$) above equilibrium ($\delta^{234}U$=+15-30‰ relative to equilibrium), increasing with weathering extent in the soil profiles. Variability in $^{234}U/^{238}U$ between size fractions of the Nepal soils demonstrates that the ^{234}U enrichment can be quantitatively explained by retention in the very fine (<0.2μm) fractions, which have measured $\delta^{234}U$>+100‰ and REE patterns characteristic of Fe-oxides. These results suggest that bulk solid phase ($^{234}U/^{238}U$)>1 can result from modern weathering processes because of retention in oxide phases.

Observed ($^{230}Th/^{238}U$) is highly variable and would imply long (tens to hundreds kyr) weathering duration based on simple models of leaching and decay. These durations require residence times that are inconsistent with the depth of weathering profiles and erosion rates inferred from ^{10}Be inventories in quartz from these locations. One possible explanation is that the measured sediment ($^{230}Th/^{238}U$) from these sites may be strongly influenced by grain size sorting.

Mo isotope signature of OAE 2

S. WESTERMANN[1-2]*, D. VANCE[1], V. CAMERON[2], C. ARCHER[1] AND S.A. ROBINSON[3]

[1]Institue of Geochemistry and Petrology, Dept. of Earth Sciences, ETH Zurich, Switzerland
[2]Bristol Isotope Group, School of Earth Sciences, University of Bristol, UK.
[3]Dept. of Earth Sciences, University College London, UK.
(* correspondence: stephane.westermann@bristol.ac.uk)

Understanding variations of redox conditions during oceanic anoxic events (OAEs) is of primary importance, particularly as recent observations and modelling have shown that processes invoked to explain the origin of OAEs are being observed today as a consequence of anthropogenic change.

Here, we compare redox-sentsitive trace metal (RSTM) distributions and molybdenum (Mo) isotope variations during a major Cretaceous OAE (OAE 2, Bonarelli event) within the western Tethys and the Northern Atlantic. Whereas RSTM have the potential to provide insights regading local depositional conditions and processes in paleoceanographic systems, Mo-isotope data can, under certain circumstances, provide quantitative estimates of how the extent of seawater anoxia may have fluctuated in the past.

The RSTM contents indicate more reducing conditions during the OAE 2 interval, reaching from suboxic to euxinic conditions. The RSTM enrichment factors (EFs) also suggest different depostional conditions and paleoceanographic processes between the Tethys and the North Atlantic. Whereas the North Atlanic sites show evidence of weak watermass restriction associated with the action of a particulate shuttle within the water column, the EFs of the Tethyan sections are characteristic of unrestricted marine systems.

Mo isotopes show surprisingly negative values along the Tethyan sections. At the onset of OAE 2, an increasing trend in $\delta^{98/95}$Mo is observed with values ranging from -0.6 to 0.6 ‰. During the 2nd half of OAE 2, the $\delta^{98/95}$Mo curve shows a progressive shift towards more negative values. In the North Atlantic, Mo isotopes are generally heavier during OAE 2, fluctuating around an average value of 1.1 ‰.

Both the western Tethys and the Northern Atlantic sites show redox variations, reaching anoxic/euxinic conditions. However, light $\delta^{98/95}$Mo values in the western Tethys suggest redox conditions may not have been fully euxinic. For the North Atlantic, our results are consistent with fully euxinic conditions and may help to improve our understanding of the global extent of euxinia during OAE 2.

New U-Pb age and □Hf signature data of metassedimentary and metabasic rocks of the front of the Southern Brasilia Orogen, south of São Francisco Craton, Brazil

A. WESTIN[1]* AND M. C. CAMPOS NETO[1]

[1]Geosciences Institute, University of São Paulo, São Paulo, SP, Brazil (*correspondence: alice.teixeira@usp.br; camposnt@usp.br)

The Brasília Orogen, located on the western and southern margin of the São Francisco Craton, corresponds to a horizontal nappe stack that was regionally transported eastward during the collision between the Paranapanema and Goiás Central Blocks and the Sanfranciscan Plate in the Ediacaran Period [1]. The front of the Southern Brasília Orogen is represented, at the base, by metassediments with lithic nature associated with amphibolite lenses, both objects of this study, followed by metapsamites and metapelites of the Carrancas Group, with a tectonically upper exotic unit of metawackes [2, 3].

The metassediments of the base are paragneiss rich in lithic fragments that vary from plagioclase-quartz-biotite-epidote gneiss with potassic feldspar and hornblende (EG) to epidote-plagioclase-biotite-quartz gneiss with carbonate (QG). Detrital zircons from EG rocks provided U-Pb ages (LA MC ICP MS) that range between 2.04 to 2.18 Ga, with mean peak age of 2.12 ± 13 Ga. The □Hf values of this crystals vary from -10.4 to +15.1, with predominance of the positive values. Detrital zircons from the QG rocks indicated a provenance age between 2.00 to 2.19 Ga, with mean peak age of 2.03 ± 11 Ga. The □Hf values range from -7.4 to +6.2, with prevalence of the negative values.

The amphibolite lenses are descontinously interbedded with the paragneiss, predominantly formed by hornblende and plagioclase (andesine), with tholeitic signature. The mean peak age of this rocks stands in 1.96 ± 22 Ga and the □Hf values vary from -16.8 to +23.5.

These data suggest that the deposition of the metassedimentary sequence iniciated after 2.0 Ga, with the related basic magmatism starting somewhat around 1.96 Ga. The □Hf values also suggest that the source area comprised rocks related to juvenile accretion and rocks having long crustal residence.

Impacts of geothermal energy storage on the microbial community composition and activity in shallow systems

ANKE WESTPHAL[1], ANNA JESUßEK[2], TOBIAS LIENEN[1], ANDREAS DAHMKE[2] AND HILKE WÜRDEMANN[1]

[1] Helmholtz Centre Potsdam, *German Research Centre* for Geosciences GFZ, wuerdemann@gfz-potsdam.de

[2] Christian Albrechts Universität zu Kiel, ad@gpi.uni-kiel.de

To investigate the effects of temperature change due to geothermal energy storage on the microbial communities and the fluid geochemistry, soil column experiments using aquifer sediment and acetate added water were performed at 10, 25, 40 and 70°C. Genetic fingerprinting revealed a change in microbial community composition and activities due to elevated temperatures. The highest DNA amount and sulphate reducing bacteria (SRB) specific gene copy number were observed in fluids of the 40°C column. Correspondingly, the highest sulphate reduction rate was detected at 40°C. Thus probably the highest number of SRB was present in this column. Due to the formation of different redox zones in the 10°C column, zones of microbial colonization were observed. In the entrance nitrate and iron reducers were identified, whereas at the outlet fermentative bacteria dominated. At 70°C sulphate reducing conditions predominated and no zoning of microbial colonization was detected. Genetic fingerprinting revealed the dominance of SRB and fermentative bacteria. Methane production was found at 25°C, only. Accordingly, quantification with quantitative polymerase chain reaction (qPCR) proved the highest number of the dominant methanogen *Methanosaeta concilii*.

Reduced C-O-H Volatiles Dissolved in Lunar Picritic Glasses

D.T.WETZEL[1]*, M.J. RUTHERFORD[1], S.D. JACOBSEN[2], E.H. HAURI[3], A.E. SAAL[1], AND S.-M. THOMAS[4]

[1]Dept. of Geological Sciences, Brown University, Providence, RI 02912 (*correspondence: Diane_Wetzel@brown.edu)

[2]Dept. of Earth and Planetary Sciences, Northwestern University, Evanston, IL 60208

[3]DTM Carnegie Institute of Washington, DC 20015

[3]Dept. of Geoscience,University of Nevada Las Vegas, Las Vegas, NV 89154

The Moon had long been considered dry, until recently, when Saal *et al*. [1,2] used SIMS to measure H_2O dissolved in the lunar picritic glasses. Before this discovery, carbon was considered the primary volatile. The formation of a CO-rich gas phase by graphite oxidation was thought to drive fire fountain eruptions on the Moon producing the glass beads [3]. The natural lunar glasses contain too little dissolved C (below detection limits) to be detected by FTIR spectroscopy. We used the Apollo 15 green glass composition to experimentally determine the solubility and speciation of C in H-bearing graphite-saturated melts. Our experiments show C dissolves in reduced lunar melts (fO_2<IW-0.55) as mainly $Fe(CO)_5$ and to a lesser extent CH_4. Under more oxidizing conditions (fO_2>IW-0.55), we find C is dissolved as carbonate in lunar picritic melts. We also determine that twice as much C can be dissolved in oxidized melts compared to the reduced melts.

NanoSIMS measurements [1] of natural glasses suggest that hydrogen is dissolved in large enough quantities (up to ~40 ppm) to be detectible by FTIR spectroscopy. We used Raman and FTIR spectroscopy to study the speciation of H in the natural orange, yellow, and green lunar glasses. We also calculated the absorption coefficients for each glass composition based on our experiments. The synthetic sample spectra were also used as a guide to baseline correct and locate the weak O-H stretching peak in the natural samples. With this work, we are able to determine the abundance and speciation of dissolved volatiles in lunar and other reduced high FeO melts and the effect of planetary degassing on the evolution of an early atmosphere.

Lithium isotope variation in waters and sediments from lake Donggi Cona and its catchment, China

M. WEYNELL[1]*, U. WIECHERT[1] AND J.A. SCHÜSSLER[2]

[1]Freie Universität Berlin; Germany (*correspondance: marc.weynell@fu-berlin.de)

[2]GFZ German Research Centre for Geosciences, Helmholtz Centre Potsdam, Potsdam, Germany

Lithium isotopes are a tracer of weathering at the Earth's surface, as documented from catchments with basaltic [e.g., 1], granitic [e.g., 2] and mixed (carbonate, volcanic and sedimentary) lithologies [e.g., 3]. In this study we examine the behaviour of lithium (Li) and its isotopes in the catchment of lake Donggi Cona, China, which is an open oligotroph freshwater lake in the northeastern part of the Tibetan Plateau. The main inflow drains an area with a high proportion of carbonate rocks and a second inflow is sourced from a catchment with a larger quantity of silicate rocks. In addition, warm springs contribute to the Li budget of the lake. Water chemistry is mainly controlled by carbonate dissolution. With the exception of spring waters, pH values are constant at ~8.8. The dissolved load (DL) of every compartment shows distinct δ^7Li values (relative to L-SVEC): main inflow +17.0 ; minor inflow +20.7 ; warm springs +11.5 and lake +16.9. Suspended loads and river sediments give δ^7Li values from -2.1 to +3.1. However, lake sediments exhibit a narrow range of -1.1 to -0.5 for distal sample locations. Detrital influenced lake sediments show positive δ^7Li values of +1.7 and +2.9. Li concentrations (DL) are 37 ng/ml in the lake, 7 to 12 ng/ml in the main inflow, 33 ng/ml in the second inflow and 125 ng/ml in warm spring waters. Li concentrations of suspended loads and sediments are in the range of 20 to 55 μg/g. Lithium concentrations and isotope ratios of the lake can be explained by mixing of waters from the 3 sources and by evaporation. High δ^7Li values (DL) in the tributaries can be explained by incorporation of light Li into secondary minerals formed in the catchments, which is consistent with low δ^7Li values of complementary sediments and suspended loads. However, compared with basaltic catchments, e.g. [1], Li concentrations in the waters are higher and δ^7Li values are lower. We suggest that this is due to a distinguished lithology and lower soil formation rates controlled by the climatic regime on the northeastern Tibetan Plateau.

Regional-scale metasomatism in the Fortescue Group volcanics, Hamersley Basin, Western Australia, constrained through phase equilibria modelling

A.J.R. WHITE*, M. LEGRAS, R.E. SMITH AND P. NADOLL

CSIRO Earth Science and Resource Engineering, Australian Resources Research Centre, 26 Dick Perry Avenue, Kensington, WA 6151, Australia (*correspondance: alistair.white@csiro.au)

Mafic to intermediate volcanic rocks of the Fortescue Group form the lowermost stratigraphic unit of the 100,000 km^2 Hamersley Basin on the southern margin of the Archaean Pilbara Craton, Western Australia. A regional burial metamorphic gradient extends across the basin from prehnite-pumpellyite facies in the north to greenschist facies in the south [1]. Superimposed on this metamorphic gradient is a heterogeneous distribution of metasomatized rocks characterized by pumpellyite±epidote+quartz assemblages.

Whole-rock geochemical data indicate metasomatism is associated with significant depletions in alkali elements, Mg and first transition series metals, with enrichments in Si and Ca. Such geochemical trends are compatible with sub-sea floor hydrothermal circulation [2].

Phase equilibria modelling with the program THERMOCALC [3], in subsets of the model system Na_2O-CaO-K_2O-FeO-MgO-Al_2O_3-SiO_2-H_2O-Fe_2O_3 (NCKFMASHO), place P-T constraints on the conditions of regional metamorphism and regional-scale metasomatism. 'Least altered', regional metamorphic rocks show a temperature gradient from <200°C in the north, to > 325°C in south, consistent with predicted burial-derived thermal gradients [1]. Highly altered, metasomatized rocks show consistent temperatures of 275 – 300°C, and pressures > 2.5 kbar, across the entire basin.

The calculated temperature for the metasomatized rocks is interpreted to represent the temperature under which hydrothermal alteration occurred. The consistent P-T estimates and geochemical data suggest a common hydrothermal event acting across the entire Hamersley Basin, covering length scales of hundreds of kilometres. This has important implications for the size of metasomatic systems in other metamorphic terranes.

Towards better Greenland source attribution for IRD via Pb-Pb in feldspar and Ar-Ar in amphibole

WHITE. L[1]*, STOREY. C[1], BAILEY. I[2] AND FOSTER. G[2]

[1]University of Portsmouth, Burnaby Road, Portsmouth. (*Presenting Author: Lee.white1@myport.ac.uk)
[2]University of Southampton, European Way, Southampton.

A major uncertantity in future climate predictions involves changes in the mass and areal extent of the Greenland ice sheet (GrIS) and its variability in a warmer climate. Understanding the growth of the GrIS during Pliocene intensification of northern hemisphere glaciation may enable the critical evaluation of existing models and aid in future validation of these models. The provenance of Ice rafted debris (IRD) deposited in marine sediments has great potential to fingerprint regions of present and past iceberg calving in the coastal zones of continental margins. As such, this could potentially be a poweful technique when confining the extent of the GrIS during past climatic intervals. However, the IRD record is only as strong as the onshore land-based record of potential sources.

Two minerals common within IRD that have been used previously and that show great promise in this regard are feldspar and amphibole. Pb isotopes in feldspar record a diagnostic signature of the continental crust within distinct geologic terranes. In particular, Greenland is composed of a number of distinct terranes with proven distinct Pb isotope signatures. Ar-Ar dating of amphiboles records the thermal history of a terrain when it was metamorphosed above or cooled below c. 550ºC. Due to distinctive metamorphic histories within different terranes this signature is also potentially diagnostic of a particular source area. The two minerals together could be particularly powerful but only if the potential areas of calving are well-characterised.

Here we present data from fluvio-glacial sediments from sites around the margins of Greenland and discuss their diagnostic characteristics. We then compare these diagnostic geochemical signatures to some circum-Greenland core top IRD samples from numerous offshore sites, acting as a proof of concept. Finally, we present data sets from Mid Pliocene IRD from ODP Site 907, from numerous depths and time intervals, to further develop the proposed method and apply it to a key period in the development of northern hemisphere glaciation.

Indium's aqueous behavior in a stream influenced by acid mine drainage

SARAH JANE O. WHITE[1,2,*], FATIMA A. HUSSAIN[2], HAROLD F. HEMOND[2], ROBERT L. RUNKEL[3], KATHERINE WALTON-DAY[3] AND BRIANT A. KIMBALL[4]

[1]Harvard School of Public Health, 401 Park Dr, Boston, MA 02215 (*correspondence: sjowhite@hsph.harvard.edu)

[4]U.S. Geological Survey, 2329 West Orton Circle Salt Lake City, Utah, 84119

Indium is an increasingly important metal in semiconductors and electronics, and its use is growing rapidly as a semiconductive coating (in indium tin oxide) for LCD displays, flat panel displays, and photovoltaic cells. It also has uses in important energy technologies such as LEDs. Despite its rapid increase in use, very little is known about indium's environmental behavior, and concerns are emerging over its health impacts.

One significant flux of indium to the environment is from nonferrous mining and smelting. Mineral Creek is a headwater stream in southwestern Colorado that is severely affected by heavy metal contamination as a result of acid mine drainage. This includes indium concentrations that are 10,000 times those found in natural rivers. There have been a variety of remediation efforts in this watershed, including the installation of bulkheads to reduce water flow from mining tunnels, and removal of tailings piles. These remediation efforts appear to have reduced metal loadings in the system, though they remain above chronic aquatic standards. Indium, however, has not been previously measured, and no standards exist for indium in natural waters. In this work, a pH modification experiment was conducted in August 2005 to investigate the effects of an active remediation proposal to increase the pH of the creek. At the existing pH of ~3, indium concentrations are 6-29 μg/L (10,000x those found in natural rivers), and exist completely in the dissolved phase. Upon raising the pH of the system to > 8, all of the indium became associated with the suspended solid phase, primarily due to sorption to iron-oxides. This work informs how much indium may be mobilized from nonferrous mine wastes globally, and provides much-needed data about the aqueous behavior of indium.

Radioactivity and Neutrino Production in the Oceanic Crust

WILLIAM M. WHITE[1]

[1]Dept. of Earth & Atmospheric Sciences, Cornell University, Ithaca, NY, 14853 USA, (wmw4@cornell.edu)

Most oceanic crust is created at mid-ocean ridges as magma rises from the mantle to fill the gap between diverging plates. This produces a relatively uniform crustal structure and composition. The upper km of so of the crust consists of basaltic lavas (called mid-ocean ridge basalts or MORB) characterized by low concentrations of incompatible element, including the heat producing elements U, Th, and K. Concentrations show a highly skewed distribution; log-normal means (which provide an estimate of the modal concentrations) are U= 94 ppb, Th = 273 ppb, and K = 1211 ppm, while mean concentrations are U = 119±26 ppb, Th = 404±77 ppb, and K = 1328±71 ppm (quoted uncertaintly is 2 standard errors of the mean based on ~2000 analyses; from Gale *et al.* , G^3, 14, 2013). Back-arc basin basalts have similar Th but higher U and K: 137 ppb U, 399 ppb Th, and 2258 ppm K. The compositions of MORB indicates that they evolve through fractional crystallization within the oceanic crust and hence do not represent the composition of the crust as a whole. Calculations based on the MELTS thermodynamic model suggests MORB have experienced an average of 39% fractional crystallizaiton. Assuming that the composition of the bulk 'fresh' oceanic crust is that of a primitive parent in equilibrium with mantle olivine, bulk 'fresh' oceanic crust is estimated to have 80 ppb U, 260 ppb Th, and 875 ppm K. Simple mass balance then indicates that 'fresh' lower oceanic crust (gabbroic section or layer 3) has 70 ppb U, 220 ppb Th, and 750 ppm K. Assuming the crust is generated by 8% melting, this implies depleted mantle concentrations of 6 ppb U, 21 ppb Th, and 70 ppm K. Hydrothermal processes modify the composition of oceanic crust, increasing K and U by 402 mg/kg and 0.307 mg/kg, respectively (Staudigel, TOC, Chapter 13, 2013). This increases U and K in the bulk oceanic crust to 110 ppb U and 1280 K. A small fraction of the oceanic crust consists of thick ocean plateaus produced by melting over mantle plumes. These plateau basalts have higher U, Th, and K concentrations: ~400 ppb U, ~1300 ppb Th, and ~1369 ppm K. Considering all these factors considered and assuming an average crustal thickness of 7 km for crust created at mid-ocean ridges, total U, Th, and K in the oceanic crust is estimated at 6.62 x 10^{14} kg, 1.55 x 10^{15} kg, and 762 x 10^{18} kg, respectively, producing 0.13 TW of energy (≤1% of the terrestrial total). These masses of U and Th would produce 3.9 x 10^6 anti-neutrinos per year.

Ion imaging and ion tomography applications in zircon geochronology

M.J. WHITEHOUSE[1]*

[1]Swedish Museum of Natural History, SE-104 05 Stockholm, Sweden (*correspondence: martin.whitehouse@nrm.se)

High spatial resolution secondary ion mass spectrometry (SIMS) has been routinely used in zircon U-Pb geochronology and geochemistry for three decades and has been central to many important geological discoveries. The unique ion microscope capability of the CAMECA IMS 1270/80 instruments, in particular using scanning ion imaging (SII) coupled with high sensitivity, high mass resolution and exceedingly low noise ion-counting multicollection remains however, a relatively underutilised tool in geochronology.

A recent study [1] of Meso- to Paleoarchean zircon from gneisses in east Antartica which have experienced ultra-high temperature (UHT) metamophism, used scanning ion imaging (SII) both to map the occurrence and measure the isotope ratio of unsupported radiogenic Pb. Numerous micrometre-sized Pb-rich clots were revealed in an 80 x 80 μm imaged area by the SII technique. These clots are independent of the distribution of other elements, notably U and Y, both of which show simple oscillatory zoning, while their elevated $^{207}Pb/^{206}Pb$ ratios clearly indicate their antiquity. Apart from explaining commonly observed Pb instability and reverse discordance [2] during SIMS analysis of UHT zircon, such ancient Pb redistribution can have implications for the geochronology of zircon from the early Earth [1].

The lateral resolution of an SII analysis is limited to the ca. 2 μm diameter of the primary beam and so the actual size of the Pb-enriched clots remains essentially unconstrained below this level, but is clearly considerably smaller given the relative uniformity in observed clot area. In an extension of the conventional SII study, an investigation of UHT zircon from southern India that exhibit similar Pb-clots, utilised a novel combination of SII and depth profiling, here termed scanning ion tomography (SIT), to add a third dimension to the Pb clots. During a typical SII analysis (comprising 100 scans), the ion beam penetration is < 5 nm and using this method, Pb-rich clots are revealed to have a size typically of only a few nanometers. The ability of SIT to reveal the true length-scale of Pb-isotope redistribution, while still uniquely recording a Pb isotope ratio, considerably aids in constraining models for the processes involved in their generation.

Persistence of early Archean style of crustal growth and near-chondritic mantle into the late Archean

M.J. WHITEHOUSE[1]* AND A.I.S. KEMP [2]

[1]Swedish Museum of Natural History, SE-104 05 Stockholm, Sweden (*correspondence: martin.whitehouse@nrm.se)
[2]University of Western Australia, Crawley, WA 6009, Australia (tony.kemp@uwa.edu.au)

The Neoarchean Lewisian Complex of north-west Scotland is one of the most extensively studied TTG gneiss terranes on Earth. It has been used to propose and refine models of crustal evolution for over a century, from the early recognition of multiple phases of crustal reworking based on cross-cutting dykes [1] to the more recent "terrane models" proposed for crustal accretion [2]. Interpretation of both geochronology and isotopic data from the Lewisian, however, remains complicated (e.g. [3]) by polyphase metamorphism, which in places attains granulite facies.

In this study, we present cathodoluminescence image-guided ion microprobe U-Th-Pb geochronology and LA-ICP-MS Hf isotopes of zircon separated from representative TTG gneisses across the Scottish mainland and Outer Hebridean Lewisian outcrop. Applying a similar methodology to that outlined in [3], we assign a preferred magmatic protolith age to each zircon population and this age is then used to calculate $\varepsilon_{Hf}(t)$ values.

Over a wide range of protolith ages from > 3.1 Ga to 2.7 Ga, zircon $\varepsilon_{Hf}(t)$ values are, on average, only slightly super-chondritic and show relatively little variation with time. A possible explanation for this trend is that younger TTG magmas are increasingly influenced by recycling of older crust, although few older zircon cores are observed to support such an *ad hoc* interpretation. As an alternative, we propose a tectonic model for the Lewisian in which mafic precursors to the TTG magmas, generated from a mildly depleted to near-chondritic mantle, were rapidly recycled over a period of >400 Ma with little or no direct input of typical contemporaneous depleted-mantle. Similar tectonic scenarios, differing markedly from "modern-style" plate tectonics, have been proposed for the early Archean (e.g. [4]) and our observations from the Lewisian TTG gneisses suggest that, at least locally, similar processes, as well as near-chondritic mantle, may have persisted into the Neoarchean.

Increasing greenhouse gas emissions in circumpolar regions due to climate change-induced permafrost retreat

M. WHITICAR*[1] J. BHATTI[2] AND N. STARTSEV[2]

[1] SEOS, U. Victoria, Victoria, BC, V8W 2Y2, Canada (*correspondence: whiticar@uvic.ca)
[2] NFC, Canadian Forest Service, Edmonton, AB, Canada

Thawing permafrost peatlands substantially influence northern ecosystems by changing the regional hydrology and mobilizing the vast carbon (C) reserves that results in increased greenhouse gas (GHGs) emissions to the atmosphere. With permafrost distribution controlled largely by topography and climate, our IPY study intensively monitored the local C-cycling processes and GHG fluxes associated with different hydrologic and permafrost environments at 4 sites along a latitudinal climatic gradient of mid-boreal, boreal, low and high subarctic ecoclimatic regions that extend south-north from the Isolated Patches Permafrost Zone (northern Alberta), to the Continuous Permafrost Zone (Inuvik, NWT). Each site encompasses a local hydrologic and vegetation gradient from upland forest and peat plateau to collapse scar.

Our multi-year measurements of peatland profiles and flux chambers for CH_4 and CO_2 concentrations and stable isotope ratios indicate processes, including methanogenesis, methanotrophy, transport and emission that control the distribution of these GHGs. These relationships are modulated by fluctuating local soil water and ecosystem conditions. The gas geochemistry shows that significant surface CH_4 production occurs by both hydrogenotrophic and methyl-fermentative methanogenesis in submerged, anaerobic peats, e.g., collapse scars, whereas methane oxidation is restricted to aerobic, drier environments, e.g., upland sites and peat-atmosphere interface. The most active methanogenesis and emissions are in the actively thawing permafrost sites contrasting with those under continuous permafrost. This degree of methanogenesis is being amplified by the increased rate of warming and the rapid retreat of permafrost in Canada's northern areas (ca. 2.5 km/yr).

For context, the present permafrost and GHG emission situation is compared with the rapid rises in temperature, CH_4 and CO_2 concentrations during the Younger Dryas-Preboreal transition (~11.5yBP). Our pCH_4 and $\delta^{13}CH_4$ work [1] on Pakitsoq, Greenland ice show that the rapid rise in pCH_4 during YD-PB is unlikely to have been due to massive marine gas hydrate release ('clathrate gun'), but that CH_4 from permafrost retreat after Last Glacial Maximum is a plausible explanation.

Absorbing aerosol radiative effects in the limb-scatter viewing geometry

A. WIACEK[1], R. V. MARTIN[2,3], A. E. BOURASSA[4], N. D. LLOYD[4] AND D. A. DEGENSTEIN[4]

[1] Division of Engineering, Saint Mary's University, Halifax, Canada
[2] Department of Physics and Atmospheric Science, Dalhousie University, Halifax, Canada
[3] Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, USA
[4] Department of Physics and Engineering Physics, University of Saskatchewan, Saskatoon, Canada

We use the fully 3-D radiative transfer code SASKTRAN to simulate the sensitivity of limb-scatter viewing Odin/OSIRIS satellite measurements to absorbing mineral dust and carbonaceous aerosols, and to sulfate aerosol and ice in the upper troposphere.

At short wavelengths (337 nm, 377 nm, 452 nm), we found that the addition of any aerosol species to an air only atmosphere caused a decrease in single-scattered radiation due to an extinction of Rayleigh scattering in the direction of OSIRIS. The reduction was clearly related to particle size first, with absorption responsible for second-order effects only. Multiple-scattered radiation could either increase or decrease in the presence of an aerosol species, depending both on particle size and absorption. The combined effect led to complex total radiance signatures that generally could not unambiguously distinguish absorbing versus non-absorbing aerosols. However, we found that scene darkening above the aerosol layer is unambiguously due to absorption whereas scene darkening within and below the aerosol layer can simply be the result of a reduction in single-scattered radiance. However, the effect did not exceed 0.2% of the total radiance due to air only for medium-sized carbonaceous aerosols.

A fortuitous, unexpected implication of our analysis is that limb-scatter retrievals of aerosol extinction are insensitive to external information about aerosol absorption.

Stable Sr isotope fractionation in synthetic barite

INOKA H. WIDANAGAMAGE[1], ELIZABETH M. GRIFFITH[2], AND HOWIE D. SCHER[3]

[1] Department of Geology, Kent State University, iwidanag@kent.edu
[2] Department of Earth and Environmental Sciences, University of Texas at Arlington, lgriff@uta.edu
[3] Department of Earth and Ocean Sciences, University of South Carolina, hscher@geol.sc.edu

Barite ($BaSO_4$) is a highly stable and widely distributed mineral that incorporates many elements (e.g., Sr, Ca, Ra) in its crystal lattice making it useful as an archive for geochemical and isotopic signals of environmental change. Abiotic precipitation of barite commonly occurs with mixing of sulfate and barium rich solutions. Barite can also precipitate in association with biological processes, such as bacterial sulfide oxdiation. We present stable Sr isotope results ($\delta^{88}Sr$) from synthetically precipitated barite to elucidate the parameters (e.g., temperature, barite saturation state, solution Sr/Ba) influencing mass dependent Sr isotopic fractionation under abiotic conditions. This work will constrain future studies of stable Sr isotopic fractionation in natural biologically-influenced barite precipitation.

We precipitated barite from solution by adding sulfate to a Sr-Ba solution under various conditions (solution Sr/Ba, temperature, and barite saturation state) that may influence equilibrium and/or kinetic mass dependent stable Sr isotopic fractionation. Isotopic measurements were made on a Thermo Neptune Plus MC-ICPMS at the University of South Carolina using a standard-sample bracketing technique that corrects for instrumental mass bias relative to a Zr reference ratio. All barite samples were less enriched in ^{88}Sr relative to the solutions from which they precipitated similar to other isotope systems (e.g., Ca).

In our experiments, Sr isotopic fractionation is influenced by both barite saturation state and temperature. However, neither dominantly controls Sr isotopic fractionation under our experimental conditions. Temperature dependent isotopic fractionation of Sr under our experimental conditions was very weak and negative (-0.0032‰/°C), however the variation of the isotopic data is largely within the analytical uncertainty of the measurement over the temperature range of our experiments, 5 to 40°C. The relationship between $\Delta^{88/86}Sr_{barite\text{-}aq}$ for all experiments and D_{Sr} was not significant, but was affected by the solution initial barite saturation state, which likely influences precipitation rate. At a constant intital barite saturation state, the relationship is significant and appears to be independent of temperature and (Sr/Ba) ratio.

Lithium isotope variation in rivers and lakes on the Tibetan Plateau

U. WIECHERT[1]*, M. WEYNELL[1], S. BARVENCIK[1], AND J. A. SCHUESSLER[2]

[1]Freie Universität Berlin; Germany (*correspondance: wiechert@zedat.fu-berlin.de)
[2]GFZ German Research Centre for Geosciences, Helmholtz Centre Potsdam, Potsdam, Germany

We report lithium abundances and isotope ratios for lakes, tributaries, and large rivers (Indus, Yarlung Tsangpo and Yellow River) on the Tibetan Plateau. In rivers we found solely calcium-bicarbonate waters, whereas lakes with sodium-chloride and sodium-sulfate waters could be distinguished. The chemical composition of the rivers primarily reflects weathering of rocks in carbonate-rich catchments. In contrast, lake water chemistry is affected by evaporation and crystallization of minerals. This is indicated by a high level of mineralization and an electric conductivity of more than 10 mS/cm, which classifies them as salt lakes. The δ^7Li of lake waters varies between +7.0 and +25 relative to L-SVEC. The δ^7Li of rivers in the south range from +4.0 to +9.0 and the Yellow River in the NE gives a δ^7Li ~ +18. The variation of δ^7Li in the water samples is, in general, consistent with fractionation of isotopically light lithium in secondary clay minerals during weathering in the catchments [1,2]. However, at the lake Tashi Namtso a systematic isotopic difference between inflow and lake provides evidence for lithium isotope fractionation in the lake. In this example a strong pH change from about 8.2 to 9.8 is observed at the transition from river to lake waters. It is suggested that formation of clay minerals at the transition cause an additional isotopic shift by ~10 ‰. In the large rivers of the southern Tibetan plateau low δ^7Li are consistent with a transport-limited weathering regime, whereas the rather high δ^7Li of the Yellow River favour a weathering-limited transport regime. The results support that riverine lithium isotopes are a powerful proxy for the intensity of silicate weathering in a catchment [3] rather than silicate weathering rates [4]. However, in some areas lithium isotope compositions of the tributaries are affected by sulfate-rich thermal waters. How much this alters the weathering budget of the large rivers is difficult to estimate because evaporates and hot springs, which are important players in the terrestrial lithium cycle, are yet to be constrained.

Prospective shale gas zones in the Kimmeridgian and Tithonian strata of Polish Lowlands

D. WIĘCŁAW[1]* AND M.J. KOTARBA[1]

[1]AGH University of Science and Technology, Mickiewicza 30 St., 30-059 Kraków, Poland (*correspondence: wieclaw@agh.edu.pl)

Kimmeridgian strata in the Norwegian and North Seas are considered to be responsible for hydrocarbon generation of large petroleum conventional accumulations [1]. Although exploration of these strata in Poland did not record commercial accumulation of petroleum, the preliminary studies [2] reveal generation of oil and gas in areas, where the Upper Jurassic strata were covered by thick Cretaceous rocks. In the present study we determinate areas and depth intervals of possible shale gas accumulation in these strata.

Results and disscusion

A total of 482 core samples: 242 from the Kimmeridgian and 240 from the Tithonian strata from 40 wells of central part of Polish Lowlands were analysed. Rock-Eval pyrolysis reveals total organic carbon (TOC) contents from 0.14 to 9.6 wt% in the Kimmeridgian samples and from 0.19 to 12.5 wt% in the Tithonian samples. The highest values were recorded in the Upper Kimmeridgian and Lower Tithonian strata (TOC, up to 12.5 wt%, usually above 2 wt%). Rock-Eval, biomarker and kerogen elemental composition data evidence domination of the oil-prone Type-II kerogen in this most prospective sequences. Organic matter mostly is immature or early mature. 1-D modelling of the petroleum generation processes [2] reveal that in selected deeply buried structures in the Łódź Trough, the Upper Jurassic source rocks reached maturities corresponding to peak of oil window (0.7 - 1.0% Ro).

Conclusion

Intense sampling and Rock-Eval analyses enabled authors to designate a ca. 60 m thick marly shale complex at the border of Kimmeridgian and Tithonian strata in Łęczyca–Koło area as the most prospective for shale gas exploration.

The study was financed by the Ministry of Science and Higher Education (Projects Nos. N307 3141 39 and 744/N-IRAN/2010/0).

Tracing local industrial pollution sources with mercury isotopes

JAN G. WIEDERHOLD[1,2]*, MARTIN JISKRA[1,2], ULF SKYLLBERG[3], ANDREAS DROTT[3], SOFI JONSSON[4], ERIK BJÖRN[4], BERNARD BOURDON[2,5] AND RUBEN KRETZSCHMAR[1]

[1]Soil Chemistry, IBP, ETH Zurich, Switzerland (*correspondence: wiederhold@env.ethz.ch)
[2]Isotope Geochemistry, IGP, ETH Zurich, Switzerland
[3]Forest Ecology and Management, SLU Umeå, Sweden
[4]Chemistry, Umeå University, Sweden
[5]ENS Lyon and CNRS, France

Stable mercury (Hg) isotope analysis offers a promising tool for tracing sources of anthropogenic Hg pollution in the environment. Mass-dependent (MDF) and mass-independent fractionation (MIF) of Hg isotopes results in two-dimensional isotope signatures of different Hg sources and can help understand transformation processes at contaminated sites.

Here, we present Hg isotope data for sediments collected in the vicinity of different industrial pollution sources in Sweden. The sampling sites covered a range of environmental conditions (salinity, organic matter, temperature) and were contaminated with either elemental Hg from the chlor-alkali industry or with phenyl-Hg used as preservative for pulp fibers in the paper industry. In addition to analyzing total sediment digests, a sequential extraction method designed to separate sulfide- and non-sulfide-bound Hg was performed on selected samples. Stable Hg isotope ratios were measured by CV-MC-ICPMS using standard-bracketing (NIST-3133) and Tl addition for mass bias correction.

The sediments exhibited a wide range of total Hg concentrations from 0.8 to 229 μg g^{-1}, consisting dominantly of organically-bound Hg(II) and a smaller pool of sulfide-bound Hg. The Hg isotope ratios of the three phenyl-Hg sites displayed nearly identical signatures (MDF δ^{202}Hg: -0.2 to -0.5‰, MIF Δ^{199}Hg: -0.05 to -0.10‰). In contrast, the four sites which had been contaminated with elemental Hg showed much greater variations (δ^{202}Hg: -2.1 to 0.6‰, Δ^{199}Hg: -0.19 to 0.03‰), but with distinct ranges for the different sites.

The sequential extraction data revealed that the smaller sulfide-bound Hg pool was in some samples up to 1‰ heavier in δ^{202}Hg than the dominant organically-bound Hg pool. The selectivity of the sequential extraction procedure was assessed using standard materials prepared with enriched stable Hg isotope tracers, which also allowed to gain insight into the exchange of Hg isotopes between different Hg pools.

Our results suggest that different industrial pollution sources can be distinguished based on their Hg isotope signatures, which can additionally record fractionation processes between different Hg pools in the sediments.

Geochemical and isotopic investigation of fluids from Lahendong geothermal field

B.A. WIEGAND[1]*, M. BREHME[2], F. TEUKU[1], I.A. AMRAN[1], R. PRASETIO[1], Y. KAMAH[3] AND M. SAUTER[1]

[1]Univ. Göttingen, GZG, Goldschmidtstr. 3, 37077 Göttingen, Germany, (bwiegan@gwdg.de)
[2]Helmholtz Centre Potsdam – GFZ, Telegrafenberg, 14473 Potsdam, Germany, (brehme@gfz-potsdam.de)
[3]Pertamina Geothermal Energy, Jl.M.H. Thamrin No.9, Jakarta 10340, Indonesia.

Lahendong geothermal field is a high-temperature liquid-dominated system located in North Sulawesi (Indonesia) with a current power production capacity of 80 MW (Operator: Pertamina Geothermal Energy). The geology of the area comprises Late Pliocene to Mid-Pleistocene volcanic rocks of Mount Tondano and younger eruptions, including basaltic and andesitic lavas and pyroclastics [1,2]. Deep reservoir fluids are dominated by Cl-SO_4-HCO_3 and Cl type, while HCO_3-rich and SO_4-HCO_3 type fluids discharge at the surface [2].

We investigated trace elements and naturally occurring isotope systems (D-O, Sr, Ca) in fluids from hot springs, shallow groundwater wells, geothermal production wells, and surface waters from the Lahendong area to elucidate solute sources and geochemical processes in the aquifer. δD and δ^{18}O values of the fluid samples suggest a meteoric origin of geothermal groundwaters. Variable trace element concentrations are subject to differences in weathering regime and geochemical equilibrium conditions in the aquifer. Deep fluids are usually characterized by high As (≤ 4 mg/L), Cs (≤ 1.4 mg/L), and Li (≤ 2.3 mg/L) and low Ca and Mg concentrations (≤ 6 mg/L). In turn, surface waters and hot springs have higher Ca and Mg concentrations but are low in As, Cs, and Li content (<0.5 mg/L). ^{87}Sr/^{86}Sr ratios are lower in surface waters and hot springs (0.7039 – 0.7043), while fluids of the deeper reservoir have higher ^{87}Sr/^{86}Sr ratios (0.7050 – 0.7057), which suggests differences in the Sr isotope composition of andesitic and basaltic rocks in the reservoir and at the surface. $\delta^{44/40}$Ca values vary between -1.50 and 0.09 ‰ and may be employed as an indicator for processes involving dissolved Ca^{2+}. These processes include dissolution of minerals, cation exchange, and precipitation of secondary Ca-bearing phases.

Source and speciation of ^{14}C in a cement-based repository for radioactive waste

E. WIELAND[1]*, J. SCHENZEL[1] AND G. SCHLOTTERBECK[2]

[1]Paul Scherrer Institute, Laboratory for Waste Management, 5232 Villigen PSI, Switzerland (*correspondence: erich.wieland@psi.ch)

[2]University of Applied Sciences Northwestern Switzerland, School of Life Sciences, 4132 Muttenz, Switzerland

Carbon-14 is an important contributor to the annual dose released from a cement-based repository for low- and intermediate-level radioactive waste in Switzerland. To date, performance assessment has to be based on assumptions regarding the speciation and mobility of ^{14}C bearing compounds. It is considered that ^{14}C mainly contributes to dose in its organic form, such as ^{14}C bearing organic compounds, which are only weakly retarded in the cementitious near field.

Compilations of the activity inventories reveal that, in the already existing and future arising of radioactive waste in Switzerland, the ^{14}C inventory is mainly associated with activated steel (~ 85 %). The inventories of activated steel and ^{14}C in the repository are well known. However, the chemical speciation of ^{14}C in the cementitious near field upon release from activated steel is only poorly investigated.

Identification and quantification of the ^{14}C bearing organic compounds formed during the anoxic corrosion of activated steel is a major challenge, firstly due to the low ^{14}C inventory of the material available for the corrosion experiment, and secondly due to the extremely low corrosion rate of steel in alkaline solution (few nm/year). Thus, the development of an analytical method with a very low ^{14}C detection limit is required, such as compound-specific ^{14}C AMS. As a first step towards the development of the technique, batch-type corrosion experiments with non-activated, carbon-containing iron powders were carried out with the aim of identifying potentially ^{14}C bearing organic compounds. The powders were immersed in groundwater- and cement-type solutions and time-dependent changes in the concentrations of dissolved and gaseous carbon species were determined using high-performance ion exclusion chromatography coupled to conductivity detection and mass spectrometry and gas chromatography coupled to mass spectrometry. The conceptual approach for a corrosion study with activated steel along with first results will be discussed.

Irradiation histories of meteoritic inclusions measured by ^{40}K

D. WIELANDT[1] AND M. BIZZARRO[1]

[1]Centre for Star and Planet Formation, University of Copenhagen, Denmark (wielandt@snm.ku.dk).

The solar and galactic cosmic rays recorded by chondrules and refractory inclusions (CAIs and AOAs) can provide unique information on their formation, transport and storage histories. To explore the irradiation histories of these objects, we have developed novel analytical protocols to accurately measure Ca/K ratios and K-isotopes by thermal ionization mass spectrometry [1]. The low abundance of ^{40}K relative to ^{39}K makes the $^{40}K/^{39}K$ ratio a sensitive indicator of spallation, whereby efficient spallogenic production of ^{40}K occurs through proton irradiation of calcium targets by $^{43}Ca(p,\alpha)^{40}K$ and $^{44}Ca(p,n+\alpha)^{40}K$. Because proton stopping and reaction depths at relevant energies are similar to the sizes of the inclusions, ^{40}K depth profiles can allow us to discriminate between solar and galactic cosmic rays. Further, the common K retains information on precursor irradiation.

We selected well characterized CAIs and AOAs from Efremovka carbonaceous chondrite (CV3red) and chondrules from the NWA 5697 ordinary chondrite (LL3). The three chondrules selected for study have variable U-corrected Pb-Pb dates and ^{54}Cr compositions [2], suggesting lateral transport and storage of these objects in the solar protoplanetary disk for at least ~2 Myr prior to their accretion in the NWA 5697 parent body. All material analyzed show large (i.e. permil to percent) positive ^{40}K anomalies that broadly correlate with Ca/K ratios, consistent with spallation of Ca. The ^{40}K anomalies in the 3 chondrules vary with their absolute Pb-Pb dates, such that the oldest chondrules register the largest doses. At face value, this is consistent with a monotonic irradiation source, suggesting that ^{40}K anomalies were generated during storage in the protoplanetary disk, likely from exposures to galactic cosmic rays. The comparable dosages recorded by CAIs and chondrules suggest a similar transport mechanism, possibly associated with stellar outflows [3]. Similarly to CAIs, we infer that some chondrules formed in the inner regions of the protoplanetary disk were ejected to large orbital distances and drifted back to the accretion regions of chondrites over timescales of a few Myr. We are currently conducting ^{40}K depth profiles of large, well characterised and Pb-Pb dated chondrules to test this conclusion.

Sieve textures in impact zircon from Vredefort, South Africa: Implications to impact geochronology

MATTHEW M. WIELICKI* AND T. MARK HARRISON[1]

[1]Department of Earth and Space Sciences, University of California, Los Angeles, 595 Charles E. Young Drive East, Los Angeles, CA 90095
(*correspondence: mwielicki@gmail.com)

The bombardment history of our planet has major implications for Earth's atmosphere, habitability, near surface conditions, and the delivery of the building blocks of life over its four and a half billion years. Constraining the impact flux to the Earth-Moon system was highlighted by the National Research Council's 2007 report "The Scientific Context for the Exploration of the Moon" as the top priority goal for lunar research. Evidence of the early impact flux has largely been based on interpretations of ^{40}Ar-^{39}Ar ages of lunar samples which can be problematic due to the presence of relic clasts, incomplete Ar outgassing, diffusive modification during shock and heating, and exposure to solar wind and cosmic rays [1]. Recent studies [2,3] have utilized zircon from Apollo samples as well as lunar meteorites to better constrain the impact history of the Moon. Sieve textures found in zircon within lunar meteorite SaU 169 have been identified as "poikilitic impact melt zircon formed during equilibrium crystallization of the impact melt" and used to better constain the age of the Ibrium impact [3]. Such textures had previously not been observed in terrestrial zircon. We report the first terrestrial sieve textures in zircon isolated from Vredefort impactites. Zircons isolated from the granophyre unit show a intimate relationship with pyroxene, similar to that seen in the lunar samples, most likely due to resorption. U-Pb analysis of such grains clearly shows that the zircons have been inherited from the target and are not neo-formed zircon that crystallized from the impact melt and thus should not be used to imply impact events. Pb-loss is highly variable in these samples and the lower intercept age of ~1985±150 Ma agrees well with that of the Vredefort impact [4,5]. Zircon geochronology offers a new tool with which to constrain planetary impact histories however effects on zircon from impact events remain poorly understood and need to be explored terrestrially prior to making interpretations on extraterrestrial samples.

Modeling nanomaterial transport and biouptake in a complex aquatic system: Exploring surface affinity as a predictor of nanoparticle fate

MARK WIESNER[1,2], MATHIEU THEREZEIN[1,2], FABIENNE SCHWAB[1,2], LAUREN BARTON[1,2], CHRISTINE HENDREN[1,2], GREGORY V. LOWRY[3,2], RAJU BADIREDDY[1,2], BENJAMIN ESPINASSE[1,2], BENJAMIN P. COLMAN[1,2], EMILY S. BERNHARDT[1,2], JEAN-YVES BOTTERO[4,2]AND MELANIE AUFFAN[4,2]

[3]Carnegie Mellon University, Pittsburgh, PA 15213
[4]Centre de Recherche et d'Enseignement de Géosciences de l'Environnement, Aix-en-Provence, France

A recent study of silver nanoparticles introduced to a simulated freshwater wetland indicated an initial period of particle removal and associated die-off of some aquatic plants. This talk considers the initial transport and fate of nanoparticles introduced to this system from the standpoint of heteroaggregation, deposition, and dissolution and the implications for short-term impacts on rooted aquatic plants. Simulations show that nanoparticles introduced in a complex, albeit greatly simplified environment exhibit a wide range of behaviors depending on their affinities for each other and their concentrations. The complexity of these interactions appears to be governed by the relative affinity of nanoparticles for each other (autoaggregation) and with background particles (heteroaggregation) and other native surfaces. Surface affinity as a predictor or nanoparticle fate is explored further in the context of interactions with plant surfaces biofilms and the potential for uptake by plants. A functional assay for determining the affinity of nanoparticles for complex mixtures of native particles is evaluated.

The end-Permian mass extinction and its aftermath

PAUL B. WIGNALL

School of Earth and Environment, University of Leeds, UK (p.wignall@see.leeds.ac.uk)

Our understanding of the timing of the end-Permian mass extinctionan subsequent recovery has improved dramatically in the past few years. For long thought to be a protracted affair spread over several million years of the Late Permian, by the 1990s it was re-evaluated as a geologically abrupt crisis. Latest work shows the marine (and probably the terrestrial) extinction to be a two-phased event that straddles the Permian-Triassic boundary whilst the record from higher northern (Boreal) latitudes suggests the extinction phase was somewhat earlier. The ~200 kyr interval between the extinction pulses saw a transient recovery of the benthic fauna. The significance of this improved resolution of extinction timings can be compared with recent advances in both our understanding of ocean redox and sea-surface temperatures at this time. The first pulse of extinction saw the onset of open ocean anoxia but only a transient pulse of low- oxygen conditions whilst the second extinction pulse, in the earliest Triassic, coincides with the long-term establishment of global marine anoxia. The contemporaneous oxygen isotope record of conodont phosphate reveals a rapid temperature rise that persisted long in to the Early Triassic.

The Early Triassic fossil and geochemical record is one of the most extraordinary of the Phanerozoic. Carbon isotope stratigraphy is highly unstable with a series of both positive and negative excursions whilst the oxygen isotope record shows similar instability reflecting major temperature oscillations within an overall exceptionally hot interval. This culminated in the latest Smithian Stage with very light $\delta^{13}C$ values (~2‰) and $\delta^{18}O$ values suggestive of equatorial sea-surface temperatures >40ºC. The marine invertebrate record is remarkbaly impoverished for 2 myrs with little in the way of recovery of the benthos whilst nektonic organisms radiated with their usual exuberance. Only after the Late Smithian Thermal Maximum can it be claimed that widespread diversification is underway although not until the Middle Triassic are conditions truly normal in marine and terrestrial habitats.

Experimental study of majorite stability in chromium rich garnets

CH WIJBRANS[1]*, S KLEMME[1] AND A ROHRBACH[1]

[1]Institut für Mineralogie, Universität Münster, Germany, (*ineke.wijbrans@uni-muenster.de)

Garnet is an important constituent of upper mantle rocks, and is stable over a wide range of pressures. At high pressures(>5GPa), silica is incorporated into the octahedral site in the garnet structure partially replacing aluminium, which results in the so-called majorite component. In mantle rocks, this will cause the pyroxenes to gradually dissolve into garnet with increasing pressure [1]. Majoritic garnets are sometimes found as inclusions in deep diamonds and in mantle peridotites. The silicon content of these garnets is often used to estimate the depth of origin of these samples [2].

In addition to pressure [1], majorite stability is also expected to depend on temperature, composition of the garnet and presence of other Al-bearing phases or melt. For instance, the presence of chromium or ferric iron may decrease majorite stability with increasing pressure. If true, this has implications for the interpretation of the formation depth of diamond inclusions as the Cr/(Cr+Al) ratio is much higher in depleted lithospheric mantle compared to fertile mantle.

To investigate this further, we performed high pressure high temperature experiments in a Walker-type multi anvil press (Bristol design) at pressures between 6 and 14 GPa, and temperatures between 1400 and 1700 °C. Starting materials consist of silicate glasses or oxide mixes in the system Cr_2O_3-CaO-MgO-Al_2O_3-SiO_2, with varying $Cr_2O_3/(Al_2O_3+Cr_2O_3)$ ratio. Major and minor element concentrations of the phases present were determined by electron microprobe.

All experiments yielded garnet, most contained opx, olivine and (minor) cpx as stable phases. At high temperatures only one pyroxene phase is stable. Preliminary results indicate that for constant pressures and temperatures, the majorite component in garnet decreases with increasing Cr/(Cr+Al) of the bulk composition. However, this effect is most notable at high pressures (>11GPa), at lower pressures this effect is smaller.

Power stations as a source of atmospheric particulate matter in southern Poland

W. WILCZYŃSKA-MICHALIK[1]*, R. MORYL[1], B. SUDER[1], AND M. MICHALIK[2]

[1]Pedagogical University, ul. Podchorążych 2, Kraków, Poland (*correspondence: wanda.michalik@post.pl), (renatamoryl@gmail.com; basia_suder@vp.pl)

[2]Jagiellonian University, ul. Oleandry 2a, Kraków, Poland (marek.michalik@uj.edu.pl)

High concentration of atmospheric particulate matter in southern Poland is a problem of great meaning. The improvement of this situation needs the recognition of the source of aerosol particles (natural or anthropogenic; local source or long distance transport). Power stations are considered to be an important source of atmospheric pollution in Poland. Changes in fuel used (coal, coal+biomass, biomass) and in combustion technology caused much bigger variability in the composition and morphology of fly ash particles than it was noted in the past when pulverized coal boilers were mainly used. Interpretation of origin of aerosol particles is also more difficult.

Fly ash from coal fired pulverized bed and fluidized bed boilers is similar in chemical composition but mineral composition differs (less mullite and glass in ash from fluidized bed boiler but more coaly irregular particles) as well as morphology of particles. Fly ash from coal and biomass co-combustion in pulverized bed boiler is rich in SiO_2, Al_2O_3, Fe_2O_3, MgO and CaO. Beside quartz, mullite, glass, Fe oxides, Ca, Ca-Mg or Ca-Mg-Fe oxides are present. Aluminosilicate spheres (<1 μm - 50 μm) are accompanied by numerous, usually porous and less regular spheres Ca or Ca-Mg, Ca-Mg-Fe oxides. Fly-ash from fluidized bed boiler fired with biomass is rich in SiO_2 (content of CaO is low; Al_2O_3 very low). Bigger particles are composed of quartz core with reaction rim or of glass, smaller (<1 mm - 10 mm) are represented by glassy spheres or irregular fragments of glassy particles.

Study was supported by NCN grant No. 579/B/P01/2011/40.

Delamination of the North China Craton: A widespread phenomenon or a one-off situation?

S.A. WILDE

Dept. of Applied Geology, Curtin University, Perth, Australia

The North China Craton is widely recognized as the type-example of delamination of an Archean craton and, although it has been extensively investigated over the past decade, many and diverse reasons have been suggested to explain the phenomenon; but with little consensus reached. Although several surface features and the Mesozoic rock record indicate it was operative in the Cretaceous, outstanding issues include: when did delamination/thinning commence; what were the mechanisms involved; was there a link to marginal orogenic belts; was paleo-Pacific plate subduction a controlling factor; and did global tectonic processes play a role? A review of geological data from the Archean to the present-day indicates a number of unique features in the North China Craton that most likely contributed to its 'decratonization' in the Mesozoic [1]. However, were these sufficient to make it a one-off situation or was this process more widespread in the geological past? This has important implications with respect to the preservation of ancient continental crust and thus for models of continental growth. Tomographic studies indicate that other cratonic areas also have thinned lithosphere, but it is uncertain if this, on its own, will ultimately lead to their destruction. Since the thickness of the lithosphere exherts an important control on the deformation of continental blocks when they get dismembered and re-distributed in supercontinent cycles, it is important to identify features that may have resulted from earlier delamination or thinning. Likewise, the fact that certain areas currently involved in collisional events, such as Tibet and Iran, have thickened lithospheres with seismic properties that resemble cratonic areas [2], indicates that 'cratons' may develop by several different mechanisms, perhaps with diagnostic characteristics. Evidence from the North China Craton will be reviewed with respect to the various models proposed to explain delamination/thinning, with the aim of resolving some of the contentious issues and leading toward a consensus.

Mobility of inorganic and organic compounds from black shales during unconventional gas production

F.D.H. WILKE [1,2]*, A. VIETH-HILLEBRAND[1], R. NAUMANN[1], B. HORSFIELD[1] AND J. ERZINGER[1,2]

[1]GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany
[2]University of Potsdam, Department of Earth and Environmental Sciences, Karl-Liebknecht Str. 24-25, 14467 Potsdam, Germany (*fwilke@gfz-potsdam.de)

Taking into account the envisaged activities of shale gas exploitation and production from black shales in central Europe we see an increasing demand in a quantitative evaluation of possible environmental risks and impacts. For the development of a shale gas play, water is mixed with proppant material (e.g. sand grains) and 0.5 – 1% of additives. Additives, such as acids, biocides, corrosion inhibitors and friction reducers are used to optimize the fracturing job.

Besides of flow-back water a varying amounts of production water will appear at the surface containing various salt compounds, gases, heavy metals, radioactive elements and organics. In order to investigate the mobility of Ca, Fe, S and trace elements such as Co, Cr, Cu, Mn, Mo, Ni, Pb, U, V, Zn and selected organic compounds during hydrofracturing we performed sequential leaching tests with 12 black shales from five locations in Europe and the US. Using five different artificial fracking fluids 24h short-term experiments were carried out at ambient pressure and temperatures of up to 100°C. Two long-term experiments lasting, respectively, 6 and 3 months, respectively, at 100°C / 100bar were performed with selected black shales from Bornholm, Denmark and Lower Saxony, Germany, using a fracking fluid with additives provided by the industry.

We characterized the black shales by XRD, XRF and ICP-MS following HF-$HClO_4$ dissolution before and after the experiments. Fluids were analysed by ICP-MS, IC, LC-OCD and Gas MS and GC.

The amount of dissolved constituents after the experiment is independent from the pH of the fracking fluid but highly dependent from the element content in the black shale and the buffering capacity of specific components, namely pyrite and carbonates. Shales containing carbonates buffer the solution at pH 7-8. Sulphide minerals (pyrite) become oxidized and generate sulfuric acid (H_2SO_4) leading to a pH of 2-3. Shales containing pyrite but only traces of, or lacking, carbonates give rise to low pH fluids responsible for the much higher concentrations of most dissolved cations (except e.g. Mo, Sr). In each experiment, less than 15% of a certain element contained in the black shale was mobilised into the fluid.

Orogenic Eclogites, Rutile and Trace Element Flux in the Subduction Zone

DARREN J. WILKINSON*, GODFREY FITTON, AND SIMON L. HARLEY

Grant Institute, The King's Buildings, West Mains Road, Edinburgh (*correspondance: D.J.Wilkinson@ed.ac.uk)

The geochemical evolution of the continental crust, oceanic crust and mantle is strongly influenced by complex geochemical processes occurring in the subduction zone. However, significant gaps exist in our understanding of these controls on the behaviour of important trace elements. Using orogenic eclogites from the Western Gneiss Region (WGR) of Norway as analogues for subducted oceanic crust, we quantitatively assess the behaviour of many of these elements.

Rare Earth Element (REE) and immobile High Field Strength Element (HFSE) compositions have shown that most Norwegian eclogites have E-MORB to N-MORB protoliths. Using elements thought to be highly immobile (e.g. Nb, Hf), we have estimated the likely total element flux for many more mobile trace elements.

We also assess the role of accessory rutile in controlling HFSE flux from the slab. Nb/Ta as well as Zr/Hf ratios in rutile vary from sub- to superchondritic, yet mean grain compositions appear essentially chondritic (19.9, 34.5 respectively). Whole rock samples reflect this variance on a much larger regional scale, since average ratios for eclogites across the whole WGR are also chondritic. We discuss possible explanations and consequences for heterogeneity in these processes.

The ε^{182}W isotope composition of the ca. 3920 Ma Acasta Gneiss Complex

M. WILLBOLD[1,3], S. J. MOJZSIS[2] AND T. ELLIOTT[3]

[1]Imperial College London, Earth Science and Engineering, London, SW7 2AZ, United Kingdom; (m.willbold@imperial.ac.uk)
[2]University of Colorado, Geological Sciences, Boulder, Colorado 80309-0399, USA; mojzsis@colorado.edu
[3]University of Bristol, School of Earth Sciences, Bristol, BS1 8RJ, United Kingdom; (tim.elliott@bristol.ac.uk)

The short-lived ^{182}Hf-^{182}W decay system ($t_{1/2}$ ca. 9 Myr) is a useful tracer to investigate accretionary and geodynamic processes on the early Earth. Variable enrichments in ^{182}W/^{184}W – expressed in the conventional ε^{182}W notation – have been documented in Eoarchean crustal rocks. These data were interpreted by invoking either a 'Late Veneer' model [1], or via early Earth differentiation processes_ENREF_2 [2]. Here we report the first ε^{182}W measurements for rocks from the Acasta Gneiss Complex (AGC), a terrane located on the western margin of the Slave craton in the Northwest Territories (Canada). The AGC is the oldest known crustal domain with primary magmatic ages that are about 3,920 Ma [3]. It is also apparent that these rocks inherited a much older (ca. 4,200 Ma) crustal component [4]. Our samples include granitoid gneisses and plagioclase-hornblende schists that define a range in ε^{182}W values comparable to those found in rocks from the ca. 3,800 Ma Isua Supracrustal Belt in southern West Greenland, which formed the basis of the 'Late Veneer' model presented in [1]. Using these new values for the AGC in conjunction with previous data, we test the two models for the W isotopic evolution of bulk silicate Earth in the terminal Hadean. Our results provide new motivation in the search for other daughter products of extinct nuclides (e.g. ^{142}Nd) in the AGC.

Archean Mo isotopic evolution: Comparing the Pilbara and the Kapvaal Cratons

M. WILLE[1], F.KURZWEIL[1], S. EROGLU[1] R. SCHOENBERG[1], N. BEUKES AND M. VAN KRANENDONK[3]

[1]Dept. of Geoscience, University of Tuebingen,Wilhelmstr. 56, 72074 Tuebingen, Germany
[2]University of Johannesburg, Auckland Park Kingsway Campus, 2006, South Africa
[3]School of Biological, Earth and Environmental Sciences, University of New South Wales, Kensington, NSW 2052, Australia

The environmental and geochemical circumstances which led to heavy Mo isotopic signatures in Archaean sediments remains elusive. Sufficiently oxidising conditions, which enable mobility of Mo in its highest oxidation state, are generally seen as one precondition for the formation of such an isotopically heavy Mo seawater reservoir. However, interpretation of temporal changes in Mo isotopic compositions stored within ancient sediments is often hampered by the fact that they are strongly influenced by paleo-environmental conditions during sediment formation. As such, sedimentary Mo isotopic signatures different to that of the continental crust are often only qualitative rather than quantitative indicators of changes in environmental redox conditions.

Here we present Mo stable isotope datasets, published and new data, from different 3.46 to 2.5 Ga old sedimentary environments from the Pilbara (Australia) and Kapvaal (South Africa) Cratons, respectively. Mo isotopic results for ≥2.76 Ga old sedimentary rocks are within the field of continentally derived detritus, indicating insufficient O_2 levels required to oxidize and mobilize this element. In contrast, Mo isotopic signatures in sediments ≤2.7 Ga are isotopically heavier than sedimentary material solely continent derived. Comparing the Pilbara and the Transvaal general trend to heavier Mo isotopic values in Mo isotopic evolution can be seen in both basins approaching 2.5Ga. These heavier Mo isotopic signatures, in conjunction with the apparent elevated concentrations of other redox sensitive elements, such as U and Re, after 2.7 Ga suggests aquatic mobilization of these elements under sufficient O_2 levels. The comparison of Mo isotopic variations in different contemporary environmental sedimentary setting allows us to ascertain the reasons for the observed Mo isotopic fluctuations.

Temporal evolution of detrital cosmogenic denudation rates in transient landscapes from *in situ*-produced and meteoric ^{10}Be

J.K. WILLENBRING[1]*; N. M. GASPARINI[2], B.T. CROSBY[3], G. BROCARD[1], M.E. OCCHI[1] AND P. BELMONT[4]

[1]Department of Earth and Environmental Sciences, University of Pennsylvania, Philadelphia, PA, USA
[2]Department of Earth and Environmental Sciences, Tulane University, New Orleans, Louisiana, USA
[3]Department of Geosciences, Idaho State University, Pocatello, Idaho, USA,
[4]Department of Watershed Sciences, Utah State University, Logan, Utah, USA, (*jane.willenbring@sas.upenn.edu)

In equilibrium landscapes, ^{10}Be concentrations within detrital quartz grains are expected to quantitatively reflect basin-wide denudation rates. In transient landscapes, though detrital quartz is derived from both the incising, adjusting lowland and the unadjusted, relict upland, the integrated ^{10}Be concentrations still provide a denudation rate averaged across the two domains. Because field samples using in situ-produced ^{10}Be can only provide a snapshot of the current upstream-averaged erosion rate, we employ a numerical landscape evolution model to explore how ^{10}Be derived denudation rates vary over time and space during long-term transient adjustment. Model results suggest that the longitudinal pattern of mean erosion rates is generated by the river's progressive dilution of low-volume, high-concentration detritus from relict uplands by the integration of high-volume, low-concentration detritus from adjusting lowlands. The proportion of these materials in any detrital sample depends on what fraction of the upstream area remains unadjusted.

On shorter timescales, a single storm can induce transience in a landscape. Meteoric ^{10}Be concentrations can be measured in submilligram-sized sediment samples and this attribute enables us to measure suspended sediment through a hydrograph. The meteoric ^{10}Be concentration in river sediment changes with the source areas and fluxes of material supplied to the stream. The average concentration from the couplet of the rising and falling limbs of the hydrograph can differ from the concentration of the sediment that is preserved in depo-centers. Using this short timescale system, we reconsider how to interpret paleoerosion rates from depo-centers derived from meteoric and *in situ*-produced ^{10}Be concentrations.

Temporal Variability of Coastal Rainwater Fe(II) Concentration and Wet Deposition to Surface Seawater

J.D. WILLEY, B.C. RICE, J.J. HUMPHREYS, R.J. KIEBER, J.R. HELMS, G.B. AVERY AND R.N. MEAD

[1]University of North Carolina Wilmington, Department of Chemistry and Biochemistry, Wilmington, NC USA 28403-5932 (*correspondence: willeyj@uncw.edu)

The concentration and stability of dissolved Fe(II) in rainwater collected in Wilmington, North Carolina, USA, have decreased by more than an order of magnitude in the preceding decade. Rainwater Fe(II) during the winter of 2003 was stable for more than 96 hours, whereas in 2011, concentrations decreased by 60% within 4 hours. A decade ago, rainwater Fe(II) was strongly complexed by organic ligands which stabilized it against oxidation. Currently Fe(II) appears to be present in rainwater predominantly as photochemically produced inorganic Fe^{2+}(aq). Spectral slope data indicates rainwater dissolved organic carbon (DOC) has become less conjugated and smaller in average molecular weight, consistent with less iron complexation. These changes in DOC may result from improved control of automobile emissions. Inorganic Fe^{2+}(aq) can be rapidly oxidized by H_2O_2 and, in rains with pH > 5 (half of all rains), by O_2. H_2O_2 has doubled in the last decade due to lower emissions of SO_2 (a sink for H_2O_2), which increases the oxidation rate of Fe^{2+}(aq) by approximately 30%.

A decade ago, rainwater was a source of soluble Fe(II) to surface seawater, where it is a phytoplankton nutrient. Because of the decreased concentration and stability of Fe(II) in rain, Wilmington NC rainwater is now a much smaller source of soluble Fe(II) to North Atlantic surface seawater, which may reduce primary productivity and hence lower CO_2 uptake in this region.

Iron isotope fingerprinting of mantle mineralogy

HELEN M. WILLIAMS [1] AND MICHAEL BIZIMIS [2]

[1]Dept. Earth Sciences, Durham University, Durham, DH1 3LE, UK; (h.m.williams2@durham.ac.uk)
[2]Dept. Earth and Ocean Sciences, University of South Carolina, Columbia, SC 29208; (mbizimis@geol.sc.edu)

Mineralogical and lithological variations in the Earth's mantle have important implications for mantle dynamics, magma generation, and the fate of recycled surface material. Directly tracing such variations is challenging. While the elemental and radiogenic isotope compositions of mid oceanic ridge and ocean island basalts (MORB and OIB respectively) are thought to reflect variable amounts of enriched mineralogies within the mantle, in the form of pyroxenite or eclogite derived from oceanic crust or metasomatised lithosphere, directly linking geochemical and mineralogical variation is difficult. Iron (Fe) stable isotopes potentially offer a solution to this problem, as the Fe isotope compositions (δ57Fe) of mafic rocks primarily reflect mineral-specific partitioning [1, 2]. Here we present Fe isotope data for sub-oceanic lithosphere peridotite and pyroxenite xenoliths from Oahu, Hawaii and demonstrate that Fe isotopes can be used as a new tracer of mantle mineralogical heterogeneity. Pyroxenite δ57Fe values are heavy (0.10 to 0.27‰) relative to MORB and OIB (δ57Fe ~ 0.15‰) [3-6] and reflect isotopic fractionation during magmatic differentiation and pyroxene cumulate formation at the lithosphere-asthenosphere boundary. In contrast, peridotites have light δ57Fe values (–0.34 to 0.14‰) that correlate with elemental and radiogenic isotope tracers of melt extraction, providing evidence for Fe isotope fractionation during partial melt extraction and the generation of depleted, low- δ57Fe peridotitic residues. The heavy δ57Fe values of MORB and OIB relative to mantle peridotites can therefore be explained by partial melting, where isotopically heavy Fe is preferentially concentrated in the melt phase. However, the considerable range in MORB and OIB δ57Fe requires a δ57Fe -heterogeneous mantle, containing enriched (pyroxenite, heavy δ57Fe) and depleted peridotite (light δ57Fe) domains. Iron stable isotopes thus provide a powerful new means of fingerprinting mineralogical variations within the Earth's mantle and identifying depleted and enriched components within the source regions of volcanic rocks.

Oxygen isotope compositions of phosphatic conodont microfossils are a more robust indicator of early Paleozoic sea surface temperatures than the O compositions of calcitic brachiopods. SIMS microanalysis allows conodont O compositions to be determined on an ~30 μm scale, so the isotopic homogeneity of individual conodont elements and of multiple elements from a single rock sample can be assessed. Analyses can be obtained on very small and/or rare specimens, and targeted on those parts of conodonts that are best preserved. Differences in composition between co-existing species from different biofacies can be measured. SIMS analyses, however, are less precise and more sensitive to differences in the chemical composition of the sample than conventional IRMS analyses. The latter is important because the conodont crown can consist of two tissue types: albid—large (>100 μm) crystals containing mostly PO_4, and hyaline—microcrystals with PO_4 and some CO_3, and a higher trace element content. Some conodonts also contain poorly mineralised basal tissue that can be isotopically contaminated. In addition, conodont crystal structure can be modified at temperatures above ~100°C. No conodont sample is available that is both isotopically uniform and abundant enough to be distributed between SIMS and IRMS labs as an O isotope standard. SIMS measurements are currently referenced to a mineral apatite standard (Durango 3 at ANU), and potential systematic bias is assessed by comparing SIMS and IRMS analyses of large bioapatite samples (e.g. shark enameloid), and of conodonts from the same or closely equivalent rock samples. As part of our study of sea surface temperatures at critical periods of biotic crisis and environmental change in the Paleozoic and Early Mesozoic using conodont O isotopes, we have addressed issues of bias, inter- and intra-conodont heterogeneity, and thermal alteration (as indicated by Colour Alteration Index). In some samples we find O variation within and between elements, but more commonly there is inter- and intra conodont uniformity between genera and species in a single rock sample within the sub-permil precision of the measurements. The rare exceptions have both biological and geological explanations.

Linking fluvial processes and elemental cycling within the Old Rifle, CO aquifer

K.H. WILLIAMS[1]*, M.J. ROBBINS[1], S.B. YABUSAKI[2] AND P.E. LONG[1]

[1]Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA, (*correspondence: (khwilliams@lbl.gov)(, mjrobbins@lbl.gov,) (pelong@lbl.gov)

[2]Pacific Northwest National Laboratory, Richland, WA 99352, USA (yabusaki@pnnl.gov)

A successive series of biostimulation experiments within the Old Rifle, CO (USA) aquifer since 2002 have focused on biogeochemical pathways arising from organic carbon injection and its role in mediating the cycling of iron, manganese, sulfur, uranium, vanadium, arsenic, and selenium. While most have concentrated on reductive pathways and their impact on contaminant mobility, recent studies have begun to explore oxidative pathways and their impact on metals dynamics, carbon modification, and the long-term viability of reductive immobilization as a remedial strategy. Insights gained from such experiments have shed light on analogous natural biogeochemical pathways that mediate element cycling in the absence of exogenous carbon amendment. Within the aquifer, such pathways are often seasonal and correlate with excursions in groundwater elevation of 1-2m associated with increased discharge in the Colorado River during spring/summer snowmelt. Imbibition of oxygen bubbles within the capillary fringe associated with such excursions is inferred to be the primary contributor to seasonally oxic groundwater, with its impact on redox-mediated reactions exhibiting close correspondence to intentional introduction of oxidants.

Superimposed upon natural and artificial redox fluctuations are relic signatures of the depositional fabric of alluvial accumulation. Specifically, ferromanganese-encrusted cobbles accumulated as channel fill deposits serve as an effective vector for iron and manganese delivery during incipient accretion of the aquifer materials. Post-depositional redox processes and oxygen incursion associated with groundwater level fluctuations enable redistribution and mineralization of iron and manganese throughout the aquifer, with subsequent implications for carbon and metals transformations. Linking such pathways within the context of a 'porous subsurface bioreactor' constitues an ambitious yet tractable means for quantifying elemental fluxes at the floodplain and potentially larger scales.

Petrologic implications of magmatic underplating: Observations from the Athabasca granulite terrane

M.L. WILLIAMS[1]*, S.J. SEAMAN[1] AND G.C. KOTEAS[2]

[1]Dept. of Geosciences, Univ. of Masschusetts, Amherst, Ma 01003 (*correspondence: mlw@geo.umass.edu)

[2]Dept. of Geology, Norwich Univ., Norwich VT

The Chipman mafic dike swarm, Athabasca granulite terrane, Saskatchewan, CA, provides a field example of mafic magmatic intraplating in the deep continental crust. The Chipman dikes were emplaced at 1.0-1.2 GPa (35-40 km) at 1.9 Ga, possibly above a magmatic underplate. The dikes are dominated by Hbl and Pla with minor Cpx. Host rocks include the 3Ga Chipman tonalite and 2.6Ga Fehr and Stevenson granites. Several effects of underplating have been documented, including tonalite genesis, granite genesis and contamination, garnet growth, and crustal densification. Only limited melting was induced in the Chipman tonalite during underplating and intraplating. Instead, the mafic dikes themselves were partially melted to Grt + tonalite. Leucosomes occur in strain shadows associated with garnet. Where melting was extensive, individual leucosomes have coalesced and tonalite dikes and veins are common. Within the Fehr granite/gneiss, partial melting was extensive. Leucosome veins, pods, and pools apparently represent the products of several melting reactions, including hydrous modal melting and both biotite and hornblende dehydration melting. Granitic partial melt apparently accumulated in an early (S1) foliation and then was mobilized during formation of a "megacrenulation" into S2. This "pumping" mechanism provides one model for melt segregation in the deep crust. Subsequent Chipman dikes mingled and mixed with the new granitic magma producing a wide range of hybrid compositions. With increasing extent of granite melting, Chipman dikes are more irregular in geometry, apparently trapped by the granite mush. Magmas moving to higher levels probably evolve from mafic to contaminated intermediate and felsic compositions over time. Other granitoids in the region were apparently heated and deformed but not melted during dike emplacement and underplating. One common reaction involves Opx + Pla = Grt + Cpx. Extensive Grt production leads to increased density, up to 3.0 g/cm^3 even in felsic rocks and may play a role in stabilization and possibly delamination of lower continental crust. Based on the Athabasca example, underplating can initiate a number of positive and negative feedbacks that ultimately result in dramatic and probably irreversible changes in character, rheology, composition of the overlying crust.

Rare Earth Element ore genesis: The Great Unknown

ANHONY E. WILLIAMS-JONES[1]

[1]Earth and Planetary Sciences, McGill University, Montreal, Canada, (anthony.williams-jones@mcgill.ca)

Economic or potentially economic REE deposits are hosted by or genetically associated with alkaline igneous rocks and carbonatites. Primary REE enrichment in silicate magmas depends on the highly incompatible nature of the REE, may be facilitated by fluoride complexation, and occurs at late stages of magma evolution through crystal settling and crystallisation of residual, fluid-saturated liquids including immiscible fluoride melts. Carbonatite magmas likely owe their REE enrichment to the high solubility of the REE, and their preference for the LREE to the similar ionic radii of Ca^{2+} and Ce^{3+}; HREE are smaller.

Hydrothermal mobilisation may be essential to the economic viability of many REE deposits. Indeed, the World's largest deposit, Bayan Obo, China, is dominantly hydrothermal. Although aqueous fluoride complexes are widely thought to be the main agent of REE transport, modelling of natural systems suggests that this is not the case. Instead, chloride complexes appear to be responsible for REE transport. Moreover, experiments suggest that REE chloride complexes can cause the observed preferential LREE mobility. Hydrothermal concentration of REE occurs when interaction of acid REE-Cl-bearing fluids with pH-buffering rocks, or mixing with neutral fluids, and/or decreasing temperature, induces REE mineral deposition.

LA-ICPMS^2: Laser ablation sampling with combined ICP-Q-MS and MC-ICP-MS detection for simultaneous trace elemental and isotope ration analyses

JULIAN D. WILLS[1], NICHOLAS LLOYD[1], LOTHAR ROTTMANN[1], CLAUDIA BOUMAN[1] AND STEVE SHUTTLEWORTH[2]

[1]Thermo Fisher Scientific, Hanna-Kunath-Strasse 11, 28199 Bremen, Germany, (julian.wills@thermofisher.com)
[2]Photon Machines Inc, USA

In situ analysis by laser ablation offers significant advantages to users in a range of applications including geochronology but interrogating the sample for all of the information required may not be possible in a single measurement. Laser ablation is a destructive sampling technique and while many samples are large enough to allow for multiple analyses on a range of instruments, geochronologically relevant samples are often so small as to preclude multiple analyses. These samples are often unique and once sampled by laser ablation, they are lost and no further information can be extracted.

In this presentation, a system for the simultaneous isotopic and elemental characterization of zircon (ZrSiO4) is described. A high performance 193nm excimer laser (Photon Machines Analyte G2) is used to sample ~50 μm diameter pits in the zircon, and the He carrier gas containing the entrained sample is split between ICP-Q-MS and MC-ICP-MS systems. A new high performance ICP-Q-MS system (Thermo Scientific iCAP Q) is used for the quantification of trace elements (both transition metals and rare earth elements) and MC-ICP-MS (Thermo Scientific Neptune Plus) is used for high precision Pb and Hf isotope ratio measurements.

The advantages afforded by such combined, simultaneous isotopic and elemental analyses of growth zones of minerals will be highlighted in the presentation

Deep ocean circulation and its link to carbon storage through glacial cycles

D.J. WILSON[1,2]*, A.M. PIOTROWSKI[2], A. GALY[2] AND V.K. BANAKAR[3]

[1] Department of Earth Science and Engineering, Imperial College London, London, SW7 2AZ (*correspondence: david.wilson1@imperial.ac.uk)
[2] Department of Earth Sciences, University of Cambridge, Cambridge, CB2 3EQ
[3] National Institute of Oceanography, Dona Paula, Goa, 403 004, India

Storage of carbon in the deep ocean during glaciation and its release during deglaciation is widely called upon in order to explain glacial-interglacial changes in atmospheric CO_2 [1,2], but the mechanisms involved remain uncertain and the locations of carbon storage are poorly quantified through time. Changes in water mass volumes in the global ocean exert one first order control on carbon storage [3], suggesting a sensitivity of atmospheric CO_2 to reorganisations of ocean circulation. However, modelling studies tend to disagree over the nature and timing of paleoceanographic changes influencing atmospheric CO_2 [4,5].

Better paleoceanographic constraints are therefore required, particularly from the deep Indo-Pacific, which has significant potential for carbon storage during glacial periods. Here we characterise its chemical evolution over the last 250 thousand years using Nd isotopes (ε_{Nd}) and benthic carbon isotopes ($\delta^{13}C$) in deep Indian Ocean core SK129-CR2 [6]. The ε_{Nd} record indicates a significant glacial reduction in the North Atlantic Deep Water component in Circumpolar Deep Water, consistent with increased oceanic carbon storage [3]. However, the ε_{Nd}-$\delta^{13}C$ relationship evolves over the course of each glacial cycle, indicating a changing global distribution of water masses and carbon. During glaciation and early glacial periods, ε_{Nd} and $\delta^{13}C$ are decoupled, revealing carbon cycling changes that are independent of Atlantic circulation changes. This decoupling may reflect the processes involved in carbon sequestration in Antarctic Bottom Water at these times. In contrast, coupled ε_{Nd}-$\delta^{13}C$ changes during late glacials and deglaciation suggest a close link between deep ocean circulation and carbon release to the atmosphere.

The uptake of arsenic (As) in calcite may represent an important immobilization process for As in calcareous rocks. Nevertheless, knowledge on this retention mechanism in the natural environment is limited since As incorporation in calcite has mostly been studied on synthetic samples.

We identified very high levels of As (up to 913 mg/kg) in travertine deposits derived from geothermal As-enriched groundwaters on the Greek peninsula Chalkidiki.. We analyzed two different types of travertine from this region using both bulk and micro-focused X-ray absorption spectroscopy (XAS and μ-XAS) and micro-focused X-ray fluorescence spectroscopy (μ-XRF) to determine the mechanism of arsenic uptake in the travertines[1]. Bulk XAS showed that in all of the studied samples As is present as arsenate (As[V]), and μ-XRF analyses revealed that As is closely associated with the calcite matrix. Iron on the other hand was found to be mainly present as a constituent of clay minerals, of presumably detrital origin, suggesting that Fe-(hydr)oxides were not sufficiently abundant to act as major scavengers for As in the Chalkidiki travertines.

From our results we estimate that the natural travertines could sequester at least 25% of groundwater As(V) via co-precipitation with calcite. The formation of As-enriched calcite is thus an efficient mechanism to immobilize As in the geothermal groundwaters of Chalkidiki and could possibly also occur in other environments characterized by high As and CO_2 contents.

Role of climatic factors on the terrestrial distribution of selenium

LENNY H.E. WINKEL[1,2], BAS VRIENS[1], TIM BLAZINA[1], RITA SCHUBERT[1], AND C. ANNETTE JOHNSON[1]

[1]1Eawag: Swiss Federal Institute of Aquatic Science and Technology, 8600 Duebendorf, Switzerland, (*correspondence: lenny.winkel@eawag.ch), bas.vriens@eawag.ch, tim.blazina@eawag.ch, rita.schubert@eawag.ch, annette.johnson@eawag.ch

[2]Swiss Federal Institute of Technology (ETH) Zurich, 8092 Zurich, Switzerland, lwinkel@ethz.ch

Selenium (Se) is of key importance for human health . However, due to the highly uneven global distribution of selenium in agricultural soils, it is estimated that 0.5 to 1 billion people have too low Se intake. As a result Se supplementation and fortification of foods are being increasingly discussed as possible strategies for improving human Se status. Despite observations that the Se distribution in the natural environment is closely related to human health issues and our growing awareness of the importance of this element, the behavior of Se in the natural environment is still poorly understood. It is therefore of major importance to better understand the factors that control this distribution.

The atmosphere is an important transient reservoir for Se, which is largely fed by volatile Se compounds formed via biomethylation in marine and terrestrial environments. In turn, the atmosphere can also function as a source of terrestrial Se when it is returned to the Earth's surface via wet and dry deposition. In this talk we will give new insights into the processes that are relevant to the atmospheric Se reservoir. We will also present new evidence on how climatic conditions play a major role in the large-scale terrestrial Se distribution, both directly as a source of Se (via atmospheric deposition) and indirectly by controlling pedoclimatic regimes and thus Se bioavailability. Therefore, it can be expected that changes in climatic conditions will have a significant impact on the Se distribution in the environment. We will show how climatic factors can be used to predict large-scale terrestrial Se distribution. This will be crucial in helping to understand and prevent future health hazards resulting from the uneven distribution of Se in the environment.

Reconstruction of humid phases in the Caribbean during the Late Pleistocene

SOPHIE WINTERHALDER[1,2]* , DENIS SCHOLZ[1] , AUGUSTO MANGINI[2], CHRISTOPH SPÖTL[3], THOMAS E. MILLER[4], AMOS WINTER[5], KLAUS PETER JOCHUM[6] AND JESÚS M. PAJÓN[7]

[7]National Museum of Natural History, Department of Paleogeography and Paleobiology, La Habana, Cuba

For the Caribbean, high-resolution terrestrial records are mainly available for the Holocene and suggest a linkage to North Atlantic climate variability (e.g. [1]). During the Late Pleistocene climate in the North Atlantic area was also subject to large and rapid changes, which are evident in climate records from Central America as well [2]. We present precise MC-ICP-MS ^{230}Th/U-dating, together with stable isotope and trace element data from three speleothems from Puerto Rico and Cuba, which grew between 80 and 7 ka BP. Growth phases of Caribbean speleothems are assumed to reflect humid phases in the tropical Atlantic. Stalagmite ENS2 from Puerto Rico grew in several phases (63-61, 40-39, 34-31 and 17-13 ka BP), coinciding with periods of weak East Asian Summer Monsoon recorded in speleothems from China [3]. A large stalagmite from Puerto Rico (Larga1) reveals a variable growth rate between 35 and 17 ka BP. Stalagmite CM from Cuba grew, interrupted by a few short-term hiatuses, between 80 and 7 ka BP. High-resolution multi-proxy (stable isotope and trace element) records from these speleothems are currently in preparation. They will deliver a deeper understanding of climate variability during the Late Pleistocene in the tropical Atlantic region and identify potential teleconnections to the North Atlantic.

H in garnet: Implications for upper mantle H_2O storage capacity

ANTHONY C WITHERS AND MARC M HIRSCHMANN

Dept of Earth Sciences, University of Minnesota, MN, USA

The maximum amount of H_2O that can be stored in mantle minerals without saturation to stabilise a fluid or melt (the H_2O storage capacity) varies as a function of pressure, temperature and peridotite phase assemblage. The systematics of H_2O storage capacity in olivine and pyroxene are relatively well established. The H_2O storage capacity of nominally anhydrous garnet, on the other hand, is poorly understood. Measurements of H in pyropes synthesised in hydrothermal experiments at 1000 °C suggest that the hydrogarnet component becomes destabilised at pressures greater than 7 GPa [1], suggesting that under conditions approaching those of the transition zone, where garnet makes up an appreciable proportion of the mantle, garnet does not contribute significantly to the mantle H_2O storage capacity. Annealing of natural pyrope under similar conditions of P and T, however, suggest that other types of H defect may result in pyrope storage capacities approaching 200 ppm H_2O at 10 GPa [2]. In contrast, H contents in excess of 1000 ppm H_2O were measured in natural, Fe-bearing pyropic garnet that was hydrothermally annealed in the presence of olivine at 1100 °C at pressures up to 9 GPa [3]. If such elevated H_2O storage capacities are applicable to mantle garnet, H_2O fluxed melting of the upper mantle overlying the transition zone would require bulk H_2O concentrations in excess of 600 ppm [4].

We have examined the systematics of H incorporation in pyrope in 24h hydrothermal experiments at 2-8 GPa and 1400 °C. Platinum capsules were loaded with 2 compositional layers such that the upper part of the capsule contained pure pyrope (py) composition and the remainder a mixture of forserite (fo), enstatite (en) + 5 wt.% Al_2O_3. Buffering of SiO_2 activity by growth of fo and en during experiments was verified by Raman spectroscopy. Grain growth in the py composition layer was facilitated by lack of grain boundary pinning. FTIR spectra of 100-700 µm pyropes from experiments at 4, 6 and 8 GPa all display a characteristic hydrogarnet absorption band. Our preliminary results suggest that H content is close to 235±75 ppm H_2O over this pressure range. At mantle temperatures, it is unlikely that garnet is a major contributor to bulk mantle H_2O storage capacity.

Comparison of LDI and ESI to study natural organic matter on the molecular level by FT-ICR mass spectrometry

M. WITT[1]

[1]Bruker Daltonik GmbH, Bremen, Germany

FT-ICR mass spectrometry of NOM

Fourier Transform ion cyclotron resonance (FT-ICR) mass spectrometry (MS) is a well known method to study natural organic matter (NOM) on the molecular level. Mainly electrospray ionization in negative ion mode is used to detect compounds in this complex mixture. However, also Laser/desoption ionization (LDI) in negative ion mode can be used to study NOM. LDI has been used recently to analyze crude oil by FT-ICR mass spectrometry [1]. LDI has the advantage to be independent of the solvent. Several NOM standards have been analyzed by ESI and LDI for comparison of both ionization techniques. Additionally the effect of collison energy and laser power has been studied.

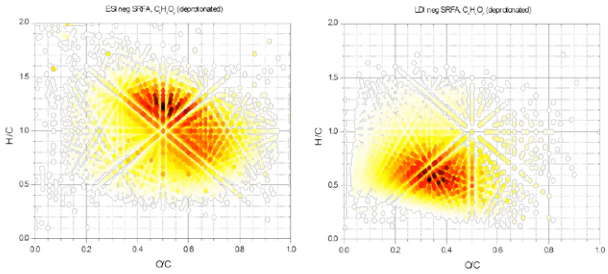

Figure 1: Van Krevelen plots of ESI- and LDI-FT-ICR MS measurement of Suwannee river fulvic acid

Discussion and results

Calculations of the molecular formulas of detected compounds were based on exact mass measurements using ultra-high resolution and high mass accuracy of FT-ICR mass spectrometry. Lower H/C as well as O/C ratios have been observed in LDI than ESI. This effect is shown in the Van Krevelen plots of Suwannee river fulvic acid in Figure 1. Therefore, highly aromatic compounds are ionized using LDI at UV-wavelength of 355 nm.

Collision induced fragmentation results mainly in a loss of CO_2. However, experiments with high laser power results only in a loss of water.

Determination and comparison of acidic gas ratios at the Stromboli Volcano and Mount Etna obtained by various active alkaline traps

J. WITTMER[1*,2], N. BOBROWSKI[2], M. LIOTTA[3,4], G. GIUFFRIDA[4], S. CALABRESE[5] AND U.PLATT[2]

[3]Second University of Naples, Dip. DiSTABiF,Caserta,Italy

[4]Istituto Nazionale di Geofisica e Vulcanologia,Palermo,Italy

[5]University of Palermo, Dip. CFTA, Palermo,Italy

Determining volcanic gas composition by direct plume sampling is still challenge in volcanic research. At most volcanoes (e.g. Stromboli volcano, Italy) scientists have to deal with difficult access to the plume, strong atmospheric dilution and varying weather conditions making a high sampling performance necessary.

Besides a more accurate quantification of the main acidic gas compounds (CO_2, SO_2, H_2S, HCl) a reduction of detection limits for less abundant species (HF, HBr, HI) were achieved in this work. For this purpose a Raschig-Tube [1] was modified and utilized for the application on volcanic plumes. The theoretical and experimental absorption properties of the Raschig-Tube (RT) and the Drechsel bottle (DB) [2] set-ups were characterized and afterwards applied simultaneously to the well-established Filter packs technqiue (FP) in the field (on Stromboli and Mount Etna). The obtained results make a comparison between the set-ups possible and help to point out the potential weakness and strength of each set-up. Additionally, the analytical procedure, including sample preparation, analysis by Titration, Ion Chromatography and Inductively Coupled Plasma Mass Spectrometry, was optimised to accurately quantify molar concentrations of dissolved compounds.

The progress in sampling and analysis led to a significant data set that covers most of the important elements. In particular, less abundant species were quantified more accurately due to the RT technqiue. Therefore, even iodine could be detected at Stromboli. Besides difficulties to determine fluorine and carbonate, influences of saturation effects on the FP results could be observed and characterized.

[5]Ion Beam Centre, Advanced Technology Institute, University of Surrey, Guildford GU2 7XH, UK

Solute mobility in geochemical fluids depends strongly on both the physical properties of the host lithology as well as mineral surface reactivity. Due to the extremely slow rates of diffusion and the typically dilute concentrations of radionuclides involved in disposal scenarios, constraining physical and chemical processes for use in risk models is challenging. Therefore predictions about the mass transfer of contaminants over time periods pertinent to geological disposal facilities (10^5 to 10^6 years) require both reliable measurements of adsorption and robust determinations of diffusive flux. Here we will present results from spectroscopic measurements designed to provide chemical details of the process of surface attachment of key radionuclides (U, Tc, Sr, Cs) to a number of mineral surfaces (magnesite, brucite, portlandite, magnetite, phyllosilicate, K-feldspar, plagioclase feldspar) that will be exposed under a range of repository conditions (pH 6-13, reducing and oxidizing conditions, low and high PCO_2). EXAFS, both standard and polarization dependent, has been used to provide unambiguous information regarding surface adsorbate bonding geometries. Evolution of surface morphology and details of thin films or surface precipatates has been studied using x-ray reflectivity and glancing incidence XRD. Bulk adsorption experiments have also been completed in order to meaasure mass uptake as a function of concentration. In addition, diffusion through low permeability rock matrices (which include the minerals used in the adsorption studies) has been directly determined via both flow-through (micro-reactor) and *in situ* (Multiple internal reflection-FTIR) experimentation. Direct measurements of contaminant uptake and diffusion length have been completed using proton induced x-ray emission (PIXE) coupled with Rutherford Back-Scattering (RBS).

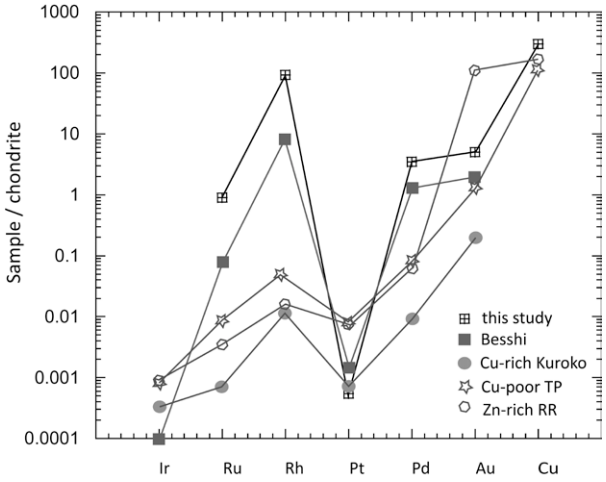
Formation and metamorphism of the Upper Sulfide Zone of the Salt River VMS deposit (South Africa)

CORA C. WOHLGEMUTH-UEBERWASSER[1,2], FANUS VILJOEN[1] AND CRAIG R. MCCLUNG[1]

[1]Paleoproterozoic Mineralization Group (PPM), Department of Mineralogy, University of Johannesburg, South Africa; (cora@geoinventio.de)

[2]PetroTectonics Centre, Department of Geological Sciences, Stockholm University, Sweden

Sulfides from the upper sulfide zone of the Salt River VMS (South Africa) were analyzed for PGE (platinum group elements), Re, Au, Sb, As, Se, Te, Cr, Co, Ni, Mn, Mo, Ag, Hg and Pb using in-situ LA-ICP-MS (laser ablation-inductively coupled plasma-mass spectrometry) techniques. The analysis of a plethora of trace elements during the ablation of one single spot was possible by using a multi standard approach, involving the analysis of several external standards before, after and between the analysis of unknowns. Chondrite normalized PGE patterns best fit data from Besshi-type deposits, implying the formation within a back-arc basin environment.



This conlusion can be drawn although the Salt River VMS deposit experienced peak amphibolite metamorphism as metamorphism of the deposit was isochemical with respect to the PGE and Au.

Surface topography controls on calcite growth kinetics: From Molecular Dynamics simulations to macroscopic-scale modelling

MARIËTTE WOLTHERS,[1,2]* DEVIS DI TOMMASO,[1] ZHIMEI DU[1] AND NORA H DE LEEUW[1,2]

[1]Department of Chemistry, University College London, 20 Gordon Street, London WC1 H0AJ, U.K. (* Correspondence: m.wolthers@ucl.ac.uk)

[2]Department of Earth Sciences-Geochemistry, Utrecht University, P.O. Box 80021, 3508 TA Utrecht, the Netherlands.

Cation dehydration is generally accepted to be the rate-limiting step to ionic crystal growth from aqueous solution. Our classical Molecular Dynamics simulations show a variation in water exchange frequency at structurally distinct calcium sites in the calcite surface of about two orders of magnitude. A process-based calcite growth kinetics model has been re-parameterized, using the water exchange frequencies computed from our molecular dynamics simulations, to represent the attachment frequencies of carbonate and bicarbonate ions. This calcite growth kinetics model illustrates the impact of variations in attachment frequencies on kink-formation frequency (Figure 1), step velocities and bulk growth rate. The calculated frequencies of kink formation show a strong variation with surface structures, which can be amplified further depending on the saturation state and calcium-to-carbonate ratio in the aqueous solution. Modelled and measured step velocities and bulk growth rates are generally in agreement, showing that surface topography might at least partially induce variations in calcite growth rates and step velocities as observed experimentally.

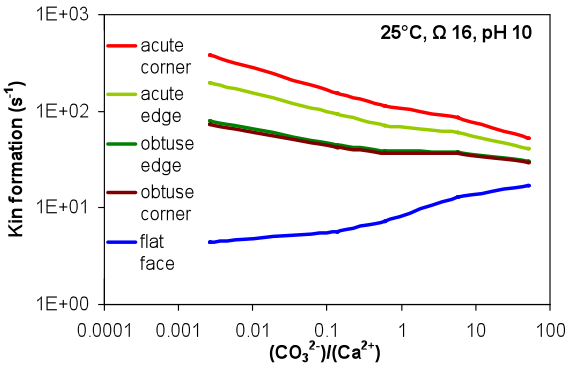


Figure 1: Variation in kink formation frequency with surface topography.

Trace elements in Catanda carbonatitic massif (SW Angola)

WOLKOWICZ STANISŁAW* BOJAKOWSKA IZABELA, WOLKOWICZ KRYSTYNA, AND SMAKOWSKI TADEUSZ

PGI-NRI, 4 Rakowiecka, 00-975 Warsaw, Poland (stanisław.wolkowicz@pgi.gov.pl)

The Catanda carbonatite massif (SW Angola) is built mainly of lapilli and lapilli-ash tuffs, ash tuffs, carbonatites and granulated carbonatites.

The studies covered 43 samples of rocks of the massif. Concentrations of Sc, Y, Li, Ta, Zr, Nb, Th, As, Ba, Co, Cr, Cu, Ga, Hf, Mo, Ni, Pb, Rb, Sr, U, V, Zn and REE were determined by the ICP-MS and ICP-OES methods after dissolving the rocks in aqua regia.

Concentrations of radioactive elements are rather low. U concentrations range from 1 to 20 ppm. Mean levels in tuffs (8.6 ppm) is higher than in lavas (5.9 ppm). Th contents range from 5 to 52 ppm. Mean levels of Th tend to be higher in lavas (30.4 ppm) than in tuffs (28.8 ppm). Nb concentrations range from 14 to 652 ppm, with mean levels equal 383 ppm for tuffs and 285 ppm for lavas. Li contents range from 9 to 55 ppm, attaining 21 ppm at the average. Cr concentrations range from 25 to 161 ppm, being markedly higher in tuffs (49 ppm) than in lavas (33 ppm). Cu contents range from 11 to 356 ppm, being much lower in tuffs than in lavas (29 and 48 ppm at the average, respectively). V concentrations range from 33 to 222 ppm (98 ppm at the average). Zn contents change from 57 to 551 (124 ppm at the average). Ba concentrations change from 250 to 1700 ppm (950 ppm at the average). Sr contents change from 0,08 to 0,54%, with mean levels clearly higher in carbonatite lavas (0.21%) than in tuffs (0.16%). Concentrations of Ga, Hf, Ni, Pb, As and Co are low and poorly differentiated as they appear generally unrelated to petrology. The rocks are also enriched in REE, especially LREE (La, Ce, Pr and Nd). Sum REE contents range from 0.25 to 0.95%. The concentrations were found to be markedly higher in tuffs (avg. 0.33%) than in carbonatite lavas (0.21%).

Carbonatite lavas of the Catanda Massif are characterized by higher mean levels of Cu, Zr, Th and HREE and the tuffs – by higher mean levels of Cr, U, V, Rb, Mo, Zn, Nb, Li and LREE. In turn, concentrations of As, Ba, Ga, Hf, Ni, Pb, Y and Sc appeared not related to the types of rocks of that massif.

Mass-(in)dependent Cd isotope fractionation during evaporation

FRANK WOMBACHER[1] AND MARK REHKÄMPER[2]

[1] Institut für Geologie und Mineralogie, Universität zu Köln, 50674 Köln, Germany, (fwombach@uni-koeln.de)

[2] Dept. of Earth Science & Engineering, Imperial College, London SW7 2AZ, UK.

Here, we investigate large mass-dependent (MDF) and very small mass-independent fractionations (MIF) of Cd isotopes that result from the evaporation of liquid Cd into vacuum at 10^{-4} mbar and ~180°C [1].

Cadmium stable isotope data were obtained using a Neptune MC-ICP-MS. To resolve small mass-independent anomalies, residual Cd metal samples were analysed at high ion beam intensities typically >20V for ^{114}Cd and long analysis times (30 min.).

MDF in the residual Cd metal samples from vacuum evaporation experiments are well described by Rayleigh distillation with a vapor-residue fractionation factor α = 0.9900 for ^{114}Cd/^{110}Cd (i.e. 10.0‰) [1]. The observed fractionation is much less than predicted from kinetic theory (α_{kin} = (mass ^{110}Cd / mass ^{114}Cd)$^{0.5}$ = 0.9823; i.e. 17.7‰), a mismatch that is frequently observed, e.g. [2].

The accurate quantification of mass-independent fractionation (MIF) in residual Cd metals required that the large mass-dependent fractionation is accurately corrected. This is facilitated using the generalized power law and normalization to ^{110}Cd/^{114}Cd of the starting material [1]. After correction, deficits ranging from 8 to 28 ppm were well resolved for ^{111}Cd/^{114}Cd, ^{113}Cd/^{114}Cd and ^{116}Cd/^{114}Cd. The observed pattern is in accord with predictions from nuclear charge radii and thus indicate nuclear volume effects [3-6]. The preferential evaporation of ^{111}Cd, ^{113}Cd and ^{116}Cd may result from their more tightly bound 5s electrons and hence weaker metallic bonds in the liquid as previously suggested for Hg [7,8], another group 12 element. The observation of nuclear volume effects thus suggests that (metallic) bonding in the melt results in reduced fractionation factors.

Melts, fluids, crystals, sulphides, metals: Trace element partitioning and geochemical applications

BERNARD J. WOOD

Department of Earth Sciences, University of Oxford, U.K. (berniew@earth.ox.ac.uk)

First there was Goldschmidt [1], then there was lattice-strain [2], so what else is there to learn about partitioning behaviour? The answer is that we are now getting to the point where the geochemical problems are really interesting. Here are the things I will talk about:

Olivine-liquid partitioning and basalt genesis: Ni partitioning was completely understood long ago [3]. Ni contents of Hawaiian olivines hence seemed to require a pyroxenitic mantle source. New experimental olivine-melt partitioning data indicate however that they can be explained by relatively high temperature of melting of "standard" mantle.

Chalcophile elements in terrestrial and martian basalts: Chalcophile partitioning between sulphide melt and silicate melt is a simple function of the FeO content of the silicate melt. This means we can quantify the influence of residual sulphide on chalcophiles in terrestrial and martian melts. Residual sulphide appears to be critical to basalt generation on Mars.

Crystal-fluid partitioning of trace elements: Although crystal-fluid partitioning is difficult to systematize, applications of the lattice strain approach show that hydrothermal minerals record the compositions of the fluids from which they were generated when corrections for fluid speciation are applied.

The "melt-effect" and trace element partitioning: It is now possible to measure trace element activities in silicate melts using partitioning into metal as a monitor. The data are applicable to determination of melt composition effects on crystal-melt partitioning and other important properties such as volatility.

Metal-silicate partitioning and planetary core formation: We are just getting to grips with the high pressures of core formation on Earth and the effects of the light element in the core on partitioning between core and mantle. For Si, O and S these effects are large for many trace elements.

Temporal evolution of the Raahe-Ladoga Shear Complex, Finland: Constraints from a sheared granitoid in the Pielavesi Shear Zone

J.WOODARD[1]*, P. TUISKU[1], A. KÄRKI[1] AND H. HUHMA[2]

[1]Department of Geosciences, University of Oulu, FI-90014 Oulu, Finland (*jeremy.woodard@oulu.fi)

[2]Geological Survey of Finland, P.O. Box 96, FI-02151 Espoo, Finland

The Fennoscandian Shield experienced several stages of brittle - ductile deformation during the Palaeoproterozoic. The Raahe Ladoga Shear Complex (RLSC) is a ~100 km wide, NW - SE striking set of strongly sheared rocks and intervening crustal blocks in which antecedent structures are preserved. These were formed by long-term and multi-phase Svecofennian convergent tectonic evolution and consist of supracrustal paragneisses and intrusive rocks. The latter are mostly pre- or syn-kinematic granitoids, but distinctly postkinematic granite veins occur in all areas. The Pielavesi Shear Zone (PSZ) in Central Finland is an important shear dominated, N-S striking unit within the RLSC.

At Heinäsuo, in the Pielavesi parish, Central Finland, pre- to syn-kinematic quartz diorite intrudes the PSZ. The quartz diorite has strong N-S foliation, likely developed during or immediately after crystallisation. This intrusion is cut by a late-kinematic, broadly N-S striking blastomylonite. U-(Th)-Pb geochronology of zircon, monazite and titanite are used to place constraints on the timing of deformation and shearing within the PSZ. Samples were collected from both the quartz diorite intrusion and the blastomylonite. Zircons were separated from the quartz diorite using standard gravitational separation methods, while polished chips of the blastomylonite were selected for *in situ* analysis of monazite. These were mounted in epoxy resin and analysed at the NORDSIM laboratory, Swedish Museum of Natural History, Stockholm, Sweden. Titanite was analysed *in situ* from polished thin sections of quartz diorite using LA-ICP-MS at the Geological Survey of Finland, Espoo, Finland.

Zircons have oscillatory zoning patterns in BSE images, characteristic of igneous zircon. Analysis of the zircons resulted in a concordia age of 1884 +/- 6 Ma, providing a magmatic age and constraining an age maximum for deformation in the PSZ. The monazite from the blastomylonite has a concordia age of 1793 +/- 3, placing the brittle - ductile shearing event at ~100 m.y. later. The titanite age, 1780 +/- 23 Ma, also indicates some recrystallisation in the quartz diorite during the late stage shearing event.

The U-Pb in speleothem chronometer: Current progress and future prospects

JON WOODHEAD[1]* AND ROBYN PICKERING[1]

[1] School of Earth Sciences, The University of Melbourne, Melbourne, VIC 3010, Australia

The chronology of speleothems by the U-Pb method has reached the point of a robust analytical methodology with enormous, but as yet largely unexploited, potential. A number of applications are beginning to appear relating to climate change, tectonics and human evolution. The next decade will likely see a major expansion of these activities. When coupled with other emerging technologies, the U-Pb chronology of speleothems from selected sites now has the potential to provide novel insights (both palaeotemperature and palaeohumidity) into ancient climate—effectively 'ancient weather stations'—from around the globe and throughout much of Earth history. Meanwhile studies of included pollens and microscopic animals offer insights into floral/faunal diversity and change through geological time. The ramifications of these many developments will be significant across diverse fields of research, from human evolution, palaeontology and ecosystem development, through studies of weathering and erosion, to the influence of tectonics on landscape evolution.

Some solid solutions involving Fe_4O_5

A.B. WOODLAND[1], K. SCHOLLENBRUCH[2], M. KOCH[3], AND D.J. FROST[4]

[1]Inst. Für Geowissenschaften, Universität Frankfurt, 60438 Frankfurt, Germany

[2]Deutsche Gemmologische Gesellschaft, 55743 Idar-Oberstein, Germany

[3]Inst. für Geowissenschaften, Universität, Heidelberg, 69120 Heidelberg, Germany

[4] Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany

The recently discovered Fe-oxide phase with Fe_4O_5 stoichiometry [1] opens up the potential for this phase being stable in Earth's mantle. This is particularly the case since [2] demonstrated that magnetite breaks down to Fe_4O_5 + Fe_2O_3 at 9-10 GPa over a large range of temperature. Thus it is important to know if this new phase can incorporate other cations and form solid solutions which would expand its stability field in terms of P and T and composition. Experiments have been performed in 3 simple systems: i) Fe_3O_4-Fe_2SiO_4, ii) Fe_3O_4-$(Mg,Fe)_2SiO_4$, and iii) Fe_3O_4-$FeCr_2O_4$ over a P-T range of 9-16 GPa and 1100-1300°C.

The Fe_4O_5 phase essentially excludes Si, even when it coexists with stishovite or a Fe^{3+}-bearing Fe_2SiO_4-rich spinel. The addition of Mg stabilizes a variety of assemblages in which the Fe_4O_5 phase occurs together with olivine, High-P clinopyroxene, spinelloid V, wadsleyite or ringwoodite. Experiments so far indicate solid solution of up to at least 25 mol % $Mg_2Fe_2O_5$ component. Molar volumes decrease from 53.76 to 53.55 cm^3 mol^{-1} over this solid solution range. Mg-Fe^{2+} partitioning is such that the Fe_4O_5 phase is the phase richest in Fe in a given assemblage, with $K_d^{phase/Fe4O5}$ usually <0.14. Cr can also be incorporated in the Fe_4O_5 structure in exchange for Fe^{3+}. In the bulk compositions studied, the Fe_4O_5 phase coexists with a spinel and/or a hematite-eskolaite solid solution. Up to 0.92 cats. Cr p.f.u. have been measured so far, implying a $Fe_2Cr_2O_5$ component of 46 mol %. Molar volumes also decrease with increasing $Fe_2Cr_2O_5$ content.

Lead isotope analysis: Removal of ^{204}Hg isobaric interference from ^{204}Pb for U/Pb dating using an (MS/MS capable) ICP-QQQ-MS

GLENN WOODS[1 A] AND JEAN-PIERRE LENER[2]

[1]Agilent Technologies (UK) Ltd. 5500 Lakeside, Cheadle Royal Business Park, Stockport, SK8 3GR United Kingdom

[2]7 Agilent Technologies, Avenue des Tropiques, ZA Courtaboeuf 2, BP 12, 91941 Les Ulis, FRANCE

Lead is an element whose isotopic pattern naturally varies more than any other element in the periodic table. The various stable isotopes are derived from uranium and thorium decay (238U – 206Pb, 235U – 207Pb; 232Th – 208Pb) with the only non-radiogenic isotope being the 204Pb isotope. Lead is an important element for providence testing (e.g. tracing the origin of an atrefact, food product, pollution event etc.) and its isotope analysis has been used in applications as far afield as pollution tracer studies for TEL (tetraethyl lead fuel additive), ore, olive oil & wine origin testing and forensic analysis of bullets.

One of the most important and difficult analyses for lead isotopes is for dating of minerals and Pb containing artefacts. For successful dating, all of the stable isotopes of Pb are required however there is an isobaric overlap from 204Hg on the 204Pb isotope. If any Hg is present in the sample, reagents or as a contaminant in the Ar gas, this would significantly bias the data whether solution or laser analysis is employed.

Removal of the Hg-based isobaric overlap can be achieved by addition of ammonia to a collision-reaction cell (CRC) equipped instrument. Mercury ions undergo rapid charge-transfer reaction in the presence of ammonia (the Hg+ ion is neutralised to Hg0 and the charge is passed to the ammonia molecule).

This could lead to the successful removal of Hg isobaric interference from Pb – however the potential issue of new molecular interferences created within the cell remain unless the reaction can be sufficiently controlled by ion pre-selection. This paper demonstrates the benefit of a MS/MS capable ICP-MS for the effective interference-free analysis of lead isotopes.

Increasing spatial resolution of lipid biomarker analysis by LDI FT-ICRMS

L. WÖRMER[1]*, M. ELVERT[1], J. FUCHSER[2], J.S. LIPP[1] AND K.-U. HINRICHS[1]

[1]MARUM and Department of Geosciences, University of Bremen, 28359 Bremen, Germany

[2]Bruker Daltonik GmbH, 28359 Bremen, Germany

Planktonic archaea and other marine microorganisms are known to adapt their membrane lipids to temperature – a phenomenon exploited in a number of molecular proxies for the reconstruction of past sea surface temperature (SST) from dated sediment cores. One widely applied proxy is the TEX_{86} index [1], which is based on the number of rings in the structure of the archaeal lipid GDGT. Given typical sample sizes and analysis by LC-APCI-MS, such SST records can resolve decadal to millennial variations, dependent on the geological setting examined. Our goal was to combine the temperature proxy potential of lipids in the sedimentological record with the high spatial resolution of laser desorption ionization (LDI) coupled to FT-ICRMS. Micrometer-scale resolution of LDI may produce estimates on sub-decadal to sub-annual scales and potentially provide crucial, previously hidden insights on the heartbeat of past climates.

We demonstrate that LDI FT-ICRMS efficiently ionizes GDGTs and that the high resolving power of FT-ICRMS is crucial for their unequivocal identification. We also observe a strong correlation between TEX_{86}-based SST analysis by LC-APCI-MS and ring distributions obtained by LDI FT-ICRMS, which proves the utility of the proposed method for correctly quantifying the different GDGT species.

We analyzed a several-cm long sediment core segment of Mediterranean Sapropel S1 with a spatial resolution of 200 μm, which corresponds to a temporal resolution of about 6 yrs. The observed GDGT distributions are consistent with short-term rhythmic variations of SST with relatively high amplitudes of several °C. Further validation of these trends is ongoing. These first results demonstrate the capacity to obtain a continuous, high resolution profile of GDGTs directly on an intact sediment core, thus setting the stage for lipid-based paleotemperature estimations with unprecedented temporal resolution and suggesting an enormous potential of this approach for future biomarker applications.

From zircon date to process rate: Interpreting zircon U-Pb dates in igneous petrology and stratigraphy

JÖRN-FREDERIK WOTZLAW[1] AND URS SCHALTEGGER[1]

[1]Section of Earth and Environmental Sciences, University of Geneva, CH-1205 Geneva, Switzerland (joern.wotzlaw@unige.ch; urs.schaltegger@unige.ch)

The precision of single crystal zircon U-Pb dates achievable by isotope dilution thermal ionization mass spectrometry (ID-TIMS) often exceeds our ability to interpret them in the context of magmatic processes. Closing this gap is presently one of the big challenges in high-precision U-Pb geochronology. Recent developments of analytical protocols allowing the analysis of various isotopic ratios and trace element concentrations in tandem with ID-TIMS U-Pb geochronology (e.g., Schoene *et al.* , 2010; Wotzlaw *et al.* , 2013) significantly improved our ability to link the timing of zircon crystallization to specific episodes during the lifetime of a magmatic system. With this contribution, we aim to highlight the potential and limitations of high-precison U-Pb geochronology in petrologic and stratigraphic applications.

We present high-*n* zircon U-Pb datasets of individual eruptive units from large-volume magmatic systems to investigate patterns of zircon crystallization during magma evolution from assembly to eruption. These data-sets display age distributions that point to discrete events of zircon crystallization that can be linked to the thermal evolution of the magmatic systems prior to eruption. When combined with isotopic and chemical information from the same crystals, individual zircons provide snapshots of the chemical and physical state of the magma at the time of zircon crystallization, allowing us to construct time-integrated petrogenetic models. However, in stratigraphic applications, where the desired age information is that of ash bed deposition, the pre-eruptive magmatic history recorded by zircons is a fundamental limiting factor. We use zircon U-Pb dates from ash beds intercalated with astronomically tuned sedimentary sequences in the Mediterranean to test the accuracy of zircon U-Pb derived age models. We evaluate various approaches to estimate ash bed deposition and construct continuous age models employing different fitting algorithms aiming to find a solution to minimize the residual offset between radioisotopic and astronomical time.

The research of sulfur early diagenesis cycle drived by AOM and methane-seep environment in the Cold Seep Area, northern South China Sea

DAIDAI WU[1] AND NENGYOU WU[2]

[1]Key Laboratory of Renewable Energy and Gas Hydrate of Guangzhou Institute of Energy Conversion,
Chinese Academy of Sciences, Guangzhou 510640, China; (wudd@ms.giec.ac.cn)

[2] Key Laboratory of Renewable Energy and Gas Hydrate of Guangzhou Institute of Energy Conversion,
Chinese Academy of Sciences, Guangzhou 510640, China; (wuny@ms.giec.ac.cn)

Abstract : The South China Sea is located at the junction of three tectonic plates: the Eurasian, the Pacific and the Indian-Australian. The northern continental slope, the South China Sea, is well known for its prospect of oil, gas, gas hydrate resources. Four areas including Taixinan Basin, Northeast Dongsha, Baiyun depression and Qiongdongnan Basin were identified as the most favourable conditions for gas seep or gas hydrate to occur, and were discovered geological, geochemical and biological evidences for cold seeps. In the seabed Cold Seep Area, the sulfate reduction drives by the organic matter oxidation, but mainly drives by anaerobic methane oxidation (AOM). However, the research of AOM-driven sulfate reduction and its important contribution to the sulfur early diagenesis cycle and sulfur buried needs to be studied. In this parper, the sediment cores and cold seep carbonates were collected from the Dongsha and Shenhu Cold Seep Area, northern South China Sea.The main geochemistry characteristics research contains the chemical composition of pore water, the microstricture fo sulfates and sulfides authigenic minerals, the distribution and content of intermediate state of sulfur and organic matter sulfide, sulfur and carbon stable isotope fractionation with comprehensive methods such as geochemistry, mineralogy, isotope geochemistry, numerical calculation methods,etc. The target is to identify the sulfate reduction drives by organic matter oxidation or AOM, obtain the proportion of sulfate consumption by AOM in the pore water, the sulfur isotope fractionation characteristics and constraints; establish a sound sulfur cycle path in marine sediment, quantitative assessment the diagenesis burial flux of iron sulfide and sulfate minerals in marine sediments and react the cold seep sedimentary environment characteristics.

Metasomatic perovskite

FU-YUAN WU*, JING SUN AND CHUAN-ZHOU LIU

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China, (wufuyuan@mail.iggcas.ac.cn) (* presenting author), (sunjing@mail.iggcas.ac.cn,)(chzliu@mail.iggcas.ac.cn)

Perovskite is one of the major minerals containing significant amount of U, Th, Sr, Hf and REE, which makes it a suitable mineral for U-Th-Pb dating and Sr-Nd-Hf isotopic analyses by TIMS and in situ techniques[1]. Generally, perovskite is occurred by magmatic crystallization in kimberlitic, kamafugitic, lamproitic, alkaline ultramafic and carbonatitic rocks[2], and rarely in carbonaceous chondrite[3]. Metasomatic perovskite, however, is rarely reported. During this study, metasomatic perovskite from numerous localities were examined for its major, trace elemental compositions, and Sr-Nd isotopic data were used to constrain its petrogenetic history.

The reported metasomatic perovskite includes those from: 1) Mantle peridotite xenolith in kimberlite, South Africa[4]; 2) Rodingite from Changawuzi in Tianshan, China; 3) Skarn formed by contact metamorphism between syenite intrusion and carbonate, Tazheran, Baikal; 4) Chlorite schist formed by dioritic intrusion into limestone in Zlatoust of Urals, Russia, and 5) Chlorite schist probably related to intrusion of the nearby syenite in San Benito of Californian, USA.

Compared with those from kimberlites and alkaline ultramafic intrusions, metasomatic perovskite is relatively stoichiometric with higher amount of Ca and Ti. In terms of trace elements, metasomatic perovskite has variable concentrations of REE, U and Th, but higher concentrations of Zr, Hf and LREE/HREE fractionation, and lower Nb, Ta and Sr.

According to our data, perovskite from Tazheran has the lowest common lead, making it a suitable standard for in situ U-Pb dating. The low Sr concentration makes it impossible to get its Sr isotopic composition using laser ablation. However, most metasomatic perovskites can be determined its Nd isotopic composition by in situ method, except those from San San Benito, which is the most stoichiometric in major elements, and has the lowest REE concentrations.

Sensitivity of carbonaceous aerosol simulations to aging schemes

SHILIANG WU[1] , YAOXIAN HUANG[1], MANVENDRA DUBEY[2] AND NANCY FRENCH[1]

[1]Michigan Technological Univeristy, Houghton, MI 49931, USA (slwu@mtu.edu)

[2]Earth System Observations, Los Alamos National Laboratory, Los Alamos, NM 87545, USA

Carbonaceous aerosols including organic carbon and black carbon have significant implications for both climate and air quality. In the current global climate or chemical transport models, a fixed hydrophobic-to-hydrophilic conversion lifetime for carbonaceous aerosol is generally assumed, which is usually around one day. We have implemented a new detailed aging scheme for carbonaceous aerosols in a chemical transport model (GEOS-Chem) to account for both the chemical oxidation and the physical condensation-coagulation effects, where the aging is affected by local atmospheric environment including atmospheric concentrations of water vapor, ozone, hydroxyl radical and sulfuric acid. The updated conversion lifetime exhibits large spatial and temporal variations with the global average calculated to be 4.3 days. The chemical aging effects are found to be strongest over the tropical regions driven by the low ozone concentrations and high humidity there. The conversion lifetime resulted from chemical aging generally decreases with altitude due to increases in ozone concentration and decreases in humidity. The condensation-coagulation effects are found to be most important for the high-latitude areas, in particular the polar regions, where the τ values are calculated to be up to 15 days. When both the chemical aging and condensation-coagulation effects are considered, the total atmospheric burdens and global average lifetimes of BC (OC) are calculated to increase by 52% (29%) compared to the control simulation. Model evaluation against data from multiple observation networks worldwide shows that the updated aging scheme improves model simulations of carbonaceous aerosols, especially for the remote regions. Further model sensitivity simulations focusing on the continental outflow of carbonaceous aerosols demonstrate that previous studies using the old aging scheme could have significantly underestimated the inter-continental transport of carbonaceous aerosols.

Chemical weathering, atmospheric CO_2 consumption, and the controlling factors of a small silicate watershed in subtropical zone

WEIHUA WU[1]*, HONGBO ZHENG [2] AND CHAO LUO [1]

[1] Key Laboratory of Surficial Geochemistry, Ministry of Education; School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China. (*correspondence: wuwh@nju.edu.cn)
[2] School of Geography Science, Nanjing Normal University, Nanjing 210046, China

Hydrochemistry of a small subtropical watershed, the Xishui River draining mainly gneisses and amphibolites is systematically investigated. By collecting samples from source area to river mouth in summer and winter, we discuss temporal and spatial variations of major ion concentrations. An inversion model is used to evaluate different contributions from atmospheric input, anthropogenic activities and rock weathering (silicate, carbonate, and evaporite), and calculate chemical weathering and atmospheric CO_2 consumption rates in the catchment.

The results show: (1) Major ion concentrations in summer are mostly higher than those in winter except for Si, which indicates that influence of intensive weathering, agricultural activities, and acid rain in summer exceeds dilution effect. (2) Contributions from atmospheric input are 13.2 % and 7.8 % in winter and summer, respectively. Anthropogenic activities provide only 2.4 % and 4.2 % major ions to the Xishui River, which has a slight influence on the hydrochemistry. Contributions from silicate weathering are 52.1 % and 48.7 %, and carbonate weathering are 28.4 % and 24.2 %. Therefore, though area of carbonate rocks only accounts for < 5 % of the drainage area, it has an important contribution to major cations in the Xishui River. Contributions from evaporite are 3.8 % and 15.1 % in winter and summer, indicating that influence of temperature on evaporite dissolution is more noticeable. (3) Silicate weathering rates are 0.64–4.44 t/km^{2}y and 4.1–21.2 t/km^{2}y in winter and summer, respectively. The atmospheric CO_2 consumption rates resulted from silicate weathering are $0.31–2.1\times10^5$ mol/km^{2}y and $1.94–10.2\times10^5$ mol/km^{2}y in winter and summer. The rates in the Xishui River are remarkably lower than those in small watersheds which had higher temperature and rainfall in tropical zone, and are higher than those in small watersheds had similar rainfall but lower temperature in central Europe and eastern France, indicating that temperature may be the most important factor influenced the chemical weathering rates in silicate watersheds.

Physiology, mineralogy and Fe isotope fractionation of Fe(II) oxidation by a marine photoferrotroph - Implications for the deposition of Precambrian BIFs

WENFANG WU[1,2], ELIZABETH D. SWANNER[2], YONGXIN PAN[1], RONNY SCHOENBERG[2] AND ANDREAS KAPPLER[2]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, wuwenfang@mail.iggcas.ac.cn
[2]Department of Geoscience, University of Tuebingen, Germany

Anoxygenic phoferrotrophs are capable of photosynthetic Fe(II) oxidation in the absence of oxygen. Because of this ability they were suggested to be involved in the precipitation of oxidized iron minerals in Banded Iron Formations (BIFs) prior to the presence of significant amounts of O_2 on Earth. Although photoferrotrophs are thought to be important for Fe(II) oxidation in ancient oceans, previous studies related to BIFs have focused on freshwater strains [1]. However, marine geochemistry differs from freshwater probably strongly affecting anoxygenic Fe(II) oxidation and consequently the mineralogy and Fe isotope composition of the Fe(III) minerals produced. In this study we therefore quantified cell growth, Fe(II) oxidation rates, Fe isotope fractionation and mineralogy of Fe(III) precipitates during Fe(II) oxidation by the marine photoferrotroph *Rhodovulum iodosum*. We found that the maximum Fe(II) oxidation rate was slower than determined for the freshwater strains. The crystalline Fe(III) oxyhydroxides goethite and lepidocrocite were produced in contrast to the poorly crystalline ferrihydrite that is typically produced by the freshwater strains. During Fe(II) oxidation, the Fe(III) precipitate enriches in the heavier Fe isotopes while the aqueous Fe(II) becomes lighter, consistent with the trend observed for freshwater strains but with a significantly smaller fractionation factor than determined for the freshwater strain *Thiodictyon* F4 [2]. Our experiments demonstrate that anoxygenic phototrophic Fe(II) oxidation shows distinct differences in marine settings compared to experiments done under freshwater conditions and will ultimately allow us to better understand their role in the deposition of oxidized Fe minerals in Precambrian Banded Iron Formations.

Pristane isomerization ratio: Novel maturity index for highly mature and overmature oils

YINGQIN WU [1,2], YONGLI WANG [1]*, TIANZHU LEI [1], SUPING MA[1], YOUXIAO WANG [1], YUAN GAO[1] AND YANQING XIA [1]*

[1]Key Laboratory of Petroleum Resources Research, Institute of Geology and Geophysics, Chinese Academy of Science, Lanzhou 730000, China (wuyingqin001@163.com) (*correspondence: yqxia@lzb.ac.cn,wyll6800@163.com)

[2] Graduate School of the Chinese Academy of Sciences, Beijing 100049, China

Thermal maturity is an important parameter in assessing petroleum evolution in sedimentary basins. However, the maturity parameters based on biomarkers cannot be applied to highly mature oils (Ro > 1.5%), especially to overmature oils (Ro > 2.0%) (e.g. the sterane and terpane isomerization ratios, methyl phenanthrene index and methyl diamantane index). The reason is that these ratios reach their equilibrium values before or at the onset of the "oil window". Therefore, the peak hydrocarbon generation stage cannot be assessed using these parameters, particularly for highly mature and overmature crude oils.

In this experiment, pristane isomers were identified in extracts from the coal samples of Junggar Basin, China. From brown coal to subbituminous coal, corresponding to Ro 0.36-2.99 %, the PIR [pristane isomerization ratio = { [6(R)10(R) + 6(S)10(S)] /6(R)10(S)] ranges from 42 to 97% for the coal extracts. The value of PIR, a molecular maturity parameter, is evaluated by analyzing a series of samples from the Junggar Basin with known values of the molecular maturity parameter based on the sterane and hopane isomerization and methyl phenanthrene index. Changes in the PIR in these highly mature Ai-13 (Ro>1.5%) and overmature Ha-01 and Ha-02 (Ro>2.0%) are still obvious and with linear correlation between PIR and Ro. As a result, our results suggest that the PIR is an appropriate indicator of maturity for the highly mature and overmature oils and sediments.

It is clear that the PIR increases with the increasing of Ro, which possibly suggests an isomerization of RS isomer into the RR and/or SS isomer.

In summary, the PIR may be potential interest as it can efficiently be used in measuring the maturity of highly mature oils, sediments and may work throughout the "oil window". However, the same case may be expected to take place in other molecular parameters, but the current work does not observe the dependence of the PIR on the kerogen type. It is necessary to make further investigation and collect data of the PIR from other samples (elsewhere) in order to attain better results of the present study.

Clarification of the effect of the iron spin state change on properties of Fp is important to address the relative abundance of Fp in the lower mantle. However, recent works addressing this question have reached different conclusions. The calculated density of a pyrolite aggregate with spin crossover-related change in iron partitioning compared well with the density in PREM up to 45 GPa [1]. In contrast, Murakami *et al*'s analysis of V_S in aggregates with variable amounts of Fp concluded that the lower mantle is more perovskitic than pyrolitic [2].

We investigated the thermoelasticity of Fp by first principles using the DFT+U functional. The calculated thermoelastic coefficients are consistent with available experimental data on samples with various iron concentrations. Results help us to understand some discrepancies among different experimental data sets regarding the shear modulus softening [3,4]. We predict velocities of Fp at lower mantle conditions and suggest that pyrolite is a reasonable compositional model for the lower mantle. Our results show the importance of constraining the elastic properties of minerals without extrapolations for analyses of the thermochemical state of this region.

Anaerobic activity of nitrite-oxidizing microorganisms affects the $\delta^{18}O$ of dissolved nitrate during microbial denitrification

ANJA WUNDERLICH[12*], RAINER U. MECKENSTOCK[1] AND FLORIAN EINSIEDL[2]

[1] Institute of Groundwater Ecology, Helmholtz Center Munich, Ingolstädter Landstraße 1, Neuherberg, Germany (anja.wunderlich@tum.de)

[2] Technische Universität München, Chair of Hydrogeology, Arcisstrasse 21, Munich, Germany

The stable isotopes of nitrate in water are frequently used to assess denitrification and sources of nitrate in the environment. It was previously assumed for terrestrial environments that a relative increase in $\delta^{18}O$ of nitrate compared to its $\delta^{15}N$ of 0.5 is indicative of denitrification.

We anaerobically incubated sediments with natural microbial populations from 3 different anoxic habitats and a pure culture of the nitrite oxidizing bacterium *Nitrobacter vulgaris* in strongly ^{18}O-labeled water with nitrate and adequate electron donors. A significant influence of $\delta^{18}O$ of water on the $\delta^{18}O$ of nitrate was found in all experiments. All incubations clearly expressed microbial denitrification. Given oxic conditions, the microbial populations of all incubations were also able to oxidize nitrite. We thus assume the presence of nitrite oxidizing microorganisms in all incubations. As nitrite oxidizers may catalyze the observed isotopic shift in pure cultures, they are likely also the driving parameter of the observed shift in the environmental incubations. This shift questions the stability of predicted $\Delta\delta^{18}O/\Delta\delta^{15}N$ ratios in the environment during denitrification. Such a shift in $\delta^{18}O$ of nitrate under anoxic conditions also questions the validity of nitrate source determination by 2D isotopic fingerprinting, specifically in respect to the $\delta^{18}O$ axis.

Nitrite oxidizing microorganisms possess a nitrite oxidoreductase enzyme (NXR) which is able to oxidize nitrite as well as reduce nitrate, depending on the redox conditions. Regular denitrifiers possess a nitrate reductase (Nar) which only reduces nitrate irreversibly. We hypothesize that the nitrate reduction reaction at the NXR enzyme by nitrite oxidizing microorganisms is reversible even under anoxic conditions, allowing the incorporation of oxygen-atoms from water into nitrate.

$$NO_3^- + 2H^+ \leftrightarrow NO_2^- + H_2O$$

It is likely that a variable activity of nitrite oxidizers in anoxic environments produces a variable shift of $\delta^{18}O$ of nitrate towards $\delta^{18}O$ of ambient water and thus varied ratios of $\Delta\delta^{18}O/\Delta\delta^{15}N$.

Geochemical impacts of carbon dioxide leakage into carbonate aquifer rocks

Leakage of CO_2 during geological carbon sequestration can prevent meeting environmental and storage goals. A significant environmental concern is acidification of groundwater with a potential subsequent increase in aqueous metal concentrations due to mineral dissolution and desorption. Even though carbonate aquifers supply about 20% of drinking water worldwide, these aquifers are somewhat neglected in the CO_2 sequestration literature, because carbonate minerals are presumed to buffer pH increases. The common carbonate minerals (calcite, dolomite) are rarely found in pure form in nature, and typically contain metal impurites. Dissolution of these minerals is very sensitive to pH changes, and we hypothesized that metals could be released during carbonate dissolution. Previous studies usually point to sulfide minerals as likely sources of toxic metals. Pressurized experiments containing natural carbonate rocks at elevated CO_2 pressures resulted in elevated aqueous concentrations of Mn, Ni, As, Cr, Sr, Ba, Co, Mo and Tl, with few elements rising above U.S. regulatory limits. Geochemical modeling (constrained by our experimental results) suggest that carbonate minerals may be the dominant contributors to metal release in a carbonate aquifers, not pyrite. Consequently, models that ignore co-release of metals from carbonates may underpredict metal release. However, geochemical modeling also demonstrates that pyrite may be an important source of metals under oxidizing conditions, and that the influence of O_2 partial pressures is equally important that of CO_2.

Microbial metabolic processes in the deep subsurface - impact on geological energy storage

HILKE WÜRDEMANN[1]*, DARIA MOROZOVA[1], STEPHANIE LERM[1], ANKE WESTPHAL, MONIKA KASINA[1] LINDA PELLIZZARI[1], HANANAH HALM[1] AND DOMINIK NEUMANN[1]

[1]Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, 14473 Potsdam, Germany

Enhanced process understanding of engineered reservoirs is a prerequisite to optimize the operation of geological storage, to increase the reliability as well as to assess the risks involved. Since microorganisms are very effective geochemical catalysts and their contribution to the mineral alteration and dissolution needs to be investigated.

The microbial diversity of a different reservoirs in the North German Basin, the Upper Rhine Graben, the Molasse Basis and the Styrian Bassin was analysed with molecular biological and geochemical methods. Interactions of microbial activity with the geotechnical use of the reservoirs were studied in a pilot plant for CO_2 storage, in bypass systems of a geothermal heat store and in long-term laboratory experiments with rock cores and reservoir fluids. Genetic fingerprinting analyses revealed distinct microbial communities in fluids depending on the temperature, the salinity and the availability of electron donors like organic substances or hydrogen. Cell counting and quantification of 16S rRNA genes and dissimilatory sulfite reductase (dsrA) genes by real-time PCR proved different population sizes in fluids, showing higher abundance of Bacteria and sulfate reducing bacteria (SRB) in systems influcenced by corrosion. SRB were accounted for corrosion damage and iron sulfide precipitates in the near wellbore area that affected plant reliability adversely.

Geoneutrino detection in the future low-energy neutrino observatory LENA

MICHAEL WURM

Eberhard Karls Universität Tübingen, 72076 Tübingen, Germany

The next-generation liquid-scintillator detector LENA (Low Energy Neutrino Astronomy) will be a versatile tool for the study of low-energy neutrino fluxes. Following up on the first successful measurements of geoneutrinos by the KamLand and Borexino experiments, LENA is aiming at a high-statistics measurement of the geoneutrino flux above 1.8 MeV. Like its predecessors, LENA will profit from the low energy threshold and the excellent background discrimination capabilities of the liquid scintillator technique, but above all from its in comparison considerably larger target mass of 50 kiloton.

For the preferred experimental site, the Pyhäsalmi mine in central Finland, we expect about 1000 inverse beta decay events per year. Far from the majority of nuclear power plants, the expected geoneutrino signal to reactor neutrino background ratio at this site is of the order of 2:1. Based on the predicted event rate and 10 years of exposure, the geoneutrino flux could be determined at 1% level. This will open the door for a precise determination of the radiogenic contribution to the terrestrial heat flow and the discrimination of geological models. Moreover, the detected geoneutrino spectrum can be evaluated to determine the relative contributions of beta-decays from the uranium and thorium decay chains to the overall neutrino flux. After 10 years, an accuracy of 5% could be reached for the U/Th ratio, thereby reaching a level of precision relevant for the study of terrestrial models.

The volatile content of Mount Etna magma: An FTIR and Raman study of glassy melt inclusions

ROBIN WYLIE

University College London, London WC1E 6BT
(correspondence: r.wylie.11@ucl.ac.uk)

The 1983 eruption of Mount Etna

Mount Etna volcano, Sicily, is amongst the highest emitters of volcanic carbon dioxide worldwide, however the origin of this prolific output is still debated. As such, characterising the occurrence of CO_2 in Mount Etna magmas has important implications for our understanding of deep Earth degassing.

Lavas from the 1983 eruption of Mount Etna have been found to contain native carbon, in the form of graphite and diamond [Adrian Jones, pers. comm.]. This unprecedented observation suggests that this, so far little-studied eruption, may have sampled an unusually deep source of carbon beneath Etna. These lavas therefore represent an ideal target for the further characterisation of the carbon output of this volcano.

By the time they are erupted, lavas are heavily depleted in CO_2, as it begins to degas at large depths within the volcanic system. Melt inclusions are small pockets of magma which become trapped within crystals growing within a magma body, and – as they are isoltated from the effects of degassing – can preserve the early volatile composition of magmas. Importantly, the analysis of H_2O together with CO_2 allows the trapping depth of these inclusions to be estimated.

Work plan

Glassy melt inclusions, hosted within olivine phenocrysts from lavas of the 1983 Etna eruption, will be analysed using FTIR (Fourier Transform Infra Red) Spectroscopy, and Raman microscopy, in order to determine the concentrations of dissolved CO_2 and H_2O, respectively, in the glasses. Using the Raman method, the presence of H_2O has already been verified in the inclusions (fig. 1), and FTIR analysis will be performed on the same samples, starting in April 2013.

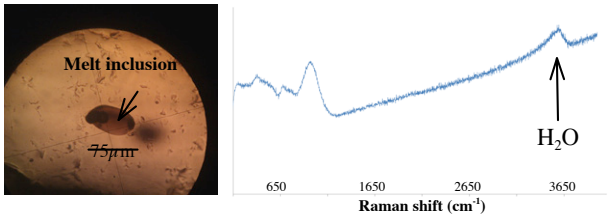

Fig. 1. Left: Sample prepared melt inclusion within its olvine host crystal; Right: Raman microprobe spectrum of the same inclusion, which shows a prominent OH peak indicating the presence of dissolved H_2O.

Seasonal distinction of hydrological variability in speleothem calcite

WYNN, P.M.[1]* FAIRCHILD, I.J.[2] SPÖTL, C.[3] HARTLAND, A.[4] MATTEY, D.[5] COTTE, AND M[6]. FAYARD, B[6,7]

[7] Université Paris-Sud, F-91405, FR (fayard@lps.u-psud.fr)

Speleothem chemical records have been employed in the reconstruction of environmental change on a broad range of timescales. Whilst sub-annual records are scarce, it is here that one of the research frontiers resides, providing a modern calibration between speleothem proxy and meteorological conditions. Here, we use Synchrotron μXRF spectrometry at ID21, ESRF, to reveal trace element patterns of Zn, Pb and S within speleothem calcite over three annual cycles. In this way, archived signals are calibrated to modes of trace element incorporation and meteorological conditions. Concentrations of Zn and Pb in speleothem Obi84 show in-phase cyclicity and are attributed to transport in complexes with natural organic matter (NOM) originating from the soil/epikarst above the cave. Peak fluorescent laminae occur on an annual basis, although banding of lower fluorescence intensity reveals multiple events at the sub-annual scale. Meteorological data reveals the delivery of NOM-metal complexes to the speleothem is dependent upon water excess, snowpack condition, and soil microbiological activity. Sulphur demonstrated annual cyclicity, with minimum and maximum concentrations coinciding with winter and summer respectively, dependent upon internal cave atmospheric conditions and the pH value to which cave drip waters degas. At the current resolution of analysis, this represents some of the first evidence linking event-based meteorological records to the trace element content of speleothem calcite and is the initial phase of work which aims at developing records of seasonal infiltration patterns and cave ventilation dynamics, building towards proxy records of winter duration and seasonal infiltration patterns as indices of climatic change.

In situ determination of REE in clinopyroxene from syenites

IRENA WYSOCKA[1] AND EWA KRZEMINSKA[1]

[1]Polish Geological Institute-National Research Institute, 00-975 Warszawa, 4 Rakowiecka, Poland (irena.wysocka@pgi.gov.pl;)(wa.krzeminska@pgi.gov.pl)

Laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) has became widely used method for the geological applications. In this work, the distribution of rare earth elements (REEs) in clinopyroxene (cpx) was studied. Cpx is significant mineral phase in foid syenite to syenite, which are late differentiates of alkaline–ultramafic Carboniferous igneous suite of Tajno and Ełk (Poland). The analyses were restricted to the phenocrysts with about 400 - 500 μm width, chemically classified as a diopside and eagirine augite.

Determination of the trace element concentrations in cpx were performed by laser ablation system LSX-500 (UV Nd:YAG 266 nm, Cetac) connected to the quadruple mass spectrometer (Elan DRC II, Perkin Elmer Sciex). The ablation conditions (spot diameter, energy and pulse rate) were optimised separately for the rocks and the thin sections.
The applied spot size was 50 or 100 μm. Cpxs were analysed for REE and trace element content using frequency of 10 Hz or 5 Hz. The measurements were carried out *in-situ* in the polished rocks and in thin sections (thickness of ~ 100-120 μm). The same thin sections and polished rock samples of each syenite were also imaged by BSE and analyzed by WDS Cameca SX100 electron microprobe at the aim of the determination of the main chemical components. The synthetic silicate certified reference materials NIST 610 and NIST 612 were used for method calibration and BIR-1, BCR-2 and BHVO-2 were used for the verification of the obtained results. Different element oxides were applied as the internal standards and the results were compared.

Based on the performed analyses we have concluded that:
1) LA-ICP-MS is appropriate method for *in-situ* measurements in the polished rocks and in thin sections of minerals and results are comparable;
2) the pronounced differences in REE content in cpx of different origin were observed;
3) the variation of the REE contents in cpx phenocrysts from alkali silicate host rocks may reflect slightly different melt evolution paths of the complexes with (Tajno syenite) and without associated carbonatites (Ełk syenite).

The huge amount of naturally occurring radioactive material (NORM) worldwide generated shows a high level of complexity for disposal purposes because of the high variability of radioactivity enrichment, therefore a case-by-case control is required. We developed a fully automated high-resolution gamma-ray spectrometer, called MCA_Rad system [1], which offers a suitable measurement technique for monitoring huge amounts of NORM. Two coupled HPGe detectors p-type with 60% relative efficiency are accurately shielded allowing to reach an environmental background reduction of two orders of magnitude. Through fully automation of operational processes up to 24 samples can be measured without any human attendance. The absolute efficiency of the MCA_Rad system is estimated by using two point sources, ^{152}Eu and a ^{56}Co and validated at 5% of relative uncertainty by measuring certified reference materials.

Study on sulfur isotopic composition of acid rain in Nanchang City,China

F. XIA[1], J-Y. PAN[1], S-H CHEN[1], H-M PENG[1] AND P.LIU[1]

[1]State Key Laboratory Breeding Base of Nuclear Rersources and Environmental, East China Institute of Technology, Nanchang 330013, China (xf730@163.com)

The acid rain is sulfuric acid type acid rain in Jiangxi province Nanchang City, its sulfur isotopic composition are different from that of other Cities.

We analyzed the sulfur isotopic composition of rain water from Nanchang City in this paper(**Fig 1**). The results indicated that the sulfur isotopic composition possesses a seasonal variation trend, isotopically heavier in spring and summer, lighter in autumn and winter. The sources of sulfur in rain water include bio-organic sulfur, anthropogenic sulfur and sulfur from the sea. In spring and summer, the sulfur in rain water comes mainly from anthropogenic sulfur. In autumn and winter,the sulfur in rain water dominantly originates from bio-organic sulfur. The sulfur in rain water from the sea may be very small in percentage.

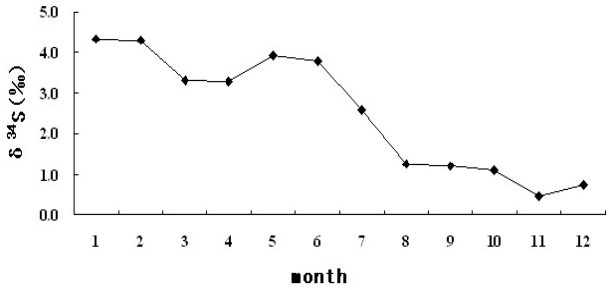

Fig. 1. Seasonal variations in sulfur isotopic composition of the precipitation

A pathway for aromatic hydrocarbon formation

YANQING XIA[1]* AND JIANG CHANG[1]

1 Key Laboratory of Petroleum Resources Research, Institute of Geology and Geophysics, Chinese Academy of Science, Lanzhou, China,(yqxia@lzb.ac.cn()*)

Though aromatic hydrocarbons, the important components in petroleum, have been studied extensively, their formation mechanism is poorly understood, except for aromatic steranes, aromatic hopanes, and some sulphur-containing biomarker compounds, which are mainly thiophenes[1]. It is difficult to make clear their formation mechanism by studying the natural aromatic hydrocarbons lonely. During researching on the reaction of sulphur with organic matter by experiment, we found another pathway for aromatic hydrocarbon formation besides the aromatization of cyclanes. Though saturated chain compounds are difficult to become aromatic hydrocarbons, they can react quite easily with elemental sulphur and generate almost all kinds of aromatic hydrocarbons found in petroleum or sediments.

Many researchers have studied the mechanism of natural sulphur incorporation into organic matter by simulation or pyrolysis reactions[2], but the role of sulphur to the formation of common aromatic hydrocarbons in petroleum has not been pay great attention to and the action of sulphur on the organic matter in sediment used to be considered incorporating into carbon skeleton and forming sulphur-containing organic compounds even though Tissot *et* noted that the quantities of aromatic hydrocarbons in petroleum were direct proportion to sulphur[3]. From the present simulation experiment, it is clear that the reaction of sulphur and organic matter not only gives rise to sulphur-containing compounds, but also form non-heterocyclic aromatic hydrocarbons. Natural sediments are rich in saturated compounds and sulphur, so the reaction between them may be one of the most important sources of aromatic hydrocarbons.

The P-T-t path of the UHT granulites from Tongbai orogen, Central China

HUA XIANG[1], ZENG-QIU ZHONG[2], LI ZHANG[2], HAN-WEN ZHOU[2] AND ZE-MING ZHANG [1]

[1] State Key Laboratory for Continental Tectonics and Dynamics, Institute of Geology, Chinese Academy of Geological Sciences, Beijing 100037, China

[2] Faculty of Earth Sciences, China University of Geosciences (Wuhan), Wuhan, China, 430074

Although the U-Pb zircon geochronometer has been widely used for dating metamorphism in moderate- to high-grade rocks, it is generally difficult to link the U-Pb age of zircon to pressure-temperature (P-T) conditions. Fortunately, the textures and chemical compositions (e.g. REEs) of zircon may provide qualitative information for correlating radiometric ages with certain stages in the metamorphic history of a rock. Additionally, zircon Lu-Hf isotopes can be used to constrain the nature of the igneous or metamorphic event in which the zircon grew.

Four stages of metamorphism are recognised in the granulites from Tongbai orogen, including a prograde stage (M1, ca.730–820°C at ca. <6 kbar), peak stage (M2, >920°C and 8.5–9.5 kbar), amphibolite facies retrograde stage (M3, ca. 700°C at ca. 7 kbr) and greenschist facies retrograde stage (M4, ca. 500 °C at ca. 5.8 kbar). Correspondingly, four distinct domains in the metamorphic zircons, which $^{206}Pb/^{238}U$ age are ca. 443 Ma, ca. 430 Ma, ca. 419 Ma and ca. 400 Ma respectively, are classified based on CL images, trace elements, U-Pb ages and Hf isotopes. The ca. 443 Ma zircons, which are suggested as the M1 minerals, are characterized by flat HREE pattern, indicating presence of garnet during formation of these zircons. The ca. 430Ma zircons from a semi-pelitic granulite are characterized by strongly depleted HREEs, resulting in low HREE partitioning between zircon and garnet (<1.0), which is consistent with the characteristics of the ultra-high temperature metamorphic zircon. The age of ca. 430 Ma is represented the peak metamorphic age. The ca. 419 Ma zircons occur as rim of the ca. 430 Ma or ca. 443 Ma zircons from a semi-pelitic granulite, and are characterized by relativly rich in HREE. This coincides with the fact of that garnet porphyroblasts were replaced by biotite + plagioclase during the retrograde stage (M3). In a mafic rock, the ca. 400 Ma zircon rims have obviously lower initial $^{176}Hf/^{177}Hf$ ratio than ca. 419 Ma zircons. It is extremely possible that hydrothermal fluids with low $^{176}Hf/^{177}Hf$ ratios were added into the rock during greenschist-facies hydrothermal event at ca. 400 Ma. We argue that the Tongbai UHT granulites is possibly related to the mid oceanic ridge subduction.

Stable Nitrogen Isotope Analysis of Amino Acids by GC/C/IRMS

HUA-YUN XIAO, REN-GUO ZHU AND ZUO-YING YIN

State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China

Measurements of the $\delta^{15}N$ values of individual amino acids have provided very specific information about the biogeochemical, environmental, and ecological processes. The combination of gas chromatography with IRMS has become a hopeful tool for nitrogen isotopic analyses of individual amino acids in mixtures.

Amino acids before isotopic determination need to be derivatized using MTBSTFA and separated by gas chromatography, and gas chromatographic effluents were combusted and sent to the mass spectrometer continuously in a helium carrier stream. The GC column temperature was programmed for the tBDMSi derivatives separation as follows: isothermal 90 ºC for 1 min, then heating up to 140 ºC at rate of 8 ºC/min and keeping it for 5 min, to 220 ºC at rate of 3 ºC/min and then to 285 ºC at rate of 12 ºC/min, and hold at final temperature 285 ºC for 12.5 min until the elution of the last component. In this study, 0.8 ~ 4.5 nmol of each of the 20 amino acids (Ala, Gly, Val, Leu, Ile, Pro, Asn, Met, Ser, Thr, Phe, Asp, Glu, Lys, Gln, Arg, His, Tyr, Trp and GABA) was injected for isotopic determination.

All the 20 derivatived amino acids could be completely resolved in 60 min by GC programm. We found a high isotopic correlation (R^2=0.9987, $p<0.0001$) between the determined values and the real values for most of the amino acids except three amino acids (Asn, Gln and Arg) which signals were much depleted. But for the three amino acids, there also existed a high isotopic correlation (R^2=0.9999, $p<0.0001$). Reproducible $\delta^{15}N$ values were obtained within different injected amounts. The reproducibility of all the 20 derivatives was between 0.3‰ and 0.8‰. The mean precision of reproducibility was 0.5‰. After calibration with the 2 correlation equations, the isotopic difference between the calibrated values and the real values was in the range of 0.1‰ to 0.5‰ for the 20 amino acids.

Using the method developed, we successfully analysed the $\delta^{15}N$ values of 20 free amino acids in tree leaves and barks.

This study work was kindly supported by the National Natural Science Foundation of China through grants 41173027.

Cell Alive System (CAS): A new method of core sample freezing for shore-based biological analyses and sample storage

NAN XIAO[1], YUKI MORONO[1], TAKESHI TERADA[2], YUHJI YAMAMOTO[3], TAKEHIRO HORISE[1] AND FUMIO INAGAKI[1]

[1]Kochi Insititute for Core Sample Research, JapanAgency for Marine-Earth Science and Technology (JAMSTEC), [2]Marine Works Japan Ltd., [3]Kochi University, Monobe B200, Nankoku, Kochi 783-8502, Japan.

We report a novel freezing technology for the long-term preservation of subseafloor core samples. Subseafloor core samples recovered by scientific ocean drilling provide unprecedented opportunities to study deep subseafloor life and biogeocheminal cycles. For the future analyses of cores using newly devleoped life science technologies, archiving precious core materials under the appropriate condition is fundamentary significant. Given such scientific requirements, the Kochi Core Center (KCC), one of the offical core repositories of the Integrated Ocean Drilling Program (IODP), has started storing some biological core samples in -80˚C deep freezers and/or in liquid N_2 tanks, so called “DeepBIOS” (Deep Biosphere Samples).

To keep quality assuarance and control (QA/QC) of the DeepBIOS, the intital freezing process is a key: however, using the conventional way (e.g., quick transfer to deep freezer), it has been confirmed that formation of ice crystals decompose biological signetures. During the JAMSTEC *Chikyu* Expedition 905, we tested a new technology called “Cell Alive System (CAS)”, which utilizes magnetic field to vibrate water molecur in the sample, following snap and hence uniform freezing of core samples at the supercooling temperature. The core samples from various depths were sub-sampled, and immediately frozen in the CAS system along with the standard freezing method under the temperature of -20˚C, -80˚C, and -196˚C. Analysis of cell abundance showed that conventional freezing methods decreased the number of microbial cells, whereas the CAS freezing resulted in almost no loss of the cells. We also tested the paleomagnetic characteristics after the CAS freezing, indicating no or very little change in remnant magnetism. No visible changes in volume of sediment was observed after the CAS freezing. Consequently, our results indicate that the CAS freezing technique is highly useful for QA/QC of scientific frozen core samples to preserve intact biological signetures, as well as other non-biological characteristics, for the long-term storage.

The transformation and co-evolution of archaea with its environment assessed by energy quantum

XIANG XIAO*, YU ZHANG, FENGPING WANG[1,2], YING HE AND JUNXU

State Key Laboratory of Microbial Metabolism and State Key Laboratory of Ocean Engineering, Shanghai JiaoTong University, Shanghai, 200240, People's Republic of China
*(Correspondence: xoxiang@sjtu.edu.cn)

Archaea are believed as key players in the biogeochemical cycling of basic elements such as carbon, nitrogen, and sulfur in various environments, yet the physiology and functions of many of them remain largely unknown mainly due to difficulties in cultivation and lack of genetic manipulation systems. By the combined utilization of high pressure bioreactors, together with OMICS enabled metabolic potential analysis, synthetic biological technologies, and single cell capturing and sequencing methods, our group aims to reveal the physiology, evolution and functions of some important archaeal groups in the deep-sea environments. As examples, we will highlight our recent progress in the systematic investigation and genetic engineering of piezophilic/thermophilic Thermococcales strains pool from deep-sea hydrothermal vents; and some novel understandings on the physiology, evolution and metabolisms of methane oxidizing archaea-bacteria syntrophic consortia. We propose a "Coevolution and Energy Quantum" (CEQ) theory as a guidance for mathematic model construction to understand the interaction and co-evolution of life and environment.

Skarn Cu-Fe-Au deposits in the East Hubei ore cluster, Middle–Lower Yangtze River metallogenic belt

XIE GUIQING[1,2], ZHU QIAOQIAO[1] AND LI WEI[1]

[1]Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, 100037, China
[2] MLR Key Laboratory of Metallogeny and Mineral Assessment, Beijing, 100037, China

The East Hubei ore cluster is one of most important skarn Cu-Fe-Au clusters in the Middle–Lower Yangtze River metallogenic belt(MLYR) because it contains >50 skarn Cu–Fe–Au deposits and over 800 km^2 of igneous rocks, which provides the best sample for studies on the origins of Late Mesozoic igneous and ore-forming event in the MLYR. With respect to mineral systems and metal associations, there are dominantly skarn Cu–Fe, Fe–Cu, Fe and Au deposits, which are all genetically associated with Late Mesozoic granitoids in the East Hubei.Previous studies mainly focused on individual skarn deposits, and comparatively studies among different skarn Cu-Fe-Au deposits have not yet been investigated.

There are similar compositions and mineral assemblages of skarn minerals, such as prograde garnet and pyroxene, among skarn Cu–Fe, Fe–Cu, Fe and Au deposits, and garnets and pyroxenes are dominantly andradite and diopside, respectively. In contrast, obviously differences between sulphur isotope and mineralized-related intrusions in different skarn types have been recognized: (1) The 137–144 Ma skarn Cu–Fe, Fe–Cu and Au deposits are genetically associated with 136–143 Ma diorite and quartz diorite, and the $\delta^{34}S$ of pyrites and chalcopyrites range from -8 to +12‰; while the 132–133 Ma skarn Fe deposits are genetically associated with 127–133 Ma diorite, quartz diorite and granite, and the $\delta^{34}S$ of pyrite range from +12 to +20‰. (2) The intrusions related skarn Cu–Fe, Fe–Cu and Au deposits show relatively high Sr/Y(25.1–201), and $(La/Yb)_N$(8.1–173), and low Yb contents(0.34–1.93ppm); whereas intrusions-related skarn Fe deposits show relatively low Sr/Y(0.66–75.3), and $(La/Yb)_N$(2.3–30.0), and high Yb contents(1.07–5.17ppm). It is proposed that the tionation of Cu, Fe and Au in the East Hubei ore cluster are possible related to different magma sources of intrusion and various evoporitic rocks involved in the formation of these skarn deposits.

Multistage refertilization of an Archean peridotite massif, N. Qaidam orogen (NE Tibet, China)

QING XIONG[1,2]*, SUZANNE Y. O'REILLY[1], W.L. GRIFFIN[1], N.J. PEARSON[1] AND J.-P. ZHENG[2]

[1] CCFS and GEMOC, Earth and Planetary Sciences, Macquarie Univ., NSW 2109, Australia (*correspondence: qing.xiong@mq.edu.au)

[2] State Key Laboratory of GPMR, Faculty of Earth Sciences, China Univ. of Geosciences, Wuhan 430074, China

A garnet (Gt) -facies peridotite massif [1] was involved in the early Paleozoic North Qaidam orogeny that generated ultrahigh-pressure (UHP) rocks during the collision between the Qaidam and Qilian blocks, NE Tibet (China) [2]. Original dunite and harzburgite now enclose fertile lherzolite zones, secondary clinopyroxene (Cpx)-rich lherzolite/wehrlite layers and rare clinopyroxenite dykes. Re-Os isotopic analyses of Fe-Ni-sulfides from the peridotite give Re-depleted model ages up to 3.0 Ga, indicating an Archean origin.

Hf-Nd-Sr-O mineral isotopic data support multiple refertilization episodes for this Archean massif. Lu-Hf isotopic ratios of Gt and Cpx in the dunites distant from the fertile rocks give an isochron age of ~1.5 Ga, similar to their Hf depleted-mantle model ages, suggesting early Mesoproterozoic melt addition from depleted asthenosphere. Parallel layers of Cpx-rich peridotites and pods of Gt+Cpx occur within harzburgite and dunite. Lu-Hf and Sm-Nd isotopic signatures indicate the formation of these secondary peridotite layers and pods was related to a refertilization by basaltic melts from the asthenosphere at ~1.1-0.7 Ga. All peridotitic minerals have moderately evolved initial Sr isotopes (0.70358-0.70873), relative to primitive mantle. Whole-rock and mineral elemental compositions of phlogopite-bearing garnet pyroxenite dykes suggest derivation from arc-related melts. Their mineral Nd-Sr-O isotopic compositions imply an evolved source, probably from subducted continental crust. However, Lu-Hf isotopic data reflect an early Paleozoic depleted-mantle origin. U-Pb ages of zircon and Lu-Hf isochrons and model ages of Gt+Cpx both show that the intrusion of the pyroxenitic melts, derived from asthenosphere contaminated by continental crust, occurred in the ealy Paleozoic, related to the coeval North Qaidam orogeny.

Gas and Water Distributed Patterns and Influential Factors in the Tight Sandstone Gas Reservoirs of Upper Triassic Xujiahe Formation in Hechuan Area of Sichuan Basin, China

ANNA XU[1]; ZECHENG WANG[2] AND CONGSHENG BIAN[3]

[1] (xan@petrochina.com.cn)

[2] (wzc@petrochina.com.cn)

[3] (bcs_1981@petrochina.com.cn)

The gas and water distribute complicatedly within the Upper Triassic Xujiahe-2 tight sandstone in the Hechuan area of Sichuan basin. The origin and formation of water in the gas reservoir is complex. Generally, the wells released gas initially but produced water instead or shut down soon after, and that affected the gas production.Understanding distributed pattern of gas-water and its main influential facters is benefit to the development solutions-making of gas reservoir, enhanced reserves estimation and exploitation profits of such gas reservoir. This paper discusses the correlation of gas-bearing capability with pore-throat size, permeability and porosity, on the basis of reservoir rock research, combined with core mercury injection experiment, gas relative permeability experiment, nuclear magnetic resonance and gas-driving water percolation experiment. We also carried out typical gas reservoir dynamic analysis and synthetic geology research, using single well testing and pilot production data. The conclusions are followings, 1) the pore structures of the Xujiahe-2 tight sandstone are dominated by fine or micro-throats, with strong heterogeneity; 2) the gas saturation relates with permeability and pore throat size in the Xujiahe-2 gas reservoirs; 3) the Xujiahe-2 gas and water have four distribution patterns, i.e. gas reservoir, upper gas with lower water, upper water with lower gas, and gas and water at the same zone; 4) the main controls on the Xujiahe-2 gas-water occurrence are gentle-slope setting, pervasively near-source gas charging and heterogeneity of the pore throat.

Geochronology of ore-bearing andesite in the Kuoerzhenkuola Au deposit, Northern Xinjiang, China

C. XU, T.F. ZHOU*, F. YUAN, Y. FAN, Y.F. DENG AND D.Y. ZHANG

School of Resources and Environmental Engineering, Hefei University of Technology, Hefei 230009, China (*correspondence: tfzhou@hfut.edu.cn)

The Sawur gold belt is in the northern Xinjiang, China, which belongs to the central south region of the Central Asian Orogenic Belt. The Kuoerzhenkuola gold deposit is the largest epithermal gold deposit in this belt, which is spatially associated with andesite.

Zircon La-ICPMS U-Pb age of ore-bearing andesite

we picked the ore-bearing andesite in the deposit district by detailed sampling. Furthermore, we tested the zircon U-Pb age of andesite is 339.4±4.8 Ma (MSWD=0.73) by La-ICPMS in Hefei University of Technology. The Kuoerzhenkuola Au-bearing andesite was intruded in Early Carboniferous Epoch.

The zircon U-Pb age of the mineralized andesite (339.4±4.8 Ma) is similar to the mineralization age (332±2.02 Ma) in Kuoerzhenkuola Au deposit within error [1],which indicate that Kuoerzhenkuola Au mineralization was genetically related to the andesitic magma [2]. In Eastern Sawur area, there several Au deposits aere are found through current exploration, including Berkesidai, Heishantou and Tasite Au deposits [3][4]. This geochronological result affords credit evidence to genetic research of the Early Carboniferous Au mineralization in the regional area.

This research was sponsored by Chinese National Science and Technology Program (2011BAB06B01).

Plutonium Immobilization and Re-mobilization by soil mineral-organic matter matrix compounds in the Far-field of the Savannah River Site (SRS), USA

CHEN XU[1], MATTHEW ATHON[1], YI-FANG HO[1], KATHLEEN A. SCHWEHR[1], DANIEL I. KAPLAN[2], ROBERTS A. KIMBERLY[2], NICOLE DIDONATO[3], PATRICK G. HATCHER[3] AND PETER H. SANTSCHI[1]*

[1]Department of Marine Sciences, Texas A&M University, Building 3029, Galveston, Texas 77553 (*correspondence: santschi@tamu.edu)

[2]Savannah River National Laboratory, Aiken, SC 29808

[3]Department of Chemistry& Biochemistry, College of Sciences, Old Dominion University, Norfolk, VA 23529

Pu is believed to be essentially immobile due to its low solubility and high particle reactivity to mineral phase or soil organic matter. For example, in sediments collected from a region of SRS, close to a wetland and a groundwater plume, ^{239,240}Pu concentrations correlated with organic carbon contents. However, previous studies reported Pu can be transported several kilometers in surface water systems through wind/water interactions [2,3]. The role of natural organic matter (NOM) in immobilizing or re-mobilizing Pu thus has been demonstrated. It was found that partitioining coefficients (K_ds) of intact humic acids (HAs) were sigificantly higher than those were treated with HF, lowering chelating sites for Pu or hydrophobicity differences between the two types HAs. K_ds of Pu (IV) with HAs were higher at low pH (4.4) than those at high pH (7.1), in contrast to the observation of Pu sorption to most mineral phases [4], possibly caused by the increased solubility of HA under more alkaline conditions. Though the colloidal fraction of HAs only accounts for a minor fraction of total OC (<5%) at pH 4.4, Pu binding to HAs accounts for 61-83% of the total added Pu, indicating colloidal organic matter as the mobile Pu carrier in the wetland area. Lastly, ^{239,240}Pu concentrations were found to be positively correlated with particulate hydroxamate and nitrogen contents, indicating binding to siderophores.

Petrographical features of the Shilu Fe-polymetallic ore deposit in Hainan Province, South China: implication for ore-deposit type

DERU XU[1], HUAYONG CHEN[1] AND ZHILIN WANG[1,2]

[1]CAS Key Laboratory of mineralogy and metallogeny, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China
[2]Graduate University of Chinese Academy of Sciences, Beijing 100049, China

The Shilu Fe-polymetallic hematite-rich deposit is situated in the western Hainan Province of South China. This deposit is characterized by upper Fe-rich ores and lower Co-Cu-rich ores, which are mainly hosted within a dominantly metamorphosed submarine siliciclastic and carbonate sedimentary succession of the Proterozoic Shilu Group that has been metamorphosed to greenschist to amphibolite facies. Two types of metamorphosed BIFs, i.e. the quartz itabirites which contain alternating hematite-rich microbands with quartz-rich microbands, and the amphibolitic itabirites which comprise alternating millimeter- to a few tens meter-scale, Fe oxide (magnetite, hematite)-rich bands with calcsilicate (garnet + amphibole + pyroxene + epidote)-rich mesobands to microbands, have been identified within the Shilu Group. A Fe-Co-Cu-rich sulfide facies, represented by the stratabound Co-Cu ores, also characterizes alternating Co-bearing pyrite + Co-bearing pyrrhotite + chalcopyrite macro- to mesobands dominantly with dolomite + calcite ± amphibole and minor with sericite + chlorite + quartz macro- to mesobands. The relic oolitic, pelletoid, colloidal and psammitic textures, and bedding structures which most likely represent primary sedimentary structures often observed in the Shilu itabirites. Hereby, the precursor precipitates to the Shilu deposit are interpreted as Fe-Co-Cu-(Si)-rich chemical sediments intercalated or mixed with variable amounts of detrital components. Input of the Fe, Si, Co and Cu from a mixed source of weathered landmass and sea-floor-derived hydrothermal fluids into a continental margin marine basin separated from an open ocean in fluctuating redox state caused primary sedimentation of the Shilu itabirites and Co-Cu ores via hydrogeneous-sedimentary processes. Further, we consider the Shilu deposit as a BIF (banded iron formation) ore deposit-type (Lake-Superior).

Rapid recovery of seawater $^{187}Os/^{188}Os$ after CAMP magmatism at Triassic-Jurassic boundary

G. XU[1], J.L. HANNAH[1,2], H.J. STEIN[1,2], R.F. GALIMBERTI[3] AND M. NALI[3]

[1] AIRIE Program, Colorado State University, Fort Collins, CO, USA
Guangping.Xu@colostate.edu (*presenting author)
[2] CEED Centre of Excellence, University of Oslo, Oslo, Norway
[3] Eni E&P, Geology and Geochemistry Labs, Milano, Italy

The Late Triassic–Early Jurassic (T-J) was a time of major global change. The end-Triassic mass extinction is one of the "big five" extinction events of the Phanerozoic. The extinction is proposed to be causally linked with volcanic eruptions from the Central Atlantic Magmatic Province (CAMP)[1][2] which produced low $^{187}Os/^{188}Os$ ratios in seawater at the period boundary. Late Triassic to Early Jurassic organic-rich shales from SE Sicily offer an opportunity to track events across the T-J boundary. Here we present Re-Os geochemistry of Hettangian Streppenosa Formation black shales from Gela #1 drillcore, SE Sicily.

Black shales from the lower Streppenosa Formation, deposited in a deep euxinic intraplatform basin, yield a Model 3 Re-Os age of 200.3 Ma and initial $^{187}Os/^{188}Os$ of 0.87. This Early Jurassic age is nominally younger than the T-J boundary of 201.3 Ma[3] and the major four pulses of CAMP volcanism, dated between 201.6 and 200.9 Ma[2].

The seawater $^{187}Os/^{188}Os$ ratio of 0.87 at 200.3 Ma is the highest ratio recorded in Triassic to Early Jurassic seawater[4]. This ratio stands in contrast to mostly low ratios reported across the T-J boundary, attributed to the sudden initiation of volcanic activity of CAMP[1][4]. Yet the high $^{187}Os/^{188}Os$ coincides with an unusual spike in seawater $^{187}Os/^{188}Os$ at the T-J boundary[4]. The high $^{187}Os/^{188}Os$ ratio at 200.3 Ma documents minimal contribution of unradiogenic Os from CAMP magmatism, and may also reflect enhanced continental weathering resulting from uplift along newly formed rifted margins. This rapid recovery of seawater $^{187}Os/^{188}Os$ after CAMP volcanic eruption likely reflects the short residence time of Os in seawater (tens of kyr).

Our results confirm that the Os isotope composition of seawater responds rapidly to large volcanic events, further demonstrating the role that seawater Os can play in identifying major environmental changes.

ENI S.p.A. provided samples and financial support.

Selenium geochemical characteristics of Ruoergai plateau wetland, eastern margin of the Qinghai-Tibet Plateau, Southwest China

J.Y. XU[1]* AND T. WANG[2]

[1]Department of Geochemistry, Chengdu Univ. of Technology, Chengdu 610059, China (*correspondence: xujinyong@cdut. cn; xujinyong@yahoo. cn)
[2] College of Materials and Chemistry & Chemical Engineering, Chengdu Univ. of Technology, Chengdu 610059, China

Ruoergai wetland is a typical plateau wetland ecosystem in the eastern margin of the Qinghai-Tibet Plateau, southwest China. This area is one of five big pastoral areas in China. On the other hand, the people's health and the development of livestock suffer from selenium deficiency symptom[1].

Here we developed a method for determination of selenium in enviroment sample by high performance liduid phase inductively couped plasma-mass spectrometry (HPLC-ICP-MS)[2]. The selenium of rock, soil, water and plant in this area were researched. Conclusions are as follows.

The selenium of rock in this area is generally lower than the crustal abundance. The selenium of the water is much lower than normal drinking water. The selenium of plant is between selenium deficiency areas and normal areas. The selenium of increased with organic matter content in soil.

Fluid and melt inclusions in the Wulaga gold deposit, Heilongjiang, China

J.H. XU[1]*, Y.H.WANG[1], H. WEI[1], Q.D. ZENG[2], J.M. LIU[2], Y.B. WANG[2] AND Q. MAO[2]

[1]Department of Resource Engineering, University of Science and Technology Beijing, Beijing 100083 (*correspondence: jiuhuaxu@ces.ustb.edu.cn)
[2] Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029

The Wulaga gold deposit, located in northeastern China, is a controversial deposit for its ore genesis[1-3]. The ore bodies are mainly hosted in cryptoexplosive breccia zone within Tuanjiegou plagioclase granite-porphyry of 106~108Ma[4], and in the layer fractures of metamorphic Heilongjiang group. Gold mineralization can be divided into 3 stages: pyrite- early white chalcedony quartz stage (stage I), smoky gray chalcedony quartz - polymetallic sulfide stage (stge II), and carbonate -quartz stage (stage III). Fluid inclusions in stage I are mainly aqueous solutions with homogenization temperatures (Th) of 154°C~355°C, mainly in 230°C~270°C. Salinities of fluid inclusions are 1.3%~8.2%NaCl eqv. Ths of fluid inclusions in stge II are 159°C~196°C, with salinities of 2.2%~3.2%NaCl eqv. Those in stage III are mainly in 170°C~230°C, with salinities of 0.5%~2.9%NaCl eqv. Ore-forming fluids in the main mineralization stages are characterized by mid to low temperatures, low salinities, and lack of CO_2, which is similar with epithermal deposits related with continental volcanic-subvolcanic rocks. There are three types of inclusions in quartz phenocryst of plagioclase granite-porphyry, that is, melt inclusions, primary L-V and L-V-S inclusions, as well as secondary L-V inclusions. Glassy melt inclusions are characterized by acid magma (SiO_2 =69.5~73.8%), with the trapping temperatures higher than 800°C. Secondary L-V inclusions in quartz phenocryst have 210°C~350°C of Th, which are coincided with those of mineralizing stage I (Q1), while salinities (5~7wt%NaCleqv.) are slightly higher than those of Q1. Melt and fluid inclusion study shows that gold mineralization is related with plagioclase granite-porphyry, and it is possible for silicate magma to produce salt-aqueous solution through immiscibility in magmatic differentiation.

Relationships between porphyry Cu–Mo mineralization in the Jinshajiang–Red River metallogenic belt and tectonic activity: Constraints from zircon U–Pb and molybdenite Re–Os geochronology

LEILUO XU [1]

[1]State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, 550002, China.

The Jinshajiang–Red River porphyry Cu–Mo metallogenic belt is an important Cenozoic porphyry Cu–Mo mineralization concentrating zone in the eastern Indo–Asian collision zone. New zircon U–Pb and molybdenite Re–Os ages and compilation of previously published ages indicate that porphyry Cu–Mo deposits in the belt did not form at the same time, i.e., the porphyry emplacement and relevant Cu–Mo mineralization ages of the Ailaoshan–Red River ore belt in south range from 36.3 Ma to 34.6 Ma, and from 36.0 Ma to 33.9 Ma, respectively, which are obviously younger than the porphyry emplacement ages of 43.8–36.9 Ma and the relevant Cu–Mo mineralization ages of 41.6–35.8 Ma of the Yulong ore belt in north. Tectonic studies indicated that the Jinshajiang fault system in north and Ailaoshan–Red River fault system in south of the Red river belt had different strike-slip patterns and ages. The right-lateral strike-slip motion of the Jinshajiang fault system initiated at ca. 43 Ma with corresponding formation of the Yulong porphyry Cu–Mo system, whereas the left-lateral strike-slip motion of the Ailaoshan–Red River fault system initiated at ca. 36 Ma with corresponding formation of the Ailaoshan–Red River porphyry Cu–Mo system. Therefore, the different ages of porphyry Cu–Mo systems, between in north and south of the Jinshajiang–Red River belt, indicate that the porphyry Cu–Mo mineralization is closely related to the divergent strike between the Jinshajiang and Ailaoshan–Red River strike-slip faulting resulted from the Indo Asian collision. The tanslithospheric Jinshajiang–Red River faulting caused partial melting of the enriched mantle sources of alkali-rich porphyries by depressurization or/and asthenospheric heating, and facilitated the migration of alkali-rich magmas and the corresponding formation of alkali-rich porphyries and relevant Cu–Mo deposits in the belt.

The Platinum-Group Element Abundance Patterns of the Meishan Permian-Triassic Boundary, China

L. XU [1]* AND S. HU [2]

[1] National Astronomical Observatories, Chinese Academy of Science, Beijing, China (*Email: xul@nao.cas.cn)

[2] Institute of Geology and Geophysics, Chinese Academy of Science, Beijing, China

It is a long-standing controversy what triggered the extinctions at the Permian-Triassic boundary, the most severe mass extinction in the geologic record (1). We analyzed all PGEs (except for Os) of a set of samples from the GSSP of the P-Tr boundary at Meishan, China. The PGE patterns have important constraints on sources of the P-Tr boundary materials. The data are also compared with previous results of known layers samples (2).

A total of 16 samples from three sections at Meishan were analyzed, which were numbered bed A to H, T, N, and bed O to S, and U. They were treated as blind testing samples, and the location information was released after the experiments. Our data reveal no significant positive PGE anomaly with the Ir contents of 0.003-0.029 ng/g. Compared with previous analyese (2), the abundance of PGEs reached the maximum at layer B-26. The layer B-25 and the pyrite lamina of B-24 (bed C and Q) that is referred to as the P-Tr event boundary, contain the lowest abundance of PGEs.

The P-Tr boundary samples show highly fractionated PGE patterns, distinct from chondrites and iron meteorites. The PGE patterns are parallel to those of Siberian flood basalts and Emeishan flood basalts, especially more similar to the former. The PGE data suggest a possible linkage between the P-Tr boundary event and the eruption of Siberian or Emeishan flood basalts.

Synthesis of Symplesite ($Fe_3(AsO_4)_2 \cdot 8H_2O$)

LIYING XU[1,2], YONGFENG JIA[2], DETONG JIANG[3], NING CHEN[4], JOEL REID[4] AND GEORGE P. DEMOPOULOS[1,*]

[1][Department of Mining and Materials Engineering, University of McGill, Montreal, Canada, H3A 0C5. (liying.xu@mcgill.ca;)(george.demopoulos@mcgill.ca)
[2][Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang, China, 110016.]
[3][Department of Physics, University of Guelph, Guelph, ON, Canada, N1G 2W1.]
[4][Canadian Light Source Inc.University of Saskatchewan, Saskatoon, Canada. S7N 0X4.]

Symplesite is the crystalline-triclinic ferrous arsenate ($Fe_3(AsO_4)_2 \cdot 8H_2O$). It has very low solubility at neutral to slightly alkaline pH (much lower than scorodite). Hence, symplesite could be a dominant compound for arsenic immobilization in suboxic environment, such as in co-precipitated tailings ponds. However, little is known about its synthesis, solubility and structure. The objectives of this work were to study the synthesis methods and to characterize the product using various techniques.

Fe(II) ($FeSO_4 \cdot 7H_2O$, 60, 90 mM pH 2, adjusted by HNO_3) and As(V) ($Na_2HAsO_4 \cdot 7H_2O$, 40, 70mM, pH 8.6) solutions ere prepared using deoxygenated DI-water in glovebox.

Different synthesis strategies were tested including raising the pH of pre-mixed Fe(II)-As(V) solutions to 4, 5, 6, 8 respectively (denoted as RMP), and mixing Fe(II) and As(V) solutions at fixed pH (4, 5, 6, 8) (denoted as TAP) to precipitate the precursor followed by aging at different temperatures (21, 45, 70 ºC). The molar ratio of Fe/As = 1.5 was applied. NaOH (0.25N) and HNO_3 (0.5N) were used to adjust media pH. The solid products were separated by filtration in glovebox and vacuum dried. XRD and SEM were used to characterize the products.

The XRD data indicated the successful synthesis of symplesite. SEM showed that the product was needle-shaped particles. The TAP method is better than RMP for the synthesis of symplesite. The media pH and temperature for precursor precipitation or crystallization during ageing are very important factors. Better crystallinity was obtained at higher temperature. The pH significantly influences the product's purity and re-crystallization. The rate of re-crystallization increased with increasing pH, but the highest pH of 8 was applied to avoid the formation of $Fe(OH)_2$.

In-situ trace elements and Li, Sr isotopes in peridotite xenoliths from Kuandian, North China Craton: Insights into Pacific slab subduction-related mantle modification

RONG XU[1], YONGSHENG LIU[1]*, XIRUN TONG[1], ZHAOCHU HU[1], KEQING ZONG[1], HUI LI AND SHAN GAO[1]

[1] State Key Laboratory of Geological Processes and Mineral Resources, Faculty of Earth Sciences, China University of Geosciences, Wuhan 430074, China

Trace element, Li and Sr isotopic compositions of major minerals in peridotite xenoliths from Kuandian, North China Craton (NCC) were analyzed *in situ* to investigate Pacific slab subduction-related mantle modification beneath the eastern NCC. The $^{87}Sr/^{86}Sr$ ratios are positively correlated with the La/Nb, Ce/Zr and Sr/Y ratios and negatively correlated with the Nb/U ratio for Cpx. Based on the trace element distribution patterns, three types of Cpx were identified. Type 1 Cpx are characterized by significant Nb-Ta-Ti depletions and the highest Sr isotopic ratios; Type 2 Cpx display Nb (or Ta) depletions and highly variable Nb and Ta fractionation; and Type 3 Cpx show no significant Nb or Ta depletion or even weak Ta enrichment and have the lowest Sr isotopic ratios. Some Cpx display a pattern of increasing Ca+Mg±Si from the cores to the rims, indicating addition of Ca+Mg±Si-rich fluids derived from a serpentinized peridotite layer above the subducting slab. These features indicate multiple mantle metasomatism events associated with the ancient subduction of the altered Pacific oceanic crust, which may contribute substantially to the destruction of the eastern NCC.

The Li contents in the Cpx (up to 34.8 ppm) and Opx (up to 28.0 ppm) are typically higher than those in the coexisting Ol (< 9.19 ppm), suggesting silicate melt metasomatism. Furthermore, both pyroxenes and Ol display remarkable zoning patterns in their Li contents and isotopic ratios, indicating a redistribution and disequilibrium fractionation of Li within and/or between minerals. The Li enrichment and low δ^7Li values in the rims of most Ol, Cpx and Opx may have arisen from diffusive fractionation during Li-rich melt/fluid metasomatic processes. However, the Li depletion and high δ^7Li in the rims of a few Ol may suggest cooling-induced Li isotope fractionation. Based on the zonation and Li diffusion coefficient at mantle temperatures, a model calculation suggests that the latest Li-rich melt/fluid metasomatic process was a recent event occurring shortly before or during the host magma eruption.

Temporal variations of Fukushima-derived ^{129}I in precipitations

SHENG XU[1]*, STEWART FREEMAN[1], XIAOLIN HOU[2], AKIRA WATANABE[3], KATSUHIKO YAMAGUCHI[3] AND LUYUAN ZHANG[2]

[1]Scottish Universities Environmental Research Center, East Kilbride, G75 0QF, UK (*correspondence: s.xu@suerc.gla.ac.uk)
[2]Center for Nuclear Technologies, Technical University of Denmark, 4000 Roskilde, Denmark
[3]Geophyscical Institute, Fukushima University, Fukushima 960-1296, Japan

The precipitation samples collected from Fukushima, Japan over 2010-2012 were analyzed for ^{127}I and ^{129}I in order to explore the atmospheric level and behaviour of radioactive iodine released from the Fukushima nuclear accident in 2011. ^{129}I concentration of 1.2×10^{8} atom/L in 2010 before the accident dramatically increased about 4 orders of magnitude to 7.6×10^{11} atom/L in March 2011 immediately after the accident with a $^{129}I/^{127}I$ ratio up to 6.9×10^{-5}. Afterwards the ^{129}I concentrations in precipitation decreased exponentially to $\sim3\times10^{9}$ atom/L until October 2011 with a half-life of about 29 days. This decline trend of ^{129}I concentrations in precipitation was interrupted around October 2011 by newly ^{129}I input to the atmosphere, and the elevated ^{129}I concentration in the atmosphere decreased exponentially again. Such a cycle of abrupt increase - exponential decrease occurred three times until present. This temporal variation can be attributed as alternation of ^{129}I dispersion and re-suspension from the contaminated local environment. A $^{129}I/^{131}I$ atomic ratio of 16±1 obtained from the rainwater sample is comparable with those estimated by analysis of surface soil samples [1]. Comparison of ^{129}I level in Europe suggests an insignificant effect of ^{129}I released from Fukushima to the ^{129}I level in the Europe.

Historical trends of heavy metal pollution recorded in sediments from Lake Qionghai, China

WEI XU, ZE-MING SHI, SHI-JUN NI AND YING GAO

Department of Geochemistry, Chengdu University of Technology, Key laboratory of Earth Science and Nuclear Techniques in Sichuan Province, Chengdu, 610059, China (weixuxw@gmail.com; shizm@cdut.edu.cn; nsj@cdut.edu.cn; ying.gaoy@gmail.com)

Heavy metals are serious pollutants due to their toxicity and long persistence in the environment. Lake sediment cores preserved the geochemical environmental changing record. A sediment core was collected in 2011 from Lake Qionghai, the second largest freshwater lake of Sichuan Province in China, to analyze the heavy metal pollution evolution of the lake.

The sediment core was 46cm in height, and was sectioned at 1cm intervals for the above 30cm while 2cm intervals for the left. The coefficients of variation of As, Cd, Cr, Cu, Hg, Ni, Pb, Zn in the sediment core are 0.32, 0.72, 0.16, 0.08, 0.34, 0.24, 0.19, 0.19, respectively, which indicates Cd varies greatly as a result of human activities, while the other heavy metals have little change mainly due to a natural origin.

The content of Cd increased distinctly and continuously to 0.87g/kg in the surficial six centimetres of the sediment core, indicating the lake had a large quantity of Cd input in the last years. According to the ^{137}Cs dating result, this interval was deposited from 1998 to 2011. Besides, the evaluation by potential ecological risk index method showed Cd in the sediments had pollution risk of medium degree. That means the lake has suffered Cd pollution since 1998.

Spatial-temporal extent of the influence of the Mongol-Okhotsk tectonic regime on China during Mesozoic: Evidence from Mesozoic igneous rocks

WEN-LIANG XU*, FENG WANG, JIE TANG, FU-PING PEI, WEI WANG AND HONG FENG

College of Earth Sciences, Jilin University, Changchun 130061, China (xuwl@jlu.edu.cn)

It has been a controversal issue whether the southward subduction of the Mongol-Okhotsk oceanic plate happen during Mesozoic. The spatial-temporal distributions of the Mesozoic igneous rocks in NE China provide a contraints on this question. Zircon U-Pb dating results indicate that the Mesozoic magmatisms in the Argun Massif adjacent to the Mongol-Okhotsk suture can be subdivided into the following stages: ~245 Ma, ~220 Ma, ~200 Ma, ~185 Ma, ~162 Ma, ~142 Ma, and ~125 Ma. The Early Mesozoic igneous rocks (~245 Ma, ~220 Ma, ~200 Ma, and ~185 Ma) consist of a suite of calc-alkaline basalt, basalt-andesite, diorite, and granodiorite. Together with the coeval porphyry Cu-Mo deposits, they reveal the subduction of the Mongol-Okhotsk plate beneath the Argun Massif. The ~162 Ma igneous rocks are composed of trachy-basalt, basaltic trachyandesite, and trachyandesite which display a transitional type between alkaline and subalkaline series, and only occur in the Great Xing'an Range and northern Hebei-western Liaoning provinces. Similarly, ~142 Ma magmatism also only occur in the same area as ~162 Ma igneous rocks and consist of alkaline ryholite, implying an extensional environment. Taken together, it is suggested that the ~162 Ma and ~142 Ma magmatisms could be related the evolution of the Mongol-Okhotsk tectonic regime and could be generated by the collapse and/or delamination of the thickened lower crust in the Great Xing'an Range and northern Hebei-western Liaoning provinces, which is also supported by two regional disconformability (beneath the Haifanggou Formation and overlying the Tuchengzi Formation, respectively). From north to south, the beginning time of ~162 Ma and ~142 Ma magmatisms gradually become younger, further implying that their formations should be attributed to the evolution of the Mongol-Okhotsk tectonic regime. The ~125 Ma igneous rocks are widely distributed in NE China and consist of bimodal ignepus rocks in the Great Xing'an Range and Songliao basin as well as a calc-alkaline volcanic rocks in the eastern Heilongjiang-Jinlin provinces, suggesting that the later could be formed under the subduction of the Paleo-pacific plate beneath the Eurasian continent, whereas the former could be generated by the delamination of the thickened lower crust and/or the subduction of the Paleo-pacific plate. This work is supported by 973 program (2013CB429803) and NSFC (41272077).

Tectonic implications for Mid-late-Neoproterozoic rift-related volcanic rocks in China

XUE-YI XU, LIN-QI XIA, ZU-CHUN XIA, XIANG-MIN LI AND ZHONG-PING MA

Xi'an Institute of Geology and Mineral Resources, China Geological Survey, Xi'an, Shaanxi 710054, China

Mid-late-Neoproterozoic rift-related volcanic rocks which had aggregated to form part of the Rodinia Supercontinet by ca. 900 Ma are widespread on several Precambrian in China. These volcanic rocks, which mainly consist of huge volumes of basic rocks and variable amounts of silicic volcanics, with small amounts or absence of intermediate rocks displaying a compositional bimodality, have attracted a number of recent studies. Several lines of evidence show most of these volcanics have a compositional bimodality, and formed in an intra-continental rift setting which may be genetically linked with mantle plumes activities.

On the basis of petrogeochemical data, these basic lavas can be classified into two major types: High Ti/Y and Low Ti/Y types, both of which can be further divided into two subtypes by different Nb/La ratios, respectively. The lavas (Nb/La <0.85) can be accounted for by lithospheric contamination of asthenospnere- (or plume-) derived magmas during their ascent, but parental magmas of others (Nb/La>0.85) may have not undergone such a process.

The rift-related volcanism at end of mid-Neoproterozoic and early-Cambrian coincided temporally with the separating between Australia–East Antarctica, South China and Laurentia and between Australia and Tarim, respectively. The mid-late-Neoproterozoic volcanism in China is the geologic record of broken-up of the supercontinent Rodinia.(This research is supported by Land and Resources Survey Project of China, Grant No. 1212011220649 and the National Natural Science Foundation of China, Grant No. 40872061)

Vanadium dynamics in soils impacted by vanadiferous titanomagnetite ore mining

Y.-H. XU[1]*, H. BRANDL[1] AND J.-H. HUANG[2]

[1] Institute of Evolutionary Biology and Environmental Studies, University of Zurich, CH-8057, Zurich, Switzerland (*correspondence: yuhui.xu@ieu.uzh.ch) (helmut.brandl@ieu.uzh.ch)

[2] Environmental Geosciences, University of Basel, CH-4056, Basel, Switzerland (jen-how.huang@unibas.ch)

Vanadium (V) plays a highly critical role in natural systems due to its potential essence and toxicity to organisms. To date, knowledge about V biogeochemistry is scarce so that assessing the impact of V enriched solids on the terrestrial environment is still difficult. Two soil profiles overlaid with and without ores and mining rests close to the vanadiferous titanomagnetite ore mining site were sampled. We attempted to characterize the mobility of soil V under the influence of mining activities and to estimate the potential risk of V to the adjacent environment by analysing the vertical V distribution, speciation of V oxidation state and its sequential distribution in different organic and mineral fractions. Additionally, HPLC-ICP-MS coupling was taken for speciation of V(V) and V(IV) in water and EDTA extracts of soils to understand V bioavailability and its potential toxicity.

Except the very high V concentrations (784 ppm) in the surface layer composed of mining rests, the soil V concentrations vary little along both soil profiles (343-356 and 143-201 ppm), suggesting the general low V mobility. Speciation of soil V based on sodium carbonate extraction indicates that more than 85% of total V in soil is tetravalent, which is generally rather insoluble and strongly absorbed [1]. Results of sequential extraction show totally different fractionation patterns comapred to the other metalloids e.g. arsenic. Vanadium prefers to enrich in crystalline fractions and residues, while arsenic is abundant in poorly crystalline fractions. Interestingly, the proportion of V in the crystalline fraction and residues is independent of the depth (~69%) in the unpolluted soils, but the relevance of these two fractions increases from 52% to 82% with the depth along the polluted soil profile, suggesting the potential influence of mining materials on V binding forms in soils. Pentavalent V predominates in both water and EDTA extracts, reflecting higher mobility of V(V) than V(IV). This further implicates elevated toxicity for the plants and soil organism due to higher toxicity of V(V) compared to V(IV).

Paleoclimate reconstruct of Late Triassic Xujiahe Formation Sichuan Basin in Southwest China

XU ZHAOHUI[1] WANG ZECHENG[2] AND HU SUYUN[3]

[1] Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, China, (tadxu@126.com)

[2] Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, China, (wangzecheng@petrochina.com.cn)

[3] Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, China, (husy@petrochina.com.cn)

Formation of Upper Triassic in Sichuan Basin China is abundant in gas resource, with proved gas resource of more than hundreds of billion cubic meters. As a result, the formation has become an important area for the gas industry of China.

Xujiahe Formation can be divided into six members with a texture of interbeded sandstones and mudstones, like a sandwich. The paleoclimate is an important reason for the texture. Three methods named palynoflora, clay minerals, and eigen elements were used in this paper to reconstruct the paleoclimate when Xujiahe Formation was sediment. Mudstone samples of the six members were taken from six different areas of the entire basin, and then analyzed to reconstruct the paleoclimate, respectively. The palynoflora indicated that the paleoclimate background of Xujiahe Formation was hot and humid, belonging to tropics-subtropics zone. Making use of clay minerals, the ratio of Kaolinite and Illite (K/I) was used to analyze the Paleoclimate, which reduced the ambiguity. Using the ratio of Calcium and Magnesium (Ca/Mg) and Strontium/Barium (Sr/Ba), the details of paleotemperature and paleomoisture (paleosalinity) were analyzed. It can be seen that the paleotemperature and paleomoisture of Xujiahe Formation fluctuated regularly against the setting of tropics-subtropics. Member Xu 1 was formed in transitional facies when the paleoclimate was hot and humid. Member Xu 2 was formed in the climate of hot and arid. When member Xu 3 was formed, the temperature and moisture were all higher than Xu 2. It belonged to palustrine environment. After shortly decrease of temperature and moisture in Member Xu 4, it became hottest and wettest during the period when Member Xu 5 was formed. The temperature and moisture declined slowly in Member Xu 6, and the paleoclimate became relatively warm and aridity. It is the fluctuation of paleoclimate that led to the forming of the sandwich sedimentation structure of Xujiahe Formation in Sichuan Basin Southwest China.

The nature of crustal components in mantle sources for Cenozoic continent basalts in southeastern North China Craton

ZHENG XU, YONG-FEI ZHENG* AND ZI-FU ZHAO

School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (*correspondence: yfzheng@ustc.edu.cn)

Cenozoic continental basalts in the southeastern part of the North China Craton exhibit depleted Sr-Nd isotope compositions and OIB-like trace element patterns. It is intriguing what kinds of crustal componenet were involved in mantle sources for the intraplate basalts. An integrated interpretation of major-trace elements and stable-radiogenic isotope data for these intraplate provides new insights into this issue. Different types of correlations occur between such variables as Ba/Th, Sr/Y, $\varepsilon_{Nd}(t)$, $(La/Yb)_N$ and SiO_2, suggesting two types of crustal components in the mantle source: altered oceanic basalt and seafloor sediment. The aletered oceanic basalt yields adakitic melt that is characterized by high $(La/Yb)_N$, Sr/Y and $\varepsilon_{Nd}(t)$ but low Ba/Th and SiO_2, whereas the seafloor sediment yields sialic melt that is characterized by low $(La/Yb)_N$, Sr/Y and $\varepsilon_{Nd}(t)$ but high Ba/Th and SiO_2. The OIB-type trace element patterns are interpreted as involvement of the oceanic crust that underwent partial melting outside the rutile stability field. These basalts exhibit low Fe/Zn and high Fe/Mn ratios, suggesting pyroxene-rich source lithology. The depleted Sr-Nd-Hf isotope compositions indicate involvement of juvenile lithospheric mantle.

We propose that westweard subduction of the Pacific plate beneath the Eurasian continent serves as the geodynamic mechanism for slab-mantle interaction in oceanic subduction channel for formation of the mantle sources. A MASH mechanism is used to account for petrogenesis of these continental basalts. The subduction-modified oceanic basalt and sediment become melted (M) during subduction to mantle depths of over 100 km. Then the melts assimilated (A) the SCLM wedge peridotite to generate a variety of ultramafic metasomes. These metasomes would be stored (S) at bottom of the SCLM wedge for a long time (maybe 50-100 Myr or longer). Finally, when the continental lithosphere was in extension during the renewed subduction of Pacific plate beneath the Eurasian continent in the Cenozoic, these metasomes were heated (H) by upwelling of the asthenospheric mantle, generating the intraplate basaltic melts.

Evidence for the hydrothermal fluid origin of Sanqisan uranium deposit in China

XU ZHENGQI [1,2]* AND SONG HAO[1,2]

[1] Department of Geochemistry and Nuclear Resources Engineering, Chengdu University of Technology, Chengdu 610059, China (*Correspondence: xuzhengqi@cdut.cn)

[2] Key Laboratory of Nuclear Techniques in Geosciences of Sichuan Province, Chengdu 610059, China

Sanqisan uranium deposit is a typical carbonate-siliceous-pelitic rock-type uranium deposit in Southwestern Guangxi. Through studies of the ore geological features, trace elements, isotope geochemical characteristics and petrology, this paper presents the evidence of hydrothermal activities, and draws the conclusions that magmatism has great significance for the formation of Sanqisan deposit, with the general basic geological features the same as the normal hydrothermal type uranium deposits. 1) Many siliceous bodies, as well as the multiphase quartz vein, have been found in field. The siliceous bodies, with a relatively high uranium content, appear in lenticular shape and a different scope, the big one being 2-3 m thick, 5-6 m long, the small one being only dozens of centimeters. 2) According to microscopic observation, the newly found pyroclastic and phyllite detritus indicate that there are signs of magma activity (or volcanic activity), and show that the main ore-bearing structure is relatively violent with large scale. 3) There are signs of multiphase hydrothermal activity, such as quartzitification, pyritization, carbonatization, etc., which intersperse with each other. 4) From the trace element analysis results, the content of some elements, such as Ni, As, Mo, Zn, Cd, Co, etc. are significantly high, more than 10 to hundreds times higher than the crustal abundance value, and the concentrating coefficient of Sb is 4630. 5) The carbon and oxygen isotopic compositions of hydrothermal calcite of the Sanqisan deposit show obvious genetic characteristics of deep magmatic source. The variation range of $\delta^{13}C$ is -0.709‰~ -3.172‰, and that of $\delta^{18}O$ is -12.451‰~ -14.516‰. 6) According to the U-Pb zircon dating, the ages for the diabase dykes in Sanqisan uranium deposit are 90Ma and 32-47Ma, which are in accordance with the age of the Sanqisan uranium deposit, indicating great significance of magmatism for the mineralization of Sanqisan deposit.

Ca^{2+} and Phosphate Ion Transport To and Calcium Phosphate Cluster Nucleation Within Collagen Fibrils In Bone Biomineralization

ZHIJUN XU[1], WEILONG ZHAO[1], YANG YANG[2] QIANG CUI[3] AND NITA SAHAI[1]

[1]Department of Polymer Science, University of Akron, Akron, OH 44325-3909, USA.(xu@uakron.edu) (wz24@zips.uakron.edu,)(sahai@uakron.edu.)
[2]Department of Chemistry and Biochemistry, Rowan University, Glassboro, NJ 08028, USA. (yangy@rowan.edu.)
[3]Department of Chemistry and Theoretical Chemistry Institute, University of Wisconsin, Madison, WI 53706, USA. (cui@chem.wisc.edu.)

Bone is a composite material consisting of collagen, an insoluble, fibrillar, protein; a non-stoichiometric calcium phosphate (Ca-P) phase idealized to hydroxyapatite (HAP); and soluble proteins. Based on TEM observations for six decades, collagen fibrils are known to be arranged in a hierarchical, "staggered" array, which controls the locations of the earliest nucleation in "hole zones" of the "a and e bands" within the fibril. However, the mechanisms for Ca^{2+} and inorganic phosphate (P_i) ion transport into the fibrils and for Ca-P nucleation in specific locations remain unknown.

We used the structure of collagen mimetic peptides and the 3-D packing structure of collagen molecules within a fibril to construct and optimize the entire collagen fibril structure with regular Molecular Dynamics (MD) simulations. Furthermore, Ca-P cluster formation and water diffusion and density distributions within the fibril were determined using Hamiltonian Replica Exchange Molecular Dynamics (HREMD), which captures even rare nucleation events. Significantly, we found that the lateral space between two adjacent collagen molecules is too small to allow prenucleation clusters larger than ~1nm to enter the fibril and reach the hole zones near the a and e bands where the earliest nucleation is observed by TEM. This result provides constraints on previously proposed mechanisms for calcium phosphate prenucleation cluster transport into the intra-fibrillar space. Further, the charged amino acid side chains (glutamate, aspartate, lysine, arginine) of the e bands are oriented to point into the hole zones, and attract Ca^{2+} and P_i ions electrostatically to form the earliest Ca-P clusters. We have shown for the first time the mechanisms by which the 3D heirarchical structure of collagen controls mineral nucleation from the Å – 10s of nm length-scale.

Carbonate speciation in depolymerized silicate melts (glasses): New evidence from ab initio calculations and ^{13}C MAS and static NMR measurements

X. XUE[1]* AND M. KANZAKI[1]

[1]Institute for Study of the Earth's Interior, Okayama Univ., Misasa, Tottori 682-0193 Japan (*Correspondence: xianyu@misasa.okayama-u.ac.jp)

Knowledge of the dissolution mechanisms of CO_2 in silicate melts and glasses is indispensible for understanding its effects on physical and thermodynamic properties. For depolymerised silicate compositions, previous IR, Raman and ^{13}C MAS NMR studies of quenched glasses all revealed CO_3^{2-} as the dominant species. However, no consensus has been reached as to whether CO_3^{2-} are linked to network-formers (e.g. Si) or bonded to network-modifiers (e.g. Ca) only (referred to as free carbonates hereafter), due to the lack of direct information for spectroscopic features of the former.

Here we report ab initio calculation results (using Gaussian 09) of vibrational frequencies (at B3LYP/6-31+G(d,p), scaled by 0.9685) and ^{13}C chemical shift tensors (at HF/6-311+G(2df,p)) for CO_3^{2-} groups bonded to one and two SiO_4/AlO_4 tetrahedra. We also report ^{13}C MAS and static NMR results for several $^{13}CO_2$-bearing depolymerized silicate glasses, e.g. diopside ($CaMgSi_2O_6$) and Ca-melilite ($Ca_{1.5}AlSi_2O_7$), prepared by quenching melts at 1.0-1.5 GPa and 1400-1600°C in a piston cylinder apparatus. The ab initio calculation revealed that the splittings of the ν_3 (asymmetric stretching) doublets for CO_3^{2-} bonded to one or two tetrahedral Si/Al are all large (around 180-480 cm^{-1}). In contrast, experimental data for CO_3^{2-} (bonded only to metal cations) in minerals show ν_3 splitting from zero to moderate, depending on local geometry. Thus, the moderate ν_3 splitting (70-100 cm^{-1}) reported for many depolymerized silicate glasses, which was used as evidence for CO_3^{2-} bonded to one Si (e.g. [1]), should be better viewed as evidence for free carbonates. Our calculations also showed that carbonates bonded to one or two Si/Al all show distinctly different characteristics of ^{13}C chemical shift tensors compared to free carbonates, similar to experimental observations for organic carbonates (bonded to one or two C). Our ^{13}C MAS and static NMR data for depolymerized silicate glasses are consistent with free carbonates as the dominant species. Its formation would lead to polymerization of the silicate structure.

Organic nitrogen cosmochemistry of ultracarbonaceous micrometeorite

H. YABUTA*, T. NOGUCHI, S. ITOH, S. TSUJIMOTO, N. SAKAMOTO, M. HASHIGUCHI, K. ABE, D. KILCOYNE, A. OKUBO, R. OKAZAKI, S. TACHIBANA, K. TERADA, T. NAKAMURA, M. EBIHARA AND H. NAGAHARA

*Dept. Earth and Space Science, Osaka University, Japan, (hyabuta@ess.sci.osaka-u.ac.jp)

Nitrogen is expected as a critical diagnostic tracer to determine the origin and evolution of organic compounds in the early Solar System. In the meteorite studies, nitrogen molecular and isotopic compositions have been debated separately for some of soluble organic compounds (e.g., amino acids) and insoluble organic solids, respectively. However, more than 10000 kinds of high molecular weight CHONS compounds remained unidentified in the solvent extract of Murchison meteorite (Schmitt-Kopplin *et al*. 2010). For understanding the formation of every discrete N-bearing organic compounds, it is very important to link soluble and insoluble components, by tracing back to more primitive organic chemistry than that of chondritic meteorites.

Amicrometeorite collected from the snow near the Dome Fuji Station, Antarctica, was investigated by SIMS, FIB-SEM, μ-XANES, and TEM in this study. From the micrometeorite, we have found an organic material in size of ~10×20 μm^2, that is more than twenty times as large as those in chondritic meteorites. The organic material is seeping into epoxy (embedding media), implying partial solubility. Its C- and N-XANES spectra are rich in a variety of nitrogen functional groups, such as imine (C=N), nitrile (C≡N), and amide (NHx(C=O)C). The N/C ratio is estimated order of 0.15, which is around five times higher than those of insoluble organic solids from chondritic meteorites (Alexander *et al*. 2007) but similar to some of comet 81P/Wild 2 dust particles (Cody *et al*. 2008). The isotopic imaging reveals that the organic material is likely sulfurized by the surrounding sulfide. The N- and S-rich organic chemistry may be related to a number of soluble CHONS compounds found by Schmitt-Kopplin *et al*. No isotopic anomalies in hydrogen, carbon, and nitrogen are observed (δD = ~ +100±300‰, $\delta^{13}C$ = ~ 0±70‰, $\delta^{15}N$ = ~ +100±110‰). The nitrogen isotopic range covers that of α-amino acids in CR chondrite (Pizzarello and Holmes, 2009), but is distinct from that of insoluble organic solids in the same meteorite group (Alexander *et al*. 2007). The TEM mineralogical characterization records a very slight degree of aqueous alteration (Yabuta *et al*. 2013). Thus, the observed N-rich organic chemical characteristics could reflect a original source of amino acids and the other CHONS in meteorites.

REE Geochemistry of ~3.2 Ga old BIFs from the Mapepe Formation and Msauli Member, Barberton, South Africa

T.R. YAHAGI[1]*, K.E. YAMAGUCHI[1,2], S. HARAGUCHI[3], R. SANO[4], S. TERAJI[5], S. KIYOKAWA[5], M. IKEHARA[6] AND T. ITO[7]

[1]Dept. Chem., Toho Univ. (6112029y@nc.toho-u.ac.jp), [2]NASA Astrobiol. Inst., [3]Atmosph. & Ocean Res. Inst. (AORI), Univ. of Tokyo, [4]Japan Chem. Anal. Ctr. (JCAC), [5]Dept. Earth & Planetary Sci., Kyushu Univ., [6]Ctr for Adv. Marine Core Res., Kochi Univ., [7]Fac. Edu., Ibaraki Univ.

A popular mechanism for Banded Iron Formation (BIF) deposition is that Fe-oxides were precipitated in deep-water setting by oxidation of dissolved Fe^{2+} supplied from submarine hydrothermal activity, by dissolved oxygen supplied from oxygenic photosynthesis in the surface ocean. When Fe-oxides precipitated, rare earth elements (REEs) were adsorbed on their surface. REE compositions of seawater have been recognized to reflect redox state of seawater and the extent of input from hydrothermal activity. In this study, we aimed to estimate Mesoarchean seawater chemistry based on REE signatures of 3.2 Ga old BIFs.

Samples were collected from outcrops of the Mapepe Fm at the bottom of the Fig Tree Gp and Msauli Member in the Onverwacht Gp, both belonging to the Swaziland Supergroup. Powdered rock samples were analyzed for their major element compositions by XRF at AORI, REE compositions by ICP-MS at JCAC, and oxygen isotope compositions. Samples with <1.0 wt.% Al_2O_3 are considered to be "pure chemical precipitates" and thus used for further discussion.

Chondrite-normalized REE patterns of the Mapepe samples show positive Eu anomaly, elevated Y/Ho ratios, and LREE>HREE. Furthermore, there exist positive correlations among the extent of positive Eu anomaly, $\sum Fe_2O_3$ contents, and Y/Ho ratios. The maximum Y/Ho ratios are surprisingly comparable to the those of the modern ocean. These characteristics suggest a coherent story for BIF deposition; Fe^{2+} emanated from submarine hydrothermal activity was oxidized to Fe^{3+}, which, with enhanced particle reactivity, absorbed dissolved REEs and Y in the 3.2 Ga ocean, producing elevated near-modern Y/Ho ratios. The Msauli samples are mostly enriched in Al_2O_3 and have clastics-dominated REE patterns, suggesting deposition at shallower, more proximal setting.

We also estimate temperature of seawater 3.2 Ga ago from which the BIF precipitated, based on their oxygen isotope compositions of silicate- and Fe-oxide phases.

Intepretation of Cs adsorption behavior based on the EXAFS, TR-DXAFS, and STXM methods

TSUYOSHI YAITA

Japan Atomic Energy Agency, 1-1-1 Koto, Sayo-cho, Sayo-gun, Hyogo 670-5148, Japan

Radioactive cesium in Fukushima has brought serious problem on our daily life since the nuclear reactor accident. Thus, verification test of decontainationof radioactive cesium has been widely carried out in Fukushima. Although this test is usually performed based on the pre-test in laboratory, radioactive cesium, however, was not sometimes able to removed from clay minerals even if used the same method. Based on this backgrounds, we first tried to clarify the adsorption mechanism on clay mineral in detail through the speciation of cesium using the advanced analytical methods such as the synchrotron based EXAFS, TR (time resolved)-DXAFS (SPring-8), STXM (ALS). Afterwards, we attempted identification of a specific adsorption site in clay minerals.

The adsorbent clay minerals were adopted vermiculite delivered from Fukushima and prepared by adsorption/desprption experiments of stable cesium in laboratory.

Figure 1 shows the time dependent radial structural function of EXAFS by TR-DXAFS. The structural differencies dependent on time were able to classified into four processes as follows, 1) diffusion of hydrated cesium in frayed edge site, 2) dehaydration, 3) adsoption on clay mineral, 4) closing of frayed edge site and fixing cesium on clay mineral site. In this presentation, we will talk about interpretation regarding the adsorption model based on the these results.

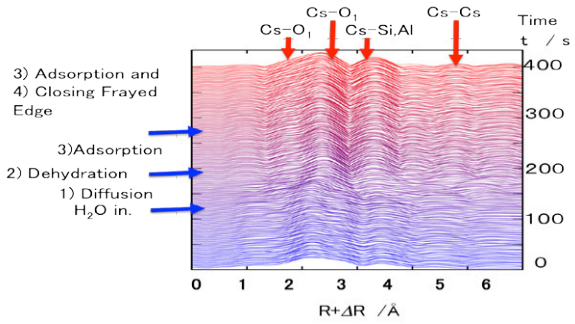

Figure 1: Time resolved radial structural functions of EXAFS for clay mineral-Cs-H_2O system. * Arrows in blue mean changing points of spectral features.

Oxygen isotopes as an indicator of corundums origin

[1]V. V. YAKOVENKO [2] S. V. VYSOTSKY[3] AND A. V. IGNAT'EV

[1]Far East Geological Institute, Far East Branch, Russian Academy of Sciences, Vladivostok, Russia(yakovenko_v.v@mail.ru)

Jewelry corundums have different origins [1]. The purpose of this study was to show dependence of oxygen isotope composition in corundum from genesis. Samples from various fields of the world were studied. The obtained isotope data testify that all studied Corundum-bearing Ural pegmatites showed range from 4.6 < δ18O < 6.5 ‰. At the same time corundum from pegmatites of the Tazheransky massif showed values within range from 10.6 < δ18O < 11.9 ‰. Corundum from plagioclasites in the ultramain breeds Tanzania, Polar Ural Mountains and Gvineniya keeps wiethin range from 4.8‰ <δ18O<5.5‰.Biotitite with corundum (Pamir) (7.4‰) it was formed of magmatic breeds, most likely under the influence of a mix of fluids: magmatic and metamorphic. Corundum was formed of Alabashka's marble and Pakistan (19.4 – 19.9‰), most likely, as a result of a regional metamorphism of carbonate breeds, at a temperature of 600-6200C under the influence of a metamorfogenny fluid [2]. Thus, the oxygen isotope composition of corundums in fields metamorfogenny, pegmatitovy and pnevmatolit-hydrothermal is dictated by oxygen isotope composition of the water containing fluid participating in their formation.

(U-Th)/He dating of native gold: Problems and perspectives

YAKUBOVICH O.V.[1,2], SHUKOLYUKOV YU.A.[1,2,*], SALNIKOVA E.B.[2], YAKOVLEVA S.Z.[2], GOROKHOVSKY B.M.[2] AND KOTOV A.B.[2]

As it has been suggested long time ago helium can easily escapes from crystal structures of minerals. However nowadays earlier preconceived ideas about the quick migration of helium from all materials should be revised.

There is a group of minerals, namely native metals, where the retention of radiogenic helium is rather high. Helium due to its very low solubility in metals tends to form atomic clusters. Migration of such stable clusters needs relatively high temperatures that are close to the metal melting point [1]. Anomalously high retention of radiogenic helium in native metals is experimentally shown on the example of native minerals of platinum. Finding paves the way for creation a novel ^{190}Pt-^{4}He method of isotope geochronology [2].

Aforementioned indicates that theoretically retention of radiogenic helium in native gold also should be high. Taking into account that the concentration of U in native gold varies from first ppb to hundreds of ppm, there are rather high possibility for the direct dating of native gold by the (U-Th)/He method. Importance of this opportunity needs no explanations.

By the way first attempts of the direct (U-Th)/He dating of native gold seems to be inaccurate. Method easily could distinguish events within hundreds of million years. Nevertheless there was large dispersion in obtained ages. And as it become clear nowadays one of the main reasons of this dispersion hides in the problem of the behavior of uranium in native gold. After extended detailed SEM study of native gold it was shown that U and Th mainly occurs in gold as submicron inclusions of phosphates of REE that are very sensitive to secondary processes. In this way reliable age determination of native gold requires careful mineralogical study and appropriate sample preparation as well as special methodological approach for release of radiogenic He from native gold.

Phase equilibria modelling of open system melting: Some implications

CHRIS YAKYMCHUK[1]* AND MICHAEL BROWN[1]

[1]University of Maryland, College Park, USA (*correspondence: cyak@umd.edu)

Decompression melting has been invoked as an important process in tectonics. To evaluate this postulate, the melt production from metapelite and greywacke during high-*T* decompression is evaluated using *P–T* pseudosections calculated in the Na_2O–CaO–K_2O–FeO–MgO–Al_2O3–SiO_2–H_2O–TiO_2–Fe_2O_3 chemical system. Both closed system (undrained) and open system (drained by episodic melt loss) conditions are investigated. In nature, closed system behaviour is unlikely to be important in crustal differentiation. For drained conditions, at each point along the *P–T* path where the melt fraction reaches 7 mol%, 6/7ths of the melt produced is removed from the bulk chemical composition and a new phase diagram is calculated for the residual composition. First, we consider melt production along schematic *P–T* paths comprising an isobaric heating segment at 1.2 GPa followed by decompression to 0.4 GPa at 750°C, 820°C, and 890°C. The maximum amount of melt produced during decompression occurs at the lowest temperature investigated (750°C). Along this *P–T* path, the melt volume does not reach 7 mol% prior to decompression; during decompression the metapelite generates 15 mol% and the greywacke 12 mol% melt. This amount is significantly less than commonly invoked in some discussions of orogenic collapse. Isobaric heating to 820°C and 890°C produces significantly more melt along the prograde segment, resulting in multiple melt drainage events prior to decompression, which leads to lower melt production during decompression. Second, we consider melt production from the solidus at 1.2 GPa to peak *P–T* of 860°C at 1.8 GPa followed by isothermal decompression to 0.4 GPa. For drained conditions along this schematic *P–T* path, the metapelite generates only 1/4 of the cumulative total of 31 mol% melt during decompression, whereas the greywacke generates 1/3 of the cumulative total of 19 mol% melt during decompression. The effects of melt loss on the dissolution of zircon and monazite are evaluated and the implications for the interpretation of U–Pb ages will be discussed. Some models for the structural and thermal development of migmatite domes and metamorphic core complexes may require reevaluation. In particular, the role of melt transfer through suprasolidus crust and melt accumulation at shallow levels in the anatectic zone should be considered rather than simply invoking the presence of large volumes of melt in decompressing crust.

An application of multivariate statistical analysis using SAS programme to identify heavy metal sources between Cebeci (Kocaeli)-Eregli (Zonguldak), Turkey

F. YALCIN [1], E. KAYA[2] AND N. ILBEYLI[3*]

[1] Akdeniz University, Department of Mathematics, 07058, Antalya, Turkey, fusunyalcin@akdeniz.edu.tr
[2] Akdeniz University, Department of Animal Science, 07058, Antalya, Turkey, ebrukaya@akdeniz.edu.tr
[3] Akdeniz University, Department of Geological Engineering, 07058, Antalya, Turkey, ilbeyli@akdeniz.edu.tr

The aim of this work is to determine heavy metal contents and their possible causes that represent the variability of The Sakarya Canyon coastal sediments using SAS programme. Results of the previous study were conducted in the same area and obtained by using SPSS programme (Yalcin et al., 2013). The results of analysis show that Zn,Cr,Zr,V, Ni,Pb,Co,Cu,Ga,As,Nb,Al,Sn,Cd,Fe,Mg,Ti and Mn are the highest values of heavy metals. Correlation analysis results display that there are high relationships between concentrations of Zn and Al,Cr and Mg,Ti,Mn,Fe and V. According to PCA, because of the eigen values that are larger than 1, three components are obtained. From the three components which are obtained: first one includes Ti,Mg,V, Mn,Co,Fe,Cr,Nb, second one contains Pb,Zn,Al, Cd and third one consists of Sn,Zr,Cu,Ga. Though, As wasn't included any of these components. The PCA that uses rotated loadings pointed out that first one variance explanation ratio is 42%, second one variance explanation ratio is 19% and finally third one variance explanation ratio is 16%. Considering all three components, total variance explanation ratio is 77%. Furthermore, PCA was performed using varimax transformation in order to obtain more interpretable results. When hierarchical cluster analysis is applied to data, resulting dendogram showed that highest similarities are between G2, G3 and G4 stations. The similarities between these stations refer to the similarities between the ambient conditions. Regression analysis of the percentage of explanatory (R2) is 0.99 and the results of analysis are shown a high degree of accuracy. According to the data, heavy metals representing different factor groups display genetic similarity.

[1] Yalcin M.G., Simsek G., Ocak S.B., Yalcin F., Kalayci Y., Karaman M.E., "Multivariate Statistics and Heavy Metals Contamination in beach sediments from the Sakarya Canyon, Turkey" Asian Journal of Chemistry, 25 (4), 2059 - 2066 (2013).

Coal petrography and depositional environments relationship of the Tertiary coals from Anatolides (Tokat Region - Turkey)

N. YALÇIN ERİK[1]* AND F. AY[2]

[1] Cumhuriyet Univ., Dep. of Geology, Sivas – Turkey (*correspondence: nyalcin@gmail.com)
[2] Cumhuriyet Univ., Dep. of Anthropology, Sivas – Turkey (farukay@gmail.com)

The study area is situated in the Anatolides, one of the major tectonic units of the Turkey The aim of the study was to understand depositional environments of the Pliocene and Eocene coal-bearing strata from two different area of the Tokat region, and this is the first detailed investigation on the coal petrographic characterization and the interpretation of coal facies and depositional environment. These Pliocene and Eocene coals are a high ash and sulphur sub-bitumnious coal which is petrographically characterised by a high huminite content, mainly gelinite macerals, relatively abundant vitrite, clarite and carbalgilite microlithotypes. The mineral matter of the studied coal samples are made up mainly of clay minerals and quartz, in which calcite is the dominant mineral phase. Generally, the Pliocene coal has slightly higher ash content than the Eocene coals. Gross calorific values similar between Eocene and Pliocene samples (respectively avr. value 2974.33 and 3051.8 Kcal/kg). These coals have similar huminite reflectance value (average R_{max} values respectively; 0.42% and 0.48%). Based on volatile matter and gross calorific value, Eocene and Pliocene coals can be characterized as "Sub-bitumnious B/C" coals. The ultimate analysis shows that these coals are low in carbon content, but have high oxygen and sulphur content. Palynological investigation in this study (especially Ovoidites parvus, the prevalence of the freshwater algae of Ovoidites ligneolus species) supports the development of that kind of vegetation in the Tokat region. Low TPI values indicate predominance of herbaceous and woody derived tissues and increased rate of subsidence that result in the poor preservation of the maceral structures. GI values indicate variable water table and suggest that the mire was not too acidic.

On the basis of the petrological parameters it is concluded that the Artova and Zile coals from Tokat interior are limno-telmatic type, formed in the lagoon in typical this formation conditions.

Chemical speciation of heavy metal elements in indoor dust by XAFS spectroscopy

H. YAMADA[1]*, H. QIN[2] AND Y. TAKAHASHI[1].

[1] Hiroshima University, Hiroshima 739-8526, Japan (*correspondence : m120941@hiroshima-u.ac.jp)
[2] Institute of Geochemistry, CAS

It is recently concerned that indoor dust can be a source of chemical materials which lead to adverse health effects for children. However, heavy metals in indoor dust have been poorly studied in Japan and China. Our previous study showed that lead (Pb), zinc (Zn), and antimony (Sb) were highly concentrated in indoor dust. Lead has been used for various industrial products, but low-level Pb exposure which leads to adverse health effect for children is concerned. Zinc is an essential element for living organisms, but can be a toxic if ingested excessively. The toxicity of Sb, which is recently recognized as an emerging element found environment, largely depends on the chemical state, especially the oxidation state. Thus, it is important to identify the chemical species of Pb, Zn, and Sb to understand their origins and assess their health effects for children. In this study, X-ray absorption fine structure (XAFS) was performed to identify the chemical species of heavy metal elements included in indoor dust and their origins.

The indoor dust was collected by a vacuum cleaner and, for comparison, soil outside of the same house was collected. The particle size fraction used for the analysis was smaller than 180 μm, the particle range of which can be ingested by children. Lead L_{III}-edge XAFS spectra for indoor dust samples in could be fitted with that of $PbCrO_4$, which was identified only in the indoor dust. It is suggested that the source of $PbCrO_4$ which may be derived from pigment possibly used in some materials indoors. Antimony K-edge bulk XANES and μ-XANES spectra of the indoor dust showed that the chemical state of Sb in most of the particles was Sb(V) which has a toxicity lower than Sb(III). Zinc K-edge bulk XANES spectra of the indoor dust collected suggested presense of ZnS originated from indoor materials.

Pu isotope in water column of the Sea of Okhotsk

MASATOSHI YAMADA[1]*, JIAN ZHENG[2] AND TATSUO AONO[3]

[1] Department of Radiation Chemistry,Institute of Radiation Emergency Medicine, Hirosaki University, Hirosaki, Japan, (*correspondence: myamada@cc.hirosaki-u.ac.jp)
[2] Research Center for Radiation Protection, National Institute of Radiological Sciences, Chiba, Japan (jzheng@nirs.go.jp)
[3] Fukushima Reconstruction Support Headquarters, National Institute of Radiological Sciences, Chiba, Japan (t_aono@nirs.go.jp)

The Sea of Okhotsk is a marginal sea of the weatern North Pacific Ocean, lying between the Hokkaido Island, the Sakhalin Island, the Kamchatka Penninsula, Kuril Islands and the Siberian coast, and is a highly productive marine ecosystem. Anthropogenic radionuclides such as ^{239}Pu (half-life: 24,100 yr), ^{240}Pu (half-life: 6,560 yr) and ^{241}Pu (half-life: 14.325 yr) mainly have been released into the environment as the result of atmospheric nuclear weapons testing. The objectives of this study are to measure the ^{239}Pu and ^{240}Pu concentrations and ^{240}Pu/^{239}Pu atom ratios in seawater from the Sea of Okhotsk and to discuss the transport processes of Pu.

Seawater samples were collected at Stn. CM-06 in the Sea of Okhotsk with acoustically triggered quadruple PVC large-volume sampling bottles during the Canis Minor Expedition of the R/V Hakuho-Maru. The ^{239}Pu and ^{240}Pu concentrations and ^{240}Pu/^{239}Pu atom ratios were measured with a double-focusing SF-ICP-MS, which was equipped with a guard electrode to eliminate secondary discharge in the plasma and to enhance overall sensitivity [1].

The ^{239}Pu and ^{240}Pu concentrations were 1.3 – 1.5 mBq m^{-3} in the surface water and they increased with depth; a broad maximum was identified at 1,000 – 2,000 m depth. The atom ratio of ^{240}Pu/^{239}Pu showed no notable variation from surface water to deep water of 3,000 m depth. The atom ratios in water column of the Sea of Okhotsk were higher than the mean global fallout ratio of 0.18. However, the atom ratios were slightly lower than those observed in the Japan Sea and the western North Pacific Ocean. The Bikini close-in tropospheric fallout Pu could be transported to the Sea of Okhotsk by ocean currents.

[3]Dept. Earth Sci., Kanazawa Univ., Ishikawa 920-1192, Japan
[4]National Inst. of Polar Res., Tokyo 190-8518, Japan

A young exposed pluton represents the recent tectonic uplift and high exhumation because a pluton is a body of intrusive igneous rock that crystallized from slowly cooling magma at depths of several kilometers beneath the surface of the Earth. The youngest exposed pluton reported to date was the Takidani Granodiorite (~ 1.4 Ma) in the Hida Mountain Range of central Japan [1]. Using LA-ICP-MS and SHRIMP U-Pb zircon dating methods, this study demonstrates that the Kurobegawa Granite, situated in the middle of Cretaceous granitic batholith in the Hida Range, is as young as ~ 0.8 Ma [2]. Our data indicate multiple intrusion episodes in this pluton since 10 Ma with a ~ 2-million-year period of quiescence; hence, a future intrusion event is likely within 1 million years.

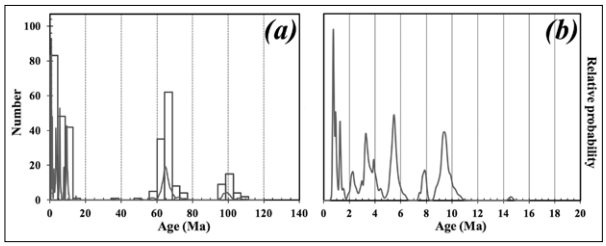

Figure 1: Age distribution of individual zircons. (*a*), Age distributions (cumulative probability distributions by *Isoplot 3.75*) for 320 grains of granitic origin with ages younger than 140 Ma. The peaks > 20 Ma are at 65 and 100 Ma. (*b*), Age distributions for 174 grains with ages < 20 Ma. The prominent peaks are 0.8, 1.3, 3.3, 5.5, 7.9, and 9.5 Ma.

Impact history of lunar highlands recorded in MIL 090034, 090036, and 090070 lunar meteorites

A. YAMAGUCHI[1]*, N. SHIRAI[2], L.E. NYQUIST[3], J. PARK[4,5], C-Y, SHIH[6], M. EBIHARA[2] AND G.F. HERZOG[5]

[1]National Institute of Polar Research, Tachikawa, Tokyo 190-8518, Japan (yamaguch@nipr.ac.jp)
[2]Tokyo Metropolitan University, Hachioji, Tokyo 192-0397, Japan
[3]NASA/JSC, Houston, TX77058, USA.
[4]LPI, Houston, TX 77058, USA.
[5]Rutgers University, Piscataway, NJ, USA.
[6]JE-23, ESGC/Jacobs Sverdrup, Houston, TX77258, USA.

Clues from feldspathic lunar meteorites help in understanding lunar crustal evolution. We performed petrological, geochemical, isotopic studies of feldspathic lunar meteorites, MIL 090034 (MIL34), 090036 (MIL36), and 090070 (MIL70) [1,2]. Here, we report petrology and impact history of the three lunar crustal rocks.

MIL34 and MIL70 are crystalline melt breccias. MIL34 contains anorthositic clasts. We found a clast of noritic anorthosite with minor phosphate and zircon that seems to be of Mg-suite rock in MIL34. MIL70 is poorer in clastic components and has coarser-grained melt matrix. Plagioclase compositions of MIL34 and MIL70 peak sharply around An_{96-97} as do those of FAN. Mg numbers of olivine vary from 58-65 with a few higher values. MIL36 is a fragmental or regolith breccia that contains fragments of K, Na-rich feldspar, phosphate, and zircon which are related to KREEP components. Plagioclase compositions vary from ~An_{84-98} with a broad peak at An_{95-97}.

Bulk chemical compositions are generally consistent with these petrologic data. The REE abundances of MIL34 and MIL70 (Sm~6×CI) are similar, whereas those of MIL36 are much higher (~30×CI) [1]. Also, MIL34 and MIL70 have similar cosmic ray exposure (CRE) ages indicating they are launch paired. MIL36 has a larger CRE age (~>70Ma) [2].

We suggest that MIL34 and 70 were derived from a large crater: MIL70 was deeply buried in the impact melt sheet, whereas MIL34 was closer to the surface on the basis of CRE and petrologic data. MIL36 was derived from a site near the KREEP-rich terrane. Ar-Ar ages for subsamples of MIL 34 and MIL70 range from 3.50±0.11 to 3.64±0.22 Ga, resp., and are 3.79±0.04 Ga for MIL36.

Introduction

In the geological disposal of Japanese TRU waste, it is important to understand the long term alteration of bentonite that is a part of the engineered barrier system. In this study, the geochemical simulations were carried out on natural bentonite suffered from Ca-rich alteration.

Discussion of Results

The alteration of bentonite in a tuffaceous bed at a Japanese island arc basin was focused as natural analogue. Based on the initial minerals estimated by MELTS[1], long term alteration of initial rock was calculated by PHREEQC[2]. In the simulation case, the initial marine sediments deposited in seawater at 5 Ma ago. This sedimentary age was based on experimental analysis of microfossils. In the simulation case, we programed that the sedimentary basin changed to land at 1 Ma ago. At the time, the porewater was set to be a 50:50 mixed rainwater-groundwater because a result of principal component analysis of present groundwater suggests this mixing ratio among rainwater and shallow hot spring water.

As a calculation result, coexistence of Na-, Ca-montmorillonite and zeolite were confirmed (Fig.2) for the past 5Ma. This coexistence is consistent with experimental results.

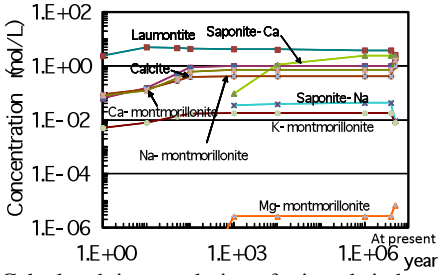

Fig.1 Calculated time-evolution of minerals in bentonite.

Biogeochemical cycling of nitrogen and carbon in the 3.2 Ga ocean: Results from DXCL-DP, NW Pilbara, Western Australia

K.E. YAMAGUCHI[1,2], D. KOBAYASHI[1], K. YAMADA[1], R. SAKAMOTO[3], K. HOSOI[4], S. KIYOKAWA[3], M. IKEHARA[4] AND T. ITO[5]

[1]Dept. Chemistry, Toho Univ., [2]NASA Astrobiol. Inst., [3]Dept. Earth & Planetary Sci., Kyushu Univ., [4]Center for Advanced Marine Core Res., Kochi Univ., [5]Fac. Edu., Ibaraki Univ.

Records of geochemical cycling of bio-essential, redox-sensitive elements have keys to decipher misteries of the co-evolution of Earth and life. In order to obtain insight into biogeochemical cyclig of those elements and early evolution of microbial biosphere from high-quality samples, we drilled through Mesoarchean strata in coastal Pilbara (Dixon Island-Clearverville Drilling Project, see [1]), and obtained 3.2 Ga old drillcores (CL1, CL2, and DX) of sulfide-rich black shales in the Cleaverville Group. We conducted a systemtic geochemical study involving sequential extractions of Fe, S, C, and N for phase-depdendenet contents and isotope compositions, in addition to major and trace element analysis, for >80 samples. Here we focus on geochemistry of N and C.

The average C_{org} contents are 0.60, 0.73m and 1.21 wt.% for CL1, CL2, and DX, respectively, with a maximum value of 3.0 wt.%. The $\delta^{13}C_{org}$ values range from –30.7 to –25.7‰ (CL1), –32.6 to –27.8‰ (CL2), and –31.8 to –26.0‰ (DX). The average $\delta^{15}N_{org}$ values are –3.8±0.9‰ for CL1 and CL2 and –2.0±1.0‰ for DX, while the $\delta^{15}N_{clay}$ values are –3.4±0.6‰ for CL1 and CL2, and –0.1±2.4‰ for DX. These data may be explained by the following processes.

Microbially mediated redox-cycling of nitrogen, possibly involving denitrification and microbial (cyanobacterial?) N_2-fixation are most likely mechanism to fully explain the obtained data set, while microbially mediated non-redox cycling of NH_3 is also possible. Sources of N are N_2 from the coeval atmosphere and/or NH_3 from submarine hydrothermal activity. Denitrifiction occurs in anoxic environments where sulfate reducton may also occurr, which is supported by sulfur isotope compositions of sulfide in the same sample set. These results are in contrast with a previous study using chert [2], but consistent with more recent study by [3].

This study suggests operation of microbial N in the Meso-archean. The atmosphere-hydrosphere system would have been sufficiently oxidized to allow redox-cycling of nitrate.

Early sulfide precipitation in basaltic magma intruding into felsic reservoir beneath the summit of Asama volcano: a melt inclusion study for the 2004 eruption

YOSHIAKI YAMAGUCHI[1], TOSHISUKE KAWASAKI[2], TAMAMI YAMAGUCHI[3] AND YASUSHI OHTA[4]

[3]Kawasaki Municipal Science Museum, Japan
[4]Pacific Metals Co., Ltd., Japan

During the 2004 eruption of Asama volcano, sulfur-rich basaltic magma repeatedly intruded into a long-lived crystal-rich felsic reservoir beneath the summit. Melt inclusion study of scoria (23 September) revealed that the major phenocrysts (plagioclase, ortho- and clinopyroxene, and Fe-Ti oxides) were principally derived from the felsic magma and the phenocrysts trapped sulfur-poor felsic melt (SiO_2 67-77 wt%, S mostly <1000 ppm). In contrast, olivine (>Fo_{80}), a rare phenocryst, was derived from basaltic magma, trapping sulfur-rich mafic melt (SiO_2 48-59 wt%, S <2600 ppm) before the mixing.

Two types of Sulfide precipitates, Cu and Ni-bearing heterogeneous sulfide spherules (Cu <31 wt%, Ni <10 wt%) and homogeneous pyrrhotite, are commonly trapped in olivine phenocryst. And they are also found to be scattered in the glassy groundmass. In contrast, the major phenocrysts includes the only homogeneous pyrrhotite, together with the sulfur-poor felsic melt.

Petrologic observation of the melt and various crystalline inclusions trapped in olivine phenocrysts here provides relevant information about the primary composition of the basaltic magma. The three pieces of information are as follows. 1) Primary large SO_4^{2-} concentration of magma. 2) A high oxygen fugacity condition (> NNO + 1) of magma. 3) Primarily hydrous nature of magma and the consequent boiling of magma during crystallization.

It is likely that, during the ascent of this SO_4^{2-}-rich hydrous magma, transformation of sulfur species on cooling from SO_2 to H_2S oxidized iron of magma, and led to the extensive precipitation of sulfide phases in the magma. The sulfur separation from the melt continuously decreased sulfur concentration of magma during the crystallization, hence, the most mafic (SiO_2-poor) and pre-boiling melts have the highest sulfur concentration (2600 ppm).

These petrologic data provide us with valuable information about the sulfur budget and the sulfur supply system. The ascent of the hydrous basalt magma transfers a large amount of sulphur, together with copper and probably other chalcophile metals, from the subduction slabs in the mantle to the felsic reservoir beneath the summit of the frontal volcanoes in central-northeastern Japan.

Apatite inclusions in Hadean zircon from Jack Hills, Australia

S. YAMAMOTO[1]*, T. KOMIYA[1], M. SHIMOJO[1], S. SAKATA[2], K. MAKI[2] AND T. HIRATA[2],

[1]Department of Earth Science and Astronomy, The University of Tokyo, Komaba, Meguro, Tokyo, 153-8902, Japan (*correspondence: syamamot@ea.c.u-tokyo.ac.jp)
[2]Laboratory for Planetary Sciences, Kyoto University, Japan

Clues about conditions during Hadean era can be deduced from detrital zircons as old as 4.4 Ga preserved in metaconglomerate at Jack Hills in the Narryer Gneiss Complex, Western Australia. Previous investigations of these grains have suggested the existence of a hydrosphere, granitic continental crust and sedimentary cycling [1]. Especially, granitic mineral inclusions, such as quartz, plagioclase and K-feldspar, in Hadean detrital zircons provide strong evidence for the existence of granitic crust on early Earth. However, [2] proposes that inclusions of plagioclase and K-feldspar in zircon do not constrain a source rock. Moreover, *in-situ* U-Pb dating of monazite and xenotime inclusions in 4.25–3.35 Ga detrital zircons from Jack Hills shows ages with 2.68 Ga or 0.8 Ga, suggesting that the most mineral inclusions suffered from metamorphic/metasomatic overprint during late stage metamorphism [3]. These results call for a reassessment of source magma based on mineral inclusions in Hadean zircons.

We investigated apatite inclusions in Hadean zircons using Laser-Raman microscopy, SEM-EDS and electronprobe micro-analyzer (EPMA). Chemistry of apatite inclusions in zircon reflects the chemical compositions of the whole rocks and can characterize the host magma [2, 4]. Although low-abundance of apatite inclusions in detrital zircons from Jack Hills compared to those in granitic rocks suggests a secondary replacement on mineral inclusions [3], we observed 6 primary apatite inclusions with no visible cracks in 106 Hadean zircons. Y_2O_3 and SrO abundances in apatite determined by EPMA negatively correlate, ranging from 0.02 to 0.9 wt% and from 0.08 to below detection limit (0.01 wt%), respectively. High concentrations of Y_2O_3 (>0.4 wt%) and low concentration of SrO (<0.02 wt%) in apatite inclusions in Hadean zircons in Jack Hills are indicative of evolved, felsic host magma >65 wt% SiO_2 [2].

Iron isotopic composition of submarine hydrogenetic, diagenetic, and hydrothermal ferromanganese deposits

K. YAMAOKA[1]*, D.M. BORROK[2], A. USUI[3] AND H. KAWAHATA[4]

[1]Geological Survey of Japan, National institute of Advanced Industrial Science and Technology, 1-1-1 Higashi, Tsukuba, Ibaraki 305-8567, Japan (*correspondence: k.yamaoka@aist.go.jp)
[2]School of Geosciences, University of Louisiana at Lafayette, 611 McKinley Street, Lafayette, LA 70504, USA
[3]Faculty of Science, Kochi University, 2-5-1 Akebono-cho, Kochi 780-8520, Japan
[4]Atmosphere and Ocean Research Institute, The University of Tokyo, 5-1-5 Kashiwanoha, Kashiwa, Chiba 277-8564, Japan

In this study, we measured the iron isotopic compositions (δ^{56}Fe relative to IRMM-14) of hydrogenetic, diagenetic, and hydrothermal ferromanganese deposits from the Pacific Ocean (1400–6000 m water depth). The hydrogenetic nodules and crusts had a consistent average Fe isotopic composition of –0.34 ± 0.15‰ (2σ). Our study contrasts with previous reports that measured larger variations in the δ^{56}Fe of these crusts in the Pacific (–0.59 ± 0.36‰) and the Atlantic (–0.27 ± 0.36‰) [1]. The consistent δ^{56}Fe values imply homogenous Fe isotopic composition of modern deep seawater in the central to northeastern Pacific. Despite differences in mineralogy and chemistry, the average δ^{56}Fe of diagenetic nodules (–0.28 ± 0.13‰) was indistinguishable from the average δ^{56}Fe of nodules of hydrogenetic origin. These observations suggest that dissolution and re-precipitation of Fe in sediments resulted in no significant Fe isotope fractionation. In contrast, the recent and fossil hydrothermal manganese deposits from the Izu-Bonin arc showed large variations in δ^{56}Fe, from –3.43 to +1.27‰. The recent manganese deposits (~30 mm thick) generally consisted of Mn-cemented volcanic sand with high δ^{56}Fe values overlying dense gray to black layers of manganese oxides with low δ^{56}Fe values. The mixing of different Fe sources is unlikely for such large isotopic variation. Given the proposed formation models [2,3], the most plausible explanation is kinetic Fe isotope fractionation during rapid oxidation of Fe(II) and precipitation of ferric oxides at the seawater-sediment interface.

Intermethod Comparison for K-Ar Dating of Clay Gouge

SEIKO YAMASAKI[1], HORST ZWINGMANN[2] AND TAKAHIRO TAGAMI[3]

[1]Geological Survey of Japan, AIST, Tsukuba, Japan, (yamasaki.seiko@aist.go.jp)
[2]CSIRO ESRE, Perth, Australia,(horst.zwingmann@csiro.au)
[3]KUEPS Kyoto Univ., Kyoto, Japan,(tagami@kueps.kyoto-u.ac.jp)

K-Ar dating of clay gouge has been reported as a suitable method for direct dating of shallow faults in recent decades. A new “unspiked” K-Ar dating system for clay samples has been set up at the Tono Geoscience Center (TGC), Japan Atomic Energy Agency. The unspiked K-Ar method is applied succesfully for age determination of young volcanic rocks, and the method could similar be useful to date young fault gouges. However, there is only one study reported that compares the age data for fault gouges by the conventional “spike” method and unspiked methods [1].

We conducted an intermethod comparison study for K-Ar dating of clay gouge in two laboratories. A unique gouge sample was collected at depth of 252.9 m from a fault on the wall of a shaft at the Mizunami Underground Research Laboratory, central Japan.

Three clay separates (<0.1, <0.4, <2 micron) were measured by the two different K-Ar methods. The conventional K-Ar method was applied at CSIRO and the unspiked method was applied at TGC.

The age data for each fraction with two method agree well in their analytical errors. Because the age calculation parameters are different, the errors of the unspiked method are larger than those of the conventional method. The ages of coarser <2 micron fractions spread slightly, suggesting sample heterogeneity. The obtained illite age range is consistent with the stability field of illite and the main temperature field of brittle deformation within the cooling history of the host granite body of the fault, which was evaluated by apatite and zircon fission-track and K-Ar biotite ages from the host rock.

The consistency of the data between two methods, and the consistency with constraints from other geochronology data, demonstrate the potential of gouge dating with the new analytical system.

[3]Grad. Sch. of Environmental Studies, Nagoya Univ., Nagoya 464-8601, JAPAN (urumu@nagoya-u.jp)
[4]Kuroshio Research Institute, Ohtsuki, Kochi, 788-0333, JAPAN (iwase@kuroshio.or.jp)
[5]NIES, Tsukuba, Ibaraki, 305-8506, JAPAN (hyamano@nies.go.jp)

The Kuroshio Current is the strongest ocean current in the world, driving the physical ocean-atmosphere system with heat transport from tropical to temperate in the North Pacific Ocean. The global environment has dramatically changed over the past 100 years, and the global sea surface temperature has increased by ~1°C since the early 1900s. The response of the Kuroshio to global warming is debatable, however, as the variability of the Kuroshio Current during the past 100 years has not been well understood. In this presentation, we describe the variability of the Kuroshio transport over the past 150 years as reconstructed from the nitrogen isotope composition of coral skeletons ($\delta^{15}N_{coral}$). $\delta^{15}N_{coral}$ has been used as a proxy to record nitrate $\delta^{15}N$ values [1-2]. *Porites* coral cores were collected from Tatsukushi Bay, on the Pacific coast of Japan and located on the Kuroshio axis. $\delta^{15}N_{coral}$ varied due to a mixture of Kuroshio water and temperate sea surface water. We discuss the relationship between $\delta^{15}N_{coral}$ and global warming, PDO, and ENSO.

P-V-T equation of state for ε-iron up to 80 GPa and 1900 K using the Kawai-type high pressure apparatus

D. YAMAZAKI[1]*, E. ITO[1], T. YOSHINOI[1], A. YONEDA[1], X. GUO[1], B. ZHANG[1], W. SUN[1], A. SHIMOJUKU[1], N. TSUJINO[1], T. KUNIMOTO[2], Y. HIGO[2] AND K. FUNAKOSHI[2]

[1]Institute for Study of the Earth's Interior, Okayama Univ., Japan
[2]Japan Synchrotron Radiatioin Research Institute, Japan
((dy@misasa.okayama-u.ac.jp)

Using the Kawai-type multianvil high pressure apparatus equipped with sintered diamond anvils, we determined the *P-V-T* equation of state of ε-iron by means of in situ X-ray observations with synchrotron radiation at pressures up to 80 GPa and temperatures up to 1900 K. The *P-V-T* data set of ε-iron was fitted to a single EOS model based on the Mie-Grüneisen equation of state as shown in Fig. 1. The present results indicate the unit cell volume at ambient conditions V_0=22.15(5) Å^3, the isothermal bulk modulus K_{T0}=202(7) GPa and its pressure derivative K'_{T0}=4.5(2), the Debye temperature θ_0=1173(62) K, Grüneisen parameter at ambient pressure γ_0=3.2(2), and its logarithmic volume dependence q=0.8(3). Furthermore, thermal expansion coefficient at ambient pressure was determined to be $\alpha_0(K^{-1})=3.7(2)\times10^{-5}+7.2(6)\times10^{-8}(T-300)$ and Anderson-Grüneisen parameter δ_T=6.2(3). Using these parameters, the density of ε-iron at the inner core conditions was estimated to be ~3 % denser than the value inferred from seismological observation. This result indicates that certain amount of light elements should be contained in the inner core as well as in the outer core but in definitely smaller amount.

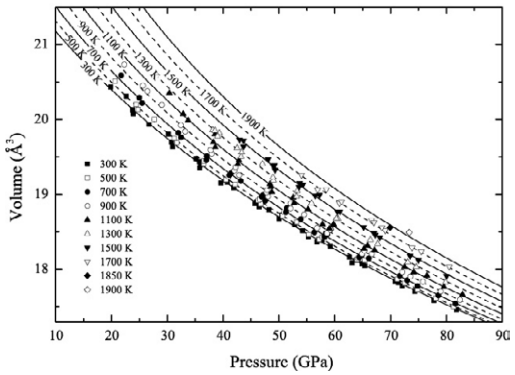

Fig. 1. *P-V* data along isotherms at 300-1900 K.

Zn isotope compostions of the Ediacaran Carbonates, Yangtze Block

B.YAN, X. K. ZHU AND S. H. TANG

Laboratory of Isotope Geology, Institute of geology, Chinese Academy of Geological Sciences, Beijing, 10037, China (yanbin703@163.com)

The sedimentary sequences of the Ediacaran Doushantuo Formation in the Yangtze block are mainly composed of alternating siliciclastic and carbonate rocks and yields abundant preserved animal fossils, thus it is critical for deciphering the evolutionary history of life during the time interval. Zn isotope fractionations are controlled by the biological processes in seawater (Maréchal *et al*., 2000; Pichat *et al*., 2003). Thus it can be used to track the evolution of primary productivity in the Ediacaran Period.

The δ^{66}Zn values of carbonate rocks in the whole Doushantuo Formation vary from 0.18‰ to 0.81‰ (relative to JMC3-0749L), with an average of 0.48‰, displaying enrichment in Zn heavy isotope. The carbonates δ^{66}Zn values of the Doushantuo Formation which comprises the four members have some positive and negative shifts. The δ^{66}Zn in the Member 1 increases from 0.41‰ at the base to 0.81‰ at the middle, and declines to 0.34‰ in the upper. The δ^{66}Zn of Member 2 increases to 0.65‰ at the base, and decreases to 0.18‰ at the middle. At the upper of the Member 2 and the base of Member 3, the δ^{66}Zn values fluctuate around 0.21‰~0.57‰. The δ^{66}Zn at the middle of Member 3 begins with an increase from 0.38‰ to 0.80‰, and decrease to 0.32‰ at the uppermost.

Those compositions are significantly higher than average continental crust (~0.2‰–0.3‰; Maréchal *et al*., 2000; Archer and Vance, 2004). This may suggest that due to biological process control of the Zn isotope composition (Maréchal *et al*., 2000), Zn light isotope is removed from the surface ocean by primary producers and transported to the deep ocean (Maréchal *et al*., 2000; Bermin *et al*., 2006). In that case, the Zn isotope ratios measured in carbonates may record the fluctuations in primary productivity during Ediacaran Period.

Distribution of cadmium and its main influencing factors in the surface sediments from five typical bays in eastern coastal areas of Guangdong Province, South China

WEN YAN, XIAOHUA ZHANG, LIFENG ZHONG AND NAN ZHANG

CAS Key Laboratory of Marginal Sea Geology, South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou 510301, China (wyan@scsio.ac.cn)

In recent years, with the rapid economic and social development in eastern Guangdong, South China, the environmental state of the coastal waters has aroused great attention by the people. Cadmium (Cd) is a heavy metal with biological non-essential and highly toxic effects, and its special chemical and geochemical properties determines its high degree of risk and difficult to control in the natural environment.

The contents of Cd were determined for 64 surface sediments collected from five typical bays in eastern coastal areas of Guangdong Province, and the distribution characteristics of Cd in surface sediments and their main influencing factors were discussed. Meanwhile, the potential ecological risk indexes were calculated referring to the background value of the continental shelf of South China Sea. The results showed that content ranges of Cd were 0.04~0.58mg/kg, 0.06~6.63 mg/kg, 0.06~0.11mg/kg, 0.04~0.20 mg/kg and 0.08~0.15mg/kg respectively in Zhelin Bay, Shantou Bay, Shanwei Bay, Daya Bay and Dapeng Bay, and different distribution trend appeared in different bay. In Zhelin Bay and Shantou Bay, the Cd content presents a high value in aquaculture areas and in the waters near of Sanbaimen dam and Cape of Good Hope, as well as the end of the Sediment Retention embankment waters, and low Cd content presents in the rest of the waters, close to or below the background values of the continental shelf sediments in the South China Sea. The Cd contents increased from inshore to offshore, west to east in Shanwei Bay, and the high levels of Cd generally appear in the Bay outside in Daya Bay and Dapeng Bay.

Organic carbon and fine-grained component of sediments are not the main factors to control the content and distribution of Cd in the study area. Cd distribution was more influenced by the heavy metal input and hydrodynamic effects, and the aquaculture was also a way to change the depositional environment, so that the spatial distribution of Cd changed.

Acknowledgments: This study was supported by the Key project of NSFC-Guangdong Joint Foundation (U1133002).

Study of lithium isotope in hydrothermal quartz veins from the Qulong porphyry copper deposit in Tibet

YANG DAN[1,2]*, YANG ZHIMING[3] AND HOU ZENGQIAN[3]

[1]Institute of Mineral Resources, CAGS, Beijing 100037, China (*correspondence:yangd_2004@yahoo.com.cn)
[2]Key Laboratory of Metallogeny and Mineral Assessment, MLR, Beijing 100037, P.R.China
[3]Institute of of Geology, CAGS,Beijing 100037, China

Evolution details of ore-forming fluids and the precipitation mechanism of ore mineral have always been the focus of metallogeny research. However, the traditional hydrogen and oxygen isotope tracing method of ore-forming fluid has been strongly questioned in recent years because it is difficult to avoid the impact of secondary inclusions and high-temperature isotope fractionation. In Qulong porphyry copper deposit , a typical representative of Gangdise porphyry copper belt of Tibet, we attempt to use the lithium isotope to trace the origin of ore-forming fluid. We analysed lithium isotopic compositions of different stage quartz veins and altered minerals. Preliminary results show that there is a positive correlation between δ^7Li and$\delta^{18}O_{V\text{-}SMOW}$ of quartz veins. From early quartz vein to late ones, δ^7Li and $\delta^{18}O_{V\text{-}SMOW}$ values decrease synchronously. This trend indicates that the early ore-forming fluid originated from degassed magma water and meteoric water gradually joined in it in late stage. This attempt may provide a reliable and effective tracing method for ore-forming fluid.

Petrogenesis of Early Cretaceous intrusive rocks from southern margin of the North China Craton: Constraints from zircon U-Pb ages and Sr-Nd-Pb-Hf isotopes

D.B. YANG, W.L. XU, F. WANG AND F.P. PEI

College of Earth Sciences, Jilin University, Changchun 130061, China (yangdb@jlu.edu.cn, xuwl@jlu.edu.cn)

The spatial extent of the influence of the deeply subducted Yangtze slab on the North China Craton (NCC) remains a controversial issue. The zircon U-Pb ages and Sr-Nd-Pb-Hf isotopic data of Early Cretaceous intrusive rocks in Sanmenxia area from the southern margin of the NCC provide a constraint for that. These intrusive rocks, including Gaomiao (GM), Quli (QL), Canfang (CF), and Wangmao (WM) intrusions, consist of quartz diorite porphyry, granodiorite, and granodiorite porphyry.

Zircon U-Pb dating results indicate that the GM, QL, CF, and WM intrusions formed in the Early Cretaceous (129 Ma, 115 Ma, 130 Ma, and 130 Ma, respectively). The occurrence of Neoproterozoic zircons (620 and 542 Ma) and inherited Late Triassic (214 - 225 Ma, n=6) metamorphic zircons within the QL intrusion, suggests that the primary magmas could be derived from partial melting of the Yangtze Craton basement that was superimposed by ultrahigh pressure metamorphism. In contrast, the occurrence of Paleoproterozoic and Archean ages within the GM, CF, and WM intrusions, indicates that their primary magmas were mainly originated from partial melting of the NCC basement.

The GM, QL, CF, and WM intrusions have high SiO_2 (60.65 - 67.62 %) and low MgO (0.35 - 1.15 %). They are enriched in LILEs and LREEs, and depleted in HFSEs and HREEs. The GM, QL, and CF intrusions have strong negative εNd (t) (-22.2 to -16.7) and εHf (t) (-29.6 to -21.4) values as well as low initial $^{206}Pb/^{204}Pb$ ratios (17.19 to 17.33), suggesting that they were mainly derived from partial melting of ancient lower crust, whereas the WM granodiorite porphyries have relatively high εNd(t) (-12.5 to -11.9) and εHf (t) (-21.7 to -16.6) values, indicating that they could be derived from partial melting of lower crustal materials with involvement of mantle components.

Taken together, we conclude that the southern margin of the NCC had been influenced by the deeply subducted Yangtze slab during the Triassic.

Structure of Weathered Clastic Crust and Its Significance in Deep Petroleum Exploration

FAN YANG, LIAN-HUA HOU AND CHUN YANG

Research Institute of Petroleum Exploration & Development, PetroChina, Beijing 100083 China(yf2010@petrochina.com.cn)

Deep, ultra-deep are on of the most important hydrocarbon exploration area in the future. 96 ultra-deep clastic reservoirs were discovered in the global since 2000, accounting for 91.4% of the total number of ultra-deep reservoirs (IHS, 2011). Most of the ultra-deep reservoirs relate to unconformity, such as Junggar Basin that locates in Western China which develops 13 regional large-middle scale unconformities. Good reservoirs whose porosity above 15% are developed at the burial depth of about 6500m because of the influence of K-J unconformity. Based on clastic outcrops and well cores in Junggar Basin, considering the lithology of weathered layers, different weathering degree of minerals and diversity of element migration capabilities, weathering index of weathered clastic crust was built mainly in view of Fe and Al contents. The weathered clastic crust was divided into 3-layer structure model, which are weathered clay, sandy eluvial zone and muddy eluvial zone. Weathered clay mainly distributed at the slopes and low places, and had an inverse proportional development relationship with the eluvial zone. Analyzing reservoir properties of rock samples from the outcrop and well cores, detailed describing reservoirs beneath the T-P unconformity in western Junggar Basin, the results suggest that the porosity of eluvial zone is greatly improved due to weathering and leaching, but the permeability depends on the clay mineral contents. The higher the clay content, the worse the permeability is. The weathered clay has a high breaking pressure and could be treated as a good cap rock. The lower limits of hydrocarbon exploration depth are greatly downward because of weathering effect. The existence of weathered crust provides effective reservoir-cap rock for hydrocarbon accumulation, enriching an important geological theory and assessment methodology in deep, ultra-deep petroleum exploration.

Re-Os analyses for Ag ores from the Kongsberg mines, southeast Norway

G. YANG[1]*, H. STEIN[1,2] AND A. ZIMMERMAN[1],

[1]AIRIE Program, Colorado State University, Fort Collins, CO USA (*correspondence: gangyang@colostate.edu)
[2] CEED Centre of Excellence, University of Oslo, Norway

The Kongsberg silver mines, hosted in Precambrian gneisses, are located along the western margin of the Permian Oslo rift, southeast Norway [1]. Native Ag-bearing late calcite veins are widely distributed in the Kongsberg metallogenic district, along with sphalerite, pyrrhotite, chalcopyrite, galena, argentite and Co-(Ni) arsenides. The main gangue minerals in the Kongsberg silver mines are calcite, fluorite, quartz, barite and locally coalblende [1].

Re-Os analysis of native Ag provides chemical challenges. Conventional sample digestion using inverse *aqua regia* produces a highly insoluble AgCl precipitate, and thus is not suitable for native Ag or Ag-bearing ores. A modified version of conventional Re-Os chemical procedures [2] was therefore implemented. Hydrochloric acid was removed from the digestion and anion resin exchange column chemistry. To determine Re and Os concentrations and Re-Os isotope systematics, we analyzed pure vein silver, disseminated silver minerals in a fine-grained carbonate-calcite matrix, and nearly-barren calcite. Re and Os concentrations for visibly pure vein silver are 89-108 ppt and 1.1-1.7 ppt, respectively. Re and Os concentrations for disseminated silver minerals are notably enriched at 10.2 ppb and 47 ppt, respectively. And, Re and Os concentrations for calcites are 3.2-6.4 ppb and 16-29 ppt. Petrography suggests that high Re and Os concentrations in the sample with disseminated Ag are derived from small inclusions and intergrowths of other sulfides. A Model 3 isochron age of 436 ± 23 Ma (MSWD = 45, n = 6) was obtained based onpure vein silver, disseminated silver minerals, and calcite with large ranges of $^{187}Re/^{188}Os$ and $^{187}Os/^{188}Os$ from 311 to 92992 and 0.21 to 671, respectively.

The suggestion of a 436 Ma isochron could allude to an older history than has been assummed for formation of the Kongsberg Ag deposits. Clearly additional work is needed on other Ag-associated sulfides to confirm a pre-Permian, Caledonian age for this historically important ore.

We thank Fred Steinar Nordrum of the Norwegian mining museum for access to Ag-bearing samples from the Kongsberg mines.

Geochemical characteristics of granites and their relationship to gold mineralization in Yangshan gold deposit, Gansu Province, China

YANG GUICAI[1,2]*,YUAN SHISONG[1,2],QI JINZHONG[3] AND GE LIANGSHENG[2]

[1] School of Earth Science and Resources,China University of Geosciences,Beijing,10083,China;
[2]Gold Geological Institute of CAPF,Langfang 065000,Hebei, China;
[3]3. Gold Headquarters of CAPF,Beijing 100055,China
*(Corresponding author: yangguicai_1979@126.com)

Yangshan gold deposit, hosted in the Devonian stratum on the north margin of Bikou Terrane, western Qinling orogenic belt, is a super-large carlin-like gold deposit discovered recently in Gansu Province,China. Many granitic dikes were found in the deposit and had spatially relationhsip to gold ore bodies. But the genetic relationship between them is still controversial. Studies show that the SiO_2,K_2O and Al_2O_3 of the granites range from 60.64% to 80.77%,2.27% to 4.32% and 11.83% to 23.71% respectively,and the A/CNK varies from 1.24 to 4.29,which indicate the granites are belong to prealuminous,calc-alkaline.The Granites are also enriched in Cs,U,K,Pb , and depleted in Ba,Nb,La,Ce,Sr,Ti. Rare earth elements (REE) content of the granites is between 14.45×10^{-6} and 143.14×10^{-6}(average 70.31×10^{-6}),with La_N/Yb_N ratios of 1.48- 37.26(average 17.08). Light rare earth elements (LREE) are concentrated evidently and heavy rare earth elements (HREE) are deficient with LREE/HREE ratios of 1.39-19.52(average 10.12).The REE patterns are characterized by slightly negative Eu anomalies,withδEu=0.50-1.21(average 0.77). Combining with the analytical data of the major and trace elements, geochronology and Sm/Nd, Rb/Sr and Pb isotope of Yangshan granites,Bikou group volcanic rock and Devonian Sanhekou section stratum from previous work,it is proposed that the granites were derived from partial melting of deep thickening crust(Bikou group volcanic rock) and mixed with Devonian stratum during ascent.That is to say that the ore-forming material of Yangshan gold deposit directly derived from granitic magma,and the Bikou group volcanic rock and Devonian stratum should be the primary source.

Source of fluid during continental subduction and exhumation: *In situ* LA-ICP-MS analysis of Sr-isotope in barite of eclogite from the Sulu UHP terrane, eastern China

H. YANG[1] A. GERDES[2] L.-F. ZHANG[3] AND F.-L. LIU[1]

[1] Institute of Geology, Chinese Academy of Geological Sciences, Beijing 100037, China (hyang@cags.ac.cn, lfl0225@sina.com)
[2] Institut für Geowissenschaften, Mineralogie, Altenhoeferallee 1, D-60438 Frankfurt am Main, Germany (gerdes@em.uni-frankfurt.de)
[3] School of Earth and Space Sciences, Peking University, Beijing 100871, China (Lfzhang@pku.edu.cn)

Barite occurs as an fluid-bearing mineral in eclogite cores distributed at 0-3000 m depth intervals of the main-hole of the Chinese Continental Scientific Drilling (CCSD) in the Sulu UHP terrane. Based on the petrographic features, barite can be divided into three types, including as inclusions of garnet at the peak ultrahigh-pressure (UHP) metamorphic stage, and as matrix mineral at the early retrogressive eclogite-facies stage and the late retrogressive amphibolites-facies stage. Its formation was genetically associated with fluid activity and metamrphic P-T conditions. This study introduces a new method of *in situ* $^{87}Sr/^{86}Sr$ analyses on the barite grains by LA-ICP-MS, and obtains three groups of Sr-isotope ratios related to the different metamorphic stage. The analyzed results show that $^{87}Sr/^{86}Sr$ ratios of barite is about ~0.7050, ~0.7067 and 0.7080~0.7125 for the peak UHP metamorphic stage, the early retrogressive eclogite-facies and the late amphibolites-facies stage, respectively, and display an increase trend from UHP metamorphism until late retrogression. This evolutional characteristics of $^{87}Sr/^{86}Sr$ ratios reveal the genetic information of fluid activity during UHP metamorphism and late retrogression. Thereinto, the fluid was mainly a mixed phase from mantle and crust source during the continental subduction, then more external crustal fluid was added during the early exhumation, and finally external crustal fluid became the dominant source when the Sulu UHP terrane was exhumed to the upper crust level.

Molybdenum isotopes during magmatic differentiation

J. YANG[1], C. SIEBERT[2], J. BARLING[1], P. SAVAGE[3], Y.-H. LIANG[1] AND A. N. HALLIDAY[1]

[1] Department of Earth Sciences, University of Oxford, South Parks Road, OX1 3AN, UK (jiey@earth.ox.ac.uk)
[2] GEOMAR, Helmholtz-Zentrum für Ozeanforschung, Wischhofstrasse 1-3, 24148 Kiel, Germany
[3] Department of Earth and Planetary Sciences, Washington University in St. Louis

This study presents the first evidence for the behaviour of molybdenum isotopes during magmatic differentiation. Molybdenum isotopic compositions, as well as rare earth elements (REE), have been determined for a sequence of lavas from Hekla volcano, Iceland, covering a compositional range from basalt to rhyolite (from 46 to 72 wt.% SiO_2), sequentially developed by magmatic differentiation from a cogenetic source. All samples are characterised by identical Mo isotopic composition with δ^{98}Mo approximating zero (with an average $\delta^{98/95}$Mo of -0.02±0.1‰ (2s.d.) relative to an Alfa Aesar standard solution (lot 011895D) [1]). This study therefore reveals that resolvable Mo isotope fractionation is unlikely to occur during such magmatic differentiation. This is conistent with the fact that Mo is consistently incompatible in this suite of lavas; the lack of fractionating phases therefore preserves the original basaltic parent magma composition.

Previous work [2] suggests that Pr and Mo are equally incompatible in basaltic systems. However, in this study it can be seen that Mo becomes more incompatible than Pr in silicic systems. Despite the fact that these are low ^{18}O magmas, hydrothermal processes and assimilation have had no effect on the Mo isotopic compositions.

Two additional volcanic samples from nearby unrelated volcanos were analysed and are indistinguishable from the Hekla data. This is consistent with a previous study which also indicates a similarity of Mo isotopic signature ($\delta^{98/95}$Mo~0.03±0.12‰) for riverine bedrocks from the vicinity of Vatnajökull glacier on Iceland [3]. Therefore, the Iceland crust appears to have a very homogeneous Mo isotopic signature (δ^{98}Mo~0±0.1‰). The insensitivity of the Mo isotope system to igneous differentiation means that it is especially well suited for studies of assimilation and water - rock interaction in magmatic systems.

Thallium isotope geochemistry of early Cambrian black shales and Ni-Mo sulfide ores in South China

YANG JING-HONG[1] , JIANG SHAO-YONG[1,2] , REHKAMPER M[3], XUE XC[3] , PI DH[1,2] AND ZHU B[1,4]

[1]State Key Laboratory for Mineral Deposits, Department of Earth Sciences, Nanjing University, Nanjing 210093, China
[2]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan, Hubei, 430074, China
[3]Department of Earth Sciences & Engineering, Imperial College London, UK
[4]Institute of Isotope Hydrology, School of Earth Sciences and Engineering, Hohai University, Nanjing 210098, China

Thallium has two stable isotopes: ^{203}Tl (29.5%) and ^{205}Tl (70.5%). The present-day oceanic residence time of Tl is estimated to be ~20 kyr, significantly longer than the mixing time of the oceans (about 1 kyr). Natural Tl isotopic composition shows a variation of about 35 ε^{205}Tl units in terrestrial samples.

In this study, we analyzed Tl isotopes for the early Cambrian Niutitang Formation black shales and the Ni-Mo sulfide ores from Zunyi, Guizhou province, south China. The Ni-Mo sulfide ore shows the highest Tl concentration (40.5 ppm) and the lowerest and negative ε^{205}Tl (-2.06), similar to seafloor hydrothermal fluid value (-1.9), but different from present-day seawater (-6.0). The black shales show smaller negative ε^{205}Tl near 0 (0 to -0.17). But the V-rich black shale has slightly higher Tl concentration (7.3 ppm) and lower ε^{205}Tl value of -0.6. The chert shows similar Tl concentration with the black shale, but significantly higher and positive ε^{205}Tl (-0.3 to 1.13). Good correlations are observed between ε^{205}Tl and Mo/TOC, Ni/TOC, and U/TOC.

In summary, the new data of Tl isotopes in black shales are useful tools: 1) To distinguish between oxic and anoxic marine deposits; 2) To indentify hydrothermal input of Tl (and other metals) for the early Cambrian black shales and polymetallic Ni-Mo sulfide bed in south China.

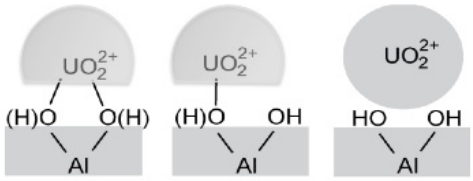
Understanding Uranyl adsorption at the water-mineral interface: A theoretical approach

PING YANG*, ERIC J. BYLASKA AND WIBE A DE JONG

W.R. Wiley Environmental Molecular Science Laboratory, Pacific Northwest National Laobratory, Richland, WA, 99352, USA. (ping.yang@pnl.gov)

In order to understand the physico-chemical properties of actinide complexes in the natural environment, we performed *ab initio* molecular dynamics (AIMD) simulations of the dynamic adsorption processes of uranyl at the water-mineral interfaces. Hydroxylated α-Al_2O_3 surface is an important model system analogues for commonly occurring soil phase such as gibbsite, boehmite, akdalaite, bayerite, etc. Our current focuses are on two targeted questions: 1.) the structure of surface complexation: inner-sphere *versus* outer-sphere; [2] 2.) surface charge effects for adsorption at pH>pH_{ZPC}, where partially deprotonated sites present on surface, illustrated in Fig. 1. Both geometric structures and energy profiling of adsorption of uranyl at will be reported.



In acidic environment, we have found that the average distance of uranium to equatorial oxygen atoms is ~2.5Å, in good agreement with extended X-ray absorption fine structure (EXAFS) spectroscopy experiment for acidic environment.[3,4] The coordination number of uranyl to surface oxygens dynamically changes, indicting multidentate bonding interactions occurring at a finite temperature. The surface charges have profound effects on the surface complexation by forming stronger surface adsorption with a shorter bond distance to the deprotonated site, suggesting a lower mobility of uranyl in a basic environment. [5]

Response of epikarst hydrochemical changes to soil CO_2 and weather conditions in Chenqi, SW China

RUI YANG[1,2], ZAIHUA LIU[1,2]*, CHENG ZENG[1,2] AND MIN ZHAO[1,2]

[1]State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, 46 Guanshui Road, Guiyang 550002, China (*correspondence: liuzaihua@vip.gyig.ac.cn)

[2]Puding Comprehensive Karst Research and Experimental Station, Inst. Geochem., CAS & Science and Technology Department of Guizhou Province, Puding 562100, China

Karst-related carbon cycle, as a result of water-carbonate rock-CO_2 gas-aquatic organism interactions, significantly affects global carbon budget. Soil CO_2 is a major chemical driving force for karst process and has significant impact on the water-rock-gas-organism system. However, few studies examined the direct correlations between hydrochemical parameters and soil CO_2 in epikarst systems.

An epikarst spring system in Chenqi, SW China was chosen to monitor soil CO_2 concentration and hydrochemical parameters with high-resolution (interval of 15 min.) and to investigate the responses of hydrochemical changes to soil CO_2 and weather conditions. It was found that both soil CO_2 and rainfall are major driving forces for karst hydrochemical variations. Soil CO_2 effect on hydrochemical variations was reflected in all seasonal, diurnal and storm-scales. There was an increasing CO_2 partial pressure (pCO_2) and electrical conductivity (EC) but a decreasing pH in groundwater caused by the increasing CO_2 in soil during spring-summer growing season, while a decreasing pCO_2 and EC but an increasing pH caused by the decreasing soil CO_2 in autumn-winter dormant season. Similar responses were also found on diurnal scales but with a time lag of a few hours during dry season, showing different groundwater recharge mode as well as the complex supply path (quick flow by conduit or slow flow by fracture). During rainy seasons, hydrochemical variations in epikarst spring were regulated by both dilution and soil CO_2 effects. Under high-intensity rainfall, the dilution effect was dominant, indicated by a quick decrease in EC, pH and calcite saturation (SI_C) but a quick increase in pCO_2. Contrastly, under low-intensity rainfall, soil CO_2 effect was dominant, indicated by an increase in EC and pCO_2 but a decrease in pH and SI_C.

To sum up, this study has shown the high sensitivity and variability of karst process to environmental change, implying that the role of karst process in global carbon cycle needs to be reappraised based on high-resolution monitoring strategy.

Chemical weathering and sediment source-to-sink processes within the Changjiang (Yangtze River) and mountainous river basins (Taiwan)

S. Y. YANG[1]*, C. LI[1], X. D. WANG[1] AND Y. GUO[2]

[1] State Key Lab. of Marine Geology, Tongji Uni., Shanghai 200092, China (*correspondence: syyang@tongji.edu.cn),
[2] School of Materials Science and Engineering, Shanghai Uni., Shanghai 200072, China,

The Changjiang is the largest river originating from the Himalayan-Tibetan Plateau and bridges the Eurasian continent and west Pacific Ocean. In comparison, the small-sized mountainous rivers in Taiwan have increasingly attracted research attentions in recent years owing to the unique geologic setting and huge sediment fluxes. Both river systems deliver huge amount of terrigenous matter into East Asian marginal seas, which exerts a great control on marine sedimentation and biogeochemical cycle. Nevertheless, the sediment source-to-sink (S2S) processes are significantly different within these two kinds of river systems.

In this contribution, we attempt to compare the weathering intensity and sediment S2S processes within the Changjiang catchment and Taiwan river basins by using various geochemical proxies. Source rock compositions and chemical weathering intensities in the catchments account for the compositional variations of the fluvial sediments. The CIA, bulk Sr-Nd isotopic compositions and age spectrum of zircon provide good constraints on sediment recycling and evolution of weathered upper continental crust under different tectonic settings. Geochemical composition of the sediment into the sea is complicated by hydrodynamic sorting and changing sediment suppliers in relation to variability of monsoon-induced precipitation in the river basin. Overall, the mountainous Taiwan rivers and the mega-river like Changjiang represent two kinds of typical river systems that shape the earth surface and drive material cycle.

Boron isotopic fractionation during magmatic differentiation: A case study of tourmalines from the Nyalam leucogranite-pegmatite system, South Tibetan Himalaya

SHUI-YUAN YANG AND SHAO-YONG JIANG*

State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, PR China
(*correspondence: shyjiang@nju.edu.cn)

The Miocene Nyalam leucogranite-pegmatite system from South Tibetan Himalaya consists of two mica leucogranite (2mg), tourmaline leucogranite (Tg) and pegmatite dykes which were extracted from two mica leucogranite magma. Tourmaline is an important constituent of the Nyalam leucogranite-pegmatite system. Tourmaline in the two mica leucogranite and tourmaline leucogranite occurs mostly as nodular tourmaline–quartz segregations. Tourmaline in the pegmatite consists of isolated, millimeter sized, euhedral crystals. In situ analyses by electron microprobe and LA-MC-ICP-MS reveal a large variation of chemical and boron isotopic compositions of tourmaline from the Nyalam leucogranite-pegmatite system. Most of these tourmalines have high Fe/(Fe+Mg) and Na/(Na+Ca) ratios, and can be considered as a typical magmatic product.

Tourmalines from the Nyalam two mica leucogranite have the $\delta^{11}B$ values between −15.8 and −12.3‰, whereas tourmalines from the tourmaline leucogranite are between −13.1 and −11.4‰. The tourmalines from one pegmatite dyke have $\delta^{11}B$ values of −13.1 to −11.5‰. But, tourmalines from another pegmatite dyke have a wide range of $\delta^{11}B$ values between −13.5 and −7.7‰. We consider that the source rock control was important for the boron isotope compositions in the granites. The two mica leucogranite was produced by biotite dehydration melting in biotite-rich metapelites, whereas the tourmaline leucogranite was produced by muscovite dehydration melting in muscovite-rich metapelites. The boron isotope variation from granite to pegmatite indicates that boron isotopic fractionation factually occurred during the magmatic differentiation process in Nyalam leucogranite-pegmatite system. The pegmatitic magma with high primary water concentration is more prone to trigonal $B(OH)_3$ complexes and therefore ^{11}B is preferentially partitioned into the extracted pegmatitic magma.

Ancient magmatic CO_2 degassing from non-volcanic area in West Taiwan: Helium and carbon isotopic evidences

TSANYAO FRANK YANG [1]

[1] Department of Geosciences, National Taiwan University, Taipei 10617, Taiwan (tyyang@ntu.edu.tw)

Representative gas samples of fumaroles, springs, mud volcanoes, natural gases were collected from Taiwan for helium isotopes measurement. Samples from northern and eastern Taiwan exhibit higher $^3He/^4He$ ratios, which indicates significant mantle-derived signature. The result is not unexpected, since hydrothermal activity is still active at those areas. Nevertheless, some abnormalously high $^3He/^4He$ ratios (up to 6.4 Ra) are obtained from non-volcanic area in western Taiwan. Carbon isotopes of CO_2 and $CO_2/^3He$ ratios in those samples are similar with those from mid-ocean ridge basalts, which believed to be derived from upper mantle. Hence, we are able to conclude that they are mantle-derived in origin.

Intrusive magmatism and/or deep normal faults occurred in western Taiwan could be the straight forward way to explain the high helium isotopic ratios observed in non-volcanic area. Considering the possible inversion of tectonic stress from compression to tension, post-collisional magmatism around northern Taiwan may have occurred since late-Pliocene. The model might explain the possible mantle source for northwest Taiwan area, however, it is still unable to demonstrate why there is no any magmatic activity reported since late-Miocene and, presently, the areas are still under severe tectonic compression environment where we found the high helium ratio samples, especially in southwestern Taiwan.

I propose that the high $^3He/^4He$ ratio gases are not in-situ mantle-derived volatiles. They may be associated with Miocene magmatism and have been trapped by impermeable formation during the stage of basin subsidence before orogenic event occurred. Consequently, the deep normal faults may be reactivated as reverse faults by continuous compressive stress and cut through the capped rock of the gas reservoir. The "old" mantle gases, hence, could be released to surface through the leakage.

Studying crystal growth with NanoSIMS: An example of zircon

WEI YANG[1]*, YANGTING LIN[1], JIALONG HAO[1], JIANCHAO ZHANG[1], SEN HU[1] AND HUAIWEI NI[2]

[1] Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China (*correspondence: yangw@mail.iggcas.ac.cn)

[2] School of Earth and Space Sciences, University of Science and Technology of China, Hefei, China

Zircon has become one of the most widely used minerals for studying the prehistory and genesis of the host rock, because it is an excellent geochronometer, geochemical tracer and geothermometer. In many applications, the partition of trace elements between zircon and silicate melts is assumed to exhibit Henry's Law behavior and the crystal growth to be an equilibrium process. However, these assumptions may not be fulfilled in natural systems. For example, oscillatory zoning, a predominant texture of igneous zircon, appears to indicate non-equilibrium crystal growth [1].

To better understand origins of oscillatory zoning in zircons, distributions of REE (represented by Ce, Sm, Dy, Lu), Y, Ti, Li and P in zircons have been investigated with Cameca NanoSIMS 50L. The QH igneous zircons with oscillatory zonings display large trace element variations by a factor up to 13.5, with Y ranging from 574 to 7754 μg/g. By contrast, the DMP06-14 metamorphic zircons without oscillatory zonings show much smaller trace element variations by a factor of 1.4, with Y ranging from 477 to 636 μg/g. In the QH zircons, the cathodoluminescence (CL) images and ion images of Y show strong correlations with the CL-dark bands having high Y abundances than those of adjacent CL-bright bands by a factor of 2 to 10. The Y abundances are strongly correlated with the concentrations of P and REE ($R^2 > 0.97$). The corrections between P and (Y+REE) can be divided into three groups, with (Y+REE)/P atomic ratios of 3.3, 1.0 and 0.5, respectively, indicating three types of solid solution substitution of phosphates in zircon.

The oscillatory zoning can be well explained by a crystal growth kinetics model associated with substitutions of phosphates. The oscillatory distribution of P in zircon could be controlled by the fluctuation of P/Zr ratio in the melt adjacent to the mineral-melt boundary, because P diffuses slower than Zr in silicate melts. Such a zoned distribution of P in turn controled the substitution types of phosphates in zircon, and consequently formed the oscillatory distributions of Y and REE in zircon.

Strontium, carbon and oxygen isotopic compositions of Silurian on the northern and southern margins of Sichuan Basin, China

YANG WEI[1], ZHANG TINGSHAN[2] AND XIAOHUI CHEN[3]*

[1] State Key Lab.of Oil&Gas G&E Engineering,Chengdu, China (rexswpu@163.com)
[2] State Key Lab.of Oil&Gas G&E Engineering,Chengdu, China (zhangtingshan@swpu.edu.cn)
[3] State Key Lab.of Oil&Gas G&E Engineering, Chengdu,China (zts_3@sina.com)(* presenting author)

The Sr , C and 0 isotopic compositions across the stratigraphic section have been obtained in the light of the systematic determinations of $^{87}Sr/^{86}Sr$, $\delta^{13}C$ and $\delta^{18}0$ values for the Upper Ordovieian-Lower Silurian strata in the northern and southern margins of the Sichuan Basin. On the basis of the isotopic Data in combination with the sedimentary facies and tectonic data and the global Silurian regressive-transgressive events , the following conclusions can be drawn:

1.The$^{87}Sr/^{86}Sr$ values are commonly higher than the average values of $^{87}Sr/^{86}Sr$ for sea water in the geologic records on the southern margin of the basin. This is because the study area was in a ramp setting governed by intraplate palaeocontinent , and the addition of a large amount of terrigenous strontium led to the increase in$^{87}Sr/^{86}Sr$ values.

2.The$^{87}Sr/^{86}Sr$ values are positively fluetuated at the Upper Ordovician-Lower Silurian Boundary and Rhuddanian-Aeronian boundary , indicating a temporary fall of sea level at that time.

3.The$\delta^{13}C$ values increased gradually on both the northern and southern margins From the Aeronian to early Sheinwoodian , while the things for $\delta^{18}0$ values are contrary.

4.The isotopic evolution shows that the Upper Yangtz area was influeneed by theTransgressive events from the Rhuddanian to early Sheinwoodian.

Early Paleozoic shale gas reservoir microscopic structure characteristics in southern Sichuan,China

YANG YANG[1] AND ZHANG TS[2]*

[1] State Key Lab.of Oil&Gas G&E Engineering, Chengdu, China (843850989@qq.com)

The well-preserved Lower Cambrian (Qiongzhusi Fm) and Lower Silurian (Longmaxi Fm)in the southern Sichuan province,China consists mainly of two lithological associations including shallow marine and lagoonal dark to black shales and shallow marine dark silty shale, with a total thickness of up to 1900 m. Using ESEM, AFM and test data and adsorption/desorption isothermal that produced from Multipoint Brunauer Emmett Teller (MBET) to do multi-researches on the types of reservoir spaces and micro-pore structure characteristics of early Cambrian Qiongzhusi Fm. and early Silurian Longmaxi Fm. shale gas reservoirs in southern Sichuan basin area. The shale gas reservoir spaces of early Cambrian Qiongzhusi Fm. and early Silurian Longmaxi Fm. mainly including residual primary intergranular pores, intercrystal pores,mineral moldic pores, secondary dissolution pores, micropores among clay minerals, organic matter pores. Through the analyses of ESEMand AFM, the micron and nanoscale pore image in the shale can be observed directly, and the pore specific surface area measurement can test samples of nano and micro nano level pores. The authors shaw that the Qiongzhusi Fm. and Longmaxi Fm. shale gas reservoirs are with great development of micro holes, and provide the large pore volume and surface area for shale gas. But the specific surface area and pore volume of Qiongzhusi Fm. are smaller than that of the Longmaxi Fm. shale. The organic carbon content and kerogen type, clay mineral type and content, and thermal evolution degree is the main factors to control the microscopic pore structure development, among them,the thermal evolution is the most obvious. Along with the thermal evolution degree, the organic carbon content and Ⅱ kerogen content increase, the numbers of the micro-pore, the specific surface area and pore volume are increased. When the thermal evolution degree developed over a certain value, the specific surface area, pore volume all along with the increase of the degree of thermal evolution decreases sharply.

Research on the Au transport of Lannigou Gold Deposit in Guizhou Province, China

YUPING YANG[1] AND CHENGHUI WANG[1]

[1]MLR Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing 100037, China (*correspondence:ypyang@pku.edu.cn)

Based on the features of ore fluids of Lannigou Gold Deposit in Guizhou Province, China, the experiments of Au-S complex in fluids which were moderate temperature, low salinity and CO_2-rich are carried out in the hydrothermal diamond anvil cell. In-situ measurements of Au species in different systems was obtained with changing temperature, pressure, fluid composition, density and acidity. Finally, fine ore-forming model of Lannigou Gold Deposit will be built and its ore-forming mechanism will be studied according to the geological features of the deposit.

Iron-containing mineral effects on hydrothermal reactions of ketones

ZIMING YANG[1]*, IAN R. GOULD[1] AND EVERETT L. SHOCK[1,2]

[1]Department of Chemistry & Biochemistry, Arizona State University, Tempe, AZ, 85287 (*correspondence: zyang20@asu.edu)

[2]School of Earth and Space Exploration, Arizona State University, Tempe, AZ, 85287

Hydrothermal organic transformations occurring in geochemical processes are influenced by the presence of minerals. This work reports the influence of several common iron-containing minerals on the hydrothermal reactions of a model ketone, dibenzylketone (DBK). Ketones are central to many hydrothermal organic functional group interconversions, and DBK was chosen because the mechanisms of its hydrothermal reactions were recently studied in water alone [1]. Under the experimental conditions (300°C, 70 MPa, and up to 168 hours), minerals were found to significantly and specifically influence the hydrothermal reactions of DBK. Quartz (SiO_2) and corundum (Al_2O_3) had no detectable effect compared to water alone, whereas hematite (Fe_2O_3), magnetite (Fe_3O_4), and ferrous sulfide (FeS) all increased DBK reactivity to various extents. Magnetite had the largest effect on the rate of DBK decomposition. Product distributions indicate that magnetite and hematite increase covalent bond fragmentation compared to water alone, whereas reduced products were observed in the presence of ferrous sulfide. The mechanisms of the mineral reactions were investigated using hydrogen balance calculations, dissolved H_2 measurements, and experiments as functions of mineral surface areas. The effects of the iron oxide minerals appear to be mainly attributable to mineral surface-promoted catalytic bond cleavage reactions. In contrast, the reactions with ferrous sulfide are best explained as arising from dissolved inorganic compounds in solution that can deliver hydrogen atoms to the organic reactants, i.e., the ferrous sulfide acted as a reagent.

100% decomposition of diatomous organic carbon during settlement through ocean columns

SAKI YASUDA[1]*, YURIKO HARA[1], HIROSI NARAOKA[1] KOZO TAKAHASHI[2] AND TASUKU AKAGI[1]

[1] Kyushu Univ., Fukuoka, 812-8581, Japan (3sc12028k@s.kyushu-u.ac.jp)
[2] Hokusei Gakuen Univ., Sapporo, 004-8631, Japan

Introduction

Two major planktonic phases responsible for biological pump are diatoms and coccolithophores. In this study, diatom-frustule dominated settling particles was analyzed for the carbon isotopic ratio to evaluate the decomposition of diatom-derived organic carbon.

The samples of settling particles were collected from two stations in 200 km north and 300 km south of the Aleautian Islands using two sediment traps, which were deployed for one whole year (2008-2009). (1) Wet oxidation was employed to decompose non-refractory organic carbon (NRC) in the trapped samples. The CO_2 from NRC was analyzed for $\delta^{13}C$. (2) The residue of the wet oxidation was recovered as refractory carbon (RC) and the amount of RC was measured by an elemental analyzer.

Results and Discussion

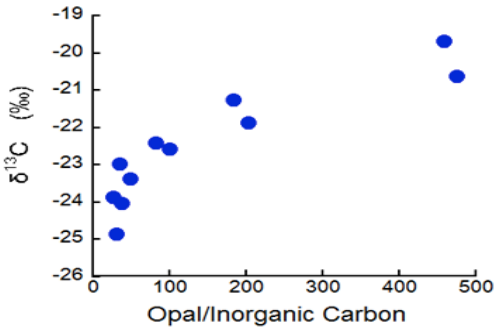

Figure 1: Relationship between $\delta^{13}C$ of NRC and Opal/Inorganic Carbon

(1) The relationship between carbon isotope ratio of NRC and Opal/Inorganic Carbon ratio is shown in Figure 1. Opal and inorganic carbon represents diatoms and coccolith+foraminifera, respectively. The carbon isotope ratio of the organic carbon in the settling particles was understood as a mixing of two end members with $\delta^{13}C$ of -19 ‰ and -25 ‰. The results of fitting suggest that the diatom-derived NRC has been almost totally decomposed.

(2) The amount of carbon recovered as RC was near the detection limit and RC was absent in most of the residue samples treated with the wet oxideation.

An insight into negative feedback mechanisms in a recovery phase of the PETM

KAZUTAKA YASUKAWA[1] AND YASUHIRO KATO[1,2]

[1]Department of Systems Innovation, School of Engineering, The University of Tokyo, Tokyo, 113-8656, Japan (4708722967@mail.ecc.u-tokyo.ac.jp)
[2]Frontier Research Center for Energy and Resources, School of Engineering, The University of Tokyo, Tokyo, 113-8656, Japan (ykato@sys.t.u-tokyo.ac.jp)

Across the Paleocene-Eocene boundary (PEB), an extreme global warming by 4-8 ºC coincided with a rapid and distinct negative carbon isotope excursion (CIE) in both marine and terrestrial environments, which is known as the Paleocene-Eocene Thermal Maximum (PETM). Several lines of evidence from previous studies strongly suggest that a massive and rapid injection of ^{13}C-depleted carbon into the ocean-atmosphere system induced the global carbon cycle perturbation and climate change. It is generally considered that, after the culmination of the global warming and CIE, enhanced continental chemical weathering and biological productivity functioned as negative feedbacks by which the excess carbon was removed from the ocean-atmosphere system.

We simulated the global carbon cycle perturbation across the PEB with a simple ocean-atmosphere box model modified from [1]. We calculated mass balances of carbon, calcium, and carbon isotopes regarding ocean and atmosphere boxes, which are connected by terrestrial weathering fluxes depending on atmospheric partial pressure of CO_2 and temperature. Earth system's negative feedbacks which appear to have worked in a recovery phase of the PETM correspond to variations of carbonate and organic carbon burial fluxes in the ocean box.

We compared our simulated results with geologic records from literatures. Our calculated organic carbon burial enhancement causes a transient positive shift in the oceanic carbon isotopes. However, to our knowledge, no such positive shift has been recognized during the PETM. A possible scenario that reconciles the simulated results with geologic records is a globally constant organic carbon burial in the ocean. While intensified continental weathering and nutrient-rich runoff may have resulted in elevated primary production on shelves, the open-ocean productivity decreased with the onset of the PETM [2]. Due to the balance of productivity changes between shelf and open-ocean environments, a global organic carbon burial flux in the ocean may have remained nearly constant across the PEB.

Characteristics of the Eemian from the Greenland Ice Sheet at GISP2

AUDREY M YAU[1]

[1] ayau@princeton.edu

The Eemian (115-128ka) is arguably the warmest the Earth's Arctic has been for the past 800ka. Recent data from NEEM (northwestern Greenland) show peak surface temperatures at ~126ka of 8 ± 4°C above the mean of the past thousand years, and a decrease in elevation of 400 ± 250m between 128-122ka. Here, we focus on Summit Greenland at GISP2. The depth interval of GISP2 between 2750 and 3040m contains clean, disturbed ice, which is largely warm ice of Eemian age. We have constrained the age of this ice by measuring CH_4 and $\delta^{18}O_{atm}$ of O_2, and analyzing the results in the context of the well-known histories of these gases from the Greenland NGRIP record to 121ka, and the Antarctic EDML and Vostok records beyond 121ka. Dating is not yet definitive but the most parsimonious interpretations align climate at GISP2 with change at NEEM. Dating of 44 sections of the warm, disturbed ice fall predominately into three distinct time periods: 104-107ka, 118-121ka, and 126-128ka. We do not find any evidence for ice between 121.5-125ka. The net change from ~127ka to ~118ka indicates an increase in total air content from 86-98ml/kg (~12%), similar to the change in observed total air content and inferred elevation at NEEM. Over the same interval, we see an increase in $\delta^{18}O$ of the ice from 128-126ka, and a decrease from 121-118ka, yielding a net increase of ~2‰ (~4°C). CH_4 concentrations in excess of 870ppb were observed at depths greater than 3030m, precluding the ability to date these samples. Our inferred elevation and temperature histories are generally consistent with recent results from NEEM, however we do not observe prevalent melt layers at the summit location.

Xenoliths, XANES and redox-related processes in the cratonic lithosphere

GREGORY M. YAXLEY[1], ANDREW J. BERRY[1], ALAN B. WOODLAND[2], BRENDAN J. HANGER[1] AND VADIM S. KAMENETSKY[3]

[1] Research School of Earth Sciences, The Australian National University, Canberra ACT 0200, Australia (*correspondence: greg.yaxley@anu.edu.au)

[2] Institut für Geowissenschaften, Universität Frankfurt, 60438 Frankfurt, Germany

[3] ARC Centre of Excellence in Ore Deposits, University of Tasmania, Hobart TAS 7001, Australia

The oxygen fugacity (fO_2) of peridotite upper mantle is predicted to decrease with increasing pressure because of molar volume changes of redox buffering reactions in peridotitic assemblages [1].

Fe K-edge XANES spectroscopy can now be routinely used to measure $Fe^{3+}/\sum Fe$ (where $\sum Fe=Fe^{2+}+Fe^{3+}$) in garnet from peridotite xenoliths [2]. Combined with conventional thermobarometry and experimentally calibrated oxybarometers [1] this enables rapid (30 min. acquisition), precise (±0.1 $\log_{10}$ units) fO_2 determinations at micron-scale spatial resolution, as well as quantitative mapping of the distribution of Fe^{3+} in garnet crystals [3].

We have used the XANES technique [2] at the X-ray Fluorescence Microscopy beamline of the Australian Synchrotron to investigate fO_2-depth variation in the Siberian Craton (Udachnaya East and Obnazhennaya kimberlites), the Slave Craton (Panda kimberlites) and the Kaapvaal Craton (Kimberley and Wesselton kimberlites).

In the Siberian and Slave cratonic lithosphere the fO_2 of peridotite xenoliths decreases with depth to $\Delta\log_{10}fO_2^{[FMQ]}$ of ≈-4 to -5 at ≈200-220 km [1,4]. Such values approach the limiting Fe-Ni precipitation curve. Metasomatic events however, have locally perturbed this trend, and lead to oxidation by 1-2 $\log_{10}$ units [3,4]. In the case of Wesselton, we mapped the Fe^{3+} distribution in compositionally zoned garnets, demonstrating that metasomatic overgrowth rims grew at fO_2>2 $\log_{10}$ units higher than the cores [3] only a very short time before eruption.

Redox conditions in the deep lithosphere are in general too reduced for carbonate melt stability [1,5], unless carbonate activity is substantially reduced by other components (silicates, halides etc).

Petrography and alteration of Cu–mineralization in the Niaz, Meshginshahr, NW Iran

M. YAZDI[1] , H. MOHAMMADIAN[1] , GH. HOSSENZADEH[2] AND F. MASOUDI[1]

[1] Faculty of Earth Sciences, Shahid Beheshti University, Iran, (m-yazdi@sbu.ac.ir)
[2] Department of Geology, Tabriz University, Iran

The Niaz area is located on the western part of the Cenozoic Alborz–Azerbaijan volcanic belt (Arasbaran sub-zone). The belt is also an important Cu–Mo–Au metallogenic province in northwestern Iran. The exposed rocks in the study area consist of a volcaniclastic sequence, subvolcanic rocks and intermediate to mafic lava flows of Paleogene age. The main host rocks are alakali granite to hornblende-biotite granite, monzonite to monzodiorite which have been intruded by andesitic to andesitic-basalt. Also several andesitic, rhyodacite to microgranite dykes have been intruded to the host rocks. The main host rock is monzonite to monzodiorite porphyry which is the host of main mineralization and alteration.

The geological and geochemical signature shows that the rocks are typical subduction-related magmatic complexes. The field observation, petrography and geochemical study show similarity to typical cu-porphyry mineralization in the area. The main factors are monzonite stock, typical potassic, phylic, prophylitic and argellic alteration (zonality of the alteration patterns from intense phyllic at the center to outward weak-phyllic, argillic), stock works and disseminated cu-mineralization, siliceous breccias and various fractures.

Actively forming Kuroko-style massive sulfide mineralisation and hydrothermal alteration at Iheya North, Okinawa Trough

C.J. YEATS[1]* AND S.P. HOLLIS[1]

[1]CSIRO Earth Science and Resource Engineering, Kensington, WA 6151, Australia (*correspondence: chris.yeats@csiro.au; steven.hollis@csiro.au)

IODP Expedition 331 drilled five sites at the Iheya North hydrothermal field within the Okinawa Trough backarc basin. At Iheya North, hydrothermal alteration and sulfide mineralisation is hosted in a geologically complex mixed sequence of coarse pumiceous volcaniclastic and fine hemipelagic sediments, overlying dacitic to rhyolitic volcanic substrate.

At Site C0016, coring adjacent to the foot of an actively venting sulfide mound intersected massive sphalerite-(pyrite-chalcopyrite)-rich sulfides that strongly resemble the black ore of the Miocene-age Kuroko deposits of Japan – the first time that such material has been recovered from an active seafloor hydrothermal system. The sulfide mineralisation shows clear microtextural evidence of formation via a combination of surface detrital and subsurface chemical processes, with at least some sphalerite precipitating into void space in the rock. Altered volcanic rocks beneath the massive sulfide exhibit quartz-muscovite/illite and quartz-Mg-chlorite alteration, reminiscent of the proximal footwall alteration typically associated with ancient volcanic-hosted massive sulfide mineralisation.

At the nearby Site C0013, a likely location of recent high-temperature discharge, intense hydrothermal alteration obliterates primary mineralogy and texture. Near surface alteration is dominated by kaolinite and muscovite with locally abundant native sulfur, suggesting acidic fluids; grading to Mg-chlorite dominated assemblages at depths of >5m below sea floor. Late coarse-grained anhydrite veining overprints the earlier alteration and is interpreted to have precipitated from downwelling seawater that penetrated the sediments when hydrothermal activity at the site waned.

Sulfide-bearing samples from Site C0016 and Site C0013 have been sectioned and mapped using scanning electron microscope (SEM) and proton induced X-ray emission (PIXE) techniques for major and trace element composition. Sphalerite from C0016 contains very little iron, which is consistent with the low overall iron budget of the hydrothermal system. PIXE analyses are currently underway and trace elemental distributions revealed by this technique will be presented.

Calcitic corals from the Red Sea as paleohydrological monitors

M. YEHUDAI[1]*, B. LAZAR[1], N. KOHN[1], Y. SHAKED[2], A. AGNON[1] AND M. STEIN[3]

[1]Institute of Earth Science, The Hebrew University of Jerusalem, ISRAEL 91904 (maayanchik@gmail.com)
[2]Interuniversity Institute for Marine Sciences, Eilat ISRAEL 88103
[3]Gological Survay of Israel, 30 Malkhe Israel St. Jerusalem, 95501 ISRAEL

While pristine aragonite corals provide information on sea level history and coastal tectonics, fossil corals that were altered to calcite (calcitified), can be used to establish the chronology of corals diagenesis by freshwater. Such diagenesis is possible provided the corals reside within the saturated zone of freshwater aquifers. Establishing the chronology of freshwater diagenesis in hyperarid areas, such as the Red Sea is extremely useful for reconstruction of past climate fluctuations. Here, we present a new open system U-Th dating method for calculating the time of deposition and the age of diagenesis of calcitic corals from the last interglacial uplifted reef terraces at the northern Red Sea. The calculated age of coral calcitification (~120 ka) is similar to closed system U-Th ages determined for aragonite corals from a nearby location[1]. These results suggest that the aragonite corals in this terrace resided in a coastal freshwater aquifer and recrystallized to calcite shortly after their initial formation. Therefore, it appears that wetter (than present) conditions prevailed during MIS5e in the currently hyperarid region of the northern Red Sea. Indication for enhanced runoff activity in this area is provided by $^{87}Sr/^{86}Sr$ ratios of foraminifers and fine detritus material from Red Sea cores[2].

Adakite-like volcanism in Boyabat Region, Turkey: Geochemistry and Petrogenesis

N. YESILOREN-GORMUS[1]* AND A. TEMEL[2]

[1]General Directorate of Mineral Research and Exploration, 06800, Çankaya, Ankara, Turkey (*correspondence: nihalyg@gmail.com)
[2] Hacettepe University, Faculty of Engineering, Geological Engineering Department, 06800, Beytepe, Ankara, Turkey

Cretaceous aged Dodurga volcanics mainly include andesitic (trachyandesite, andesite), dacitic (dacite, trachydasite) volcanic rocks and volcaniclastics. Volcanic rocks have typical hypocrystalline porphyric texture and mineralogically contain amphibole, plagioclase (zoning-polysynthetic twinning), biotite, quartz and opaque minerals, in varying quantity.

Dodurga volcanics have subalkaline and calc-alkaline characteristics. Major, trace and rare earth element data exhibit fractional crystallization which is effective process, in generation of volcanic rocks. Furthermore, effects of crustal contamination and/or subduction zone process were also determined. MORB and Chondrite-normalized spider diagrams indicate LILE, LREE content enrichments, compared with HFS elements. Besides, negative anomalies, observed in Ta, Nb and Ti elements reveal fractional crystallization, subduction and/or crustal contamination effectively, in occurrence of the volcanics. In Dodurga volcanics, SiO_2 content varying between 61%-65.1% (averagely 63.3%), Al_2O_3 between 16.1%-17.8% (averagely 16.9%), Sr between 385.9-611.4 ppm (averagely 505.2 ppm), Y between 5-14.5 ppm (averagely 9.5 ppm), Yb between 0.5-1.3 ppm (averagely 0.9) and Zr/Sm ratio 46.2-89.5 (averagely 65.6) were determined. In $(Yb)_N$-$(La/Yb)_N$ and Y-Sr/Y diagrams, the majority of Cretaceous Dodurga volcanics scattered in adakite area and partially in the classic arc volcanics were observed. In primitive mantle-normalized spider diagrams, Dodurga volcanics have typically low Nb, Ce and positive Sr contents, compatible with adakite-like volcanics.

According to the partial melting modeling diagrams, the Cretaceous Dodurga volcanics were formed as low degree batch melting of spinel-lherzolite which was a shallow depth lithospheric resource. All geochemical data and especially La/Nb>1 and Ba/Nb>28 ratios show Dodurga volcanics to have typical island arc volcanic characteristics, derived from lithospheric resources.

Atmospheric chemistry and dynamics recorded in the isotopic ordering in O_2 and CO_2

LAURENCE Y. YEUNG,[1]* EDWARD D. YOUNG,[1] EDWIN A. SCHAUBLE,[1] HAGIT P. AFFEK,[2] KRISTIE A. BOERING,[3] JOHN M. EILER[4] AND MITCHIO OKUMURA[5]

[1]Department of Earth and Space Sciences, University of California, Los Angeles, CA, USA (*correspondence: lyyeung@ucla.edu)
[2]Department of Geology & Geophysics, Yale University, New Haven, CT, USA
[3]Departments of Chemistry and Earth & Planetary Science, University of California, Berkeley, CA, USA
[4]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA, USA
[4]Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, CA, USA

Molecules in Earth's atmosphere undergo photochemical oxidation while being transported through regions where they are mixed and/or stratified. Chemistry, transport, and mixing all alter the distribution of gases in the atmosphere, and tracing these processes over large spatial and temporal scales is therefore challenging. Concentrations of the short-lived free radical oxidants that drive atmospheric chemistry are especially difficult to quantify due to short chemical lifetimes and spatial and temporal variations in source strengths.

Our studies of O_2 and CO_2 molecules containing more than one rare stable isotope ($^{18}O^{18}O$ and $^{16}O^{13}C^{18}O$) suggest that these species preserve signatures of isotope-exchange reactions in the stratosphere and troposphere [1,2]. For instance, $^{16}O^{13}C^{18}O$ can be used to constrain the isotopic signature of $O(^1D)$ in the midlatitude stratosphere as well as the chemistry and dynamics of the stratospheric polar vortex. In contrast, atmospheric $^{18}O^{18}O$ traces $O(^3P)$ chemistry and stratosphere-troposphere exchange.

Our most recent measurements of $^{18}O^{18}O$ in stratospheric air and in air drawn from the firn layer in Antarctica bolster the case for $O(^3P) + O_2$ isotope exchange reactions governing the distribution of $^{18}O^{18}O$ (i.e., Δ_{36}) throughout the atmosphere. Using these observations together with laboratory experiments and modeling, we show that Δ_{36} in the atmosphere is sensitive to $O(^3P)$ concentrations. Because $O(^3P)$ is linked directly to NO_2 and O_3 in the troposphere, Δ_{36} is a proxy for global NO_2 and O_3 concentrations.

$\delta^{66}Zn$ values: An isotopic tool for comprehension of metallurgical slags weathering

N.H. YIN[1,2,3]*, Y. SIVRY[1], P.N.L. LENS[2] AND E.D VANHULLEBUSCH[3]

[1]Univ. Paris Diderot, Sorbonne Paris Cité, IPGP, UMR 7154, CNRS, F-75205 Paris, France (*correspondence: yin@ipgp.fr, sivry@ipgp.fr)
[2]UNESCO-IHE, 2601 DA Delft, The Netherlands (p.lens@unesco-ihe.org)
[3]Univ. Paris-Est, LGE (EA 4508), 77454 Marne-la-Vallée, France (eric.vanhullebusch@univ-paris-est.fr)

The considered slags are originated from Lead Blast Furnace (LBF) and Imperial Smelting Furnace (ISF) Smelters. LBF and ISF slags contain 9.8 wt% and 8 wt% of Zn respectively, embedded in CaO-SiO-FeO matrix. Complete acid digestions showed that these bulk materials are enriched in heavy isotopes, with $\delta^{66}Zn_{JMC}$ $+0.77 \pm 0.06$‰ and $+0.12 \pm 0.06$‰ in ISF and LBF in agreement with previous studies [1]. Chemical dissolution kinetics were conducted at fixed pH values (4, 5.5, 7, 8.5 and 10), both in open-air and nitrogen atmospheres.

Zn dissolution was shown to be strongly governed by its mineral bearing phases: Spinel $Zn(Al_{0.8}Fe_{0.2})O_4$ and Wurtzite (ZnS) in ISF, and Franklinite $[(Zn,Mn^{2+},Fe^{2+})(Fe^{3+},Mn^{3+})_2O_4]$ in LBF. Zn from Spinel phases was more resistant to weathering comparing to Zn from sulfide phases and from glassy silicates matrix. Furthermore, Zn dissolution in both slags was enhanced by the collateral dissolution of matrix elements such as Ca, Fe and Si. At all pHs tested, dissolved Zn of ISF reached higher concentration when there was no secondary precipitates formation like Zincite (ZnO) and Zinc carbonate ($ZnCO_3$), i.e. under N_2 atmosphere.

Such dissolution was related to extremes zinc isotopic signatures in the leachate solutions collected under open-air atmosphere. Both ISF and LBF displayed the same trend: heavier $\delta^{66}Zn$ values at low pH than at high pH (i.e. $+0.91 \pm 0.06$‰ and -0.19 ± 0.06‰ at pH 4 and 10, respectively for ISF, and $+0.10 \pm 0.06$‰ and -1.25 ± 0.06‰ at pH 4 and 10 respectively for LBF).

In open-air atm., $\delta^{66}Zn$ values remained constant with time from 48 to 200hrs (e.g. -0.19 ± 0.08‰ and -0.27 ± 0.06‰, respectively, for ISF), whereas they became enriched in heavier isotopes under N_2 atm. (e.g. $+0.07 \pm 0.06$‰ and $+0.71 \pm 0.06$‰ after 48 hrs and 200 hrs, resp.). This may imply that the absence of secondary precipitates allows more congruent slag dissolution and, thus, weathered Zn reaches isotopic signature closer to the bulk slag.

Study of Pb isotopic compositions during metallurgical slags leaching experiments

N.H. YIN[1,2,3], Y. SIVRY[1]*, P.N.L. LENS[2] AND E.D VANHULLEBUSCH[3]

[1]Univ. Paris Diderot, Sorbonne Paris Cité, IPGP, UMR 7154, CNRS, F-75205 Paris, France (*correspondence: sivry@ipgp.fr, yin@ipgp.fr)
[2]UNESCO-IHE, 2601 DA Delft, The Netherlands (p.lens@unesco-ihe.org)
[3]Univ. Paris-Est, LGE (EA 4508), 77454 Marne-la-Vallée, France (eric.vanhullebusch@univ-paris-est.fr)

Chemical leaching of both Lead Blast Furnace (LBF) and Imperial Smelting Furnace (ISF) slags were conducted at different pH (4, 5.5, 7, 8.5 and 10) under open air and nitrogen atmospheres. LBF and ISF slags contain 3.62 wt% and 1.26 wt% of Pb, as metallic droplets embedded in CaO-SiO-FeO matrix. According to total acid digestion, ISF slag exhibits a more radiogenic composition ($^{206}Pb/^{207}Pb$: 1.1479 ± 0.0018) than LBF ($^{206}Pb/^{207}Pb$: 1.0733 ± 0.0018) for which the ratios are comparable to previous studies [1].

Dissolved Pb constantly increases with time in ISF (and to a lesser extend LBF) leaching solutions under open-air atm., which is consistent with SEM imaging of weathered slags, showing the increasing weathering of slag's surface over the long term period, releasing Pb included in metallic droplets. On the contrary, dissolved Pb quickly reaches a plateau under N_2 atm. This difference may be related to Pb precipitates formed in both cases: few $Pb(OH)_2$ were formed for both LBF and ISF under N_2 atm. at pH 8.5, whereas PbO_2, $PbCO_3$ and $Pb_3(CO_3)(OH)_2$ are controlling the dissolved Pb under open-air atm. for both slags. Furthermore, the Pb concentration remains higher at pH 10 than at pH 8.5 in both slag leachates, with 4 mg L^{-1} and 1 mg L^{-1}, resp.

Globally, ISF slag dissolution under open-air atm. is related to a more radiogenic Pb isotopic composition in the leachates, compared to N_2 atmo. experiments: $^{206}Pb/^{207}Pb$ in leaching solution was typically 1.1569 ± 0.006 and 1.1378 ± 0.002, resp. at pH 10. Moreover, $^{206}Pb/^{207}Pb$ remains close to the bulk slag value at pH 8.5, with values of 1.1495 ± 0.002 and 1.1477 ± 0.002, under N_2 atm and open-air atm., resp. Under N_2 atmosphere the $^{206}Pb/^{207}Pb$ ratio in LBF slag leachate displays extremely radiogenic values compared to initial bulk ratio (i.e. i.e. 1.0806 ± 0.002 and 1.0785 ± 0.001 at pH 8.5 and 10, resp. against 1.0733 ± 0.002). Thus, assuming an homogeneous isotopic composition of lead included in metallic droplets, such results would indicate an isotopic fractionation during dissolution and/or sorption processes.

Allende Chondrule Chronology Revisited: Eroding Age Gap between CAIs and Chondrules

Q.-Z. YIN[1], A. YAMAKAWA[1], M. SANBORN[1] AND K. YAMASHITA[2]

[1] Department of Geology, University of California at Davis, Davis, CA 95616, USA (qyin@ucdavis.edu)
[2] Okayama University, Okayama, JAPAN

We have recently suggested [1-3] that carbonaceous chondrites, as undifferentiated primitive objects formed in the protoplanetary disk, were accreted very early, within the first 1 Ma at the beginning of the Solar System. We have further suggested that the current ^{53}Mn-^{53}Cr data for bulk carbonaceous chondrites [1-3] imply that chondrules in them must also have formed early, given the logical necessity of forming chondrules first before accreting chondrites (we need "sand grains" first to form the cosmic "sandstone"). This argument was supported by examination of Allende chondrules with ultra high precision Mn-Cr isotope systematics [2]. This simple temporal relationship is at odds with the currently accepted paradigm of chondrule chronology of ^{26}Al-^{26}Mg and some Pb-Pb ages [e.g., 4, 5], which at face value requires a minimum age gap between CAIs and chondrules by 2-3 Ma. However, a younger chondrule age poses a serious dynamic problem for the early solar nebula, known as the "storage problem" [6], namely, how could CAI-sized particle float in the protoplanetary disk for over 2-3 Ma until chondrules form, then accrete together to form chondrite, without facing head wind and spiraling into the Sun rapidly. Gas drag would efficiently remove the CAI-sized dust particles in the solar nebula in a timescale far less than 2-3 Ma. Although some new theoretical models were subsequently developed to solve the long term storage problem of CAIs [e.g. 7], new high precision U-Pb ages once again supported chondrule formation started contemporaneously with CAIs [8]. Since our initial report [2], $^{235}U/^{238}U$ isotope composition was shown to be no longer a constant [e.g. 9], thus some of the relative age anchors require readjustment. We will reexamine the emerging stories in the light of new measurements.

Granulite xenolith constraints on the modification of the lower crust beneath the northern margin of the North China craton

JI-FENG YING*, HONG-FU ZHANG AND YAN-JIE TANG

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (*correspondence: jfying@mail.iggcas.ac.cn)

It has been well accepted that the lithosphere of the North China craton was severely destroyed in Mesozoic, in that the cratonic thick lithosphic mantle was replaced by manlte with oceanic affinity. A large amount of studies on the peridotite xenoliths entrapped by basalts of varied ages have invariably confirmed such catastrophic transformation. Howerver, it is still unclear whether the crust, espceically the lower crust also experiences significant modification or just keep stable and intact since its formation in Archean. A suite of granulite xenoliths captured in Cretaceous alkline basalts in the northern margin of the North China provide valuable constraints on the evolution of the lower crust. These xenoliths are mainly two-pyroxene granulites. We performed in situ U-Pb dating and Hf isotopic analyses on zircons separated from these xenoliths. CL images revealed that the majority of zircons are of igneous origin, though some zircon rims are metamorphically recrystallized. Zircons from one sample are discordant and show an upper intercept age of 2.5 Ga, representing the crystallization age of the protolith, which is consistent with the granulite terrain-based conclusion that the lower crust was mainly formed in 2.5 Ga ago. Apart from the Archean xenoliths, there are samples in which zircons are concordant with ages ranging from 200 to 300 Ma and peaking at 250-280 Ma, their Hf isotopic compostions, with εHf(t) values trending towards positive suggest that mantle materials contributed to the formation of their protoliths. Their relative younger model ages also ruled out their origin of mere remelting of preexisted lower crust, and underplating of mantle-derived magmas plays a considerable role in modifying the lower crust. Furthermore, the timing of magmatic underplating is colsely correlated with the closing and subsequent evolution of the Paleo-Asian ocean. We conclude that the modification of the lower crust beneath the northern margin of the North China craton was mainly, if not totally attributed to the southward subduction of Paleo-Asian oceanic slab and subsequent magmatisms.

The comparison experiments of acid leaching and bioleaching of sand-type uranium ore

ZHOU YIPENG[1,2], SHEN ZHAOLI,[1], SHI WEIJUN[2], LIU JINHUI[2] AND LIU YAJIE[2]

[1] China University of Geosciences, Beijing 100083, China
[2] East China Institute of Technology, Fuzhou, Jiangxi 344000, China

A series of comparison experiments of acid leaching and bioleaching of sand-type uranium ore were conducted in laboratory. The average grade of ore is 0.416‰, and the main size of the ore particles was 0.3-0.6mm. Acidibacillus ferrooxidans and Acidibacillus thiooxidans, by which Fe^{2+} was oxidized to Fe^{3+} to produce ferric acid leaching solution, were employed in the bacterial leaching processes.

For experiments under different conditions, 2.4kg uranium ore were divided into 12 uniform parts and each was put into a 500ml conical flask. Then these 12 flasks were ranged equally into three groups. Sulphuric acid solution was used for ore acidification; concentration of 2.0g/L was for group 1, 3.5g/L for group 2, and 5.0g/L for group 3. When the pH value of leaching system went down below 2.0, bacterial ferric acid solution with different concentration of Fe^{3+} and H_2SO_4 were added into different flask for bioleaching; a uniform acidity was also applied for all individuals in a same group, 2.0g/L was for group 1, 3.5g/L for group 2, and 5.0g/L for group 3; the ferric concentrations of 0g/L, 2.0g/L, 3.5g/L and 5.0g/L were applied respectively for those four flasks of every group.

Results showed that the uranium yield had been influenced by the solution acidity both in acid leaching and bioleaching processes; the yield could be increased by 2~3 percents as the solution acidity rose by 1.5g/L. The yield also determined by leaching technique. Comparing to acid leaching, bioleaching using bacteria solution of 2-5g/L Fe^{3+} could raise the yield by 6-11 percents. However, the leaching efficiency of 5g/L Fe^{3+} did not gain advantage over that of 2g/L; it indicated that concentration of 2g/L of Fe^{3+} in the bacterial leaching process was effective and economical.

Ge/Si atomic ratio of siliceous deposit formed from geothermal water: as an indicator of silica source of BIF

T. YOKOYAMA[1]* AND H. OHMOTO[2]

[1]Faculty of Science, Kyushu University, Fukuoka 812-8581, Japan (yokoyamatakushi@chem.kyushu-univ.jp)
[2]Department of Geochemistry, Penn State University, University Park, PA 16802

The source of iron and silica in BIF has been argued for a long period. For the source of iron (Fe^{2+}) of BIF, most of the geoscientists agree with the submarine hydrothermal activity. For the source of silica, however, there are different ideas based on the difference in Ge/Si atomic ratio: whether it is hydrothermal or is continental in origin. Hamade *et al*. found that the Ge/Si atomic ratios of iron-poor silica layer in the Brockman BIFs are essentially identical to present-day seawater (~0.8 x 10^{-6}), suggesting that the silica in Fe-poor layers formed from silica derived from the weathering of continental crust (input from river) rather than from hydrothermal fluids [1]. On the other hand, the Ge/Si atomic ratios in the Fe-rich layers are as high as ~20 x 10^{-6}, which are similar to those in MOR hydrothermal fluids. In order to well-establish the reliability of Ge/Si atomic ratio as an indicator for the source of silica in Fe-poor layer in BIF, it is essential to show the relationship between Ge/Si atomic ratios in hydrothermal fluid and in siliceous deposit which precipitated directly from the fluid. In this study, we measured the Ge/Si atomic ratios of geothermal waters and siliceous deposits at geothermal power plants.

The distribution ratio of Ge into siliceous deposit from geothermal water was low. The Ge/Si atomic ratio of siliceous deposits formed in geothermal water in the aging tank at the Hatchobaru geothermal power plant was in the range from 3.72 to 5.42 x 10^{-6}. This values of Ge/Si atomic ratio can be considered to be an indicator showing the hydrothermal origin. The Ge/Si atomic ratio of iron-poor silica layer of Temagami BIF was in the range from 3.3 to 7.9 x 10^{-6}, suggesting hydrothermal origin.

^{142}Nd isotope anomaly in chondrite revisited

TETSUYA YOKOYAMA[1]*, HIROKAZU TAKAHASHI[1] AND HIROSHI YAMAZAKI[1]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Japan. (*: tetsuya.yoko@geo.titech.ac.jp)

Chondrites and differentiated meteorites possess isotope differences from the terrestrial composition for some heavy elements, suggesting heterogeneous isotope distribution in the early Solar System. For Nd, carboneceous chondrites have ^{142}Nd/^{144}Nd ratios >20 ppm lower than the terrestrial [1]. The finding most likely suggests the occurrence of a large scale silicate differentiation that fractionated Sm-Nd in early history of the Earth when short-lived ^{146}Sm existed. However, most of the Nd isotope data in chondrites were obtained using incomplete sample digestion that could not dissolve acid resistant, isotopically anomalous presolar grains, resulting in variable ^{145,148,150}Nd/^{144}Nd ratios [2]. To resolve this issue, we have developed a new method for determining Nd isotope ratios in meteorites with ultra-high precision using a TIMS (TRITON plus at Tokyo Tech), coupled with complete sample decomposition technique using a pressure digestion system (DAB-2, Berghof, Germany). Meteorite samples were put in Teflon inserts together with a mixture of HF, HNO_3 and H_2SO_4. The insert was placed in a stainless jacket and heated at 240 ºC for >12 hours under high pressure. The existence of H_2SO_4 facilitated digestion of acid resistant presolar SiC. The resulting solution was dried and dissolved in 1M HCl, and passed through cation exchange resin and Ln spec to isolate Nd. In the TIMS analysis, we monitored ^{140}Ce interference using a compact discrete dynode, resulting in an excellent analytical precision of ^{142}Nd/^{144}Nd (2 ppm, 2SD) for repeated analysis of 500 ng of JNdi-1 standard. Using the technique, we determined Nd isotope compositions in four chondrites; Murchison (CM2), Saratov (L4), Chergach (H5) and NWA 4814 (R4), as well as terrestrial samples. These chondrites have ^{142}Nd/^{144}Nd ratios of 23±3ppm lower than the terrestrial samples, although the ^{145,148,150}Nd/^{144}Nd ratios were not resolvable from the terrestrial. This indicates that Nd isotopes were homogenously distributed in the early Solar System. Our result supports the existence of an enriched hidden reservoir in the Earth's mantle whose chemical composition is complementary with a depleted mantle that was produced by silicate differentiation in the early history of the Earth while ^{146}Sm existed.

Speciation and fate of As in calcite formed under anoxic condition

Y. YOKOYAMA[1]*, T. IWATSUKI[2] AND Y. TAKAHASHI[1]

[1]Hiroshima University, Hiroshima 739-8526, Japan (*correspondence: yoshiyuka@hiroshima-u.ac.jp)
[2]Tono Geoscience Center, Japan Atomic Energy Agency, Toki, 509-6133, Japan

Speciation analyses for arsenic (As) in natural calcite, precipitated in fracture of deep underground sedimentary strata (Hokkaido, Japan), were performed using micro X-ray fluorescence and XAFS (μ-XRF-XAFS) technique to infer how calcite limit As migration in groundwater system.

Chemical data of pore water and groundwater collected from the sedimentary strara showed that arsenite (As^{III}) is predominant aqueous As species in the water phase. Nevertheless, As in the natural calcite is arsenate (As^{V}) [1]. This inconsistency of As species between calcite and water phases has already been observed in our laboratory experiment [2]. In calcite supersaturated solution, aqueous arsenite could be oxdized to arsenate, which is induced by complexation of arsenate with Ca^{2+} ion [2]. On the other hand, other minerals in the sedimentary strara (Fe oxide, siderite, biotite, and pyrite) contain As as arsenide and arsenite species. These Fe (secondary) minerals are frequent in As-contaminated sediments and considered to be effective sink for As. Among the minerals formed under anoxic condition, only calcite immobilized arsenate even in the arsenite system by selective incorporation of arsenate produced by the complexation-induced arsenite oxidation.

This property differentiates calcite from other minerals as a unique scavenger for As under anoxic condition. Calcite could preserve As as relatively insoluble arsenate from anoxic groundwater, while the arsenide and arsenite in the Fe secondary minerals easily leach from host minerals into aqueous phase depending on the change of the environmental condition such as redox. Mobilization of arsenate from calcite to aqueous phase hardly occur regardless of redox condition. Calcite seemed to be a rare mineral scavenging As as arsenate in groundwater system with low risk of As leaching to natural water. The present study about distribution behavior of As to calcite is also expected to lead a understanding of incorporation mechanism of redox sensitive oxyanions into calcite, which might be a useful tool for reconstruction of paleo-redox environment in which the calcite precipitated.

Adsorption experiment of rare earth elements on clay minerals: Implication to the formation of ion-adsorption type REE deposit

KOTARO YONEZU[1], MASAHIRO NISHIDA[1], KOICHIRO WATANABE[1] AND TAKUSHI YOKOYAMA[2]

[1]744 Motooka, Nishi-ku, Fukuoka, 819-0395 Japan, (yone@mine.kyushu-u.ac.jp)
[2]6-10-1 Hakozaki, Higashi-ku, Fukuoka 812-8581 Japan

Supply of rare earth elements (REE), especially heavy rare earth elements (HREE), highly depends on China. REE are essential for advanced environmental protection technology. HREE ore is mainly produced from ion adsorption type deposit. In order to clarify the role of the surface of clay minerals on the adsorption of REE, the adsorption and desorption (sequential extraction) experiment of REE were demonstrated in this study. Kaolin minerals such as kaolinite and halloysite were focused as adsorbents. In addition to the above experiment, some of hydrothermally altered rocks and clay vein were applied to the desorption experiment.

The adsorption experiments were conducted at room temperature and pH 6 with magnetically stirring in $NaNO_3$ or NaCl solutions (0.025M and 0.5M). At 0.5M, significant fractionation of REE on clay minerals from LREE to HREE was observed (HREE rich). However, no significant effect of the different electrolyte could be observed on any clay minerals at 0.5M. In order to understand an adsorption mode on clay minerals, the desorption (extraction) experiment were subsequently carried out. Three types of samples are used: REE on montmorillonite, 10Å-halloysite and pyrophyllite. Most of REE, especially LREE were preferentially extracted from montmorillonite and halloysite by neutral salt extraction step, suggesting that those extracted REE are considered to be concentrated by ion exchangeable form. Relatively more strongly adsorbed REE by forming chemical adsorption may be extracted by the following proton exchangeable step.

Feedbacks between biological retention of nutrients, carbon-mineral sorption, and pore space generation along an earthworm invasion chronosequence

KYUNGSOO YOO[1]*, KIT RESNER[1], AMY LYTTLE[1], CINDY HALE[2], ANTHONY AUFDENKMAPE[3] AND STEPHEN SEBESTYEN[4]

[1] University of Minnesota, St. Paul, MN 55108, USA (correspondence*: (kyoo@umn.edu,) (resne005@umn.edu,) lytt0004@umn.edu)
[2]University of Minnesota Duluth, MN 55811, USA (cmhale@d.umn.edu)
[3]Stroud Water Research Center, PA 19311, USA, (aufdenkampe@stroudcenter.org)
[4]USDA Forest Service, Northern Research Station, Grand Rapids, MN 55744, USA (ssebestyen@fs.fed.us)

Partitioning and transport of chemical phases in soils are governed by the complex interactions between competing biotic and abiotic processes that are difficult to quantitatively and mechanically separate. Addressing this challenge, we study an ~200 m long earthworm invasion chronosequence in a hardwood forest in Minnesota. The forests in the Great Lakes region have evolved without native earthworms since the Last Glacial Maximum. Exotic earthworms were recently introduced due to agriculture, recreational fishing, and logging activities. The transect represents an invasion history of ~40 yrs with its invasion front proceeding at a rate of ~5 m/yr. We quantified the degree that biological retention of elements (Si, Ca, P, K), sorption of organic matter on mineral surface, and generation of pore space respond to the arrivals of different earthworm functional groups. Invasive earthworms critically and systematically impact the three key biogeochemical processes. We quantitatively and mechnistically reveal that strong feedbacks among the three processes are present, and that the feedbacks systematically evolve with ongoing earthworm invasion. We determined biomasses and species compositions of earthworms, elemental chemistry (ICP), soil mixing intensity (^{137}Cs), and carbon-mineral sorption (BET), and adopted the geochemical mass balance approach with Zr as an immobile element. This study illustrates how and to what degree invasive earthworms – by altering bioturbation and consuming particulate organic matter – cause cascading effects on the dynamics and interactions between nutrients and carbon fluxes.

Light-absorbing aerosol radiative forcing in the Kathmandu Valley during Suskat-ABC Field Campaign

SOON-CHANG YOON[1], SANG-WOO KIM[1], JIHYOUNG KIM[1], CHAE YOON CHO[1], JIN-YOUNG JUNG[2], AND MAHESWAR RUPARKHETI[3]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea (yoon@snu.ac.kr)
[2]Korea Polar Research Institute, Incheon, Korea
[3]Institute for Advnaced Sustainability, Potsdam, Germany

Light-absorbing aerosols, such as black carbon (BC), are major contributors to the atmospheric heating and the reduction of solar radiation reaching at the earth's surface. In this study, we investigate light-absorption properties of aerosols (i.e., BC mass concentration, aerosol solar-absorption efficiency) in the Kathmandu valley during Sustainable atmosphere for the Kathmandu valley (SusKat)-ABC campaign, from December 2012 to February 2013. Kathmandu City is among the most polluted cities in the world. However, there are only few past studies that provide basic understanding of air pollution in the Kathmandu Valley, which is not sufficient for designing effective mitigation measures (e.g., technological, financial, regulatory, legal and political measures, planning strategies). A distinct diurnal variation of BC mass concentration with two high peaks observed during wintertime dry monsoon period. BC mass concentration was found to be maximum around 09:00 and 20:00 local standard time (LST). Increased cars and cooking activities including substantial burning of wood and other biomass in the morning and in the evening contributed to high BC concentration. Low BC concentrations during the daytime can be explain by reduced vehicular movement and cooking activities. Also, the developmements of the boundary layer height and mountain-valley winds in the Kathmandu Valley paly a crucial role in the temproal variation of BC mass concentrations. Detailed radiative effects of light-absorbing aerosols will be presented.

Origin and distribution of sedimentary organic matter in Yellow Sea and northern East China Sea studied with carbon and nitrogen stable isotopes and radiocarbon

SUK-HEE YOON[1], JONG-GU GAL[1], HI-IL YI[2] AND KYUNG-HOON SHIN[1]*

[1]Hanyang University, Department of Marine Sciences and convergent technology, Ansan, Rep of Korea, (Correspondence: shinkh@hanyang.ac.kr)
[2]Korean Ocean Research Development Institute, Ansan, Rep. of Korea,

In order to investigate the source and distribution of organic matter in the surface sediment of Yellow Sea and northern East China Sea, we have collected surface sediment samples from more than 300 sampling sites, and have measured their stable carbon and nitrogen isotope ratios. The distributions of organic carbon and nitrogen stable isotopes ratios are described in the entire Yellow Sea and northern East China Sea, indicating apparently lighter carbon isotope ratios at the sites near Sangdong Peninsular. In addition, 14C values of organic carbon at the surface sediments are also determined at the same sites. 14C values of organic carbon range from 10930±80 to modern. In the near Sangdong Peninsular, the oldest 14C age of organic carbon corresponds to the lighter stable carbon isotopes ratios, reflecting large contribution of terrestrial organic carbon. However, 14C value of organic carbon in the central basin of Yellow Sea is close to modern, which is mainly contributed by marine organic carbon. Other sites in the shelf regions show around 2000 of 14C age. Some sedimentary organic carbon was younger than 2000 14C age in the northern East China Sea where is the area affected by Tsushima Current. In the current study, the 14C values of organic carbon in the surface sediment of Yellow Sea and northern East China Sea seems to be strongly influenced by the transport of terrestrial organic carbon as well as petroleum derived organic carbon from the coastal regions.

Mineralogical characterization of thermal treated chrysotile and tremolite asbestos in soils

SUNGJUN YOON[1], HYEONYI JEONG [2], WONJIN MOON[3] AND YUL ROH[4]*

[1]Chonnam National University, Gwangju, Korea, (sungjunyoon8@naver.com)
[2]Chonnam National University, Gwangju, Korea, (happy11hyun@nate.com)
[3]Korea Basic Science Institute, Gwangju, Korea, (wjmoon@kbsi.re.kr)
[4]Chonnam National University, Gwangju, Korea, (*correspondence: rohy@jnu.ac.kr)

Asbestos-containing soils occur mainly at ultramafic rocks and hydrothermally altered carbnate rocks in S. Korea. Remediation of asbestos-containing soils is considered a high priority by the Korean Government because these soils, if left untreated, represent a hazard to the environment and human health. Thermal transfomation asbestos-containing waste used to detoxify asbestos may potentically be adapted to achieve remediation of the asbestos-containing soils. The objectives of this study were to provide information related to the thermal effects on asbestos and to examine mineralogical characteristics of the thermal treated asbestos-containing soils.

Two soils, a soil weathered from serpentinite rock and a soil weathered from hydrothermally altered carbonate rocks, were selected for thermal treatment and mineralogical characterization. The mineralogical characterization approach was designed to obtain basic information relating to the nature of asbestos in the soils. TG-DTA anlysis was used to find the optimum temperature for thermal treatement of the two asbestos-containg soils. PLM, XRD, SEM, TEM and EDS analyses were used to examined the mineralogical properties of asbestos in soils before and after the thermal treatment.

PLM, SEM and TEM analyses showed chrysotile contained in the soil weathered from serpentinite rock and tremolite asbestos contained in a soil weathered from hydrothermally altered carbonate rocks. Chrysotile and tremolite asbestos in soil were transformed to forsterite and diopside at 820℃ and 1060℃, respectively. Chrysotile fibers were transformed into rod-shaped forsterite at 820℃. Tremolite asbestos was transformed into non-fibrous diopside 1060℃. The theramal treated asbestos, chrysotile and tremolite asbestos, was non-fibrous. These results indicated that thermal treatment of asbestos-containing soils was effective for detoxification of the asbestos and can be applied to treat the asbestos-containing soils.

Natural radionuclides as tracers in surface water and groundwater interaction

YOON YEOL YOON, SOO YOUNG CHO, KIL YONG LEE, AND YONG CHUL KIM

Korea Institute of Geoscience and Mineral Resources, Gwahang-no 124, Yuseong-gu, Daejeon, 305-350, Korea,(yyyoon@kigam.re.kr, sycho@kigam.re.kr, kylee@kigam.re.kr, yckim@kigam.re.kr)

Determining the relationship between rivers and adjacent groundwater systems is critical to understanding hydrogeological systems, protecting riverine ecosystems, and managing water resources. Due to its high activities in groundwater, the radionuclide ^{222}Rn is a sensitive natural tracer to detect and quantify groundwater . In this study ^{222}Rn and ^{3}H were used as a tracer in groundwater and river water interaction.

^{222}Rn and ^{3}H were used as a natural radiotracer to study groundwater and river water interaction. Study area is used groundwater as a water curtain house in winter, so shortage of groundwater problem is occurred and groundwater-river water interaction was severely varied at this time. This variation was studied with ^{222}Rn and ^{3}H during water curtain house operation period and the results was showed in figure 1 and the interation difference was compared with upper and below river dam.

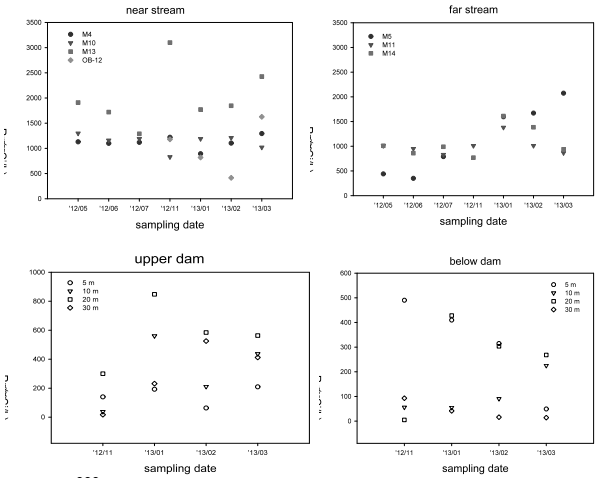

Fig. 1. ^{222}Rn contents variation with water curtain house operation period.

Cathodoluminescence of terrestrial and extraterrestrial halite

E. YOSHIDA[1], H. NISHIDO[1], N. NIMURA[2] AND K. NINAGAWA[1]

[1] Department of Biosphere-Geosphere Science, Okayama University of Science, 1-1 Ridai-cho, Okayama 700-0005 Japan (correspondence: nishido@rins.ous.ac.jp)

[2] Okayama Astronomical Museum, 3037-5 Honjou, Asakuchi, Okayama, 719-0232 Japan

Luminescence of natural alkali halides such as halite and sylvite is characterized by structural defects related to F-center(+p) and V-center(+e). Their CL (cathdoluminescence), however, have not been reported so far. Since asteroidal water was discovered as fluid inclusion in halite from H5 chondrite, Monahans (1998), alkali halides in meteorites have been extensively investigated for understandings of aqueous alteration and thermal metamorphism on the parent body. Therefore, luminescence features of halides can provide valuable information on such issues. In this study we have measured CL spectra of terrestrial halite and ones in meteorites to clarify luminescence centers in various types of halite.

Several halite crystals of terrestrial origin and small halite particles in ureilite meteorites were selected for CL spectral measurements. All samples were prepared using oil while cutting and polishing without water.

All samples exhibit weak blue to greenish blue CL with broad band emissions from 350 to 650 nm. CL spectra corrected for total instrumental response were converted into energy units for spectral deconvolution using a Gaussian curve fitting. The analysis of terrestrial halite results in two emission components at 3.02 eV (410 nm) and at 2.22 eV (557 nm). Former can be assigned to F center and the latter to V center. Halite in ureilite gives two components at 3.10 eV (399 nm) for F center and at 2.61 eV (475 nm), which is different from any luminescence centers previously reported. Therefore, the emission at 2.61 eV might be defect center derived from the damage induced by high-energy radiation in cosmic space.

[4] Fukuoka Univ., Fukuoka 814-0180, Japan

Calcic amphibole-bearing spinel harzburgites from the Pinatubo 1991 dacite are characterized by residual mantle mineral chemsitry and abundant fluid inclusions of saline solutions and magnesite in mantle minerals. Some xenoliths have zoned selvages composed of amphibole, phlogopite, plagioclase and orthopyroxene. The peridotite xenoliths show more or less metasomatized textures; fine-grained orthopyroxene-rich parts with amphibole, olivine, spinel, and phlogopite, replacing primary olivines. We determined trace element compositions of amphiboles of the least metasomatized harzburgite using LA-ICP-MS.

Chondrite-normalized trace element patterns of the amphiboles show depletion in LREE with various degrees of negative Ti and positive Sr amomalies, in contrast to LREE enriched amphiboles with negative anomalies of HFSE, Eu and Sr from the selvages. This suggests that the harzburgites were metasomatised before entrainment in the host dacite. Amphiboles inside the harzburgite xenolith show continuous chemistry from magnesiohornblende to tremolite. These amphobles can be classified into primary and secondary ones in paragenesis and chemical composition. The secondary amphiboles are contained in the fine-grained orthopyroxene rich parts and show relatively low TiO_2 and Al_2O_3, and high SiO_2 and MgO contents. Their trace element patterns are similar to those of primary amphiboles but with lower concetrations. These LREE-depleted amphiboles have been observed in the subcontinental lithspheric mantle peridotites metasomatised by subduction-related hydorus fluids, because hydrous fluids do not carry large amounts of REE [1, 2]. The compositional features of the amphiboles suggest that the primary amphiboles were formed through a reaction between pyroxene and subduction-related SiO_2-rich aqueous fluids and the secondary amphiboles were formed from more diluted fluids at lower temperature conditions.

Apparent inverse carbon isotope effects during the anaerobic oxidation of methane

MARCOS YOSHINAGA[1], GUNTER WEGENER[1,2*], THOMAS[2] HOLLER, TOBIAS GOLDHAMMER[2], BENJAMIN BRUNNER[2], JOHN POHLMAN[3], MARCEL KUYPERS[2], KAI-UWE HINRICHS[1] AND MARCUS ELVERT[1]

[1]Marum, Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany (*presenting author)

[3] U.S. Geological Survey, Woods Hole Coastal and Marine Science Center, Massachusetts, USA

Large amounts of methane are produced in marine subsurface sediments. Their emission to the hydrosphere is suppressed by microbial consortia, which perform the sulfate-dependent anaerobic oxidation of methane (AOM) in distinct sulfate-methane transition zones (SMTZ). According to conventional isotope systematics, the biological consumption should result in ^{13}C-enriched residual methane. Instead, within the SMTZs methane is often depleted in ^{13}C, a pattern frequently interpreted as evidence of concomitant methane production.

Here we tested if AOM alone can yield ^{13}C-depleted methane. We incubated sediment-free AOM-cultures devoid of background methanogenesis at low sulfate concentrations. As a result of decreasing sulfate availability (<0.5 mM), the system switched from ^{13}C-enrichment towards ^{13}C-depletion in the methane pool. We explain this apparent inverse carbon isotope effect by AOM-mediated equilibrium isotope exchange, which predominates during sulfate-limited AOM. Our results are representative of SMTZs, where generally low sulfate concentrations prevail. Evidence that ^{13}C-depleted methane can form by a non-methanogenic process expands our current understanding of the methane biogeochemistry in marine sediments. Microbially mediated equilibrium isotope exchange might be common in marine subsurface habitats, which are generally characterized by limited substrate availability combined with low energy yields.

Methane production potential of subsurface microbes in Pleistocene sediments from a water-dissolved natural gas field in central Japan

HIDEYOSHI YOSHIOKA*, HANAKO MOCHIMARU AND SUSUMU SAKATA

Institute for Geo-Resources and Environment, National Institute of Advanced Industrial Science and Technology (AIST), 1-1-1 Higashi, Tsukuba 305-8567, Japan (*correspondence: hi-yoshioka@aist.go.jp)

As much as 20% of the world's natural gas resources is estimated to be of biogenic origin [1]. This implies that subsurface anaerobic microbes are important producers of natural gas. However, it is unclear when and where the microbes produced methane and what kind of substrates they utilize. To address these issues, we investigated microbial methanogenesis in Pleistocene sediments from Minami-Kanto gas field in central Japan. The gas field is widely distributed in the southern area of the Kanto Plain and the gas dissolved in the formation water consists almost solely of biogenic methane [2]. Mochimaru *et al*. found that methanogens are living in the formation water from production wells [3].

Core sediments from the depth of 287-607 m were obtained by drilling, and sludge sediments were collected from the settling ponds which were located downstream of the gas-water separators. Methane production rates from the sediments were measured in the tracer experiments using [^{14}C]-bicarbonate and [2-^{14}C]-acetate. Cumulative amounts of methane produced from the sediments were monitored in the long-term (tracer-free) incubation experiments.

The tracer experiments showed that CO_2 reduction was the main pathway of methane production. The highest rate of 1.1 nmol CH_4 cm^{-3} day^{-1}, obtained from the muddy sediment at 607 m, was comparable with those in the sediments from the Blake Ridge gas-hydrate region [4].

In the long-term incubation experiments, intense methanogenesis ocurred and continued for a few months. Mass balance evaluation indicated that most of the methane was derived from kerogen. This study has demonstrated that subsurface microbes can utilize a substantial fraction of the recalcitrant sedimentary organic matter as the source of methane production.

In-situ iron isotope analysis of pyrite in *ca*. 3.8 Ga metasediments from Isua supracrustal belt, Greenland

KAZUMI YOSHIYA[1], YUSUKE SAWAKI[2], TSUYOSHI KOMIYA[3], SHIGENORI MARUYAMA[1] AND TAKAFUMI HIRATA[4]

[1] Earth Life Science Institute, Tokyo Institute of Technology, Japan (yoshiya.k.aa@m.titech.ac.jp)
[2] Dept. of Earth and Planetary Sci., Tokyo Institute of Technology, Japan
[3] Dept. of Earth Sci. and Astro., Komaba, Univ. Tokyo, Japan
[4] Dept. of Geology and Mineralogy, Kyoto Univ., Japan

The timing of emergence of life still remains one of the unresolved questions in the early Earth. Early life could be identified and characterized by its metabolic processes, which must be deposited and preserved in the old rocks. The oldest (*ca*. 3.8Ga) sedimentary rocks on Earth occur in the Isua supracrustal belt (ISB), southern West Greenland. These rocks have been subjected to until amphibolite facies metamorphism [1,2]. Despite the contribution of the intense thermal metamorphism, carbon isotope compositions from the Isua metasediments suggested the evidence for biological carbon fixation [3,4,5]. Microbial dissimilatory iron reduction (DIR) is also considered to be one of the earliest metabolisms on Earth [6,7]. δ^{56}Fe value of Fe^{2+}_{aq} generated by DIR is expected to have lower value, whereas negative δ^{56}Fe values lower than -1 ‰ are not found in the sedimentary record prior to 2.9Ga. Here, we report the *in-situ* iron isotope analysis of pyrite in sedimentary rocks from the ISB, using femtosecond laser ablation multi-collector ICP-MS technique (fs-LA-MC-ICP-MS)[8]. We obtained a large variation of iron isotope data from -2.41 to +2.35 ‰ in δ^{56}Fe values, from 212 points of pyrite grains in 15 rock specimens, including metachert, muddy metachert, BIF, carbonate rock and conglomerate. The distribution of δ^{56}Fe values varies depending on the lithology, whereas no correlation could be found berween δ^{56}Fe values and the metamorphic zone.

Low δ^{13}C values of graphite in ISB muddy metachert suggested the existence of biological carbon fixation [5]. δ^{56}Fe values of pyrite grains from the same samples show lower δ^{56}Fe values, which suggested the occurrence of microbial DIR in the Early Archean.

A lithospheric mantle source for Etna magmatism

H. PATRICK YOUNG[1], ZHENGRONG WANG[1] AND MARK BRANDON[1]

[1]Department of Geology and Geophysics, Yale University, New Haven, CT 06520, USA. (Hobart.young@yale.edu)

Mt. Etna has important geochemical and petrologic similarities with other sodic volcanics in the region. We compared the chemistry of rocks from Mt. Etna with those from other nearby volcanoes (e.g., Pantelleria and Ustica) which have the least contribution from the subducted slabs, in order to better understand the nature of the regional mantle source that is supplying melts for Mt. Etna. We obtained Sr-Nd-Pb-O isotopes, as well as trace and major element data for rocks spanning the ages and compositions of these volcanoes. Among them, lavas from Etna, Pantelleria and Ustica have more radiogenic Pb-isotopes than MORBs. Their mantle-like oxygen isotope composition indicates that the radiogenic component might originate directly from the mantle. Moreover, the isolation of a high-μ (HIMU = old material with initially high U/Pb ratio) source for ~500 Ma is required to generate the Pb isotope compositions in these lavas. Interestingly, these melts are similar to experimental melts of amphibole in peridodite [1]. However, amphibole and most other hydrous silicates are unstable above ~1100 ºC, which is significantly below asthenospheric temperatures, requiring that the source veins were frozen into the lithospheric mantle during ingrowth of radiogenic Pb. We suggest that the source of Mt. Etna magmatism might be related to extensional decompression, or alternatively, heating by a hot plume, resulting in melting of a metasomatized sub-continental lithospheric mantle.

Cerium sequestration in fractures in the upper kilometer of granitoids, SE, Sweden

C.X. YU[1]*, H. DRAKE[1], M. ÅSTRÖM[1] AND F. MATHURIN[1]

[1]Linnaeus University, 39182 Kalmar, Sweden (*correspondence: changxun.yu@lnu.se)

This study seeks to define geochemical processes governing the accumulation and sequestration of Ce in granitoidic fractures down to >700 m depth, revealing past intrusions of oxygenated waters. The fracture coatings (secondary mineral precipitates in open fractures) gathered from the study area (Laxemar, SE Sweden) are characterized by high levels of Ce (Fig. 1b) compared to host rock cocentration (average: 86 ppm, n=65) and show a striking feature of distinct positive Ce anomalies (Ce_{WN}*=1.21-3.95, n=8) in the uppermost 20 m of the bedrock (Fig. 1a).

Cerium and Mn X-ray absorption spectroscopy (XAS) of selected fracture coatings, together with existing data (e.g. fracture mineralogy and groundwater chemistry), indicate that: (1) Ce(IV) occurs down to c.a. 70 m depth and is exclusively associated with Mn oxides which occur as todorokite and triclinic birnessite as suggested by Mn EXAFS spectra; (2) Since Mn is largely speciated as Mn^{2+} in the present bedrock groundwaters, the Ce(IV)-bearing Mn oxides most probably resulted from oxidative weathering of wall rock and fracture coating minerals when oxygenated waters intruded into the bedrock (down to several hundred meters depth) during deglacation events (>13000 BP); (3) Unlike other samples, clear XAS features of a poorly-crystalline hexagonal-birnessite-like phase and larger proportion of aqueous Mn^{2+} were observed in the sample with strikingly positive Ce anomaly (Ce_{WN}* = 3.95) (Fig. 1b) at the depth of 0.87 m, suggesting an ongoing dynamic accumulatinon of Ce(IV), i.e. dissolution and reprecipiation of Mn oxides while Ce(IV)-enriched residue largely remained.

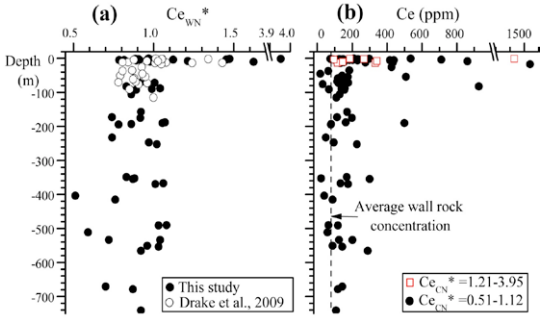

Fig. 1. Distribution of Ce anomalies (Ce *=Ce /(La *Pr)1/2 in WN WN WN WN fracture coatings (a), where WN denotes normalization to average wall rock; and concentrations in the fracture coatings (b).

Oxygen Before Cyanobacteria implied from Magnetotactic Bacteria

HANG YU AND JOSEPH L. KIRSCHVINK

Geological and Planetary Sciences, California Institute of Technology, Pasadena CA 91125, USA (*correspondence: kirschvink@caltech.edu)

Magnetotactic bacteria (MTB) position themselves magnetically at oxic/anoxic and sulfate/sulfide transitions in redox stratified sediments. As opposed to the earlier polyphyletic idea[1], recent functional gene studies of magnetosome formation support a common origin of MTB[2-4], but their evolutionary relationship with other bacterial groups remains obscure. We analyzed over 700 MTB 16s rRNA sequences to elucidate the origin and evolution of MTB in relation to other Bacterial groups as shown below.

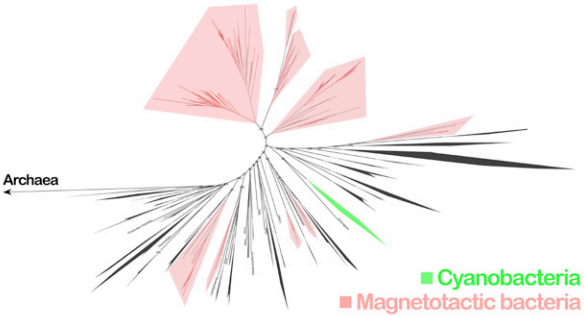

Figure 1. A Bayesian tree showing the molecular phylogeny of Bacteria, with special emphasis on magnetotactic bacteria.

Our phylogenetic analysis suggests a ubiquitous presence of MTB throughout all but the oldest branches of the bacterial tree. Four phyla with MTB appear before the cyanobacterial divergence, indicating a much earlier origin for this group than hypothesized. Horizontal gene transfer is an unlikely explaination based on the genetics and biochemistry of magnetsome formation. This result suggests the presence of pre-Cyano redox stratified environments in the Archaean, such as the peroxide-rich glacial runoff settings where oxygen mediating enzymes may have evolved[5]. Together with peroxidase and reactive oxygen species (ROS) scavenging properties of magnetosomes[6], MTB might have contributed to the adaptation to oxygen by mediating ROS toxicity in ancient microxic environments.

Eco-geochemistry and Kashin-Beck Disease-A case study in Aba, Sichuan

T. YU[1], Z.F. YANG[1]*, Q.Y. HOU[1], W.J. MA[2] AND L.X. JIN[3]

[1]School of Earth Sciences and Resources, China University of Geosciences, Beijing 100083, China (*correspondence: zfyang@up-point.com)

[2]Peking University Health Science Center, Beijing 100191, China

[3]Sichuan Institue of Geological Survey, Chengdu 610081, China

Kashin-Beck disease (KBD) is a chronic, endemic osteochondropathy (disease of the bone), but it is not clear what is the cause. There are still new cases of KBD in part of the Tibet, Qinghai and Sichuan province in recent years[1], severely damage the wellbeing of the local population.

The distribution characteristics of selenium(Se), calcium(Ca), molybdenum(Mo), iron(Fe), zinc(Zn) and strontium(Sr) in environmental media, plants, animals and human blood, urine and hair in Aba, Sichuan were studied with the theory and method of eco-geochemistry. Elements related to KBD were disclosed. The geochemical processes of migration and transformation of Se and other elements, the healthy risk and the KBD eco-geochemical model of the population in studied area were established. The practical prevention and control measures for KBD in the area were suggested.

It is proved that the Se, Ca, Zn, Fe, Mn, Mo, Sr are all deficient in these environmental media in the area, the Se in soil is 0.12mg/kg on average, far lower than that of in Chengdu Economical Zone□0.28mg/kg□and the average of whole country (0.26mg/kg).

New KBD cases are all from inhabitence on the slopes in the valley, where in contrast to the control area, Ca, Se and some other elements in surface soil were severely leached and most soil pH was nearly acidic to neutral.

The results of the present study could be applied to the improvement of the environment in KBD area and reduce the KBD incidence, is an important progress on eco-geochemistry and KBD research.

Re-evaluation of electron transfer budgets for oxidation and incorporation of bisulfide by dissolved organic matter under anaerobic conditions

ZHIGUO YU[1,2] AND KLAUS-HOLGER KNORR[1,2]

[1] Department of Hydrology, University of Bayreuth, Bayreuth, Germany

[2] present adress: Hydrology Group, Institute for Landscape Ecology, WWU Muenster, Germany, (zhiguo.yu@uni-muenster.de)

While it is known that functional groups of organic matter, such as quinones, can reversibly transfer electrons, there is little known about electron transfer (e-transfer) processes in redox reactions of reactive species, such as sulfide, with organic matter.

We investigated the chemical oxidation of H_2S with a reduced (as control) and non-reduced dissolved humic acid (HA), in batch experiments at pH 6 under anoxic conditions. Thereafter, electron transfer budgets were calculated from sulfide consumption and production of oxidized sulfur species formed.

Sulfide reacted rapidly with DOM and thereby regenerated more oxidized forms of sulfur, either inorganic sulfur species (S^0 and $S_2O_3^{2-}$) or organic products (e.g. as carbon bonded sulfur). Lower concentrations of HA in solution reacted more effectively towards sulfide (25 ppm C: moles S/moles C = 0.024; 75 ppm C: moles S/moles C = 0.015). The main reaction product was S^0 (making up about 40~50 %), important intermediate was $S_2O_3^{2-}$ (about 13~32 % reaction for 48 hours). Total recovery in the inorganic fraction accounted to 60~78%, while a gap remained in the budget of about 22~40% of sulfur that had presumably added to the HA as organic sulfur. Thus, in all non-reduced HA treatments, 10-30 μmol/L sulfide added to the HA as organic sulfur (22~40%), and X-ray absorption spectroscopy data supported organic sulfur to be approximate zerovalent sulfur. E-transfer capacities of non-reduced HA towards sulfide based on formation of organic sulfur was therefore about 0.8~1.24 μeq/mg C. The amount of electrons transferred to reduced HA was comparable to the difference of e-transferred to oxidized HA minus e-transferred to HA pre-reduced with H_2/Pd.

In conclusion, the results showed that HA chemically reoxidized sulfide under anoxic condition at significant rates, and formed reduced organic sulfur compounds that provided a sink for sulfur and reduces the amount to be recycled.

Uranium reduction on magnetite: An electrochemistry approach

KE YUAN*, RODNEY C. EWING[A] AND UDO BECKER

Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI 48109, USA (*correspondence: keyuan@umich.edu)

Electrochemical methods provide a unique approach that allows one to measure or control the redox environments close to the surface of semiconducting minerals. Cyclic voltammetry and potential step voltammetry have been applied in order to investigate the redox reactions of aqueous uranyl on the electrodes made of bulk and nano-powder of crystalline magnetite. *In-situ* Atomic Force Microscopy and Raman spectroscopy were used to probe the surface morphology and phase change as a function of the redox potential.

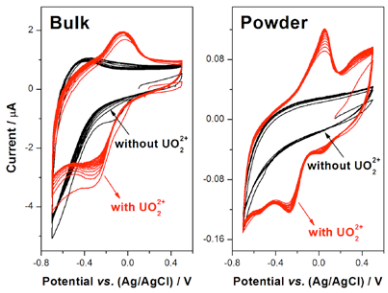

Figure1: Cylcic voltammetry of the bulk and the powder magnetite electrode in solution with and without uranyl and the AFM height image of the bulk electrode surface after the reaction (220×220nm).

Two sets of redox peaks were found on the cyclic voltammogram of magnetite nano-powder in blank solution, showing its high reactivity, but none was detected on the bulk crystalline electrode. The one-electron reduction from U^{6+} to U^{5+} was verified by fitting the potential step voltammetry of the crystalline electrode. The U^{6+} to U^{5+} reduction peak was evident at a more negative potential (-0.33 V *vs*. Ag/AgCl) on the cyclic voltammetry of the bulk electrode as compared with that of powder electrode (-0.27 V *vs*. Ag/AgCl). This reflects the slower kinetics of the electron transfer on the bulk magnetite surface. After immersion in a uranyl sulfate solution, the surface roughness of the magnetite increased as the redox potential decreased from -0.22V to -0.30V within one hour. Island-like features of about 20 nm height were found on the magnetite surface, which could be iron hydroxides resulting from the oxidation of magnetite.

Petrogenesis of the Syenite Granites in Kuluketage Block: Constraints from Petro-Geochemistry,Zircon U-Pb Dating and Hf Isotope

Q. YUAN, X.B. LÜ*, X.F. CAO, X.D. WANG AND E.L YANG

Faculty of Earth Resources, China University of Geosciences, Wuhan 430074 ,China
(*correspondence: lvxb_01@163.com)

Kuluketage block is the best area for Precambrian geology in Xinjiang, NW China. In this paper, we studied the petrology, geochemistry, zircon LA-ICPMS U-Pb chronology and zircon Hf isotope research of Daxigou syenite granite(DSG) which is located in Kuluketage. Zircons from the intrusions display oscillatory zoning and high Th/U ratios (0.16-2.11), implying their magmatic origin. Zircon U-Pb dating results of DSG indicate that they formed in Paleoproterozoic with the weighted 207Pb/206Pb average age of 1767±46Ma,which is coincidentally identical with its associated diorite age within the error range. Studies of petrogeochemistry suggest that DSG belong to medium-sodium and rich-potassium peraluminous calc-alkaline type, rich in Pb, La, Th and LILE, significant poor in HFSE(Gd, Nd, Ta). The chondrite-normalised REE pattern is slightly to the right form. The average ∑ REE is 56.57×10-6; HREE show moderate fractionation (LREE/HREE averaged 10.28, (La/Yb)N average of 13.04) N; average (La/Sm) N of syenite is 4.96, average (Gd/Yb) N is 1.67 and the δEu, δCe are not obvious. Their initial Hf isotope ratios and Hf two-stage model ages range from-7.74 to -4.02 and 2.74Ga to 2.67Ga, respectively. Taken together, it is suggested that DSG is the typical S-type granite and its primary magma could be mainly derived from partial melting of the Neoarchean crust and mainly formed in the syn-collision arc environment, which recoded the tectonic-magma activities response of Tarim refers to the amalgamation of the supercontinent Columbia.

Copper-mediated oxidation of hydroquinone under conditions typical of natural saline waters

XIU YUAN[1], A. NINH PHAM[2], CHRISTOPHER J. MILLER[3] AND T. DAVID WAITE [4]

School of Civil and Environmental Engineering, the University of New South Wales, Sydney, NSW 2052, Australia
[1] (xiu.yuan@unsw.edu.au,) presenting author;
[2]((anninh.pham@unsw.edu.au;) [3] (c.miller@unsw.edu.au;)
[4]((d.waite@unsw.edu.au.)

Copper (Cu) is an essential transition metal that is involved in a variety of photoreactions and physiological processes. The redox chemistry between cuprous copper (Cu(I)) and cupric copper (Cu(II)) in the upper water column plays a significant role in its speciation, transport and bioavailability [1]. As electron transfer mediators, quinone moieties in natural organic matter (NOM) play important roles in essential biogeochemical processes [2-3]. In this study, detailed kinetic model has been developed to describe the oxidation of 1,4-hydroquinone (H_2Q) by Cu(II) in the presence O_2 in 0.7 M NaCl solution at pH range 6.5 – 8.0. Cu(II) catalyzed the overall oxidation of H_2Q in a strongly pH dependent manner with concomitant formation of benzoquinone and H_2O_2.

The kinetic model indicated the mono-anion HQ^- is the active species to reduce Cu(II) with an intrinsic rate constant of 5.0×10^7 $M^{-1}{\cdot}s^{-1}$. While the semiquinone radical ($SQ^{\bullet-}$) generated from one-electron oxidation of hydroquinone or one-electron reduction of benzoquinone acts as a chain propagating species, the presence of O_2 in the system is also essential in terms of supplying Cu(II) by continuously oxidizing Cu(I) and rapidly removing $SQ^{\bullet-}$ to generate $O_2^{\bullet-}$. The development of the kinetic model should assist in understanding and predicting the factors controlling copper transformation, speciation, bioavailability and toxicity in aquatic systems.

The genesis of Jadeitite: A viewpoint from Zirconology

T.F. YUI[1]*

[1]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan (*correspondence: tfyui@earth.sinica.edu.tw)

Jadeitite is a rare rock type formed in subduction zones. Its genesis has attracted much attention recently. Two formation mechanisms have been proposed: the whole-sale metasomatic replacement and the vein precipitation. These two mechanisms would imply different chemical cycling paths for elements such as Al, Na, Zr and Hf, in subduction zones as a result of different physical-chemical conditions. Correct deciphering of jadeitite genesis around the world could therefore provide important information on subduction environment/processes. Recent advance on in situ micro-analysis of zircons provide a unique opportunity to tackle this issue.

Zircon as an accessory mineral in jadeitite would be either inherited from igneous protolith or recrystallized/newly-formed through metasomatic processes. Theoretically, jadeitite fromed from whole-sale metasomatic replacement would contain both types of zircon, while jadeitite fromed through vein precipitation may only have metasomatic zircon. Mineral inclusions, trace-element and isotopic compositions, as well as textures of zircon have been employed as criteria to distinguish magmatic from metasomatic zircons in recent studies on jadeitite. Unfortunately, with more case studies, it turns out that none of the criteria mentioned above is conclusive. For example, mineral inclusions of metasomatic origin may actually be pseudo-inclusions in inherited, but not metasomatic, zircons. The resetting rate of trace element compositions and U-Pb isotope system of zircon, as well as zircon texture changes, may not take place “in phase” during zircon recrystallization in association with jadeitite formation. Even with “apparent” metasomatic textures, zircons may not necessarily display metasomatic chemistries or yield metasomatic ages. Only through careful and detailed examination of integrated data can the correct interpretation on the origin of zircons, and hence the genesis of jadeitite, be retrieved. A thorough review shows that most jadeitites that have been studied recently would have formed through whole-sale metasomatic replacement processes. Jadeitite formed through vein precipitation process can only be convincingly identified from north of the Motagua fault, Guatemala.

Inverse Modeling of Asian Dust Emission with MODIS AOT and the SPRINTARS Adjoint Model

KEIYA YUMIMOTO[1,*] AND TOSHIHIKO TAKEMURA[2]

[1] Meteorological Research Institute, Japan Meteorological Agency, Nagamine 1-1, Tukuba-city, 305-0052, Ibaraki, Japan (*Correspondence; yumimoto@mri-jma.go.jp*)

[2] Research Institute for Applied Mechanism, Kyushu University, Kasuga Park 6-1, Kasuga, 816-8580, Fukuoka, Japan (*toshi@riam.kyushu-u.ac.jp*)

In this study, we performed inverse modeling of Asian dust using MODIS coarse-mode aerosol optical thickness (AOT) and the adjoint of global aerosol climate model [1] for four years (2005–2008). Gridded (T42 horizontal resolution; approximately 2.8° × 2.8°) and daily dust emissions in Asian dust sources were optimized. The adjoint inverse modeling generally increased dust emissions from the Gobi desert, and emphasized the daily and inter-annual variations of dust emission amount, comparing with a priori emission (Figure 1). For a sever dust storm in late March 2007, the peak of dust emission was shifted by one day earlier by the inverse modeling. The inversion results were widely validated independent observations (e.g. lidar observation network).

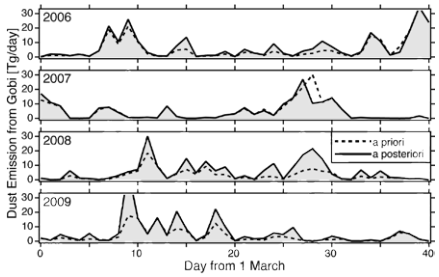

Figure 1. Time series of dust emission in the Gobi desert. Solid and broken lines represent a priori and a posteriori emissions, respectively.

Direct Aerosol Radiative Forcing (DARF) for dust aerosol was estimated with a posteriori dust emissions. The increase of dust emissions leaded increases of longwave DARF at both the top of atmophere and surface. A posteriori DARF exhibits the different trend and the larger inter annual variations than a priori one.

Geodynamics of the layered mafic – ultramafic intrusions in the East Sayan (Russia)

A. N. YURICHEV* AND A. I. CHERNISHOV

Tomsk State University, Tomsk, Russia
(*juratur@sibmail.com)

Within the Central Asian folded belt, the most of the layered low-titaniferous and high-aluminous peridotite-troctolite-gabbro massifs are comparable with the products of Early Paleozoic island arc magmatism by the time of their formation [1]. In addition, their spatial relation to axial parts of island-arc systems is being discussed. One of the representatives of this formational type is the Talazhin mafic-ultramafic intrusive massif in the northwestern part of the Eastern Sayan studied by us. It is composed of troctolites, which dominate over plagiodunites, as well as lenses anorthosite, and gabbro with high anortite ratio (An_{75-99}). The relatively high Fe content in olivine (Fa_{20}) and similarity in behavior of trace elements to island-arc high-aluminous basalts indicates that the massif rocks are comagmatic with IAB-type volcanites. Mineralogical characteristics of gabbro of the Talazhin massif are similar to the allivalite and eucrite xenoliths in modern island-arc volcanites. The geochemical features of the massif rocks indicate that their generating is a result of crystallization differentiation of high-aluminous olivine-bearing basalt magma. The rocks are characterized by high magnesium at low concentrations of HFSE (Ti, Zr, REE), as well as enrichment in LREE, and the positive Eu-anomaly. Sharp minimums for Ta and Nb, and maximums for Ba and Sr can be seen in the spider diagrams. It is suggested that the formation of the Talazhin massif occurred as a result of magma forming in the suprasubduction setting.

This study was funded by the Russian Ministry of Education and Science (projects 14.B37.21.0686, 14.B37.21.1257).

Ordering of isotope composition for H, N and O between planets

H. YURIMOTO[1]*

[1]Hokkaido University, Sapporo 060-0810, Japan
(*correspondence: yuri@ep.sci.hokudai.ac.jp)

Hydrogen, Nitrogen and Oxygen are among the most abundant elements of the universe. Isotopic compositions of these elements between molecules are highly variable in molecular clouds. Due to highly volatile nature of these elements, the chemical forms are easily changed between vapor and solid (ice) by environmental temperature and pressure. Thus, the standard planetary formation model of the solar system suggests that inner planets deplete these elements, but outer planets enrich as major elements. Isotopic compositions for planets of these three elements should be determined spontaneously according to the standard planetary formation processes. Therefore, the isotopic variation between planets would be an important key to clarify how to form planets in the solar system. In this report, we propose new systematic approach to infer isotopic compositions for H, N and O of outer planets.

We have proposed a model for oxygen isotopic evolution in proto-planetary disk [1], and infered O isotopic compositions of outer planets [2]. The augmented model based on [2] in this study assumes the initial condition of isotopic compositions of molecules observed in molecular clouds and in chondrites, and includes two key points, i.e., 1) temporal preservation of chemical species fractionated in mass and 2) astronomical space separation by dynamic coupling/decoupling due to the chemical form changes for H, N and O in the disk.

The model infer systematic increase of heavier isotope components of H, N and O for outer planets towards increasing redial distance from the sun, whereas relatively uniform isotopic composition for inner planets. Infered H isotope variations between outer planets are quantitatively consistent with observation data by planet explorations [e.g. 3]. We infer enrichments of ^{15}N in the order of Jupiter, Saturn, and Uranus/Neptune. The $^{15}N/^{14}N$ ratio of Uranus/Neptune would be larger than the Earth's value. Oxygen isotope systematics between outer planets would be mass independent and ^{16}O component would be depleted in the order from Jupiter towords Neptune. The isotopic compositions of inner planets suggest significant accretions of ices from outer solar system during planetary growth and as late veneer.

Causes of Late Pleistocene Lake Victoria water level change, derived from clumped isotopes in land snails and fresh water mollusks

SHIKMA ZAARUR[1]*, HAGIT PAFFEK[1] CHRISTIAN TRYON[2], DANIEL PEPPE[3] AND J. TYLER FAITH[4]

[1]Yale University, Geology and Geophysics , New Haven, CT, USA (shikma.zaarur@yale.edu)
[2]New York University, Anthropology, New York, NY, USA
[3]Baylor University, Geology, Waco, TX, USA
[4]Univ. of Queensland, School of Social Science, Australia

Carbonate clumped isotopes thermometry is based on the dependence of 13C-18O bond abundance (D47) on carbonate formation temperature. Most marine and fresh water biogenic carbonates agree with the D47-T calibration. The clumped isotope thermometry is particularly useful in terrestrial environments where the interpretation of carbonate d18O is limited by difficulty in estimating paleo-water composition.

Clumped isotopes - derived temperatures of land snails are generally higher than the ambient environmental temperatures, but show no evidence for disequilibrium. We attribute these higher body temperatures to eco-physiological snail adaptations. Combined with shell $\delta^{18}O$, we use these temperatures to calculate snail body water composition, that serves as a paleo-hydrological indicator.

We combine Δ_{47} and $\delta^{18}O$ in modern and fossil fresh water mollusks and land snails from Rusinga and Mfangano Islands in Lake Victoria to examine lake paleo-hydrology, testing hypotheses about the mechanism of a significant rise in lake level in Lake Victoria ~35-40 ka BP.

Outcrops of paleo-beach deposits ~18 m above the modern day lake levels indicate high water stands at ~35-40 ka BP. Such increase in lake level could be driven by local mean annual precipitation that is significantly greater than modern. However, this is inconsistent with regional climate reconstructions, suggesting that either lake level was controlled by non-climatic factors, or that local climate in the Lake Victoria basin was different than regional patterns of climate across eastern Africa. We analyze modern and fossil shells from this 18 m beach outcrop on Mfangano Island to compare with modern lake water $\delta^{18}O$ values and to calculate paleo-water compositions. We combine these results with calculated land snail body water $\delta^{18}O$ from Rusinga and Mfangano Islands, to study hydrological changes of Lake Victoria and to evaluate the relative importance of climate change and tectonics as mechanisms for the Late Pleistocene expansion of Lake Victoria.

A cold slab-mantle interface: Constraints from exceptionally well preserved lawsonite eclogites

THOMAS ZACK[1]

[1]Department of Earth Sciences, University of Gothenburg, Sweden, (zack@gvc.gu.se)

The area around Halilbagı in the Tavşanlı Zone, Turkey exhibits the largest known continuous unit (>5 km^2) at which lawsonite eclogite facies conditions (circa 460- 520°C and 2.2- 2.4 GPa, [1,2]) were attained and peak metamorphic assemblages preserved. Within this area, a wide range of rock types can be found, of which metamafic (lws-gla-omp-grt bearing), Mn-rich metachert (piedmontite-phe-qtz bearing), marble (with aragonite pseudomorphs) and serpentinites (with antigorite) are of particular relevance. Critical is the recent finding of rare lws-epi-chl assemblages at the direct contact between serpentinite lenses and metamafic rocks, interpreted as metasomatic blackwalls formed close to peak metamorphic conditions. This argues for an intimate mixing of mantle-derived and crust-derived components at great depths (in contrast to incorporation of nearby low pressure serpentinites during exhumation).

The exceptional preservation of those mineral assemblages (especially with lawsonite) has been a matter of discussion. Cetinkaplan et al (2008) [1] calls for cooling through continued underplating of crustal material during exhumation. The discovery of a second generation of lawsonite and glaucophane in a chlorite matrix that replaces garnet supports that model, as it confirms the assumption that on the cooling path at temperature below 400°C, lawsonite was still stable. I would like to add that the underplating of very H_2O-poor lithologies (especially cherty limestone of the Afyon Zone) [3] helped to minimize the availability of retrogressing fluids.

These findings imply that the formation of lawsonite eclogite is not only possible in the interior of a downgoing slab, but also in direct contact to the overlying mantle wedge. Therefore it can be concluded that rather low temperatures (460-520°C) are achieved at a depth of ca 70 km at the slab-mantle boundary, and this at moderate to low convergence rates (ca 2 cm/a) after less than 20 Ma of convergence [4]. This places tight constraints on any thermal model of subduction zones, ruling out several recent models predicting much higher slab-mantle temperatures at such depths.

Atmospheric trace gases and isotopologues using mid-IR laser direct absorption spectroscopy

MARK ZAHNISER, BARRY MCMANUS, DAVID NELSON, JOANNE SHORER, SCOTT HERNDON, JOSEPH ROSCIOLI, TARA YACOVITCH J AND CODY FLOERCHINGER

Aerodyne Research, Inc., Billerica, Massachusetts, USA

Recent advances in mid-infrared laser technology have greatly facilitated field measurements of atmospheric trace gases to identify and quantify their sources and sinks. Newly available non-cryogenic mid-infrared lasers and detectors, long path length, small volume sampling cells, and advances in direct absorption techniques with have led to smaller, lighter, and more robust instrumentation for measurements from mobile and aircraft platforms, field sites at remote locations, and laboratories for clumped isotopologues. The reliability and reproducibility of the mid-infrared lasers has led to long term monitoring and turn-key operation. Trace gas detection in ambient air at the low part-per-trillion levels are now feasible. Fractional precisions of less than 1 part in 10,000 allow for isotopologue ratio measurements of carbon dioxide, methane, and nitrous oxide at atmospheric mixing ratio levels. Applications to measurements of greenhouse gas emissions of methane and nitrous oxide, high precision measurements of carbonyl sulphide (OCS), measurements of ethane (C_2H_6) to determine sources of methane, and isotopologue measurements of CO_2, CH_4, N_2O and H_2O, will be presented.

Impacts and LIPs: $^{187}Os/^{188}Os$ signatures across the K-Pg boundary

JESSICA ZAISS[1], GREG RAVIZZA*[1] AND BIGER SCHMITZ[2]

[1]Geology & Geophysics, SOEST, University of Hawaii, Manoa, Honolulu HI 96822 USA. (zaiss@hawaii.edu), c(orrespondance: ravizza@hawaii.edu)

[2]Dept. Geology, Lund University, Solvegatan 12 SE-22362, Lund, Sweeden. (Birger.Schmitz@geology.lu.se)

Both impacts and large igneous provinces (LIPs) can introduce unradiogneic Os into the global ocean producing excursions to lower $^{187}Os/^{188}Os$ in pelagic sediments. The $^{187}Os/^{188}Os$ excursion caused by the late Eocene Popigai impact is consistent with abrupt addition of soluble meteoritic Os to the ocean [1]. In contrast, previously reported $^{187}Os/^{188}Os$ excursions related to LIPs show greater variability and longer duration than the Popigai Os excursion. It is well established that the Chicxulub impact event is coincident with the K-Pg mass extinction and that eruption of the Deccan Traps began before, and continued after, the extinction event. Comparison of the Popigai excursion to the Cretaceous-Paleogene (K-Pg) boundary $^{187}Os/^{188}Os$ record provides a means of assessing whether or not eruption of the Deccan liberated significant amounts of mantle-derived Os to the ocean-atmosphere system coincident with the K-Pg mass extinction. In the Equatorial Pacific, South Atlantic and Atlantic-sector of the Southern Ocean the recovery of the marine $^{187}Os/^{188}Os$ record to higher pre-extinction levels [2] closely resembles the shape and duration of the Os recovery from the Popigai impact event. This similarity does not support claims [3] that the main phase of the Deccan volcanism is closely linked to the K-Pg mass extinction. However, an Indian Ocean site (ODP 738C) on the Keguelen Plateau displays $^{187}Os/^{188}Os$ ratios consistantly below those from other ocean basins during the Paleogene. In close proximity to the K-Pg boundary in ODP 738C, the Os-Ir-$^{187}Os/^{188}Os$ siganture is unequivoally meteoritic. Upsection, low $^{187}Os/^{188}Os$ ratios as far as 4.5m above the boundary (≈ 1.2 M.Y.) are unlikely to be related to the Chicxulub impact event. These low $^{187}Os/^{188}Os$ ratios in the Indian Ocean may be fingerprint of Paleogene LIP activity associated with either the Deccan or Kerguelen, but other interpretations are possible. The marine $^{187}Os/^{188}Os$ record allows large impact events to be differentiated from the emplacement of LIPs, and may preserve regional gradients in seawater $^{187}Os/^{188}Os$ controlled by the proximity to active volcanism.

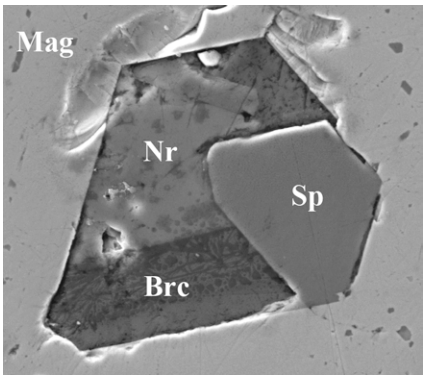
Magnetite-hosted melt inclusions from phoscorites and carbonatites (Kovdor, Kola): A hydrous analog of Oldoinyo Lengai natrocarbonatites?

A.N. ZAITSEV[1,2]*AND V.S. KAMENETSKY[3]

[1]St. Petersburg State University, St. Petersburg 199034, Russia (*correspondence: burbankite@gmail.com)
[2]Natural History Museum, London SW7 5BD, UK
[3]University of Tasmania, Hobart, Tasmania 7001, Australia

Kovdor is a well-studied Devonian complex from the Kola peninsula, Russia consisting of various ultrabasic and alkaline rocks, phoscorites and carbonatites [1]. Silicate minerals composing these diverse rocks often contain primary melt inclusions, particularly in carbonatites,with Na–K–Ca and Na–Mg carbonates as common daughter minerals [2]. Magnetite is a major to minor mineral in Kovdor rocks and SEM study of a mineral from the early-formed calcite-rich phoscorite and calcite carbonatite revealed presences of abundant negative-shaped polymineralic crystallized melt inclusions. SEM/ED analyses and Raman spectroscopy indicate occurrence of various minerals within inclusion including (1) oxides – spinel, baddeleyite, pyrochlore, (2) hydroxides – brucite, (3) silicates – phlogopite, (4) carbonates – nyerereite, eitelite, bradleyite, tychite, calcite, dolomite, (6) phosphates – apatite, (7) halogens – sylvite, and a number of unindentified mineral phases. Coexistance of brucite and unaltered nyerereite in crystallised melt inclusions (Fig.) indicate existance of hydrous and alkali-rich carbonate (±phosphate, sulphate) melt from which Kovdor phoscorites and carbonatites were crystallised.



Spinel (Sp), brucite(Brc), nyerereite (Nr) in magnetite (Mag).

The effect of silicate melt composition on the volatile/melt partitioning of oxidized sulfur

ZOLTAN ZAJACZ[1]

[1]Inst. of Geochemistry & Petrology, ETH Zürich, Switzerland (correspondence: zoltan.zajacz@erdw.ethz.ch)

Sulfur is the third most abundant volatile element in magmas and it impacts society via volcanic degassing and by its essential role in the formation of magmatic-hydrothermal ore deposits. Therefore, it is necessary to understand the partitioning of S between silicate melts and exsolving volatile phases. The construction of a thermodynamic model that predicts the volatile/melt partition coefficients of S ($D_S^{volatile/melt}$) requires the understanding of the dissolution mechanism of S in silicate melts.

I conducted experiments at P=500 MPa and T=1240 °C in a piston cylinder apparatus to assess the effect of melt composition on $D_S^{melt/volatile}$, which was used as a measure of the silicate melt's affinity to dissolve oxidized sulfur species. Iron-free, three- and four-component silicate melts were equilibrated with H_2O-S volatiles with $X_S \leq 0.02$ at an fO_2 imposed by the Re-ReO_2 buffer. At these conditions, SO_2 is predicted to be the dominant sulfur species in the volatile phase and S^{6+} is the dominant oxidation state of S in the silicate melt. The values of $D_S^{melt/volatile}$ were calculated by mass balance. The results show that $D_S^{melt/volatile}$ increases exponentially with the degree of depolymerization of the silicate melt structure expressed with the parameter NBO/T=[Na+K+2(Ca+Mg)-Al]/(Si+Al). At a constant NBO/T of 0.4, $D_S^{melt/volatile}$ in equilibrium with sodium-aluminosilicate (NAS) melts is more than an order of magnitude higher than in equilibrium with calcium-aluminosilicate (CAS) melts, and more than two orders of magnitude higher than in equilibrium with magnesium-aluminosilicate (MAS) melts. The variation of $D_S^{melt/volatile}$ in equilibrium with various CNAS and MNAS melts indicates that alkalis are only availabe for sulfate complexation when they are present in excess compared to the required amount to charge balance for the Si^{4+} to Al^{3+} substitution in the melt structure. Calcium has moderate, Mg has very minor affinity to replace alkali elements in this charge balancing role.

At subvolcanic depth, decompression induced degassing of S is more efficient at reducing than at oxidizing conditions, in particular from mafic and peralkaline felsic melts. Effective transfer of S to the ore-forming environment from such magmas requires relatively low fO_2 or advanced degree of crystallization.

Controls on the composition of magmatic volatiles in the crust: Implications for ore genesis and volcanic degassing

ZOLTAN ZAJACZ[1], PHILIP CANDELA[2], PHILIP PICCOLI[2] AND CARMEN SANCHEZ-VALLE[1]

[1] IGP, ETH Zürich, Switzerland (correspondence: zoltan.zajacz@erdw.ethz.ch)
[2] LMDR, University of Maryland, College Park, USA

Volatile elements dissolved in silicate melts not only serve as the driving force for explosive volcanic acitivity, but also facilitate the formation of magmatic-hydrothermal ore deposits and have a significant impact on the Earth's atmosphere and climate. Though water and CO_2 are the most abundant volatile components in most magmatic systems, the effect of sulfur and halogens on atmospheric chemistry and ore-forming systems is more pronounced.

We will discuss the most important parameters controlling the composition of exsolving magmatic volatiles in the middle to upper crust including numerous new experimental data on the effect of melt composition and P-T on the parition coefficients of S, Cl and some economically important metals such as Au, Cu and Mo.

Experimental data suggests that sulfur is the most easily degassed volatile element after carbon, in particular at relatively low fO_2 (<Ni-NiO) where FeS and H_2S are the dominant sulfur species in the silicate melt and the volatile phase, respectively. Similarly to CO_2, a large fraction of reduced S may be lost from the magma during moderate degree open system degassing induced by decompression. On the other hand, at subvolcanic depth, effective degassing of oxidized sulfur, and in particular Cl will require significant amount of crystallization. Crystallization will promote the transfer of these elements to the volatile phase by decreasing the melt volume, and increasing the volatile/melt partition coefficients by increasing the degree of melt polymerization. The maximum amount of S in the volatile phase is limited to a few mol% by the saturation of sulfide and/or sulfate minerals at P-T-fO_2 conditions typical of subvolcanic reservoirs in arc settings.

Considering metallic elements, Au can be effectively degassed by H_2S-bearing volatiles even from mafic magmas in the early stages of evolution. However, the extraction of Cu will become efficient only from felsic melts exsolving Cl-rich volatiles. The relative timing of saturation in sulfide and volatile phases may have a significant impact on metal extraction efficiencies if the sulfides are fractionated by entrapment in rock forming minerals or gravitational settling.

Biogeochemical poly-barrier qualities in plants

L.V. ZAKHARIKHINA AND YU. S. LITVINENKO

EcoGeoLit Ltd., Moscow, Russia (ecogeolit@mail.ru)

In terms of the ability to accumulate chemical elements in relation to their concentration in the soils, two types of plant species are distinguished, barrier and barrier-free ones.

Our studies of moss and pine purple grass (Calamagrostis langsdorffii) show a more complicated correlation of the amounts of elements in the "soil-plant" system. Often the plants show biogeochemical poly-barrier qualities: as the concentration of the element in the soil increases, the barrier mechanism is repeatedly turned on and off.

The graph below shows the poly-barrier display in mosses with respect to Ni, the x axis being the logarithms of the average values for the selected content intervals for the element in soil (lnCs), the y axis being logarithms of average Ni content in mosses (lnCv), growing on these soils (fig. 1).

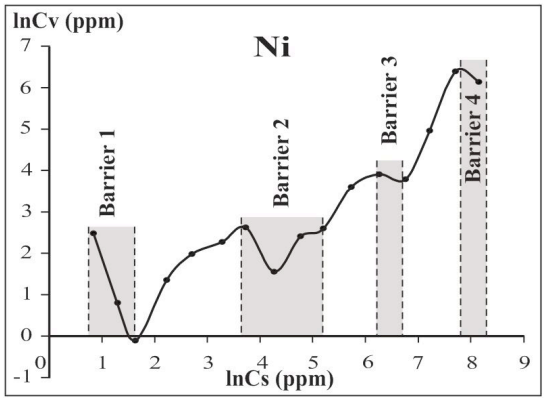

Figure 1: poly-barrier qualities of moss with respect to biological accumulation of Ni.

During the biogeochemical monitoring it is necessary to take into consideration that the cessation of the growth and the decline in the elements in plants are not always connected with the environmental conditions' improvement on the territory. It might as well be conditioned by activation of intermediate biogeochemical barrier. On the other hand, a sharp increase in contents of elements in the vegetation does not definitely mean the deteriorating environmental conditions, it can possibly be the consequence of the barrier being "broken". It is necessary to perform a full ecological-geochemical monitoring of the soils and vegetation to determine biogeochemical poly-barrier qualities in plants.

Heavy metals mobility: Surface water processes (The Copperbelt Case Study)

K. ŽALUDKOVÁ[1] AND J. ZEMAN[2]

[1]Department of Geological Sciences, Masaryk Univ., Brno 611 37, Czech Rep. (voda.dobra@centrum.cz)
[2]Department of Geological Sciences, Masaryk Univ., Brno 611 37, Czech Rep. (jzeman@sci.muni.cz)

Exemplary well monitored mining areas such as the Copperbelt in Zambia with contaminated reservoirs may provide a better insight into the heavy metals mobility as well as defining principles of the system stability by precipitation or sorption onto either sedimentary clay or organic content at the river bottom sediments.

Processes and heavy metals mobility were evaluated using Surfer® Mapping System Ver. 8.00 and Geochemist´s Workbench® ver. 8.0.11 and 9.0.7 modelling on data acquired in the years 2004 – 2008 during a case study of the semiarid central African Copperbelt in surface waters in the Kafue river and its tributaries, and adjacent soils. Results indicate fluxes and main processes relations affecting the elements mobility.

Mostly all the contamination in tributaries does not exceed limits entering the Kafue river. Important role is attributed to the leaching process, dilution and decomplexation.

The main contaminants Cu and Co mined as a source sulphidic ore are processed in smelters using liming. Fine-grained fraction is washed from the mine waste deposits during rainy seasons and therfore contaminates surface water.

The 4-year monitoring reflected a time evolution and seasonal changes in system parameters. Mostly neutral and slightly alkaline pH decreased down to 2, accompained by high EC in the vicinity of processing plants and causing metals mobilisation from the bottom sediments.

Griffin and Shimp [1] found the relative mobility of nine metals through montmorillonite and kaolinite: $Cr^{VI} > Se > As^{III} > As^{V} > Cd > Zn > Pb > Cu > Cr^{III}$. However, the data from the Copperbelt assume the mobility observed in the real environment: $Co = Mn^{+II} > Zn > Cu = Mo > Ni > Pb > Zn > Hg$ considering local redox conditions, sediments and subsoil.

Modelling showed the Co concentration was determined by decomplexation of $HCoO_2^-$ and by dissolution of secondary cobalt oxide Co_3O_4 in case of higher Co concentrations. Cu also showed boundary conditions between dissolved $CuOH^+$ Cu^{2+} and precipitates.

[1] Griffin & Shimp (1978) Attenuation of pollutants in municipal landfill leachate by clay minerals. EPA-600/2-78-157, pp. 128 - 135.

Hydrogeochemistry Technogenesis Zone Gold Deposits Baley Ore Field (Eastern Transbaikalia, Russia)

L.V. ZAMANA

INREC of SB RAS, Chita, Russian Federation, 672014 (correspondence: l.v.zamana@mail.ru)

Baley ore field in the middle of the last century was one of the main centers of gold mining in the f. Soviet Union. It is presented adjacent to each other deposits – Baley (BD) and Taseevsk (TD), which were developed respectively in the 1929-1983 and 1948-1995 years. During the period of operation produced more than 450 tons of Au reserves of it in both fields have not been developed.

The ore field is confined to the Mesozoic graben depression, made mainly of sandstones and conglomerates (J_3-K_1). Gold-bearing quartz veins of the BD are located in granodiorite stockwork forming a ledge of the foundation. The total content of sulfides (pyrite, arsenopyrite, chalcopyrite, and others) in the ores is 0.5-5%, and 20% of carbonates and sheet silicates and up to 20%. TD ore in the form of quartz veins and vein mineralization occur in sandstones and contain sulfides and veined minerals in about the same amount [1]. The enclosing sandstones are pyritized.

Different levels of sulfides in the host rocks resulted in the formation of two types of geothecnogenic hydrogeochemical systems with contrasting physical and chemical parameters. In mining objects TD (quarry, waste dumps, tailings) of sulfate acid water with pH less than 3-4 (at least 2.69) and high concentrations of Al, heavy metals, F, Ca, Mg. Identified concentrations reached (mg/l): SO_4^{2-} - 4900, Al - 150.8, Mg - 724.6, Fe - 774.1, Mn - 88.1, Cu - 3.18, Zn - 6.31, Pb - 1.94, Ni - 3.44, Co - 1.08, Cd - 1.1, F - 11.9, As - 1.3. The isotopic composition of sulfate sulfur is ligther than starting sulfides ($\delta^{34}S_{CDT}$ –1.7…–6.5 and –1.18…+1.10‰ respectively), which indicates the involvement of bacterial processes in the oxidation of sulfides and thus enrich acidic waters metals. Water quarry BD is alkaline (pH to 8.40), with relatively low concentrations of ore and petrogenic elements. According to thermodynamic calculations, metals are mainly in ionic form, fluorine, as in the acidic waters of tungsten deposits [2], in the form of complexes with Al. Equilibrium minerals are calculated (quartz, celestine, gypsum, fluoride and etc.).

This work was supported by the RFBR (11-05-98043).

Constraining current oceanic nitrous oxide (N_2O) Emissions and reducing uncertainty for future emissions

L.M. ZAMORA[1]*, A. KOCK[1], A. OSCHLIES[1] AND H.W. BANGE[1]

[1]GEOMAR Helmholtz Centre for Ocean Research Kiel, 24105 Kiel, Germany (*correspondence: lzamora@geomar.de)

N_2O is the third most important greenhouse gas, and the 2007 IPCC estimated that oceans provide 10-30% of annual N_2O flux to the atmosphere [1]. The large range in previously estimated oceanic emissions is primarily due to uncertainties in parametrizing microbial N_2O production and consumption within the ocean and to spottiness of data coverage. Here we better constrain ocean N_2O fluxes to the atmosphere by using a complementary dual data-based and modeling approach. First, we estimate current day emissions from the new MEMENTO database, in which gaps in ocean N_2O data coverage have been improved from previous studies [2]. We find oceanic emissions at ~8.6 Tg N_2O yr^{-1}, which falls into the higher end of the 2007 IPCC estimate of 2.8-9.1 Tg N_2O yr^{-1} emitted from the ocean [1]. Our estimate falls on the high-end of previous estimates primarily due to better data coverage in oceanic N_2O emission hotspots.

The new atmospheric N_2O fluxes from the MEMENTO database gives us valuable insight into the importance of oceanic N_2O emissions. However, improved estimates of the fluxes alone will not allow predictive capacity for future marine N_2O emissions. Therefore, we use the improved present-day emissions estimate calculated here to constrain N_2O parameterizations for a marine biogeochemical model. The marine biogeochemical model incorporates the ranges of literature uncertainties in N_2O biological production and consumption and provides the associated N_2O emissions. Given the known range in current-day fluxes, we are now able to better constrain some of the uncertainties in biogeochemical model parameterizations, thereby enabling a better predictive capacity for future N_2O emissions from the oceans.

Tephrostratigraphy and tephrochronology of the Last 130 Ka in the Mediterranean Basin for synchronizing past climatic events

G. ZANCHETTA[1]

[1]Dipartimento di Scienze della Terra, University of Pisa, Via S.Maria 53, 56126, Pisa, Italy (*correspondance: zanchetta@dst.unipi.it)

With the explosion of palaeoclimatic and palaeoenvironmental research following the concerns related to global warming, few volcanologists could have imagined their role to have changed so dramatically from their traditional focus. In the last two decades, this sector of the scientific community was compelled to move towards a tighter link with Quaternarists, geomorphologists, archaeologists, palaeoceanographers and more in general palaeoclimatologists. Tephrostratigraphy and the identification of tephra layers in different archives will become a mandatory request of many projects for synchronizing archives and improving chronological control of palaeoclimatological records.

The Mediterranean basin is probably one of the most significant areas globally where tephrostratigraphy can reveal its full potential and benefit different disciplines, due to the very large number of explosive volcanoes with very distinctive geochemistries. However, for the correct identification and separation of the different tephra events on distal archives, detailed micro-analytical work is necessary, in some cases including trace elements and observations of peculiar mineralogical associations along with stratigraphic information. Now well dated, chemically well characterized and widely dispersed tephra layers allow us to propose very detailed reconstruction of succession of climatic events for the last 130 ka.

Prominent, sub-Milankovitch climatic instability dominates the palaeoclimate record for the last glacial period, particularly in archives sourced from the North Atlantic region. A growing number of studies have suggested this climatic instability affected the Mediterranean basin. We present a continuous, highly resolved (decadal to centennial scale) isotopic record obtained from Corchia Cave. The isotope time series has been assembled by stacking four separate stalagmites records spanning the period between 140 and 90 ka. The lowest $\delta^{18}O$ values, representing the wettest and probably the warmest interval, started at 130 ka and ending abruptly at 126 ka. A long-term trend of increasing $\delta^{18}O$ values is present between ca. 126 and 114 ka, which is punctuated by century-scale abrupt events of increasing $\delta^{18}O$ and $\delta^{13}C$ values at ca. 126, 123, 121, 119, 116 and 114 ka. Some of these events appear to correlate with cooling events C25-C27 in North Atlantic. Two prominent cooling/drying events are clearly recognizable centred at ca. 109 and 104 ka (corresponding to C24 and C23 cold events in the North Atlantic), which are in excellent agreement with two dry/cold events at Monticchio pollen record in Southern Italy. The record terminated with a cold/dry phase at ca. 88 ka corresponding to C21 cooling in North Atlantic.

Magma storage and ascent conditions beneath Pico And Faial Islands (Azores Islands). A study on fluid inclusions

V. ZANON AND M.L. FREZZOTTI

Vittorio.VZ.Zanon@azores.gov.pt

In the islands of Faial and Pico (the Azores), fluid inclusions are hosted in megacrysts of olivine (Mg#80-88) and clinopyroxene (Mg#79-90) in highly porphyritic lavas and in mineral assemblages of ultramafic xenoliths. Only few inclusions are contained in olivine phenocrysts (Mg#<80) and plagioclases in poorly porphyritic lavas. Trails of late-stage inclusions are predominant over isolated early stage inclusions. The former experienced re-equilibration and consist of pure CO_2 (Tm = -56.5÷ -57.2). The latter have the same composition but may contain dypingite or Mg-calcite, which indicates that in earlier times water was present along with CO_2.

Barometric data indicate that inclusions in xenoliths re-equilibrated at 570-586 MPa (19.7-21.2 km), in poorly porphyritic lavas from fissure zones and at the central volcano of Faial, at 465-508 MPa (16.4-18.1 km), and at Pico Volcano at 342-437 MPa (12.5–16.5 km). Shallow conditions of trapping/re-equilibration were recorded at 156 MPa for the volcano of Faial (5.6 km) and at 194 MPa for the volcano of Pico (7.1 km) in phenocrysts of the mugearites. These pressures correspond to the magma ponding and to its crystallization and can be useful for tracing the progressive thickening of a dense transition zone, below the geophysical Moho. The ability to rapidly withdrawal of the stored magmas from these volcanic systems strictly depends on the different tectonic styles, acting in the transition zone. Tectonics also plays a major role in the evolution of magmas, favouring the formation of small-lived intracrustal reservoirs, not necessarily coaxial with main conduit system.

Evaluation of the pollution in the agricultural grounds irrigated by waters: Case Of The High Valley Of Oued Bounamoussa, Algerian Northeast

[1]* L. ZAOUI AND [2] M. BENSLAMA

[1] Département of Pharmacy. Faculty of medical Science. Hadj lakhder University. Batna. Algeria

[1,2] Laboratoire grounds and sustainable development, department of Biology. Faculty of Science. Badji Mokhtar University. B.P.12, Annaba, 23000 AlgeriaPhone :(213)(0)38 87 53 99(*Lilia_zaoui@yahoo.fr)

The pollution represents a severe problem for the environment because of the discharges cross-posted in rivers and ponds hillsides. Under the influence of the continuous activity of the People), the ground receives and absorbs wastes which form the pollution of subterranean waters. The region of El Tarf is extremely situated northeast Algerian.

With the aim to know the current state of the quality of waters in the region of the Algerian northeast, we led a study which concerns the quality of waters and the grounds of the agro-system of the plain of Bounamoussa situated in the wilaya of El Tarf which is an essentially rural zone where water resources are strongly requested for agricultural activities.

The evaluation of the analyses of grounds and waters in the various points of observation was the object of a treatment of data realized during a cycle allowed to notice that waters of the plain of Bounamoussa are of an even strong average salinity, generally suiting in the irrigation of the tolerant cultures in salts on well drained grounds, very sensitive to the variations of the chemical aspect connected to the irrational use of artificial fertilizers. The evolution of the salinity must be however controlled.

That is why it is imperative, in front of a susceptibility of pollution such as the agricultural irrigation of waters of the plain, to estimate the contents of these chemical elements in the ground, to appreciate really the scale of the risk as well as for knowledge the origins of the contamination of waters of the plain under the influence of the impact of waters of Oued Bounamoussa.

First-principles modeling of hydrolysis reactions for nuclear waste glass forms

P. ZAPOL[1,2]*

[1]Materials Science Division, Argonne National Laboratory, Argonne, IL 60439, USA (*correspondence zapol@anl.gov)[2]Chemical Science and Engineering Division, Argonne National Laboratory, Argonne, IL 60439, USA

First-principles informed models of dissolution behavior of glass waste forms in aqueous environments can potentially can have potentially lead to reduced uncertainties in predictions of long-term behavior. As a starting point, we have developed a model using a well characterized crystalline aluminosilicate (orthoclase) that has a known structure, but possess key characteristics of waste form glass, such as compositions with multiple cations, pH dependence and formation of secondary phases in dissolution. A Kinetic Monte Carlo study based on first-principles calculations of barriers for water reactions at neutral, protonated and deprotonated sites provided information on the overall dissolution rate and rate-limiting steps. The dissolution rate far from equilibrium is compared to experiments. We have also extended this approach to multi-component glasses, where we calculated reaction energies and barriers from first-principles. Insights into the molecular-level mechanisms of glass dissolution will be used for a coarser scale modeling. This work is aimed at better understanding of the dissolution behavior and development of predictive models for dissolution rates.

Non-Innocent role of electron-mediating ligands in reductive dissolution of hematite

PIOTR ZARZYCKI[1], DIANA TOCZYDLOWSKA[1], SHAWN CHATMAN[2] AND KEVIN ROSSO[2]

[1]Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland [2]Physical Sciences Division, Pacific Northwest National Laboratory,WA

Reductive iron (III) oxide dissolution is a primary source of soluble ferrous ions in environment [1]. It can be mediated biotically (e.g., by dissimilatory metal reducing bacteria) or abiotically (e.g., by organic reductive pollutants in anthropogenic environment) [1]. The reductive dissolution is promoted by surface protonation, adsorption of chelating electron-donating ligands (e.g., ascorbate, hydroquinone. sulfide) [2,3,4,5] and chelating electron-mediating ligands (e.g., dicarboxylic acids) [1,6]. Despite the decades of research, we still do not fully understand mechanism of iron(III) oxide reductive dissolution on a molecular level. For instance, in some cases addition of the Fe(II) ions facilitates dissolution (e.g., in the presence of oxalate, ascorbate, EDTA) [7,8], whereas in others it inhibits iron reduction (e.g., AH_2DS, microbial systems) [9-11]. The same appears to be true for surface-bound ligands, that is, some are able to promote surface dissolution by assisting Fe(II) detachment (e.g., oxalate, citrate) [9], while others block surface sites (e.g., chromate, arsenate) [1,11]. Surface protonation plays also an important, synergestic role in hematite dissolution [1].

Here we report the molecular modelling and electrochemical studies of the non-innocent role of the electron-mediating ligands bridging the surface ferric ions with the external reductants.

[3]Institute of Earth Sciences, Academia Sinica, Nankang, Taipei, Taiwan[4]Geology Department, Yangon University, Yangon, Myanmar

Rubies and sapphires attract scientific and commercial interest, e.g. the renowned Mogok, Myanmar gem field. These gemstones are corundum colored by transition elements within the alumina crystal lattice: sufficient Cr^{3+} gives red in ruby and Fe^{2+}, Fe^{3+} and Ti^{4+} ionic interactions color sapphires; a minor ion, V^{3+} introduces slate to purple colors and color change effects in some sapphires, but its role in coloring rubies remain enigmatic. Trace element and oxygen isotope values provide genetic signatures for natural corundum and assist geographic typing. Precise LA-ICP-MS analysis of ruby and sapphire from Mogok placer and *in situ* deposits reveal V can exceed 5000 ppm, giving V/Cr, V/Fe and V/Ti ratios up to 26, 78 and 97 respectively. Such values significantly exceed those elsewhere and are focused on a specific area, suggesting a geological control on V-rich ruby distribution. Our results demonstrate that detailed geochemical studies of ruby suites can reveal new gemmological, gem grading and gem exploration insights. They give V a greater role as a ruby tracer, encourage comparisons of V/Cr-variation between ruby suites and widen modelling of ruby genesis.

Parental Growth Media Of Siberian Diamonds – Relation To Kimberlites

D.A. ZEDGENIZOV[1,2]*, A.L. RAGOZIN[1,2], V.S. SHATSKY[1,3] AND W.L. GRIFFIN[4]

[1]Sobolev Institute of Geology and Mineralogy, 3 Koptyuga ave., 630090, Novosibirsk, Russia (*correspondence: zed@igm.nsc.ru)
[2]Novosibirsk State University, 2 Pirogova str., 630090, Novosibirsk, Russia
[3]Vinogradov Institute of Geochemistry SB RAS, 1a Favorsky str., 664033, Irkutsk, Russia
[4]CCFS/GEMOC, Macquarie University, NSW 2109, Australia

Microinclusions in natural diamonds represent a bulk sample of fluids/melts from which they crystallized [1], and provide a unique opportunity to characterize diamond-forming media and to understand their origin and evolution. In comparison with the worldwide database, the parental fluids/melts in Siberian diamonds (fibrous, cloudy, coated) define a continuous range of carbonatitic to silicic compositions; only a few fall into the first half of the range from carbonatitic to saline. Several individual diamonds show core to rim variations from carbonatitic to silicic or vice versa, or from chloride-carbonate to predominantly carbonatitic.

The trace-element patterns of the microinclusions are generally similar to those of kimberlites and carbonatites, but there are significant differences in major elements. The relative abundance of K in the fluids is significantly higher than observed in the host kimberlite and carbonatites. The pattern of HFSE in the microinclusions shows some depletion in Ti, Zr and Hf. The REE pattern reveals low abundances of the heavy REE and high light REE concentrations. Many samples with carbonatitic composition have a negative anomaly in Y.

These studies have revealed that there are many geochemical features consistent with a genetic link between the diamond-forming media and ephemeral carbonatitic and silicic liquids (HDF's) which may be precursors of the host kimberlite. These HDF's may originate either from the metasomatic influx of volatile agents; some may be liberated by low-degree partial melting of eclogites and peridotites. The absence of any marked correlation of $\delta^{13}C$ of diamonds with the compositions of their microinclusions suggests that carbon-isotope compositions are generally related to the primary source of diamond-forming HDF's. Some elemental variations may be explained by the fractional crystallization of such fluids/melts, or mixing between liquids with different compositions.

Bioreduction Of Sb-Substitued Goethite :A Mechanism Of Sb Mobility And Bioavailability?

A. ZEGEYE[1], P. BILLARD[1] AND C. MUSTIN[1]

[1] Université de Lorraine, Laboratoire Interdisciplinaire des Envrionnements Continentaux, UMR 7360, BP 70239 Vandoeuvre-lès-Nancy, F-54506, cedex France
(*correspondance: asfaw.zegeye@univ-lorraine.fr)

Antimony (Sb) is the ninth most mined metal for industrial uses worldwide. It is frequently used in a variety of industrial products although Sb and its compounds are considered as pollutants of priority interest. Due to their large surface area and reactive surface properties, iron oxide can be important sorbents of antimony (Sb). The incorporation of Sb into synthetic and natural iron oxides has been demonstrated [1]. However, extensive research is still required to evaluate whether the co-precipitation of antimony with iron oxide can serve as a possible long-term sink.

The aim of this work was therefore to synthesize Sb substituted goethite and to analyze the mobilization of Sb during the bioreduction process by *Shewanella puterfaciens* MR-1, an iron respiring bacteria. Additionally, the bioavailibilty of Sb was assessed using a whole cell GFP-based bacterial biosensor. Depending on the synthesis pathway, our data show that up to 1% of antimony can be substituted in the goethite structure affecting the coherence domain size of the mineral. The modification of the coherence domain size affects in turn the goethite's bioreduction and the bioavailibilty of Sb.

Nanoscale probing of the reactivity of biologically *versus* chemically formed green rusts

A. ZEGEYE[1,2]*. M. ETIQUE[1,2]. P. SCHAAF [3]. C. RUBY[1,2]. AND G. FRANCIUS[1,2].

[1] Université de Lorraine, Laboratoire de Chimie Physique et Microbiologie pour l'Environnement, UMR 7564, Villers-lès-Nancy, F-54601, France(*correspondance: asfaw.zegeye@univ-lorraine.fr)[2] CNRS, Laboratoire de Chimie Physique et Microbiologie pour l'Environnement, UMR 7564, Villers-lès-Nancy, F-54601, France[3] Institut Charles Sadron, CNRS UPR 22, BP 84749, Strasbourg Cedex 2, F-67034, France

Iron containing nanoparticles such as green rusts (GR) display very high reactivity against organic and inorganic contaminants and present a great potential for the remediation of polluted surfaces and subsurfaces. Since GR can either be formed by chemical or biological pathways, an understanding of their reactivity at the nanoscale level is fundamentally necessary for establishing an efficient remediation process. For the first time, we demonstrated that the combination of atomic force microscopy and chemical force microscopy is a powerful platform for probing the reactivity of GR at the nanoscale. In the presence of nitrate, we probed the nano minerals surface of both the chemically and biologically formed GRs, which enabled us to show a significant deprotonation of the H^+ present on the basal surface of the chemically formed GR, in contrast the biologically formed GR displayed virtually no reaction. Furthermore, by using the free chain model to model the force curves obtained from our spectroscopy data, we showed that the absence of reactivity of the biological GRs was due to the presence of biopolymers on its surface.

Undoubtedly, the experiments and results presented in this study open new avenues for understanding the potential difference in reactivity between biologically and chemically formed GR.

The oldest zircons of Africa - Their implications for Hadean to Archean crust-mantle evolution

A. ZEH[1,*], A. GERDES[1] AND R. STERN[2]

[1]Goethe University Frankfurt, Altenhöferallee 1, D-60438 Frankfurt am Main, Germany (correspondence: a.zeh@em.uni-frankfurt.de)[2]Canadian Centre for Isotopic Microanalysis (*CCIM*), University of Alberta *Edmonton*, AB T6G 2E3, Canada

More than 450 detrital zircon grains from Limpopo Belt quartzites were carefully investigated by CL/BSE imaging, U-Pb dating, $\delta^{18}O$, and Lu-Hf isotope analyses in order to get faithful information about the early Earth's crust - mantle evolution. The zircon grains have crystallisation ages between 3.95 Ga and 3.40 Ga, show near chondritic to subchondritic εHf_t between +1 to -15 (±1 ε-unit), and $\delta^{18}O$ mostly between +5.5 and +8.1 ‰ (±0.2‰)VSMOW. Trace elements point to zircon formation in (mostly) granitoid rocks.

The new U-Pb-Hf-datasets provide evidence for three distinct crust evolution (εHf_t-age) trends. All three trends start from nearly chondritic mantle sources at about 4.5 Ga (trend 1), 4.05 Ga (trend 2), and 3.75 Ga (trend 3), and require $^{176}Lu/^{177}Hf$ between 0.018 and 0.020, typical for mafic crust. $\delta^{18}O$ values mostly above 6.0 ‰ (VSMOW) indicate that the mafic crust has been altered, perhaps by interaction with cold oceanic water.

The new datasets from the Limpopo Belt and compilation of data from worldwide sources indicate a significant εHf_t-gap of about 5 epsilon units between trend 1 and 2. Furthermore, they reveal that many zircon analyses plot well below trend 1 (mostly at ages <4.3 Ga), or have (super)chondritic composition between 4.4 and 4.0 Ga. These findings together support an interpretation that the early Earth was covered by a long-lived, but volumetrically insignificant Hadean mafic protocrust, perhaps an unstable "stagnant lid" [1], which was affected by internal reworking [2], and injected and overlain by melts from chondritic and (highly) depleted mantle sources. This mafic protocrust was locally transformed into a TTG crust starting at <4.3 Ga [3], perhaps due to successive resurfacing [4], accompanied by crust cooling and enhanced foundering. Eventually, the complex Hadean protocrust became re-worked completely during new crust formation at <4.05 Ga.

[5]Instito de Geociências, Universidade de Brasilia
[6] Univ. Paris Diderot, Sorbonne Paris Cité ITODYS UMR CNRS 7086

The modification of Ni availability and lability consequently to mining and metallurgical activity was studied in the two ultramafic complexes of Barro Alto and Niquelândia (BA and NIQ, resp., Goías State, Brazil). Soils, ores, metallurgical wastes as well as surface waters samples were collected.

Stable Isotopic Exchange Kinetic technique (SIEK, [1]) was applied to solid samples to assess both the kinetic of solid-solution transfers and total exchangeable pool of Ni (E_{Ni}). Moreover, for the nearly first time, this technique was performed on natural water samples to quantify the pool of isotopically exchangeable Ni from the suspended particulate matter (SPM) in water, defined here as E^{W}_{Ni}. Goethite, chlorite, talc and serpentine were identified by XRD, SEM-EDS and TEM as the main Ni bearing phases in SPM located far from metallurgical activity (BA site), while in samples located in the area influenced by metallurgy (NIQ site) Ni was mainly associated to spherical micrometric particles related to fly ash produced by the ore combustion.

This difference in Ni bearing phases between BA and NIQ sites induces a difference of Ni exchangeable pool: up to 565 mg L^{-1} in NIQ samples (E^{W}_{Ni} value) while in BA it only reached 62 mg L^{-1}. These E^{W}_{Ni} values correspond to total exchangeable Ni in SPM (E_{Ni} values) of 49,000 and 2350 mg kg^{-1} for BA and NIQ sites, resp.

Consequently, sites located in the metallurgy influence area display higher E_{Ni} amount and slower exchanges kinetics, revealing that anthropic activity significantly enhances Ni (bio)availability through the modification of its bearing phases [2].

The Isothermal Evaporation Phase Equilibria for Salt – Water System Focused on Zabuye Salt Lake

Y. ZENG[1,2]*, X. D. YU[1], J. J. LI[1], Y. PENG[1,2], S. FENG[1,2] AND R. L. WANG[1,2]

[1]College of Materials and Chem. & Chem. Eng., Chengdu Univ. of Technology, Chengdu, 610059, P.R. China;
[2]Mineral Resources Chemistry Key Laboratory of Sichuan Higher Education Institutions, Chengdu, 610059, P. R. China (* correspondence: zengyster@gmail.com)

There are a larger number of salt lakes in the Qinghai – Xizang Plateau, more than 200 salt lakes that spread out over 1 km^2. Of all salt lakes in Tibet, Zabuye salt lake has distinct characteristics from others, with an area of 247 km^2, and is famous for its high concentration of potassium, lithium and borate resources. Low concentrations of calcium and magnesium are advantageous for recovering lithium from brine. The potassium reserves of Zabuye Salt Lake is 7.43 million ton, Li_2CO_3 reserves is 1.74 million ton, B_2O_3 reserves is 0.71 million ton.[1] The composition of Zabuye salt lake falls under the complex system which includes lithium, sodium, potassium, carbonate, sulfate, chloride, and borate.

To exploit brine resources, it is essential to make use of local climatic resources such as wind and solar energy for solar pond techniques. The climate in the region of the Zabuye salt lake is windy, aried and the average temperature is about 273 K. Therefore, the isothermal evaporation phase equilibria, which was determined in the laboratory under the similar conditions, can objectively describe the interactions among the brine minerals and reveal the crystallization path of various salts.

By now, a series of researches about the stable and metastable phase equilibria of the salt – water system focused on Zabuye salt lake have been down at 273 K, 288 K, and 298 K.[2-6] Comparisons between the stable and metastable phase diagrams at different temperatures can obtain the information about the crystalloid forms and crystallization zones of salts at multi-temperature. These information, especially the solubilities of salts change with the temperature, co-existing ions, and the total concentration of salts in solution, are useful for the exploiting of brine. However, most of the previous researches focused on temperature above 288 K, and the isothermal evaporation phase equilibria at 273 K are only some subsystems of the complex system, the results are not enough for the comprehensive utilization of the brine, thus, the investigation about the more complex system are necessary.

Aluminum Oxide In Submarine Hydrothermal Sulfide From East Pacific Rise Near 13°N

Z.G. ZENG[1]* AND H.Y. QI[1]

[1] Seafloor Hydrothermal Activity Laboratory of the Key Laboratory of Marine Geology and Environment, Institute of Oceanology, Chinese Academy of Sciences, Qingdao 266071, China (*correspondence: zgzeng@ms.qdio.ac.cn)

Seafloor hydrothermal activity is a window into the subseafloor ocean. Studying hydrothermal products aids in understanding the deep processes of hydrothermal circulation. Aluminium (Al) is highly enriched in hydrothermal vent fluids compared to seawater (10-20 μmol/kg versus 10 nmol/kg) [1]. Al in seafloor hydrothermal sulfides is also common both in deposits in mid-ocean ridges and in back-arc basins or volcanic arcs. The Al concentration of seafloor hydrothermal sulfide deposits has received only cursory attention. Previous geochemical studies had shown Al to be present to varying concentration (form 52.8 ppm at North Fiji basin to 4396 ppm at East Pacific Rise (EPR)) in seafloor hydrothermal sulfides, which are believed that Al may be present in clay minerals [2, 3].

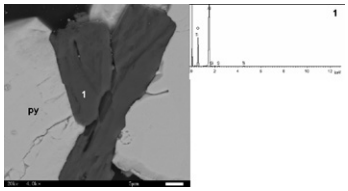

Figure 1: Backscattered electron microprobe images of Al oxide microcrystallite in pyrite from the EPR near 13°N. 1 and Py represent Al-oxide and pyrite, respectively. 1. Energy dispersive X-ray spectrum of Al-oxide microcrystallite.

We report data on the concentration of aluminum in sulfide from EPR near 13°N is from 13.7 ppm to 1071 ppm, which Al is present in Al-oxide. A positive correlation exists between Al and Ti, Zr, Nb, Sr, Ni, Y, and REEs in the sulfides of the EPR near 13°N, which means REEs, Y, Ti, Sr, Ni, Zr, and Nb occur in the minor Al-oxide of the sulfides from the EPR near 13°N.

Response Of The Global Nitrogen Cycle To The Great Oxidation Event

A.L. ZERKLE[1], S.W. POULTON[2], R.J. NEWTON[2], M.W. CLAIRE[1] AND A. BEKKER[3]

[1]Department of Earth and Environmental Sciences, University of St Andrews, St Andrews, Fife, KY16 9AL, Scotland, UK (aubrey.zerkle@ncl.ac.uk; m.claire@uea.ac.uk)

[2]School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, England, UK (s.poulton@leeds.ac.uk; R.J.Newton@leeds.ac.uk)

[3]Department of Geological Sciences, University of Manitoba, Winnipeg, Manitoba, R3T 2N2, Canada (Andrey.Bekker@ad.umanitoba.ca)

Nitrogen isotope values in kerogens from the ~2.32 Ga Rooihoogte and Timeball Hill formations (R-TH), South Africa, record a reorganization in global nutrient cycling in response to changes in ocean chemistry during the Great Oxidation Event. These units were deposited immediately after the disappearance of sulfur isotope mass-independent fractionation, indicating that atmospheric O_2 levels rose to greater than 1ppm level. The shales of the R-TH document a dramatic swing in the $\delta^{15}N$ values of marine organic matter from -14 to +13‰, unprecedented in sedimentary records. The extremely ^{15}N-depleted values and associated geochemical signatures of iron and carbon preserve evidence for a redox-stratified ocean with primary productivity dominated by anoxygenic photoautotrophs utilizing a large pool of bioavailable ammonium as a nitrogen source. An increase in $\delta^{15}N$ across the formation boundary represents titration of this ammonium by continued assimilation and nitrification utilizing newly available marine oxidants. In the upper part of this succession, the $\delta^{15}N$ values settle to around modern values (~+5 ‰) in both deep- and shallow-water sediments, where they remain for much of the rest of Earth history. We propose that this trend records a change in the dominant form of nitrogen available for global primary productivity, from ammonium to nitrate, as a direct consequence of changes in ocean chemistry. We will present a box model of marine nitrogen concentrations and isotopes to test this hypothesis.

Volumetric properties of multi-electrolyte aqueous solutions at elevated temperatures and pressures

D. ZEZIN[1], T. DRIESNER[2] AND C. SANCHEZ-VALLE[3]

[1](denis.zezin@erdw.ethz.ch),
[2](thomas.driesner@erdw.ethz.ch,)
[3](carmen.sanchez@erdw.ethz.ch)

Aqueous solutions play a vital role for many geological processes in various environments, such as geothermal and magmatic hydrothermal settings or sedimentary basins. In order to perform a detailed geochemical modeling to describe these processes quantitatively, one needs accurate thermodynamic data for all constituents, with aqueous fluid being the essential part of a system. The fluids are typically multi-electrolyte aqueous solutions of a wide range of salinity predominantly comprising chlorides and sulfates of alkali and alkali earth metals. However, the thermodynamic properties of such solutions have remained largely unstudied at elevated temperatures and at pressures above the vapor pressure saturation curve, affecting the accuracy of geochemical modeling at geologically relevant conditions.

We present the results of an experimental study of the volumetric data of multicomponent electrolyte solutions over a wide range of temperatures, pressures, and compositions. This study provides the volumetric properties of aqueous solutions containing binary mixtures of chlorides and sulfates of Na, K, Ca and Mg at temperatures up to 250 °C and pressures up to 70 MPa for ionic strengths up to 12 molal. A vibrating-tube densimeter was used to measure the relative density of aqueous solutions with respect to pure water. The mean apparent molar volume of the electrolyte mixture, calculated from the experimental data, was used for evaluation of the partial molar volume of dissolved components and limiting partial molar volume of these solutes. The obtained data were used for direct evaluation of the pressure dependence on water-rock equilibrium, e.g., anhydrite dissolution and Na-K-(Ca) geothermometry reactions. Such experimental data may also provide important information about the structure of a solution and ionic interactions occurring in aqueous liquids.

The presented experimental data will be employed for the parameterization of thermodynamic models describing the properties of aqueous mixtures of electrolytes. The results of this study will find use in hydrothermal and geothermal fluid-related modeling, petroleum and geothermal reservoir engineering, processing and utilization of industrial brines and CO_2.

Mineralogical evidence of high-fluoride oxidizing fluid in Baiyanghe U-Be-Mo Deposit, Xinjiang, China

CHENGJIANG ZHANG[1], WANG GUO[1,2], SONG HAO[1], CHEN FENXIONG[2] AND WANG BAOQUN[2]

[1] Chengdu University of Technology, Chengdu 610059, China (*Correspondence: zcj@cdut.edu.cn)[2] Geologic Party No. 216, CNNC, Urumqi 830011, China

Baiyanghe uranium-beryllium-molybdenum deposit, located in the western of Xuemisitan volcanic rock belt, is formed in late Palaeozoic mature island-arc environment, the north marginal active belt of Junggar. According to incomplete statistics, the unique similar to this deposit is the Spor uranium-beryllium deposit in Utah, USA, and the elements combination in Spor are U-Be-F, while Baiyanghe deposit are U-Be-Mo-F.

In space, there is both overlap and separation phenomenon exist in uranium-beryllium-molybdenum ore bodies. There are mainly three kinds of spatial relations: Firstly, the uranium-beryllium-molybdenum ore bodies are coincided basically with the space or roughly consistent; Secondly, the single uranium ore body without beryllium and molybdenum; Thirdly, the beryllium and molybdenum ore bodies without uranium.

This type of ore deposits are associated with high silicon-rich fluorine acidic volcanic rocks, and the ore-forming fluid derive from the fluorine-rich gas-liquid containing molybdenum, beryllium and uranium from the immiscibility of the later volcanic magmatism[1,2]. The migration of the three elements in fluid are in various complex forms, such as fluoride, beryllium fluoride complex, carbonate complex, uranyl ions carbonate, the fluoro carbonate of uranium, uranyl ions molybdenum acid radical. Thus, the volatile, such as F and CO_2, play an important role in the migration and precipitation of uranium, beryllium and molybdenum.

The sulfide mineral are rare in Baiyanghe deposit, and the vast oxide minerals, such as hematite, manganite, pyrolusite, indicate that the ore-forming fluid are oxidizing fluid properties. At the late ore-forming stage, there are small amounts of sulfide mineral, such as pyrite, gelenite and molybdenite.

Early diagenesis how to impact C/N and organic isotopic compositions in the Lacustrince Sediments

ZHANG CHENGJUN[1] AND FAN RONG[2]

[1]School of Earth Sciences & Key Laboratory of Mineral Resources in Western China, Lanzhou University, Lanzhou, 730000, China
*(correspondence: cjzhang@lzu.edu.cn)
[2]College of Resource and Environmental Sciences, Lanzhou University, Lanzhou, 730000, China

C/N, organic carbon isotopic compositions and organic *n*-alkane components have been analyzed in surface sediments from 28 lakes in the Koh Xil area and 26 lakes in the northeastern China. Early digenesis can impact the ratios of C/N and the values of $\delta^{13}C_{org}$ at the beginning of terrestrial and aquatic plants inputting the lake water bodies, and lower the C/N and $\delta^{13}C_{org}$ obviously in the process of transferring and accumulation of organic matter. Changed C/N and $\delta^{13}C_{org}$ cannot indicate organic sources very accurately. Submerged plants, algae and C4 grasses degrade most intensively in the evolvement process of organic matter. Original values of organic isotope may be in the range of -17‰ to -20‰; Organic matter mainly from terrestrial plants changes in minimum and original organic isotope is about -26‰~-30‰; floating aquatic and emergent macrophytes are in the mid, and original isotope is about -20‰~-26‰. In general, organic matter in the lakes is remade with types of organic matter, water characteristics, depth and residue time of lake waterbodies. Organic isotopic compositions of endogenous algae and aquatic merged, submerged and floating plants lower more obviously than that of the terrestrial plants which changed less can indicate primary environments preferably.

Keywords: lake; organic matter; early diagenesis; C/N; organic isotopic composition;

Geochronology of ore-bearing granites in the Baishan Mo Deposit, Eastern Tianshan, Xinjiang

D.Y. ZHANG, T.F. ZHOU*, F. YUAN, Y. FAN, Y.F. DENG AND C. XU

School of Resources and Environmental Engineering, Hefei University of Technology, Hefei 230009, China
(*correspondence: tfzhou@hfut.edu.cn)

The Baishan Mo deposit is located in the eastern section of Jueluotag tectonic belt, Eastern Tianshan, Xinjiang, China. In this study, we sampled the deep (1500m below surface) ore bearing granite from the latest exploration drill core. Furthermore, we tested the zircon U-Pb age of ore-bearing granites is 228.5±8.9 Ma (MSWD=3.1) by La-ICPMS in Hefei University of Technology.

The zircon U-Pb age of the ore-bearing granites (228.5±8.9 Ma) is the same with mineralization age (227.7± 4.3 Ma) in Bashan Mo deposit within error [1], which further confirms that Baishan Mo mineralization was genetically related with the granite body[2].

In Eastern Tianshan-Beishan area, there are numerous Mo deposits was found through current exploration, including Dongebi, Huaheitan and Xiaohulishan Mo deposits [3][4]. The Baishan Mo-bearing granite was intruded in Mid Triassic epoch. This geochronological result affords credit evidence to genetic research of the Mid Triassic Mo mineralization in the regional area.

This research was sponsored by Chinese National Science and Technology Program (2011BAB06B01), the National Key Basic Science Research project of China (2007CB411304 and 2001CB409806) and the National Natural Science Foundation of China (40772057).

Metamorphism and *P-T* evolution of high pressure granulite in Chicheng, Northern part of the paleoproterozoic Trans-North China Orogen

DINGDING ZHANG AND JINGHUI GUO

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (correspondence: zhangdingdingx @163.com)

It is widely accepted that the North China Craton formed by collisional amalgamation of the Eastern and the Western Blocks along the central Trans-North China Orogen (TNCO) at ~1.85 Ga. However, the continental subduction process has not been well recorded by previously reported high-pressure (HP) granulites due to lack of prograde metamorphism because of high peak temperature. Recently, we have identified a set of HP mafic granulites with well preserved prograde metamorphism in the Womakeng of ChiCheng, northern part of the TNCO. They developed among a granulite facies mafic to felsic metavolcanic rock association. The prograde metamorphic stage (M1) has been revealed by distinct growth zone of garnet porphyroblasts with inclusion rich core and inclusion free mantle. The peak metamorphic mineral assemblage (M2) consists of Grt and Cpx predominantly with minor Pl, Rut, Amph and Qtz. The Pl+Amph symplectite or corona surrounding garnet and Cpx+Ilm symplectite arround titanite documented the post-peak decompression (M3) stage. Phase equilibria modelling by THERMOCALC software yielded a consecutive clockwise *P-T* path with a remarkable prograde metamorphic section, during which the tempretures increase from 630~680 ℃ to 700~750 ℃ as coincident increase of pressures from 9~11 kbar to the peak (14~16 kbar). During decompression after peak from 16 kbar to 10 kbar, the temperature keeps increasing from 700~750 ℃ to 750-800 ℃ indicating a thermal relaxation, and then decreases as the pressure further descends. The new defined *P-T* path of the HP granulites provide a better metamorphic evidence for the subduction process during the continental collision along the Trans-North China Orogen.

The effect of chemical evolution in ^{137}CsCl on radionuclide leaching

F. ZHANG[1], N. A. MARKS[1], J. D. GALE[1], Q. KANG[2], B. P. UBERUAGA[2], C. R. STANEK[2] AND N. HENSON[2]

[1]Nanochemistry Research Institute, Curtin University, PO Box U1987, Perth, Western Australia 6845, Australia
[2]Los Alamos National Laboratory, Los Alamos, New Mexico 87545, USA

A critical component of nuclear waste disposal strategy is to prevent radionuclides from leaving the waste form and entering the environment. However, radiation damage and leaching studies over the past 30 years have focused on the performance of the candidate waste form at t=0, with far less attention paid to the phase stability, and subsequent durability, during the course of daughter product formation. As a case study in chemical aging, we consider here the system of ^{137}CsCl, capsules of which exist in storage pools at Hanford, Washington State. We combine density-functional-theory (DFT) calculations with pore sale modeling to gain a sense of how radionuclide leaching varies as a function of time due to in-growth of the daughter products.

In previous calculations of bulk material we have shown [1,2] that beta-decay of ^{137}Cs to stable ^{137}Ba generates a rocksalt BaCl daughter phase in which the Ba does not have the expected 2+ oxidation state. This phenomenon is an example of a process we term radioparagenesis [3], in which decay of a major lattice constituent gives rise to a novel solid state daughter phase. Here we study radioparagenesis at surfaces, finding that isolated Ba atoms are most stable in the sub-surface layer, while pairs of Ba atoms have a large binding energy. The Ba atoms also enhance segregation of Cs and Cl vacancies to the surface, suggesting that although Ba will not easily migrate to the surface of the crystal, it significantly modifies the behavior of other defects. In particular, when water interacts with the CsCl surface, the dissolution energy will depend on whether there is Ba nearby or not. Using Schottky defect formation energies derived from DFT, pore-scale modelling simulations were used to predict dissolution of CsCl into water at 20 °C. The models show that the CsCl leaching rate significantly increases when Ba is present, suggesting that chemical aging should be considered as an additional factor in waste form design.

Effect of pressure on oxygen fugacities in magma oceans

H. ZHANG AND M. M. HIRSCHMANN*.

310 Pillsbury Drive SE, Minneapolis, MN, 55455 *Presenting Author: (mmh@umn.edu)

Oxygen fugacities in a magma ocean (MO) may have a crucial influence on removal of siderophile and volatile elements to the core during metal-silicate interaction and may control the composition and redox state of the overlying primitive atmosphere. However, the f_{O2} prevailing at depth where metal equilibrates with silicate could be quite variable and remains controversial. Importantly, the f_{O2} at the MO surface may not be similar to that at depth, owing to the effect of pressure on the chemical potentials of redox-sensitive elements, most notably iron.

Iron is the most abundant multi-valent element in silicate melts and so magmatic $Fe^{3+}/\Sigma Fe$ ratios are linked directly to MO f_{O2}. In a vigorously convecting, well-mixed MO, the variation with depth in the f_{O2} may be set by a uniform $Fe^{3+}/\sum Fe$ ratio of the silicate liquid, which in turn is fixed by magma-metal equilibration at high pressure. To determine this effect, one must know how magmatic $Fe^{3+}/\sum Fe$ varies with pressure at known f_{O2} and temperature. Experiments on an andesitic liquid up to 7 GPa and 1750°C, analyzed by Mossbauer spectroscopy, show that $Fe^{3+}/\sum Fe$ ratios decrease with increasing pressure and temperature. If this trend continues at higher pressure, it suggests a MO with fixed $Fe^{3+}/\Sigma Fe$ is more reduced in its shallow portions than it is at depth. However, considering the different compressibilities of Fe^{2+} and Fe^{3+} in silicate liquid, the trend may reverse at higher pressure and experiments above 7 GPa are in progress.

It is clear that the oxidation state of atmospheres overlying MOs may be related to the depth at which equilibrium is established between Fe-rich alloy and silicate, with consequences for evolution of early atmospheres and climate, and the origin of life. If shallow MOs are related to reducing atmospheres and deep high pressure ones related to oxidizing atmospheres, then smaller planets that equilibrate with iron at low pressure may yield early atmospheres rich in CO and H_2. Larger ones equilibrating with Fe at higher pressure, may yield early atmospheres rich in CO_2 and H_2O.

Elasticity and structure of mantle pyroxenes

J S ZHANG[1], L SANG[1,5], J D BASS[2]*, B REYNARD[3], G MONTAGNAC[3] AND P DERA[4]

[1]Geology Department, University of Illinois, 1301 W Green St., Urbana IL 61801 USA,
[2]COMPRES, 1301 W Green St., Urbana, IL 61801 USA
[3]ENS Lyon, FR
[4]GSECARS and University of Chicago IL USA
[5] Texas A&M University

To understand complex upper mantle seismic structure we must know the single-crystal elastic properties of the constituent minerals at high pressures and temperatures. Here we report recent work on the single-crystal elastic properties and phase transitions in Ca-poor orthopyroxene and Ca-rich clinopyroxene at high pressures. The elastic properties of natural orthoenstatite (OEN) and natural diopside have been determined at high pressures to over 14 GPa at room temperature by Brillouin spectroscopy. Single crystals of Fe-bearing orthoenstatite from San Carlos were used in the study. Sound velocity data display a pronounced change upon cold compression to above 12 GPa, and an abrupt change in velocity anisotropy. Single-crystal X-ray structure refinements show that OEN transforms to a new high-pressure phase with space group P21/c, with the transition pressure bracketed between about 10-14 GPa. No evidence of a C2/c structure was observed. Raman spectroscopy on nearly pure Mg OPX, a high-alumina sample, and an Fe-rich sample show that Al and Fe both effect the transition pressure, but that the high-pressure phase is still P21/c in all cases.

The single-crystal elasticity diopside was measured to transition zone pressures using Brillouin spectroscopy. It shows a markedly different behaviour to that of OEN. The C_{ij}'s as a function of pressure were obtained. Aggregate bulk elastic properties are in very good agreement with polycrystalline acoustic measurements. In the case of diopside single-crystal Brillouin and polycrystalline acoustic measurements give highly consistent results.

Data-processing and multi-type anomaly recognition in the geochemical survey in the south slope of the Dongying Depression, East China

LIUPING ZHANG [1], GUOPING BAI[2] AND YINGQUAN ZHAO[3]

[1] Key Laboratory of Petroleum Resource, Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O. Box 9825, Beijing 100029, China

[2] State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing 102249, PR China

[3] Chengdu University of Technology, Sichuan 610059, China

Surface geochemical survey was not widely used in petroleum exploration. To resolve problems in data-processing and anomaly recognition, we have worked up a series of fundamental equations and methods for eliminating surface interference and influences of geological conditions on anomaly intensities and recognizing multi-type anomalies of uni- and multi-variates, by using statistics, fractal geometry, wavelet analysis and artificial neural networks. One of these equations illustrates that the threshold (the boundary between background and micro-seepage anomalies) is determined by means, standard deviations and prior probabilities of background and micro-seepage anomalies when multi-normality is met, and that the traditional equation for the threshold (background mean plus one or two standard deviations) is not correct. In the face of many new equations and methods, it is important how to comprehensively use them to resolve the problems in geochemical surveys. A geochemical survey in the south slope of the Dongying Depression, eastern China provides a good opportunity to address this issue. We iteratively applied the wavelet-analysis-based methods to eliminate the surface interference and geological influence, and statistical methods with new fundamental equations to recognize uni-vairate anomalies of seepage and microseepage. And then, multi-vairate anomalies of seepage and microseepage were recognized with our fundamental equations and methods. In the results, the seepage anomalies display a string-bead-shaped pattern and are distributed along faults, and the micro-seepage anomalies are ring-shaped and coincide with oil/gas pools, sandbodies or traps. Therefore, processing of geochemical data with our fundamental equations and methods combined in the iterative manner can resolve the complicated problems in data-processing and anomaly recognition and thus greatly improve the predictive capability of surface geochemical survey.

Phenylnaphthalenes and terphenyls in mesozoic-cenozoic source rocks of the Qaidam Basin, China

MINGFENG ZHANG[1], JINCAI TUO[1], CHENJUN WU [1,2] AND RU CHEN [1,2]

[1]Key Laboratory of Petroleum Resources Research, Institute of Geology and Geophysics, Chinese Academy of Sciences, Lanzhou, China zhangmingfeng_9@hotmail.com)

[2]Graduate University of the Chinese Academy of Sciences, Beijing, China

Source rocks from an inland lake depositional setting from Mesozoic-Cenozoic formations in the Qaidam Basin (west, China) were analysed for aromatics using capillary gas chromatography-mass spectrometry (GC-MS). The triaromatic members of the new series, Phenylnaphthalenes(PhNs) and terphenyls(TrPs), are found in different type of source rock(Ⅱ and Ⅲ) investigated. The isomeric composition of the phenylnaphthalenes and terphenyls was found to depend on thermal maturity. In the lower maturity samples abundances of 1-PhN and o-TrP are higher. Increase in sample maturity is indicated by an increase in the relative abundance of 2-PhN as well as m-TrP and p-TrP. Three thermal maturity parameters of the organic matter based on the relative abundances of the PhN and TrP isomers are proposed: PhNR=2-PhN/1PhN, TrP1=p-TrP/o-TrP, and TrP2=(m-TrP+p-TrP)/o-TrP[1]. In general their values are positive correlation versus vitrinite reflectance (Ro) in a range of 0.47-2.75%, While correlation of the conventional biomarker maturity parameters (C_{29} ααα sterane -20S/(20S+20R), C_{31} αβ hopane 22S/(22S+22R), MPI1 ratio) are less apparent with vitrinite reflectance (Ro) in a range of 1.32-2.75%. So the new parameters perhaps are effective reflecting degree of thermal evolution of organic matter in mature-high maturity.

Dissolution kinetics of some femic-silicate minerals in water from 20 to 435°C, 23mpa: Effect of water solvent properties within the critical region

RONGHUA ZHANG*, SHUMIN HU AND XUETONG ZHANG

Laboratory of Geochemical Kinetics, MLR Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources, Chinese Academy of Geological Sciences, Baiwanzhuang Road 26, Beijing 100037, P.R.China (*correspondence: zrhhsm@pku.edu.cn)

Experiments for measurements steady-state dissolution rates of hedenbergite, diopside, actinolite , garnet, in water were performed using flow through reactor (continuous stirred tank reactor, and packed bed reactor) at temperatures from 25 to 435°C at 23 MPa. Minerals used in experiments are collected from natural, examined through microscope, cleaned and analyzed chemically. Usually, all reactive solutions were undersaturated with respect to the minerals, while run the experiments at high flow rates. A few secondary product phases were found on the reacted surface while using SEM observations. We tested the release ratio of molar concentrations of metal M_i versus molar concentration of Si in outlet solutions $\Delta Mi/\Delta Si$. We found that the dissolutions of those minerals are often incongruent. The dissolution is stoichiometric, when $\Delta Mi/\Delta Si$ is identical to the stoichiometric number N_i in silicate mineral. Dissolution rates (r_{Si}) for hedenbergite, diopside, garnet in water increase with increasing T from 25 to 300°C, and decrease with continued increasing T from 300 to 400°C. The maximum release rates (r_{Si}) for the minerals are always reached at about 300°C. The different metals in the minerals often behave the different release rates at a given temperature. The r(Ca) reach maximum at 200°C; The maximum r(Na), r(Mg), r(Fe) are found at 20 to 100°C. Usually, the rates of Na, Ca, Mg, Fe are often higher than r(Si) at T<300°C, when. release rates are controlled by Metal-H^+ exchange reactions. Water properties vary strongly within the region from a sub-critical to a supercritical state: lowering density and dielectric constant in the temperature range 300–400°C, which lead to break the hydrogen bond network of water molecules. Thus water molecules easily break polarized bond, such as Si-O-Si. The hydrolysis of Si-O-Si bond is dominated at T ≥ 300°C, and thus r(Si) is relatively faster the others. Using SEM and HRTEM, we examined the reacted surface of the minerals at T ≥ 300°C and found amorphic leaching layer at the surface, which is a Fe rich, Si-deficient nano layer.

Phosphorus speciation in the sediment profile of Lake Erhai, Southwestern China by fractionation and 31P NMR

R.Y. ZHANG* AND L.Y. WANG

State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: zhangrunyu@vip.gyig.ac.cn)

Distribution characteristics of phosphorus (P) forms in the sediment profile of Lake Erhai, in Southwestern China has been investigated by sequential extraction and ^{31}P nuclear magnetic resonance spectroscopy (NMR) of NaOH extracts to understand P dynamics and its potential contribution to lake eutrophication. Contents of P fractions varied in the order of NH_4Cl extracted P (NH_4Cl-P) < bicarbonate-dithionite extracted P (BD-P) < HCl-P, Residual-P < NaOH extracted P (NaOH-P). The highly available NH_4Cl-P represented less than 1% of total P (TP). BD-P and NaOH extracted reactive P (NaOH-rP) averaged 39%, while the ratio of Fe/P was higher than 15, indicating low P release from the sediments under permanent oxic condition. The less bio-available HCl-P, NaOH extracted nonreactive P (NaOH-nrP) and Residual-P contributed 61% of TP. Regression analysis revealed that BD-P, NaOH-rP and HCl-P were positively correlated with the contents of Fe and Mn, Al and Fe, and Ca, respectively. The investigation of P compound groups in NaOH extracts by ^{31}P NMR showed that ortho-P and monoester-P were the largest two constituents of the P pool, followed by diester-P, phosphonate and pyro-P. A comparison of vertical variations of P groups in the sediment profile suggested that these compounds were involved in the P recycling to different extents in Lake Erhai. In particular, the lake exhibits high potential for labile P release from the surface sediments, which should be taken into consideration even after the outsourced P runoff ceased.

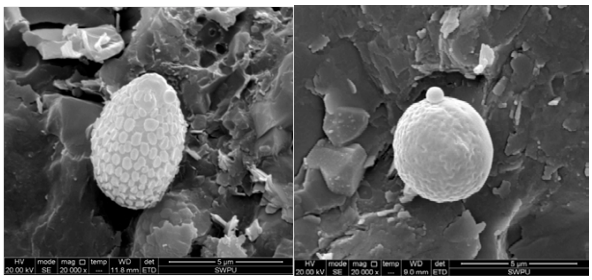
The early cambrian microbial-like fossils: New insights from their potential for hydrocarbon-generation

TINGSHAN ZHANG[1]*, ZHAO GUOAN[2] AND LIU ZCHENG[3]

[1].State Key Lab.of Oil&Gas G&E Engineering,Chengdu,China (zts_3@sina.com) (* presenting author)
[2].State Key Lab.of Oil&Gas G&E Engineering,Chengdu,China (zhaoga@petrochina.com.cn)
[3]. State Key Lab.of Oil&Gas G&EEngineering,Chengdu,China (rex_swpu2005@126.com)

The well-preserved Early Cambrian in the southern Sichuan,China consists mainly of two lithological associations including dark to black shales and dark silty shale, with a total thickness of up to300 m. Some microbial-like fossils(they are similar to the present-day picoplankton and cyanobacteria found in the oceans) have been identified in it. The well-preserved microbial-like structures consist of spheroids about 1.0 μm diameter resembling picoplankton forms (Fig.1).



According to Agawin etc(2000) , more than 90% of all production DOC is the largest reservoir of organic carbon in marine system, even more important is the most of which come from the releasing of picoplankton. The dark to black shales have been recognized under anoxic conditions. Warm climate and anoxic conditions in the Early Cambrian oceans may have facilitated high microbial productivity and organic burial in sediments. Abundant microbially induced organic carbon is from 3 to 7% in ϵ_1. and their potential for hydrocarbon-generation (shale gas) have been recognized.

Large perturbations of the carbon cycle during the middle-late Ordovician in Southeastern Poland

TONGGANG ZHANG[1]*, YANAN SHEN[2] AND WIESLAW TRELA[3]

[1]State Key Laboratory of Petroleum Resource and Prospecting, China University of Petroleum at Beijing, Beijing 102249, China (* Correspondence: zhang.tonggang@cup.edu.cn)
[2]CAS (Chinese Academy of Sciences) Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China
[3]Polish Geological Institute-National Research Institute, Holy Cross Mts Branch, Zgoda 21, 25-953 Kielce, Poland

It is a puzzle that a major glaciation occurred in the Late Ordovician when greenhouse climatic conditions were prevailing on the Earth. The Late Ordovician glaciation resulted in significant changes in global environment as well as the biosphere. Many reports focused on the environmental changes and the great mass extinction associated with the Late Ordovician glaciation. However, debate still remains in the timing and causes of the transition to the icehouse climate from greenhouse conditions in the Late Ordovician. To investigate the Late Ordovician carbon cycle, we conducted detail analyses of carbon isotopic compositions of organic carbon, TOC, and trace elements in the Ordovician sediments from Poland.

No correlations between TOC and $\delta^{13}C_{org}$ values , low thermal maturity, and global correlations indicate that the primary signal of carbon isotopic compositions were well preserved in the Polish sediments. The Caradocian sediments show low $\delta^{13}C_{org}$ values, rich in TOC, and high V/(V+Ni). In contrast, the Ashgill samples show high $\delta^{13}C_{org}$ values, depleted in TOC, and low V/(V+Ni). Two positive excursions of $\delta^{13}C_{org}$ occurred in the Middle Caradoc and in the Latest Ashgill, respectively. We suggest that anoxic environment developed in the Caradoc Stage have contributed to the burial of organic carbon. Elevated primary productivity indicated by the Ba/Al ratios resulted in positive shift in $\delta^{13}C_{org}$ values of Ashgill sediments those were deposited in an oxic environment. Carbon isotopic records suggest that the transition to an icehouse climate possibly occurred in the Early Ashgill Epoch of Late Ordovician.

NH_4HF_2- assisted digestion of silicate rocks for multi-element analysis by ICP-MS: A new development in open vessel digestion

WEN ZHANG[1], ZHAOCHU HU[1]*, YONGSHENG LIU[1], HAIHONG CHEN[1], SHAN GAO[1] AND RICHARD M. GASCHNIG[2]

[1]State Key Laboratory of GPMR, China University of Geosciences, Wuhan 430074, China (*correspondence: zchu@vip.sina.com)

[2]Department of Geology, University of Maryland, College Park, Maryland 20742, United States

Complete digestion is prerequisite to obtain accurate analytical results for geological samples [1,2]. A new digestion technique using NH_4HF_2 in Savillex screw-top Teflon vials has been developed for multi-element analysis, including felsic rocks that contain refractory minerals such as zircon.

NH_4HF_2 has a higher boiling point (239.5 °C) than conventional acids such as HF, HNO_3 and HCl, which allows for an elevated digestion temperature in open vessels, enabling the decomposition of refractory phases. A digestion time of 2–3 hours for 200 mg NH_4HF_2 in a Savillex Teflon vial at 230 °C is sufficient to digest 50 mg of the felsic rock GSP-2, which is ~6 times faster than using conventional closed-vessel acid digestion at 190 °C (high-pressure PTFE digestion bomb). No insoluble fluorides are present in the final sample solution in this method, even when the sample mass is as large as 200 mg. It appears that the low pressure environment inhibits the formation of insoluble fluorides. The ready production of an ultrapure NH_4HF_2 reagent by sub-boiling distillation makes the proposed NH_4HF_2 digestion method suitable for ultratrace-multielement analyses in various geological samples.

The new method combines the advantages of both the open- and closed-vessel digestion methods, providing us with an effective, simple, economical, and comparatively safe dissolution method.

Nd-Sr isotopic evolution of Asian dust: Tectonic And climatic implications

WENFANG ZHANG[1]*, GAOJUN LI[1], ZHONG CHEN[1] AND JUN CHEN[11]

MOE Key Laboratory of Surficial Geochemistry, Department of Earth Sciences, Nanjing University, Nanjing 210093, China. (*correspondence: nic_langdi@163.com)

The eolian deposits archived in the loess and Pacific pelagic sediments provide important information on the late Cenozoic atmospheric circulation and paleo-environmental condition of the source regions. In recent years, Nd-Sr isotope was widely used to trace the source of eolian dust. Systematic investigation on the Nd and Sr isotopes of potential source materials in recent years provides a solid bases to interpret the Nd-Sr isotopic evolution of Asian dust[1]. Here we present new sedimentary records of Asian dust from Chinese Loess Plateau and Northwest Pacific, which may shed new light on regional tectonic and climatic evolution since the late Oligocene.

The Nd isotope of Chinese loess decreases while the Sr isotope increases progressively during 22-1.2Ma. This record is based a very narrow grain size range (28-45 μm) of silicate fraction so that potential influence of weathering and mineral sorting on Sr isotope is eliminated. Similar Nd-Sr isotopic evolution of Asian dust has also been detected in Northeast Pacific site GPC3[2]. We interpret decreasing Nd isotope and increasing Sr isotopic ratio during 22-1.2Ma may reflect progressive uplift of Northeast Tibetan Plateau. The source region of Asian dust manly receives debris eroded from North Tibetan Plateau and Gobi Altay Mountains. Compared to Gobi dust, Tibetan materials have much lower Nd isotopic ratio and higher Sr isotopic ratio. Uplift may increase the relative contribution of Tibetan material, and thus shift the Nd and Sr isotope to Tibetan values. Since 1.2 Ma, the loess record indicates that the detritus contribution from Tibet drops rapidly in compare with that from Gobi. As large-scale topographic changes would not be expected in such a short time period, the source shift since 1.2 Ma is interpreted by the differing erosional responses in North Tibetan Plateau and Gobi Altay Mountains to the development of full glacial climate after the middle Pleistocene transition.

However, the patterns of Nd-Sr isotopic evolution observed in Chinese loess and pelagic sediment of Northeast Pacific has not been detected in ODP 1208 core in Northwest Pacific. We find that a separate contribution of pure Gobi dust by winter monsoon may explain the very different pattern recorded in ODP 1208 core. The Nd-Sr isotopic record in ODP 1208 core may reflect competition between Taklimakan dust and Gobi dust, which may have great potential in paleoclimatic and tectonic applications.

New dating result of the Caledonian granitoids and related mineralization of Miaoershan-Yuechengling area, South China

WENLAN ZHANG [1], DI ZHANG [1] AND RUCHENG WANG [1]

[1] State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, P.R. China

It has been accepted that W-Sn-(Mo) rare metal mineralization in South China are in close association with the Yanshanian granites, whereas the granites of the other ages results in minor metallogenic process. The effect of Caledonian granites on such kind ore deposits is considered to be neglectable. However, more than 100 mineralization pots and deposits are recently found around Miaoershan-Yuechengling area, which are hosted in Indosinian and Caledonian granitoids. This report presents three typical mineralization samples in Luchongping, Shengxianyan and Niutangjie with dating results of host granites and ore minerals.

(1) Luchongping deposit is of greisen-quartz vein type W-Cu mine in the middle south of Miaoershan. The host rock is a middle-fine grained biotite granite with zircon date of 396-402 Ma; (2) Shenxianyan develops a greisen type W-Mo deposit in the south Miaoershan. The host rock is also the middle-fine grained biotite granite with zircon date of 433.5 Ma; (3) Niutangjie is a strata-banded scheelite deposit of skarn type in the southwest margin of Yuechengling. This deposit is a relatively large ore deposit in this area, which has been mined tens of years. Its host rock is fine-grained muscovite granite. The zircon dating results is 411-422 Ma. The mineralization age is 421±24 Ma.

Based on the above dating results, it it suggested that the Caledonian mineralization is of great importance in the studied area. It is revealed that the primary host rocks are those middle-fine grained biotite granites and the major ore mineral is scheelite. This mineralization feature has already been identified from the Yanshanian metallegenic process in the central Nanling area, South China, where the host rock is mainly fine-grained muscovite granite and the major ore mineral is wolframite.

Isotope fractionation by alternative nitrogenases and oceanic anoxic events

X. ZHANG[1], D. M. SIGMAN[1] AND A. M. L. KRAEPIEL[1]

[1]Princeton University, Princeton, NJ 08544, USA (*correspondence: xinningz@princeton.edu)

The $^{15}N/^{14}N$ of marine N (quantified by the parameter $\delta^{15}N$) is used to reconstruct the N cycle in the modern and ancient oceans[1]. Anomalously low $\delta^{15}N$ values reaching -5‰ have been measured in sediments from mid-Cretaceous oceanic anoxic events (OAEs)[2,3]. These low values, which fall below that of newly fixed N from N_2 fixation (currently believed to average -1‰), cannot be explained by current isotopic models .

We show that the $\delta^{15}N$ of newly fixed N can be as low as -7‰, depending chiefly on the type of nitrogenase that catalyzes N_2 fixation. Alternative nitrogenases, which contain catalytic vanadium (V) or iron (Fe) rather than molybdenum (Mo), produce fixed N that is significantly lighterin ^{15}N than canonical Mo enzymes (-6‰ for V-, -7‰ for Fe-, -2‰ for Mo-nitrogenase), regardless of N_2 fixer phylogeny or metabolism.

Thus, a N cycle in which alternative nitrogenases account for a large fraction of N_2 fixation provides a straightforward explanation for the extremely low $\delta^{15}N$ of OAE sediments. Low Mo bioavailability combined with high Fe inputs under the euxinic conditions proposed for OAEs may have led to greater reliance on alternative nitrogenases. Results indicate that the role of alternative nitrogenases may have been underestimated in low oxygen/sulfidic environments, and understanding their importance in modern environments is imperative.

Kinetic study of syenite-water interactions at temperatures from 20°C To 435°C And at pressures up to 36mpa

XUETONG ZHANG*, RONGHUA ZHANG AND SHUMIN HU

Laboratory of Geochemical Kinetics, MLR Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources, Chinese Academy of Geological Sciences, Baiwanzhuang Road 26, Beijing 100037, P.R.China (*correspondence: zhangxuetong@cags.ac.cn)

The kinetics experiments of syenite in water are performed in the temperature range of 20-435ºC and at pressures of 23-36MPa using flow through packed bed reactor. The results indicated that the release rates of Si, Al, K and Na of the syenite increase with increasing temperature, and reached maximum values at 400°C. The release rates of Ca, Mg reached maximum values at 200°C. The release rates of Fe reached maximum values at 374°C. Another important impact factor of the reaction between syenite and water is pressure. The release rates of Si did not vary with pressure, as pressure was changed from 23 to 36 MPa. The release rates of K and Al in seynite increase with increasing pressure.

Dissolved metallic elements are abundant in aqueous solutions after water reacted with syenite. The maximum release concentrations and maximum release rates of most metals (Si, Al, K, Na, Fe, Ni, Zn, Cu, Mo, V, Ag, Pb and Ti) are observed at T≥300 °C, Ca, Mg, Mn, Sr and Ba at 200°C. As a result, fluids that have reacted with syenite are metal-rich fluids. The most metals (Si, Ca and ore-forming elements) easily release in to aqueous solutions at 23 MPa. If increasing pressure from 23 to 36 MPa, most molar concentration ratio of metal Mi vs Si, Mi/M_{Si} in the effluent solutions decreases with pressure.

The in situ measurements of electric conductances of the water-rock interaction system at temperature range from 20-435°C, 23-36MPa were performed using the flow system. The in situ measurements of electric conductances combined the kinetic experiments found that the maximum electric conductances are present at 374-390°C, 23-36MPa, and simultaneously the maximum release rates of Si, Al, K are reached at the same temperature range. Geology and geochemistry of basic intrusive rocks in the eastern fault depression of Liaohe Basin

YAN ZHANG,[1] WEIHUA BIAN[1], YULONG HUANG[1], XIAOJIAN YU[1], YOUFENG GAO[2] AND HUAFENG TANG[1]

[1] College of Earth Sciences, Jilin University, China, yan_zhang@jlu.edu.cn[2] Research Center of Palaeontology Stratigraphy, Jilin University, China

Basic intrusive rocks are widely developed in the third member of Shahejie formation in the eastern fault depression of Liaohe Basin. Their heat accelerated source rocks maturity, and themselves can be reservoirs. In fact, lots of oil and gas shows have been found in intrusive rocks in eastern fault depression of Liaohe Basin.

According to core of wells, main lithology in the region is diabase. Samples are chosen for geological and geochemistry investigation. Through rock-mineral identification, diabase mainly consist of plagioclase and pyroxene, some pyroxene are altered into chlorite, a small amout of amphibole, quartz, biotite and alkali feldspar.

The composition of diabase shows that diabase in the eastern fault depression of Liaohe Basin is sodic alkaline series rocks. REE appear to negative anomaly ofδEu, light REE enrichment, obvious crystallization differentiation, crystallization differentiation degree of light REE is higher than heavy REE. Based on the analysis of geological setting and geochemical characteristic, the intrusive rocks might form in the settings of continental intraplate.

The characteristics of fluid inclusion from Ordovician carbonate reserviors in Western Ordos Basin

ZHANG YANLING[1], GUO YANRU[A] AND LIU JUNBANG[3],

[1] Research Institute of Petroleum Exploration & Development,PetroChina, Beijing, 100083, China; zhangyanling07@petrochina.com.cn
[2] Research Institute of Petroleum Exploration & Development,PetroChina, Beijing, 100083, China; gyr2005@petrochina.com.cn
[3] Research Institute of Petroleum Exploration & Development,PetroChina, Beijing, 100083, China; liujunbang@petrochina.com.cn

The study area is located in the western thrust belt region of the Ordos Basin, China. Due to the multi-period tectonic movement and evolution of mechanical mechanism, It resulted in complicated block structure and complicated geological conditions. For western Ordovician reservoir, when were the oil and gas filling accumulation? How many times filling had It experienced? These issues will directly affect effectiveness of the trap and the exploration.

In this study, we respectively carried out samplings of the fluid inclusions in reservoirs of Zhuoxishan group and Kelimoli group Ordovician of QT1, YT1 wells in the Western Basin, made microscopic petrography analysis, homogenization temperature test and microscopic laser Raman microprobe analysis of samples. we analyzed reservoir characteristics of the fluid inclusions of kelimoli and Zhuozishan groups in Ordovician.

There are 4 views: bitumen, hydrocarbon residues, as well as a large number of hydrocarbon fluid inclusions were prevalent in cracks and pores in reservoir of kelimoli group and Zhuozishan group Ordovician which fully shows that oil-gas migration and filling have occurred within the Ordovician reservoirs. Inclusions of microscopic petrography analysis shows 2 issues were prevalent in hydrocarbon filling in Ordovician limestone reservoir. The 1th hydrocarbon inclusions in the Ordovician period were dominated by the dark brown and brown liquid hydrocarbon inclusions, capturing hydrocarbons maturity is relatively low; the 2nd grey-gaseous hydrocarbon inclusions were in the hydrocarbon inclusions, capturing hydrocarbons maturity is relatively high. The first homogenization temperature distribution has a bimodal characteristics of kelimoli group Ordovician;The second homogenization temperature distribution has an asymmetrical single peak, Wide at front and rear is narrow.

Oligocene – Early Miocene North Pacific temperatures based in clumped isotopes in Kamchatka Bivalves

YI GE ZHANG[1]*, HAGIT AFFEK[1], ANTON OLEINIK[2], ZHENGRONG WANG[1] AND PING HU[1]

[1]Department of Geology and Geophysics, Yale University, New Haven, CT 06520-8109
[2]Department of Geosciences, Florida Atlantic University, Boca Raton, FL 33431

The Oligocene through early Miocene was an important transitional interval in the development of the Neogene "Icehouse World". However, very little is known about the details of ocean temperature evolution at that time, particularly in high-latitude areas. We use clumped-isotope based paleotemperature reconstructions derived from the Oligocene - early Miocene shallow water molluscan faunas coupled with the MBT/CBT-based soil temperataure reconstruction and $^{87}Sr/^{86}Sr$ dating to examine North Pacific paleoceanography. Fossil mollusks were collected from the Cape Ugol'nyi section in northwestern Kamchatka Peninsula. Sample minerology and seasonal signals in $\delta^{18}O$ along bivalve growth axis suggest that these samples have not experienced significant diagenetic alterations during burial.

Clumped isotope analyses were applied to 2 modern samples and 16 fossil samples, with $^{87}Sr/^{86}Sr$ ages range from ~32.6 to 19.9 Ma. In the modern samples, clumped isotopes derived growth temperature is 10-12°C, consistent with satellite-based summer temperatures. Fossil samples have a larger temperature variability, between 21°C and 7°C. Both early Oligocene and early Miocene are warm (~16°C), with the coldest temperature (9°C) found in the late Oligocene, slightly lower than the modern growth season temperature at the same location. This late Oligocene cooling event was obtained from a stratigraphic horizon with $^{87}Sr/^{86}Sr$ age of 27.8-29.1 Ma, coinciding with the marine benthic $\delta^{18}O$ positive excursion Oi2b-Oi2c. Organic biomarkers extracted from a rock sample at the same horizon give a MBT/CBT-based soil temperature estimate of 6°C, in support of a prevailing cold temperature both on land and in the ocean.

The colder-than-today temperatures in the late Oligocene is intriguing because the Oligocene world is thought to be warmer, as suggested by lower global benthic $\delta^{18}O$ stack and higher atmospheric CO_2. The dramatic cooling during Oi2b may be a consequence of reorganization of surface circulation patterns in the North Pacific, with the cold North Pacific becoming a major source for bottom-water production during this time interval.

Indonesian mineralization event in the Wulashan District, Northwest China: Evidence of isotopic geochronology

Y.M. ZHANG[1], X.X. GU[1], W.L. YANG[1] AND W.P. ZHU[2]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing 100083, P.R. China (bzzym@163.com)

[2]China Aero Geophysical Survey and Remote Sensing Center for Land and Resources, China

The Wulashan district has a great economic potential for Mo–Au mineralization and attracted wide attentions of geologists. More than thirty ore deposits have been discovered in this region since the late 1980s. Representative deposits mainly include the medium-sized Xishadegai porphyry Mo deposit and the superlarge-sized Hadamengou-Liubagou alkaline-related Mo–Au ore field. Previous opinion of mineralization epoch was Hercynian, however, Indonesian ages have been recognized recently. Re-Os isotopic dating on seven molybdenites from the Xishadegai Mo deposit defines model ages of 223.2-232.6 Ma and an isochron age of 225.4 ± 2.6 Ma, whereas LA-ICP-MS dates on zircon from the Xishadegai host granite yield an age of 245.3 ± 9.6 Ma. Stepwise ^{40}Ar-^{39}Ar dates on K-feldspar of auriferous quartz-K feldspar vein (ores) give a plateau age of 217.9 ± 3.1 Ma in the Liubagou deposit, in accordance with the previously reported ^{40}Ar-^{39}Ar data (239.8 ± 3.0 Ma) for sericite separated from ores in the Hadamengou deposit. Considering that the dating minerals showed clear co-existing textures with ore-stage mineral assemblages, the mineralization process mainly occurred during early Indonesian. In addition, LA-ICP-MS dates on zircon from associated granitoid (Shadegai granite) give an isochron age of 231.4 ± 3.1 Ma. The geochronological data, together with the regional geological setting, suggest that the early Indosinian (231-245 Ma) magmatic activities induced a coeval magmatic hydrothermal mineralization (218-240 Ma) under a post-collisional extensional setting. This magmatism-mineralization event is significantly recorded and should be highly valued in the north margin of the North China Craton.

The research was funded by the National Natural Science Foundation of China under grants of 40930423 and the Specialized Research Fund for the Doctoral Program of Higher Education (SRFDP, 20130022120016).

Superchondritic Mantle Is Partially Depleted MORB Mantle

YOUXUE ZHANG

Department of Earth & Environmental Sci, Univ of Michigan, Ann Arbor, MI 48109-1005, USA, (youxue@umich.edu)

The composition of the bulk silicate Earth (BSE) is often modeled by the "chondritic" model, in which the refractory and lithophile elements such as REEs in BSE are assumed to have chondritic ratios (Jagoutz *et al*., 1979; Sun, 1982; Zindler and Hart, 1986; Allegre *et al*., 1995; McDonough and Sun, 1995; Palme and O'Neill, 2004). Recently, high-precision measurements reveal that ^{142}Nd/^{144}Nd ratios in terrestrial samples are higher than those in chondrites by about 0.2 epsilon units (Boyet and Carlson, 2005, 2006). The results were interpreted to mean that the primordial Sm/Nd ratio in BSE was higher than chondritic ratio, namely superchondritic. Since then, there has been much discussion about the "superchondritic" mantle (Caro *et al*., 2008, Caro and Bourdon, 2010, Campbell and O'Neill, 2012), although the jury is still out (e.g., Huang *et al*., 2013; Gale *et al*., 2013).

If BSE is indeed superchondritic, it is necessary to estimate the SuperChondritic BSE (SC-BSE) composition, to distinguish it from previous BSE composition based on the "chondritic" assumption. The latter is hereafter referred to as chondritic BSE (C-BSE). To estimate SC-BSE composition, isotopic constraints can be converted to the following elemental ratio constraints (Caro and Bourdon, 2010):

$(Sm/Nd)_{SC\text{-}BSE} \approx 1.06(Sm/Nd)_{C\text{-}BSE}$;

$(Lu/Hf)_{SC\text{-}BSE} \approx 1.12(Lu/Hf)_{C\text{-}BSE}$;

$(Rb/Sr)_{SC\text{-}BSE} \approx 0.70(Rb/Sr)_{C\text{-}BSE}$.

The more incompatible elements are depleted in SC-BSE compared to C-BSE, consistent with depletion of the mantle. To quantitative examine whether the SC-BSE is partially depleted MORB mantle (DMM), it is necessary to quantify the incompatible element sequence (Sun and McDonough, 1989): **Rb** > Th > U > La > Ce > **Sr** > **Nd** > *Pm* > **Sm** ≈ **Hf** > Eu > Gd > Tb > Dy > Ho > Er > Tm > Yb > **Lu**. The quanfication is achieved by comparing DMM composition (Salters and Stracke, 2004; Workman and Hart, 2005) with C-BSE composition (McDonough and Sun, 1995) to define the Compatibility Index (CoI) calculated as $\ln(C_{DMM}/C_{C\text{-}BSE})$. It was found that the Sm/Nd, Lu/Hf, and Rb/Sr ratios in SC-BSE over those in C-BSE are well related to the difference in CoI between the numerator element and the denomenator element, implying that SC-BSE can be regarded as partially depleted DMM. The concentrations of other elements in SC-BSE are then obtained. SC-BSE likely formed by some early depletion event in Earth. The complementary subchondritic material might be in D" layer or in the lower crust.

Geochronological and geochemical constaints on sequences of the Cangshuipu group and their implications for the amalgamation between the Yangtze and Cathaysian blocks

YUZHI ZHANG[1], YUEJUN WANG[1]* , HUICHUAN LIU[1] AND YONGFENG CAI[1]

[1] State Key Laboratory of Isotope Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China (*correspondence: yjwang@gig.ac.cn)

This contribution documents a synthesis of geochronological and geochemical analytical data for the Cangshuipu Group, which is composed of the Yinzhuba volcanic agglomerates and Linjiawan conglomerates and represents an angular unconformity between the Lengjiaxi and Banxi Groups in Hunan, South China.

The Yinzhuba volcanic agglomerates are characteristic by high-Mg andesites and dacites, which are enriched in LILEs and depleted in HFSEs and the $\varepsilon_{Nd}(t)$ values ranging from -1.7 to -4.7. They are dated at 824±7 Ma and 822±28 Ma by zircon U-Pb analytical technology, representing the formation age of the Yinzhuba volcanic sequences.

The Linjiawan conglomerates are mainly composed of dacite and rhyolite, without high-Mg component. Most of the samples are dominanted by quartz and plagioclase phenocryst, moinor magnetite, with cryptocrystalline matrix, typical characteristics of felsic volcanic rocks. The youngest zircons from the conglomerates exhibit a weighted mean age of 831±27 Ma, representing the maximum depositional age of the Linjiawan conglomerates.

Integrated with other geological data, the Cangshuipu Group are composed of the the Yinzhuba volcanic agglomerates at the upper part and the Linjiawan conglomerates at the basal part. And the amalgamation of the Yangtze and Cathaysian Blocks along the Jiangnan orogen occurred at ca. 831~822 Ma as a part of an exterior accretionary orogen along the periphery of Rodinia rather than that of the Grenvillian-aged orogenic events.

Building of the Deep Gangdese Arc, South Tibet: Linking granulites, and magmatism and crustal growth in the active continental margin

ZEMING ZHANG, XIN DONG AND HUA XIANG

Institute of Geology, Chinese Academy of Geological Sciences, Beijing 100037, China

The present-day formation of continental crust is generally attributed to magmatic processes in the palte convergence margins and those within intra-plate settings. Therefore, the deep-seated magmatism and metamorphism in active continental margins can provide important clues to understand the formation of the continental crust.

The Gangdese arc along the southern Lhasa terrane is a product of the Mesozoic Andean-type orogeny derived from the northward subduction of the Neo-Tethys. In the Eastern Himalaya, owing to Late Cenozoic rapid uplift and erosion, the high-grade metamorphic Complex is well exposed. Petrological and geochronological studies reveal that the complex experienced intense Paleocene subduction-related magmatism, and almost synchronous granulite-facies metamorphism accompanied by the formation of S-type granites. The subduction-related intrusive rocks show geochemical features typical of continental magmatic arcs. Their zircons yielded the U-Pb ages of 65–56 Ma, and commonly display positive εHf(t) values of -3.0 – +11.7, indicating juvenile source. The syn-intrusion high-grade metamorphism indicates that the plutons were emplaced at the middle to lower crustal depth. The S-type granitoids are characterized by peraluminous nature and contain garnet and muscovite. Their zircons yielded the U-Pb ages of 66–55 Ma, and have distinct but negative εHf(t) values of -18.4 – -6.8. The inherited detrital zircons from the metasedimentary rocks yielded variable U-Pb ages of 2910–235 Ma. The metamorphic zircons from the metaplutonic and metasedimentary rocks yielded ages of 67 Ma–53 Ma. Phase equilibria modeling shows that the granulite-facies metamorphism and partial melting form under the conditions of 9.7–10.2 kbar and 710–810 °C. We argue that the late Mesozoic compressional orogeny resulted in the deep burial of the Mesozoic sedimentary rocks, and that the accretion and loading of voluminous asthenosphere-derived and deep-stated intrusions resulted in the extensive crustal thickening and heating to generate the granulite-facies metamorphism and S-type magmas.

Iron deposits in China: Distribution, types and tectonic setting

ZHAO-CHONG ZHANG[1] AND TONG HOU[1]

[1] State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China (zczhang@cugb.edu.cn)

All types of iron deposits have been recognized in China, but Banded Iron Formations (BIFs), skarn, Kiruna, submarine volcanic-hosted and Ti–Fe–(V) oxide deposits are the most economically imporant. However, the high-grade iron ores are predominantly from skarn, Kiruna and submarine volcanic-hosted types although BIFs occupy 48% of total iron reserves in China. The special feature can be ascribed to prolonged interaction of the Central-Asian, the Circum-Pacific and the Tethys–Himalaya systems or absence of strict cratons due to multiple tectonism. BIFs are mainly distributed in the North China Craton (NCC), and Neoarchean (ca. 2.5 Ga) metamorphic rocks are the most important hosting rocks, which are primarily meta-volcanic rocks and minor meta-sedimentary rocks. The submarine volcanic-hosted iron deposits are widely distributed in orogenic belts, mostly located in western China, including Tianshan, Beishan, Altay, and western margin of Yangtze Craton (YC). They formed in a considerable age range, from Proterozoic to Mesozoic, but with more than 70% formed in Late Paleozoic, and mostly related to subduction settings. Ti–Fe–(V) oxide deposits are predominantly associated with ca. 260 Ma mafic-ultramafic layered intrusions in the Panxi region, central part of the Emeishan large igneous province and Mesoproterozoic (ca. 1.8 Ga) anorthosite complex in the Chengde region of NCC. The Panxi region is the most important V and Ti ore cluster in the world, and has been genetically attributed to mantle plume event. In ontrast, the Mesoproterozoic anorthosite complex have been considered to be related to rift event in NCC. The skarn iron deposits are widespread, concentrally the uplift areas at the margin of down-faulted basins of Eastern China. The hosting rocks are mainly Early Cretaceous intermediate-felsic intrusions, which lithospheric extension following subduction of paleo-Pacific plate. Comparably, the Kiruna iron deposits, commonly associated with dioritic subvolcanic intrusions, are present in the Cretaceous terrigenous volcanic basins in the northern margin of YC, and they were formed in the same tectonic setting with those skarn iron deposits in the eastern China.

Lipid biomarkers in the sediments of Lake El Junco and their possible sources

ZHAOHUI ZHANG[1], PIERRE METZGER[2] AND JULIAN P. SACHS[3]

1. School of Earth Sciences and Engineering, Nanjing University, 22 Hankou Road, Nanjing, 210093, China
2. Université Pierre et Marie Curie, BioEMco, CNRS UMR 7618, 4 Place Jussieu, Paris, France3. University of Washington, School of Oceanography, Box 355351, Seattle, WA 98195, USA

Lipid biomarkers contained in suspended particles and sediments from Lake El Junco, Galápagos demonstrate for the first time that all three races of the alga *Botryococcus braunii* (A, B & L) have co-existed intermittently during the last 460 years. *Cis* and *trans* C_{25}-C_{31} *n*-alkadienes and a C_{29} triene indicated race A, a series of $C_{34}H_{58}$ botryococcenes indicated race B, and a $C_{40}H_{78}$ hydrocarbon, *trans, trans*-lycopadiene indicated race L (Zhang *et al*., 2007) .

Other biomarkers include C_{25} HBIs from diatoms, long-chain alkenols, diols and a triol, keto-ols, hydroxy acids and keto acids. Saturated and monounsaturated long chain diols from C_{30} to C_{36} had terminal hydroxyl groups and hydroxyl groups between the ω16 and ω20 positions. Vicinal diols with hydroxyl groups at ω9 and ω10 were likely from the floating fern *Azolla*. C_{30} to C_{36} keto-ols, mid-chain hydroxy and keto acids had mid-chain functional groups at similar positions to the diols, suggesting common origins. The predominance of ω20-hydroxy acids and diols, together with 20,21- dihydroxy-nonacosanoic acid is indicative of an *Azolla* source, while ω16 and ω18 hydroxy acids and diols imply a microalgal source.

Long chain (C_{30}–C_{36}) *n*-chloroalkanes and chloroalkenes have a chlorine atom at the terminal position. The *cis* and *trans* alkenyl chlorides have double bonds near the middle of the hydrocarbon chain. The lipid chain lengths and the positions of functional groups imply a structural relationship between chloroalkenes and some alkenols, diols and (or) hydroxy acids that most likely derive from algae.

A rapid crater detection method for statistics of crater on planetary surface

Z.B. ZHANG*, W. ZUO, G.H. ZHANG AND L. GENG

National Astronomical Observatories, Chinese Academy of Sciences, Beijing, China (*correspondence: zzbin@nao.cas.cn)

Impact craters are key geomorphological structures formed by the collision of a meteoroid, asteroid or comet with a planetary surface. They can accumulate over a long period of subsequent bombardment or slow surface erosion, which provide us with the relative age of the surface unit and more information on the planetary surface geology and its evolution. As statistics of crater form the basis for geologic stratigraphy, planetary surface chronology and so on, automatic crater measurement, detection and derived crater size frequency distribution become a routine activity in planetary science.

There are many publications devoted to various techniques of crater detection, but the efficiency is quite a problem when much of these methods come to high resolution planetary image due to the extremely high computational complexity. In our study, we employ a method derived from face detection technique, which significantly improve the efficiency while remaining a robust performance in two ways: 1) using several Haar-like features to model some basic crater characteristics, such as crater rim, illumination mode, which can be computed very rapidly on a so-called integral image; 2)cascade of classifiers trained by a AdaBoost algorithm [1], where simpler classifiers in previous stages are used to reject the majority of negative targets before more complex classifiers are called upon to make further more complex computation on a promising positive target.

Geochemistry and tectonic significace of Neopaleozoic Granitoid in Alxa Area, Inner Mongolia, China

HONG ZHAO [1,2]*, BEN DANG [1,2], BIN LIANG[1], LU-JUN LIN[1] AND JING REN[1]

[1] School of Earth Sciences and Resources, Chang'an University, Xi'an 710054, China;

[2] Key Laboratory of Western China's Mineral Resources and Geological Engineering, Xi' an 710054, China (*correspondence: xacdzh@126.com)

Alxa area located in the southern edge of Central Asia Orogenic Belt and the western margin of the North China plate. The study area has numerous granite, particularly in the Neopaleozoic (Carboniferous-Permian) granites are most widely distributed, which Contain much abundant information of tectonic evolution. Carboniferous-Permian is the key period to the formation and evolution of Central Asian Orogenic Belt, Moreover, Carboniferous-Permian are the most important periods for large-scale mineralization.At the present, the research of granites in geological age, petrogenesis and tectonic setting are very absent. Based on analyzing of geochronology, petrology and geochemical of granitoid in the study area, the Carboniferous-Permian petrogenesis and tectonic setting have been discussed. The results indicate that these granitoid are dominated by monzonitic granite, granodiorite, tonalite, quartz diorite and diorite, which emplaced in Carboniferous, later Early Permian and Late Permian. The samples of Carboniferous are metaluminous, calc-alkalic, I-type granitites, but the samples of Permian are metaluminous to peraluminous, calc-alkalic to alkalic, I-A type granites. These granitoid show not only the characteristics of within plate setting, but also that of subduction zone. And their arc-like geochemical features (such as Nb-Ta depletion) should have been inherited from the protoliths(pre-existing island arc igneous rocks), rather than inflection of their tectonic setting when they formed and contaminationed by old crust materials during magma ascending and emplacement. It is concluded by comprehensive analysis that Carboniferous-Permian granitoid of the study area are formed in post-collision tectonic setting, and are the product of the tectonic transition from compression to intraplate extension.

Geochronolgy and geochemistry of two triassic A-Type granites in South China: Implication for petrogenesis and Indosinian transtentional extension

ZHAO KUI-DONG, JIANG SHAO-YONG AND PU WEI

State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing Universtiy, Jiangsu, 210093, P. R. China

We carried out a detailed study of LA-ICP-MS zircon U-Pb dating, major and trace element compositions, and Sr-Nd-Hf isotope geochemistry of the Caijiang granite in Jiangxi Province and the Gaoxi granite in Fujian Province, South China. Both of the Caijiang and Gaoxi granites were emplaced at Triassic with ages of about 228-230 Ma. Textural examination of the two granites reveals that biotite crystals occur along the boundary of euhedral plagioclase and quartz, which imply the primary magma could be anhydrous. The two granites have high total alkalis contents (Na_2O+K_2O=7.81-12.15%), high field strength element contents (e.g. Zr=240-458ppm, Y=16.8-38.0ppm, Nb=13.5-33.8ppm and Zr+Nb+Ce+Y=382-604ppm), Ga/Al ratios (10000×Ga/Al=2.41-3.53). The Caijiang granite has relatively high $(^{87}Sr/^{86}Sr)_i$ ratios (0.71288-0.72009), low $\varepsilon_{Nd}(t)$ values (-9.9--9.3) and low zircon $\varepsilon_{Hf}(t)$ values (peak value of -7.5). Whole-rock Nd isotopic model ages and zircon Hf isotopic model ages mostly vary from 1.65 to 1.80 Ga. The Gaoxi granite has also high $(^{87}Sr/^{86}Sr)_i$ ratios (0.71252-0.71356), low $\varepsilon_{Nd}(t)$ values (-13.8) and zircon $\varepsilon_{Hf}(t)$ values (peak value of -12.0). Nd isotopic model ages and zircon Hf isotopic model ages mostly vary from 1.95 to 2.10 Ga. The two granites might be derived from partial melting of pre-Cambrian crustal rocks that had been granulitized during an earlier thermal event. Our study of the Caijiang and Gaoxi granites, together with previous studies on Triassic alkaline syenites (Tieshan and Yangfang) in Fujian Province and A-type granite (Wengshan) in Zhejiang Province in South China, define a wide transtensional tectonic environment in the Cathaysia Block at lease lasting from 254 to 225 Ma. When combined with all the available studies for the Indosinian granites and tectonic evolutions in South China, we suggest that the formation of A-type granites was related to the local NE-trending extensional faults which were caused by collision between the South China Block and the Indochina Block or the North China Block.

CO_2 absorption and precipitation in $MgCl_2$-NH_3•H_2O Solutions: Relevance to CO_2 sequestration

LIANG ZHAO [1], CHEN ZHU [1], SIJIA DONG[1] AND H. HENRY TENG[1,2]

[1] Department of Earth Sciences, Key Laboratory of Surficial Geochemistry, Ministry of Education; Nanjing University, Nanjing, 210093, China; [2] Department of Chemistry, The George Washington University, Washington, DC, 20052, USA**Email: (zhaoliang@nju.edu.cn)**

Mineral sequestration of CO_2 is one of the safer options in the portfolio of available CCS stratagems. To optimize the absorption of CO_2, numerous approaches, such as MEA/DEA/Ammonia based post combustion scrubbing and O_2/CO_2 recycle combustion, were tested. These methods, however, did not address the costly issue of carbon storage. Following a newly proposed pH-swing CO_2 mineralization process (Kodama, *et al*., 2008) which showed capability of capturing and storing CO_2 simultaneously, we investigated the rate and kinetic controlling factors for CO_2 absorption and mineralization in $MgCl_2$-NH_3 solutions. Experiments were carried out at 298 K in solutions of different compositions (0.05~0.2molL^{-1} $MgCl_2$) to measure the reaction kinetics using a wetted wall column setup similar to those reported in Pacheco (1998) and Victor (2011). Conditions were maintained where brucite precipitation was not allowed, and magnesium concentration was analyzed by ICP-AES with interval sampling. The absorption solution was then cycled between the column and a jacked glass reactor with its pH maintained constant and the transmittance at 546 nm monitored in real-time. Preliminary results indicate that initial concentration of Mg in solution has little effect on CO_2 absorption. Although absorption rate increased slightly over time with increasing ammonia addition, pH appeared to be the dominant controlling factor. The higher the solution pH was, the faster the absorption rate increased. Upon reaching saturation, nesquehonite precipitated as indicated by the decreased laser transmittance, leading to rapid addition of aqueous ammonia. However, precipitation of nesquehonite unexpectedly showed little influence on CO_2 absorption, suggesting that the interaction between aqueous CO_2 and OH^- or ammonium ions in liquid film may be the rate limit step during the absorption process, further indicating that the gas-liquid interaction barrier should be treated seriously in order to optimize CO_2 capture efficiency. Due to the low gas-liquid reaction area (0.005 m^2L^{-1}), extended time period (2~3 hours) was needed to dissolve enough CO_2 for nesquehonite to reach supersaturation. Measured typical absorption rates under these experimental conditions are between 0.000668 mol $s^{-1}m^{-2}$ (pH=8.74, pCO_2= 15495Pa, 298K) and 0.001997 mol $s^{-1}m^{-2}$ (pH=9.16, pCO_2= 15403Pa, 298K).

Reservoir characteristics of volcanic rocks in the Northeast of Junggar Basin, China

ZHAO XIA[1]*, ZHANG XIAOFENG[2], GAO XIAOHUI[1], HOU LIANHUA[1] AND WEI YANZHAO[1]

[1] RIPED, Petrochina, Beijing, China (*correspondence: zhaox601@petrochina.com.cn)[2] CCAD Petrochina, Beijing, China.

The Junggar basin is a part of central Asia orogenic belt and the Carboniferous is an important transition period of ocean to continent in the basin. Based on the comprehensive analysis of petroleum geology and exploration practice, it is proved that Carboniferous is a primary petroleum exploration domain of this basin, and volcanic rocks are the main reservoir. This paper studied reserved space type and controlling factors of volcanic reservoir, it is basic research for further study of favorable reservoir distribution.

The reservoir characteristics including lithologic characteristics, lithofacies characteristics, pore type, reservoir physical property of the Carboniferous volcanic rocks in the northeast of Junggar basin were analyzed by observing core and thin slice with microscope and scanning electron microscope. The reservoir accumulation type and the main affecting factors of reservoir physical property were also analyzed.

Volcanic cone and weathering crust are two important factors of the distribution of favorable volcanic reservoir. Volcanic reservoirs have three types reservoir space of primary porosity, secondary porosity and fracture in Junggar basin. The reservoir property is controlled by volcanic rock lithology and lithofacies as well as post-reformation function, weathering leaching and structural stress are all beneficial for reservoir property. The cone volcanic mechanism has controlled function to lithology, lithofacies, weathering leaching and corrosion reformation, besides, fracture is well developed in the center of volcanic mechanism.

The cone volcanic mechanism has significant controlling effect for the favorable volcanic reservoir distribution. This conclusion has been confirmed by the gas & oil exploration findings in the Junggar basin. So the cone volcanic mechanism is the important direction for research of the volcanic gas & oil reservoir in this basin.

Tight oil in the continuous sandbody in the A'er Sag of the Erlian Basin, China

XIANZHENG ZHAO[1], LIUPING ZHANG[2], FENGMING JIN[1], QUAN WANG[1] AND QIANG LUO[1]

[1]Huabei Oilfield Company, PetroChina, Renqiu 062552, China[2]Key Laboratory of Petroleum Resource, Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O. Box 9825, Beijing 100029, China

Since the discovery of the A'er sag with the area of 650 km^2 in the Erlian Basin of Inner Mongolia in 2006, more than one billion barrels of oil reserves has been found. In the cetral part of this sag, there is a large syncline without well-developed fault systems except areas along the sag margins. The largest oil pool was discovered in this syncline, within a continuous tight sandbody at the top of the lower part in the first member of the Cretaceous Tengge'er Formation (K_1bt^{1L}). In the early stage of exploration, two wells revealed this sandbody with an average porosity of 11.2% and permeability of 40.3 mD in the east slope of this sag. Compaction and carbonate cementation are the main factors reducing porosity and permeability of the sandbody. The sedimentary facies study based on core, logging and seismic data indicated that the sandbody at the top of K_1bt^{1L} is continuous in the main parts of the sag. This continuous sandbody with the buried depths of 1300-2300 m and dip angles of 0-11° is sandwiched by two sets of petroleum source beds. Oil-source correlation of biomarkers illustrates that the oil came mainly from the underlain source bed. We inferred that the porosity, permeability and dip angle of the sandbody decrease from the east slope to the center of the sag and there is a relatively large oil pool without downdip water in the sag-centered area. Twelve wells were then drilled step by step in the sag-centered area. All of them have produced commercial oil after acid-fracturing and revealed a continuous oil pool. This work demonstrated that economically viable oil exists in continuous tight sandbodies with low dip angles even in central areas of small faulted basins if there are source kitchens.

Tectonic control of volcanism in Potassic Volcanic Belt in NE China

ZHAO YONGWEI[1] AND FAN QICHEN[2]

[1] Key Laboratory of Active Tectonics and Volcano□ Institute of Geology, CEA, Beijing 100029, China, email: (zilongzhao1981@yahoo.com.cn)[2] Key Laboratory of Active Tectonics and Volcano□ Institute of Geology, CEA, Beijing 100029, China, email: (fqc@ies.ac.cn)

Quaternary potassic volcanic rocks are found in several dispersed potassic volcanic fields in Heilongjiang province in NE China, including volcanic fields of Xiaogulihe, Keluo, Wudalianchi, and Erkeshan, composing a North-South trending potassic volcanic belt(PVB) in northeastern China. The volcanic belt extends for about 318km. All the volcanic fields in the PVB show a 160 degree linear arrangement with a separation distance of about 50km. Most of volcanoes in PVB are in Wudalianchi and Keluo. Cones in Keluo show 58 degree linear arrangement, and cones in Wudalianchi show 41 degree linear arrangement. Previous volcanism mode proposed that preexisting NE trending rifts controlled the distribution of cones in this belt, while the preexisting NNW-NS trending deep rift may control the upwelling of basaltic magma. Specially, Nen river fault, a pre-existing NNE trending normal fault on the surface and changes into a low angle detachment fault in the deep crust, are thought controlled the volcanism. However, this mode cannot explain the decoupled formation time and emplacement location between the fault or rift and the volcanic activity. The Nen river fault are formed in Mesozoic and Cenozoic, but the belt show apparent volcanism since middle Pleistocene. The volcanic belt are emplaced 100km far from the detected Nen river fault.

In the context of NE and NNE compression with dextral shearing in NE China in the present day, we propose that the coeval NS trending slip-strike deformation in lithosphere take an important part in controlling the volcanism, resulting in en echelon arrangement of NNE and NNE trending fractures in the deep lithosphere. Although the fractures are short in the lateral, they are vertical deep and can reach to mantle lithosphere, resulting in decompression and melting of magma source rocks. The magma ascends through these fractures, forming violent volcanic activity since middle Pleistocene.

Non-linear rates of fluid-mineral reaction in metamorphic fluid flow

ZHIHONG ZHAO AND ALASDAIR SKELTON

Department of Geological Sciences, Bolin Centre for Climate Research, Stockholm University, Sweden

It is well known that fluid-mineral reactions record the infiltration histories of fluid tracers (such as H_2O, CO_2 or CH_4) through the Earth's crust [1]. Early studies mainly employed linear reaction rate laws to model metamorphic fluid flow [e.g. 2-4]. Although some studies indicate that a linear reaction rate law is appropriate near equilibrium [e.g. 5, 6], Lasaga [7] concluded that reaction kinetics are likely to be non-linear in most fluid-mineral reactions. Therefore, the main objective of this study is to investigate the effects of non-linear reaction rate laws on metamorphic fluid flow parameterisations obtained using inversing modeling.

The transport model applied to metamorphic fluid flow with non-linear reaction kinetics was numerically solved and incorporated into a general inverse modeling framework based on the differential evolution method. The flux, duration of metamorphic fluid flow and rates of fluid-mineral reactions were constrained for four metamorphic sills with varying Péclet (Pe) and Damköhler (Nd) numbers in the SW Scottish Highlands. It is verified that the linear reaction rate law yields reliable first order estimates of time-averaged and time-integrated fluxes and the duration of metamorphic fluid flow. However, with increasing reaction order, the apparent reaction rate constant changed considerably. The magnitude of this effect is shown to be dependent on the combination of Pe and Nd. Our estimates of apparent reaction rate constants for non-linear reaction kinetics are in agreement with experimentally-based kinetic data based on linear reaction rate laws, but much larger than other measurements based on natural systems [6]. This indicates that accurate quantification of the order of fluid-mineral reactions is important if reaction rates are to be calculated.

Permeability of the continental crust – Experimental study and insight from the petrological and seismological data

A.V. ZHARIKOV[1,3]*, M.V. RODKIN[2] AND V.M. VITOVTOVA[3]

[1]Institute of Geology of Ore Deposits, RAS, Moscow, Russia (*correspondence: vil@igem.ru)
[2]Institute of Earthquake Prediction Theory and Mathematical Geophysics, RAS, Moscow, Russia
[3]Institute of the Experimental Mineralogy, RAS, Chernogolovka, Russia

Permeability is one of the key properties governing the fluid regime, mass and heat transfer in the continental crust. The results of the laboratory experiments show that the values of rock permeability can change by decimal orders due to the effect of high temperature and pressure. In general it was found that permeability of the continental crust rocks decreases with depth. In contrast, it increases at PT-parameters of progressive metamorphic transformations.

The results of petrologic studies reveal both the marks of long periods of very low permeability and events of high permeability.

The conception when long periods of low permeability are coupled with short periods of high permeability is supported by seismic data. The burst of hypocenters clouds to the Earth surface and/or their systematical movement up to the Earth surface are found using the data of the earthquakes localization. Identification of such events with front of fluid propagation allows to estimate high permeability values as ($>10^{-13}$ m^2).

However, the mechanism of permeability increase in low and mid-crust is unclear. Moreover, we suggest that some episodes of the crust permeability increase could be related to the positive feedbacks, between microcrack initiation due to rock metamorphic transformations resulting in increase of permeability and active deep fluid infiltration which in its turn accelerates the rate of metamorphic transformations.

Iron and sulfur speciation of sliding mud from Xieliupo Landslide in South Gansu Province, NW China

GUODONG ZHENG[1], SHOUYUN LIANG[1,2] AND NI ZHANG[2]

[1] Key Lab Petrol Resources Res, Inst Geol and Geophy, CAS, Lanzhou 730000, China
[2] Key Lab Mech Disast Envir W China (Lanzhou Uni), Mini Edu, Lanzhou 730000, China

Gray and/or black mud materials are often observed within many slipping zones of landslide, especially those landslides in large scale and long history of action, which are always known as sliding mud and considered as a key factor corresponding to landslide development and even the slipping actions. The sliding mud is attractive to many researchers and engineers working on landslide protection. However, there is still a large space to understand the formation mechanism and accumulation process of sliding mud. There are several famous landslides with thick layers of sliding mud in the Longnan district, south part of Gansu province, NW China. In order to check the possible relationship between the sliding mud properties and landslide development, 13 samples were collected from one vertical profile cross the sliding surface of the Xieliupo Landslide and analyzed for their mineral and chemical compositions as well as chemical species of iron and sulfur using XRD, XRF, and Mössbauer spectroscopy and K-edge XANES, respectively. The mineral and chemical composition of the samples showed the sliding mud was different from both the upward debris rock and beneath bedrock, being agreed well with their surface properties such as color and partial sizes. Mössbauer spectroscopy revealed a clear variation of iron species between the sliding mud and the debris and bed rocks. The sliding muds contain much more ferrous iron than the sliding (the debris) rocks and the bedrocks, indicating a relatively stronger reducing condition within the slip zone. In addition, the sliding mud in darker colors near the sliding surface showed much more ferrous iron than the sliding mud in light gray color relatively far from the sliding surface. K-edge XANES also revealed the vertical variation of sulfur species that was similar to iron speciation, the slip zone was enriched with reduced sulfur species and the debris and bed rocks contain relatively much more oxic sulfur species. All data of mineral and chemical composition, and also iron and sulfur species revealed a relatively reducing condition in the slip zone. Such a reducing condition could be favored for the gray and/or black mud materials precipitated and accumulated, and furthermore resulted the weakness of sliding zone along with the process of landslide development.

Numerical interpretation of laboratory and field data showing CO_2-induced groundwater changes

LIANGE ZHENG[1], RUTH M. TINNACHER[1], CHARULEKA VARADHARAJAN[1], NICOLAS F. SPYCHER[1], MARCO BIANCHI[1], PETER S. NICO[1], JENS T. BIRKHOLZER[1], ROBERT C. TRAUTZ[2] AND JOHN D. PUGH[3]

[2] Electric Power Research Institute (EPRI), Palo Alto, California 94304

[3] Southern Company Services, Birmingham, Alabama 35291

The potential impact of leaking CO_2 on shallow groundwater quality is one of the issues related to the risk assessment of CO_2 geological sequestration. Here we discuss CO_2-induced geochemical changes in a shallow sandy aquifer at ~ 50 m depth, focusing on the mobilization of trace elements and the underlying chemical mechanisms revealed by a controlled-release field experiment, laboratory tests and numerical modeling. The field test involved a dipole system in which the groundwater was pumped from one well, saturated with CO_2 at the pressure corresponding to the hydraulic pressure of the aquifer, and then re-injected into the same aquifer using a second well. Groundwater samples for chemical analyses were collected in four monitoring wells. A series of lab-scale sequential leaching experiments were also carried out with synthetic groundwater solutions at different pH and CO_2 concentrations. Upon introduction of CO_2, a rapid increase in concentrations of some trace elements (e.g. Ba, Sr) was observed in both the field and lab tests; the lab experiments suggest that metal release was primarily driven by the decrease in groundwater pH from ~8 to ~5. Geochemical modeling was employed to interpret laboratory and field results and gain insights on the mechanisms potentially involved in the CO_2-induced mobilization of trace elements. The increase in concentrations of alkali and alkaline earth metals can be explained by the dissolution of trace amounts of calcite and subsequent calcium-driven cation exchange reactions. Modeling also indicates that the magnitude and extent of metal mobilization depends not only on metal-mineral associations and sediment pH buffering characteristics, but also on the residence time of CO_2-impacted groundwater relative to the rates of metal-release reactions, with the effect of slow reactions only noticeable under conditions of slow groundwater velocity.

Navigating troubled waters

YAN ZHENG[1,2]

[1]Queens College, City University of New York, Flushing, NY 11367, (yan.zheng@qc.cuny.edu)[2]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY 10964, (yzheng@ldeo.columbia.edu)

In September 2000, the General Assembly adopted the United Nations Millennium Declaration. Under Article III development and poverty eradication, item 19 states “we resolve further to halve, by the year 2015, …to halve the proportion of people who are unable to reach or to afford safe drinking water.” In 2012, the Joint Monitoring Program (JMP) of the World Health Organization and UNICEF reported that the drinking water target of the Millennium Development Goal has been achieved. In 2010, the proportion of the global population still using unimproved sources is estimated at only 11 per cent, which is less than half of the 24 per cent estimated for 1990. However, this is based on a proxy indicator for safe drinking water: an improved water source defined as those that, by the nature of their construction, are protected from outside contamination, particularly fecal matter. It is increasingly clear that this proxy indicator is inadequate beause naturally occurring chemicals such as arsenic and fluoride that are harmful to humans can render the water unsafe. In addition, poor sanitation frequently leads to fecal contamination of shallow groundwater. Here, occurrences of arsenic in groundwaters in Bangladesh, China and United States are used as examples to illustrate research by hydrogeochemists that have been impactful on safe drinking water supply. A critical contribution made by hydrogeochemists over the last decade was the evaluation of the sustainability of the low arsenic groundwater sources as a safer drinking water source.

Bangladesh is the only country in the world when access to improved water source is reported by the JMP, a correction has been made for arsenic occurrence in groundwater. Based on a national drinking water quality survey conducted in 2009, access to improved water sources containing less than 50 μg/L As was estimated to be 81%. The vast majority of improved water sources in rural Bangladesh is a private, shallow tube well. The rapidly developing China saw the access to improved water increasing from 67% in 1990 to 91% in 2010, with 2/3 of the improved sources being water piped on premises. However, millions of rural Chinese are still exposed to As and F. Likewise, more than 10 million rural Americans relying on private well waters are at risk of exposure to > 10 μg/L As. Much work remain to identify alternative water sources to protect human health.

Zircon U-Pb geochronology of hosting rhyolites and mineralized quartz veins at the Tiemurt Pb-Zn-Cu Deposit: Insights for ore genesis

YI ZHENG[1,2]*, LI ZHANG[2] AND YAN-JING CHEN[3]

[1]Dept. of Earth Sciences, Sun Yat-sen University, Guangzhou, China, 510275. (*correspondence: zhengyi@gig.ac.cn)
[2]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China, 510640[3]Key Laboratory of Crust and Orogen Evolution, Peking University, Beijing 100871, China

This contribution reports the finding of zircon-bearing rhyolites and mineralized quartz veins at the Tiemurt deposit, which occurs as veins controlled by NW-extending structures in the Devonian volcanic-sedimentary basin of the Altay orogenic belt Xinjiang, China.

The zircons separated from two hosting meta-rhyolites samples yield weighted mean $^{206}Pb/^{238}U$ ages of 403.1±5.1 Ma and 393.3±4.9 Ma, respectively. Integrated with their automorphic crystal, the lack of fluid inclusions, high Th/U and high ∑REE values, the $^{206}Pb/^{238}U$ ages ranging from 393Ma to 403Ma can be interpreted as the eruption age of the volcanic rocks in the Early Devonian.

The four mineralized quartz samples yield complicated zircon U-Pb ages. At least two age peaks are recognized, ca. 400Ma and ca. 220Ma. The age of ca.400Ma may be the joining age of the hosting volcanics. The zircons with ca. 220Ma age contain abundant hydrothermal fluid inclusions and coincide with the Ar-Ar ages of biotite in the polymetallic quartz veins. Therefore, the age ca. 220 Ma can represent that of the flowing metamorphism fluids migrations.

In term of the geological characteristics, structural, geochemical and geochronological characteristics of the zircon, the Tiemurt Pb-Zn-Cu deposit may be an example of epigenetic orogenic Pb-Zn+Cu systems formed in the settings of intercontinental collision at the Early Trassic of ca.220Ma.

Phosphorus-bearing pyroxenes in flood basalts with native iron, Khungtukun, Polar Siberia, Russia

L.M. ZHITOVA[1,2]*, V.V. SHARYGIN[1,2], V.S. KAMENETSKY[3], N.S. KARMANOV[1] AND E.N. NIGMATULINA[1]

[1]V.S. Sobolev Institute of Geology and Mineralogy SD RAS, Novosibirsk 630090, Russia (*correspondence: zhitova@igm.nsc.ru)[2]Novosibirsk State University, Novosibirsk 630090, Russia[3]University of Tasmania, Hobart TAS 7001, Australia

Native iron from the Khungtukun trap intrusion contains melt inclusions, some of which show silicate-silicate liquid immiscibility [1, 2]. We studied in detail composition of the immiscible inclusions (0.2-1 mm). The silicate melts in them represent the aluminosilicate (60-77 wt% SiO_2) and silica-poor, Fe-Ti-Ca-P-rich (in wt%: SiO_2 15-46; FeO 15-22; TiO_2 2-7; CaO 11-27; P_2O_5 5-30) conjugate liquids; one of components mainly occurs as globules in other (Fig. 1).

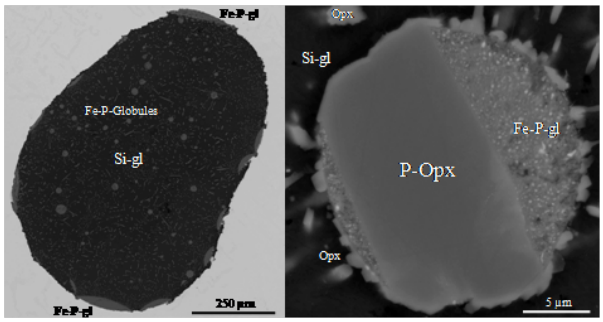

Figure 1: BSE images of an immiscible inclusion in native iron and one of Si-poor, Fe-Ti-Ca-P-rich globules in it.

In contrast with Si-rich part, the Si-poor globules contain ortho- and clinopyroxene with high P_2O_5. Composition of orthopyroxene is (in wt%): SiO_2 42.2-44.7; P_2O_5 3.3-4.3 (0.1-0.15 apfu); TiO_2 2.5-3.2; Al_2O_3 4.7-6.0; FeO 20.7-22.7; MnO 0.8-0.9; MgO 15.3-18.1; CaO 4.8-6.1; Na_2O 0.05-0.2; Mg# 55-61. Clinopyroxene is richer in P_2O_5 (up to 13 wt%) and has formula $Na_{0.05}Ca_{0.55}Fe_{0.7}Mg_{0.6}Ti_{0.1}(Al_{0.4}P_{0.4}Si_{1.2})O_6$. In general, Si-poor and P-rich nature of an immiscible liquid and reduced conditions were favourable to incorporation of P in the tetrahedral site in the structures of pyroxenes.

Carbon-13 and Uranothorianite age dating in the Botogol Alkaline Massif Graphites (Eastern Sayan, Russia)

S.M.ZHMODIK[1]*, A.G.MIRONOV[2], N.S.KARMANOV[1], V.A.PONOMARCHUK[1], D.K.BELYANIN[2], I.S.KIRICHENKO[1] AND A.S. ZHMODIK[1]

[1]Institute of Geology and Mineralogy SB RAS, Pr. Koptug, 3, Novosibirsk, 630090, Russia (*zhmodik@igm.nsc.ru)

Botogol alkali pyroxene and nepheline syenite rock massif located in the Altai-Sayan region in the southwestern part of the Siberian platform's folded framing. Alkaline rocks intruded through carbonate-shale strata of Proterozoic age. Graphite is widespread in alkaline massif rocks and has a form of stockworks, veins and small veinlets as well as disseminated occurences. There are several types of graphite identified: a massive, tree-like, droplet-like, fishscale-like. Pure graphite containing massive graphite areas with high concentrations of U (up 0.4%) and Th (2%), in the forms of uranothorianite and thorite. There are "crystals" with unusual decay structures founded. Cubic "crystals" (1-3 mm), consisting of graphite filled with concentrically zoned uranothorianite spherulites (30-50 microns). The center of the spherulite consist of a cubic uranothorianite crystal (5-8 microns), surrounded by splitted radially grown crystals of uranothorianite. Mineral occurences of this type may indicate a joint transport of U, Th and C, in the form of a volatile compounds. The uranothorianites age was determined based on results of chemical analysis using scanning electron microscope MIRA 3 equipped with INCA Wave 500 microanalysis system and defined as 510±13 - 519 ± 10 Ma. This age dating is in the good agreement with the results obtained for the Botogol massif using Rb-Sr isochron (492 ± 11 Ma) and also K-Ar (biotite, 521 and 492 Ma) [1]. These age data indicates that graphite and uranothorianite were formed during the magmatic stage. The isotopic values of carbon in the graphite associated with uranothorianite (in the mikrosamples of ~ 1 mg) were equal to -8.1/-5.7 and pure graphite values are -5.1/-10.7 permille. These data indicate mantle source of carbon. Botogol alkaline massif origination corresponds to the time of Neoproterozoic plume magmatism development (520-460 Ma).

This work was supported by the IP 89 and RFBR 12-05-01164; 12-05-31324.

Geological characteristics and mineralization stages in the Yaojialing Zinc-Gold ore deposit, Tongling Ore District, Anhui

G.X. ZHONG, T.F. ZHOU* AND Y. FAN

School of Resources and Environmental Engineering, Hefei University of Technology, Hefei 230009, China (*correspondence: tfzhou@hfut.edu.cn)

The Yaojialing deposit is located in the Tongling ore district, Middle-Lower Yangtze River Belt, East China. The deposit has measured reserves of 1.2 Mt of Zn with an average grade of 3.64%, 32 t of Au (5.02g/t Au), and Pb,Cu and Ag as by-products[1]. The main orebodies, whose shapes mainly include lenticular or bedded, situate along the contact zone with Early Permian limestone of the Qixia Formation and Late Jurassic granodiorite porphyry intrusion or occur inside limestone xenoliths entrapped within the intrusion. The mainly encountered ore minerals include sphalerite, chalcopyrite, galena, pyrite, gold and magnetite, gangue minerals are represented by calcite, quartz, garnet, diopside, vesuvianite, fluorite. Euhedral to anhedral granular texture, metasomatic texture and disseminated-massive structure are considered to be the dominating ore texture and structure. Hydrothermal alteration is well developed and is primarily composed of skarnization, K-feldspar alteration, silicification, carbonatization, sericitization, clayzation. Needs to be emphasized that silicification and carbonatization are closely related to mineralization. The mineralization process of it can be divided into three stages and from early to late they are: (1) skarn stage, which witnesses filling of garnet and diopside in the contact zone or inside the intrusion; (2) oxidization stage, which is the magnetite stage; (3) Quartz-sulfide-carbonate stage, in which most economic Zn and Au mineralization is formed.

Conclusion: From what has been discussed above, it could be inferred that Yaojialing ore deposit is a skarn-type ore deposit.

Zircon U–Pb geochronology and Sr–Nd–Hf isotopic geochemistry of the Yuanzhuding Granitoid Porphyry, Shi-Hang Zone, South China: Implications for petrogenesis and Cu–Mo mineralization

LIFENG ZHONG[1], JIE LI[2], TOUPING PENG[2] AND BIN XIA[3]

[1]Key Laboratory of Marginal Sea Geology, South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou 510301, China

[3]School of Marine Sciences, Sun Yat-sen University, Guangzhou 510006, China

The Shi-Hang zone is an important NE–SW-trending Mesozoic magmatic belt in southern China that is dominated by granites with high εNd(t) values and young TDM model ages. Here, we present zircon U–Pb ages, major and trace element whole-rock compositions, and Sr–Nd–Hf isotope data for the Yuanzhuding porphyritic granitoids, located in the southwest of the Shi-Hang zone, and use these data to determine the origin of this granitoid and its relationship to Cu–Mo mineralization. Zircon U–Pb dating indicates that these granitoids were emplaced in the Later Jurassic (~158 Ma), and they have initial 87Sr/86Sr ratios of 0.70941–0.71398, εNd(t) values of –3.15 to –2.02, and in situ zircon εHf(t) values of +1.71 to +6.17. Whole-rock geochemical and isotopic data suggest that these granitoids were formed by partial melting of Proterozoic metasedimentary basement within the lower crust, with additional input at relatively high temperatures (~790°C) from basaltic magmas. These magmatic systems are highly oxidized. This process played a crucial role in the development of Cu–Mo mineralization within the Yuanzhuding that is genetically related to these granites. The discovery of the Yuanzhuding deposit indicates that the Shi-Hang zone should be considered prospective for mineral exploration for porphyry Cu–Mo deposits.

Role of material properties on Tio_2 nanoparticle agglomeration

DONGXU ZHOU[1,2], ARTURO A. KELLER[1,2]ZHAOXIA JI[2], DARREN R DUNPHY[3] AND JEFFREY BRINKER[3,4]

[3] University of New Mexico Center for Micro-Engineered Materials and the Dept. of Chemical Engineering[4]Sandia National Laboratory, New Mexico

Emerging nanomaterials are being manufactured with varying particle sizes, morphologies, and crystal structures in the pursuit of achieving outstanding functional properties. These variations in these key material properties of nanoparticles may affect their environmental fate and transport. To date, few studies have investigated this important aspect of nanoparticles' environmental behavior. In this study, the agglomeration kinetics of ten different TiO_2 nanoparticles (5 anatase and 5 rutile each with varying size) was systematically evaluated. Our results show that, as particle size increases, the surface charge of both anatase and rutile TiO_2 nanoparticles shifts toward a more negative value, and, accordingly, the point of zero charge shifts toward a lower value. The colloidal stability of anatase sphere samples agreed well with DLVO theoretical predictions, where an increase in particle size led to a higher energy barrier and therefore greater critical coagulation concentration. In contrast, the critical coagulation concentration of rutile rod samples correlated positively with the specific surface area, i.e., samples with higher specific surface area exhibited higher stability. Finally, due to the large innate negative surface charge of all the TiO_2 samples at the pH value (pH=8) tested, the addition of natural organic matter was observed to have minimal effect on TiO_2 agglomeration kinetics, except for the smallest rutile rods that showed decreased stability in the presence of natural organic matter.

Mineral characteristics of Tungsten-bearing granite in the Jiangnan orogenic belt: A case study of the Qingyang pluton

JIE ZHOU[1,2]*, YAO-HUI JIANG[1] AND WEIYA, GE[2]

[1] State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Jiangsu, 210093, P.R. China(*correspondence: zhoujie0517@sina.com)

South China is the most important tungsten-concentrated zone in China and even in the world, famous for the Nanling Tungsten ore belt. A series of Tungsten deposits, related with the late Yangshanian granites, have been recently discovered in the Jiangnan orogen, northeastern Qinzhou-Hangzhou metallogenic belt. The Qingyang composite granite is one of a tungsten-bearing granites in the east of Jiangnan orogenic belt. It crops out over an area of approximatedly 750 km^2. The Baizhangya tungsten-molybdenum deposit was found near this pluton. New LA-ICPMS zircon U-Pb dating suggests that the crystallization age of the Qingyang body is 145.5±0.5Ma. The Qingyang pluton has zircon, apatite, fluorite, titanite, rutile, ilmeite, limonite, anatase and magnetite. The main rock-forming minerals including amphibole, biotite, plagioclase were analysed chemical compositions. The biotite is characterized by high MgO and low FeO contents with high Mg/(Mg+Fe) ratios (0.58-0.61), plotted in the crust-mantle zone. The oxygen fugacity calculated by biotite compositions is above Ni-NiO (NNO). The amphiboles are magnesiohornblende. The pressure of the granite estimated by Al-in-hornblende barometer is 1.79~2.50kbar. An amphibole-plagioclase thermometry and a semiquantitative hornblende thermometer yield a forming temperature of ~714ºC. The plagioclase is oligoclase (An~29.5%). The mineral characteristics of Qingyang pluton are differenct from the Nanling tungsten-bearing S-type granites. The Jiangnan tungsten ore belt is NE-trending and distinct from the Nanling belt in terms of metallogenic age, tungsten-bearing granite type etc. and require further study.

Molecular simulation study of rectorite

Rectorite is a special kind of clay mineral, consisting of illite layer and smectite layer in a regular order [1]. Rectorite and organo-intercalated rectorite can be applied in many fields. In this study, we use molecular simulations to investigate the interlayer properties of pristine and organo-rectorites. First, we use grand canonical monte carlo and molecular dynamics methods to investigate the hydration properties of rectorite with the comparison with montmorillonite. The results indicate that rectorite shows a similar swelling pattern as montmorillonite but a different interlayer cation distribution [2]. Second, we employ classical molecular dynamic simulations to study the microscopic interlayer properties of $HDTMA^+$-intercalated rectorites with and without water at different $HDTMA^+$ loading levels [4]. According to our simulations of organo rectorite, we find that as the loading level changes, different configurations of $HDTMA^+$ occur. And water addition leads little influence on the mobility of Na^+, but decreases the mobility of alkyl chains. Also we observe the behavious of anions in system exceeding 1 CEC.

Natural gas genetic types in the Northern Margin of the Qaidam Basin, NW China

S. X. ZHOU[1],S. H. GONG[12], J. LI[12], D.L.FU[12] AND H. K. ZHANG[12]

[1] Key Laboratory of Petroleum Resources Research,Institute of Geology and Geophysics, CAS, Lanzhou, 730000 (sxzhou@lzb.ac.cn)

[2] Graduate University of CAS, Beijing, 1000049

There is abundant natural gas resources present in the northern margin of the Qaidamu Basin. Based on chemical composition and carbon isotopic values of natural gases, natural gases can be divided into three different origins. Natural gases in Lenghu and Nabaxian structural belt are typical coal-derived gases with $\delta^{13}C_1$ ranging from -25.3‰ to -31.0.‰ and $\delta^{13}C_2$ values range from -26.1‰ to -28.2‰. Lower Jurassic mudstone in Yikeyawuru Sag was regarded as main source rocks for these natural gases.

Natural gases in the Mabei and Mahai have different geochemical characteristics, their $\delta^{13}C_1$ range from -34.3 to -40.9‰, $\delta^{13}C_2$ values range from -25.0‰ to -27.7‰. It is showed that natural gases in these structural belt are generated probably from Middle Jurassic source rocks.

Special geochemical characteristics for natural gases in the Hulusan, Yahu, Yikeyawuru , Eboliang, Nabei and Jiansan structural belt have been observed. The methane carbon isotope compositions range from -18.1‰ to -22.6‰, and $\delta^{13}C_2$ values range from -17.6‰ to -23.0‰; some gases show carbon isotopic reversal ($\delta^{13}C1>\delta^{13}C2$), this natural gas type maybe related to deep Lower Jurassic or Carboniferous source rocks at high levels of thermal maturity, which is new natural gas exploration field in Qaidam Basin.

Source And Geochemical Characteristics Of Carbon And Nitrogen In Poyang Lake Sediments

ZHOU WENBIN [1, 2], HUANG DAN[1, 2], LOU QIAN [1, 2], LI LIYANG[1, 2] AND HU CHUNHUA [1, 2]*

[1] School of Environmental and Chemical Engineering, Nanchang University, Nanchang, 330031, China (*correspondence: nchuchunhua@163.com)

[2] Key Laboratory of Lake Poyang Environment and Resource Utilization, Ministry of Education, Nanchang University, Nanchang, 330029, China

A certain proportion of organic carbon (OC) deposited onto the sediments will be mineralized and the remainder will be buried over geological timescales. The OC that reaches the lake sediment surface will partly be mineralized to CO_2 or CH_4 by heterotrophic microorganisms [1]. Lake is a rather considerable carbon source and sensitively responding to regional and global climate changes [2]. In this paper, we study geochemical proxies of total organic carbon (TOC), N, $\delta^{13}C$ and $\delta^{15}N$ in lake sediments of Poyang Lake to estimate its source of organic matter in 2012.

Results show that the organic matters source in sediments were mainly autochthonous in Poyang Lake, of which the terrigenous were less, especially in the south. Before 1970s, sediment organic matters were less affected by human activities, mainly from the deposition of aquatic plants in the northern Poyang Lake. From 1970s in the last century to the present, the main source were constant, however, there were more and more terrigenous. As for in the southern, deposition of aquatic plants were the main source before 1960s. From 1960s to1980s in the last century, organic matters were mainly derived from soil erosion and death of algae. From 1970s to the present, the source of organic matters were autochthonous and terrigenous. In addition, the terrestrial source of nitrogen were increasing.

LOMU Geochemical Signiture Of The Cenozoic Ultrapotassic Volcanic Rocks In NE China: Implications For A Relic Ancient Mantle Segment Beneath The Eastern CAOB

XIN-HUA ZHOU[1]*, JI-FENG YING[1], YANG SUN[1] AND JI'AN SHAO[2]

[1] Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (*correspondence: xhzhou@mail.igcas.ac.cn)

[2] College of Earth & Space Sciences, Peking University, Beijing 100871, China

In the past several decades, the Sr-Nd-Pb isotopic features of oceanic basalts have been elegantly described as mixtures of depleted mantle (DMM) and a spectrum of enriched endmember components, such as EM I, EM II and HIMU. The applications of these mantle endmembers in the petrogenesis of basalts in continental tectonic setting have revealed that the EM I signiture is invaribaly related with the cratonic subcontinental lithsophere. In this study, we reported a suite of Pleistocene basic, high potassic to ultrapostassic volcanic rocks from NE China. These rocks are characterized with modal leucite and have SiO_2=42-45%, K_2O=9-11% with K_2O/Na_2O as high as 4. Geochemial data show these rocks are highly enriched in REE with extremely fractionated LREE/HREE ratios (55-70), LILE are also enriched withou apparent HFSE depletion. Though their $^{87}Sr/^{86}Sr$=0.70558-0.70580 and εNd= -5 - -12 demonstrate a typical EM I affinity, it is more accurate to define it as a LOMU signature in terms of Pb isotopes, as these rocks exhibit very low $^{206}Pb/^{204}Pb$ (16.34 – 16.45), $^{207}Pb/^{204}Pb$ (15.27-15.39) which is comparable with other leucite-bearing potassic volanic rocks found elsewhere in the world, such as Leucite Hill and Smoky Butte in North America. We proposed that these potassic rocks were derived from an ancient (Arhcean?) phlogopite-rich garnet facies subcontinental lithopheric mantle which is decoupled from the overlying crust that was formed since Neoproterozoic accompanying with the evolution of CAOB. As two Archean cratons, namely the Aldan Shield and North China cratons exist on the northern and southern side of the CAOB, respectively, it is speculate that the mantle source feeding these potassic rocks is likely a relic cratonic segment of either Aldan or North China cratons.

Petrogenesis of the Early Paleoproterozoic Garnet-Bearing Monzonite in the Lushan Area, Southern Margin of the North China Craton

YANYAN ZHOU[1]*, TAIPING ZHAO[2] AND MINGGUO ZHAI[1]

[1] State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (correspondence: llylz_b3@163.com)

[2] Key Laboratory of Mineralogy and Metallogeny, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China

LA-ICP-MS zircon U-Pb dating indicate that the garnet-bearing monzonite, exposed in the Lushan area, southern margin of the North China Craton (NCC), formed at 2134±18Ma. Electron microprobe analyses reveal that the magmatic garnets are homogeneous without substantial chemical zoning. They contain 61.94 to 66.39 mol% almandine, 18.60 to 23.40 mol% grossular, 10.06 to 15.11 mol% pyrope and 1.09 to 4.32 mol% spessartine. They have high CaO and low MnO contents with high Fe/Mn ratios, comparable to those crystallized from high pressure basaltic granulite, but different from those in I, S and A type granites. Garnets have strongly LREE-depleted chondrite-normalized REE patterns with limited HREE variation. The MREE show equally partition between garnet and zircon, whereas HREE prefer zircon to garnet, suggesting crystallizing temperatures at 800 to 850°C. Moreover, in terms of the trace element distribution coefficients between zircon and garnet, our data well agree with experimental data at 800℃ and granulite-facies samples. Considering strongly various HREE/LREE, and low MgO, we envisage that the host melt of garnet might be ever modified by granitic melts.

The monzonite contains SiO_2 from 57.0 to 58.9 wt% with high K_2O+Na_2O contents (7.46 to 9.14 wt%), consistent with intermediate shoshonite series. The calculated magmatic zircon ε_{Hf} (t) values are mostly positive (+0.02 to +4.10) with T_{DM}^C from 2492 to 2388 Ma, except four analyses give negative ε_{Hf} (t) values (-0.97 to -0.98) with T_{DM}^C from 2508 to 2496 Ma, suggesting that they derived from a depleted mantle-derived basaltic source with contamination of older granitic components. On the basis of their high Zr (598 to 926 ppm) and Zr/Y ratios (17 to 21), and enrichments of Rb, Cs, Ba, Hf, Th, U and REE, similar to OIB, we suggest that they have formed in an intra-plate setting, related to lithospheric thinning and asthenospheric mantle upwelling, further constraining that the NCC probably underwent a rifting event during the Paleoproterozoic (2.2 to 1.95 Ga).

Modelling gas-fluid-mineral interactions in a CO_2 injection analogue site with noble gases

Z. ZHOU[1]*, M.J. BICKLE[2], A. GALY[2], H.J. CHAPMAN[2], N.KAMPMAN[2], B. DUBACQ[2], M. WIGLEY[2], O. WARR[1], T. SIRIKITPUTTISAK[1] P. HANNAH[3] AND C.J. BALLENTINE[1]

[1]University of Manchester, M13 9PL, UK (*correspondence: zheng.zhou@manchester.ac.uk)
[2]Department of Earth Sciences, University of Cambridge, UK[3]Full-Spectrum Monitoring, LLC, USA

We carried out an artificial noble gas tracer injection experiment in a CO_2 EOR project in a depleted oil field in the USA. In this experiment, 2 STP litres of ^3He and 2 STP litres of ^{129}Xe were injected together with the EOR CO_2 stream. Samples were collected both from the CO_2 injector and 4 monitoring wells before, during and after injection.

Natural background of $^3He/^4He$ and $^{129}Xe/^{132}Xe$ ratios in fluid sampled from this field are 0.07Ra and 0.98 respectively. Measured spiked CO_2 stream has $^3He/^4He$ and $^{129}Xe/^{132}Xe$ ratios of 49.0Ra and 23.94 respectively. Tracers were detected in monitoring wells both updip and downdip of the injector in a short period after the tracer injection. This is completely different from a simple PHREEQC model prediction that is based on one-dimensional tracer dispersion in a dual porosity column. It reflects the complexity of the reservoir system. Although tracers are present in monitoring wells, the peak tracer ratios are at a level that is orders of magnitude lower than the injected ratios. Simple mass balance calculation assuming phase equilibrium between gas and groundwater shows that water volume involved in this system is 3-4 orders of magnitude higher than the gas volume. This is not reasonable and groundwater alone cannot account for observed tracer concentrations and ratios. Other processes that could affect tracers present in monitoring wells include multi-phase interaction, dissolution into oil, diffusion and adsorption into immobile reservoir porosity, etc. In this presentation, we discuss models that take into account these processes in this complex reservoir system to explain observed data. This work demonstrates huge potential of exploiting artificial noble gases in crustal fluid studies.

Silicon isotopes as a new tool to identify the main cause of the field-lab apparent discrepancy of feldspar dissolution rates

CHEN ZHU[1], CHAO WANG[1] AND GEORG, R.B.[2]

[1]Indiana University, Bloomington, Indiana, USA; [2] Water Quality Centre, Trent University, Canada. (*correspondence: chenzhu@indiana.edu)

In 2004, Zhu, Blum, and Veblen proposed a new hypothesis for explaining the apparent discrepancy between lab-measured and field-estimated feldspar dissolution rates [1]. They identified the coupling of dissolution and precipitation reactions as the main contributor to the apparent discrepancy. In the intervening nine years, we have tested this hypothesis by conducting a series of batch experiments at elevated temperatures [2-5] and numerical simulations of coupled dissolution and precipitation reactions [4, 6]. The results show that taking into account of reaction coupling is able to reduce the gap between the field and lab rates by about two orders of magnitude at elevated temperatures of 200-300 ^oC [4]. A chapter in volume 70 of *Review in Mineralogy and Geochemistry* [7] has summarized the historical development of the topic and its role in the overall picture of water-rock interaction.

A field study of Si isotopes of groundwater, feldspars, and secondary clays demonstrated the promise of Si isotopes as a new tool to unravel the coupled reactions [8]. We are now employing the new tool for laboratory experiments. A methodology paper on using Si isotopes was just published [9]. This presentation will discuss results of new experimental data, as well as the potentials and pitfalls of this new tool.

Tracing the sources of sulfur in Beijing rain water with stable isotopes

GUANGXU ZHU[1], QINGJUN GUO[1,*], HARALD STRAUSS[2] AND MARC PETERS[1]

[1] Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing 100101, China (*correspondence: guoqj@igsnrr.ac.cn)

[2]Westfälische Wilhelms-Universität Münster, Corrensstr. 24, 8149 Münster, Germany

Acid rain is one of the prominent atmospheric environmental problems in Beijing, China. The stable isotopes of sulfur were used as environmental tracers of sulfur in rain by tracing its sources and identifying rain sulfur turnover rates. 74 rainwater samples in Beijing were collected between August 2010 and December 2012 and the concentrations of SO_4^{2-}, the sulfur isotopic composition and pH were analyzed. The results showed that mean pH in precipitation was 6.42, the acid rain frequency in 2011was 26.9% compared to 13.6% in 2012. The concentrations of SO_4^{2-} ranged from 2.23-82.36 mg/L with a weighted average of 22.44 mg/L, whereas the average value of $\delta^{34}S$ was 4.8 ‰ within range of 2.1‰ and 12.8‰. A pronounced seasonal pattern is discernible for $\delta^{34}S$ in precipitation with data for the winter (7.0‰) > autumn (5.7‰) > summer (3.9‰) ≈ spring (3.8‰), SO_4^{2-} concentration in summer was significantly lower than in the other seasons. $\delta^{34}S$ indicates that the sources of sulfur in rain water include bioorganic sulfur, anthropogenic sulfur (coal combustion) and sulfur from sea spray. Anthropogenic sulfur contributes the majority to the sulfur in rainwater, especially in winter and autumn. For several rainstorms sulfur dominantly originated from sea spray. Results provided important information about the sulfur sources in rain which will help to decrease acid rain and improve air quality in Beijing.

Research On The Super-Long Life Of Deep Carbonate Oil Reservoir

GUANGYOU ZHU[1], SCHUICHANG ZHANG[1] AND JIN SU[1]

[1] PetroChina, Research Institute of Petroleum Exploration and Development, Beijing 100083, (huguangyou@petrochina.com.cn)

Reservoir's destroy is a universal phenomenon and more than one half of the reservoirs are formed later than Oligocene Epoch, which average age is 35 Ma and the average live age is 55 Ma (Macgregor, 1996). As for the ancestral marine basin of China, Palaeozoic marine strata experienced multicycle movements, reservoirs are reformed and destroyed seriously, and there mainly be secondary reservoir. Recently, large ancient deep carbonate reservoirs generated in 290-250 Ma ago have been discovered in the north of Tarim basin. This discovery not only changed the reservoir toplimit age (95Ma) but also brought great belief in exploring ancient reservoir.

The reservoirs distributed in 5500-7200m, and reservoir is Ordovician carbonate, and cap rock is upper Ordovician finely carbonate and mudstone. The oil came from middle-upper Ordovician hydrocarbon source rock in late Permian. Based on hydrocarbon generation history, fluid inclusion, burial history, authigenic Illite K-Ar aging, trap formation and evolution process and so on, the reservoirs formed during 290-250 Ma and were conserved with depth increasing.

For Tarim basin, late Permian is an important generating and expelling hydrocarbon period. Since the Triassic, Ordovician oil reservoirs preserved had been in the process of increasing buried depth with increasing thick cap rock, and the location and form of Ordovician trap are always the same. With depth more than 7000m and reservoir temperature more than 160 °C, the crude oil hasn't been cracked by now, so the zone more deeper is predicted still filled with oil.

Gold tube thermal simulation experiments show that oil cracking depth of Tarim basin is about 7500m and peaked in 9000-9500m combining the compensation effect of the low geothermal gradient and late quickly buried process of Tarim basin. The reservoir temperature of oil cracking is higher than 210°C, and liquid oil can be exist above 9000m. Therefore, the ancient oil reservoirs discovery brings great belief in searching for native marine oil reservoir in complex structure area of Tarim basin, believing the exploring depth can be expanded to 9000m.

The Isotopic Composition Of Selenium In Chinese Coals

JIAN-MING ZHU[1,2]*, THOMAS M. JOHNSON[2]*, LIANG LIANG[1] XIANG-LI WANG[2], HAI-BO QIN[1] AND ZUO-YING YIN[1]

[1]State Key Lab. of Environmental Geochemistry, Inst. of Geochemistry, CAS, Guiyang, 550002, China. (zhujianming@vip.gyig.ac.cn) (*present author)
[2]Department of Geology, University of Illinois at Urbana-Champaign, Urbana, 61801, USA.(tmjohnsn@illinois.edu)

Selenium generally occurs in relatively high abundance in coals, black shales and other organic-rich rocks. Coal mining, combustion and weathering are the important pollution source in China, which released a large of Se into the environment, increasing its concentration in the air, soils, water and plants, and in some areas of China, Se from coal combustion poses human health concerns. So comprehensive studies on Se isotopes in Chinese coals are very important to understand Se biogeochemical cycling and its geochemical behavior in surface environment[1].

Here, using HG (hydride generator)-MC-ICP-MS[2] and a ^{74}Se-^{77}Se double spike technique to achieve high precision, we determined Se isotopic compositions of Chinese coals from the different coal fields and geological ages. The $\delta^{82/76}$Se values ranged from -4.01‰ to 4.75‰ in our samples already analyzed. The overall range of $\delta^{82/76}$Se was 8.76‰, indicating Se isotopic variation occurs in a relatively moderate range compared to most shales. Systematic differences in Se isotopic composition between high sulfur and low sulfur(Total S<1%) Chinese coals were not observed.

However, the Se isotopic composition of coals from different geological ages are different. The average $\delta^{82/76}$Se values of Chinese coals formed in Tertiary, Jurassic-Triassic, and Permian-Carboniferous Period are 2.10±0.74‰, -0.07±0.68‰, and 1.50±0.25‰, respectively. The difference in $\delta^{82/76}$Se values may be related to their original precursor plant speices, or further reflect the paleoclimate change, continent weathering situation and depositional plaeoenvironment. Additionally, our results also provide some hope that Se isotopes may be used to trace atmospheric Se sources in the different regions of China.

Geochemistry of Huashan A-Type Granitoid Complex, South China, and its geotectonic significance

ZHU JINCHU

Department of Earth Sciences, Nanjing University, Nanjing 210093, CHINA (jczhu@nju.edu.cn)

The Huashan A-type granitoid complex in NE Guangxi Province, South China, with an exposure of more than 500 km^2 in area consists of three granitoid bodies: The Huashan main body biotite granite batholith, the Niumiao diorite stock in the SE periphery, and the Tong'an quartz monzonite granite stock in the W periphery. This complex is 160~163 Ma in emplacement age, acidic to intermediate in composition. The mafic enclaves with mingling feature are frequently seen. This complex is characterized by high contents of alkalis (especially K) and enrichment in LILE (Rb, K, Ba, Pb, etc.) and HFSE (Th, U, REE, Y, Nb, Ta, Zr, Hf etc.). The whole rock I_{Sr} values are between 0.70472 ~ 0.70714, εNd(t) values between -0.37 ~ -3.21, and $\varepsilon Hf(t)$ values of zircons between -2.8 ~ +2.1. These geochemical data indicate an A type feature and significant involvement of mantle materials. Combining the regional geological and geochemical data, we suggest that strong mixing of mantle-derived and crust-derived magmas under an intense crustal extension and thinning environment during the Mid-Late Jurassic period might be the major mechanism for generating the A-type Huashan granitoid complex.

Microbial carbonate precipitation under high alkaline condition and its implications in concrete restoration

TINGTING ZHU[1], CARLOS PAULO[1] AND MARIA DITTRICH[1]*

[1]University of Toronto Scarborough, 1265 Military Trail, Toronto, ON, M1C 1A4, Canada (*correspondence: mdittrich@utsc.utoronto.ca)

Microbial carbonate precipitation (MCP) has been demonstrated to have a potential in constructional restoration. The repair of concrete by MCP requires microorganisms that can survive high alkaline conditions in the cracks. Although heterotrophic organisms showed promising results in concrete restoration, they generate contamination (e.g., NH_4^+) to the environment. This study aims to examine the potential of phototrophic microorganisms for MCP in the cracks of concrete. Among the several autophototrophic strains, PCC8806 showed the highest rate of biomineralization [1]. However, it is unknown whether they can survive under high alkaline conditions and impact MCP.

In this study, carbonate precipitation by PCC8806 under high alkaline conditions has been investigated. Calcium chloride (50 mM) was added to an initial solution, which was prepared from concrete mix by adjusting the pH to 11.7. Ten ml of washed cells, with a concentration of 3.53×10^9 cells/ml, was inoculated into solution. Another experimental set without bacteria was monitored as control. Samples were taken at the starting point, and after 1h, 2h, 3h, 6h, 18h and 24h to determine the solution composition by atomic adsorption spectroscopy (AAS), and to observe morphology of the precipitates by optical and scanning electron microscopy (SEM), and Atomic Force microscopy. The precipitates were examined by X-ray diffractometry and Raman spectroscopy.

After 24 hours of reaction, the pH dropped 0.5 unit in control and 1 unit with PCC8806. In the presence of PCC8806, the calcium concentration decreased by 5 mM/L by the end of the experiment, while there was no change in control. As it has been confirmed by SEM, a large amount of calcium carbonates with diverse morphologies were formed, some of which were attached to cells. AFM images and Raman spectra indicated that the calcium carbonates were mostly calcites. Our study showed that PCC8806 can survive high alkaline conditions in concrete cracks and strongly impact MCP compared to the abiotic experiments.

Mg and Fe isotope constraints on the genesis of Bayan Obo ore deposits, Inner Mongolia, China

X. K. ZHU, J. SUN AND S. Z. LI

Laboratory of Isotope Geology, MLR, Institute of Geology,CAGS, Beijing, 100037, PR China (XIANGKUN@CAGS.AC.CN)

The giant polymetallic Bayan Obo REE-Nb-Fe ore deposit is the largest REE deposit in the world. Its origin, however, remains controversial. A number of genetic models have been proposed, including sedimentary origin, magmatic origin, hydrothermal origin or origin with multiple processes. Mg and Fe isotope compositions of H8 Dolomite (the ore-bearing bed), carbonatite dykes nearby, mesoproterzoic sedimentary carbonate and micrite from Sailinhudong have been systematically investigated to constrain the genesis of Bayan Obo deposit. The results show that $\delta^{26}Mg_{-DSM3}$ of the H8 dolomite varies from -1.13‰~-0.10‰, with average δ^{26}Mg-DSM3 of -0.53‰, which is closer to those of igneous rocks, but much heavier than micrite carbonate rocks (its δ^{26}Mg ranges from -1.99‰ to -1.93‰). The Fe isotope compositions of the deposit are rather homogeneous with an average in δ^{56}Fe values of -0.03‰, which are very different to those of Precambrian sedimentary Fe ores, but similar to those of igneous rocks.

Overall both Mg and Fe compositions are inconsistent with either sedimentary or hydrothermal origin, but consistent with an igneous genesis.

Discussion on the characteristics and influence factors of specific surfaces in argillaceous source rocks

XIAOJUN ZHU[1], JINGONG CAI[1]*, GUOQI SONG[2] AND JUNFENG JI[3]

[1] State Key Laboratory of Marine Geology, Tongji University, Shanghai 200092, China (*correspondence: jgcai@tongji.edu.cn) [2] Shengli Oilfield Company, SINOPEC, Dongying 257015, China

[3] State Key Laboratory of Surficial Geochemistry, Nanjing University, Nanjing 210093, China

Samples of argillaceous source rocks were taken at different depth in well S of Dongying Sag (Bohai Basin), and also separated the clay fractions (<2μm) to measure the specific surface areas (SSAs) by using nitrogen adsorption method (BET) and ethylene glycol monoethyl ether method (EGME), as well as performing the X-ray diffraction for mineral compositions determination, for discussing the characteristics and influence factors of specific surfaces in argillaceous source rocks. The analysis results show that a) the specific surfaces of argillaceous source rock consist of inner surface and external surface, and clay minerals (smectite in particular) have great contributions to the inner and external surface area in source rocks, however non-clay minerals basically only have external surface, b) the influences of diagenesis to minerals etc. make the evolution of SSAs in burial depth have episodic characteristics, which is much more obviously in the inner surface area in particular, meanwhile there is a strong inhibition for SSAs (especially the inner surface) when the content of carbonate minerals is more than 40%, and it exists a threshold of carbonate minerals content (20~40%) that makes the external surface area stable, c) the inner and external surface in source rocks are more abundant in argillaceous siltstone whose external surface area is large, and the SSAs of mudstone (mainly inner surface) is bigger than the sandstone (chiefly external surface).

According to the difference between inner surface and external surface in argillaceous source rocks, the analyses give the results that the specific surfaces of argillaceous source rocks are influenced by the factors of rock types, mineral compositions and diagenesis, etc., and it is of great significance for the research of organic matter and hydrocarbon occurrence and petroleum exploration and exploitation in argillaceous source rocks, especially should be concerned in the research of unconventional petroleum.

Mineralogy and elemental geochemistry of coal in Southeast Chongqing, Southwest China

ZHU ZHENGJIE[12] AND XIANG XIAOJUN[123]

[1]Chongqing Key Laboratory of Exogenic Mineralization and Mine Environment, Chongqing Institute of Geology and Mineral Resources, Chongqing 400042, China;

[2]Chongqing Research Center of State Key Laboratory of Coal Resources and Safe Mining, Chongqing 400042, China

E-Mail: (zhuzhjie@163.com)

The coal-bearing stratum in the southeast Chongqing coalfield is the Wujiaping Formation (P_3w, Late Permian age). Mineralogy and elemental geochemistry of coal in this area were investigated by using inductively coupled plasma mass spectrometry (ICP-MS) and X-ray diffraction (XRD) techniques. The results showed that minerals in the coal are characterized by dominant clay minerals and pyrite, with the minor calcite, quartz and anatase. Compared with the average concentration of the China coal, the element Zr and rare Earth element (REE) in Southeast Chongqing coal is enriched, with the average content of 678.15μg/g and 413.95μg/g, respectively, approaching the industrial grade of the weathering deposit of Zr and REE. Besides these two elements, concentrations of Li, Sc, Ga are also higher than that in the China and the world coal. However, the element Nb, Ta is depleted, which may be attributed to the lack of tonstein in the coal seam. The model of REE in southeast Chongqing is enriched in LREE, with the LREE/HREE ratio between 1.9 and 7.91. Otherwise, the REE model also showed the negative Eu anomaly, the slightly negative Ce anomaly, similar with that of the Emeishan basalt. Valuable elements Zr, REE are concentrated in southeast Chongqing coal, which would have the potential economic value, and be deserved to research in future.

Garnet and spinel in the Upper Mantle: Results from thermodynamic modeling in fertile and depleted compositions

L. ZIBERNA*[1,3], S. KLEMME[2] AND P. NIMIS[3]

[1]Bayerisches Geoinstitut, Universität Bayreuth, Germany, (correspondence: luca.ziberna@uni-bayreuth.de)
[2]Institut für Mineralogie, Universität Münster, Germany, (stephan.klemme@uni-muenster.de)[3]Dipartimento di Geoscienze, Università di Padova, Italy, (paolo.nimis@unipd.it)

Spinel–garnet relations in the upper mantle have long been investigated from different perspectives, by means of petrological studies on natural samples (orogenic massifs, xenoliths, diamonds), high-P-T experiments, thermodynamic calculations, and geophysical observations. Here we report a refined thermodynamic model that allows one to predict phase relations and mineral compositions in a wide range of realistic mantle compositions [1]. The generated phase diagrams show that the garnet+spinel stability field is always broad at low temperatures and progressively narrows with increasing T. In lithospheric sections with hot geotherms, garnet coexists with spinel across an interval of 10–15 km, at ca. 50–70 km depths. In colder, cratonic, lithospheric sections, the width of the garnet–spinel transition strongly depends on bulk composition: in fertile mantle, spinel can coexist with garnet to about 120 km depth, while in a strongly depleted harzburgitic mantle spinel is stable to over 180 km depth. These results are in agreement with the observed extension of the Hales gradient zone (a seismic impedance increase in the mantle that is usually attributed to the spinel-to-garnet transition) in various geodynamic settings. The model predicts that formation of chromian spinel inclusions in diamonds is restricted to pressures between 4.0 and 6.0 GPa. The calculated modes of spinel decrease rapidly to less than 1 vol% when garnet enters the equilibrium assemblage, hence spinel grains can be easily overlooked during the petrographical characterization of small mantle xenoliths. The very Cr-rich nature of many spinels from xenoliths and diamonds from cratonic settings may simply be a consequence of their low modes in high-P assemblages and does not require ultra-depleted compositions. The model also shows that large Ca and Cr variations in lherzolitic garnets in equilibrium with spinel can be explained by variations of pressure and temperature along a continental geotherm and do not necessarily imply variations of bulk composition.

Factors controlling the distribution of Neodymium isotopes and REEs in tropical atlantic seawater

M. ZIERINGER[1], M. FRANK[1]* AND E. HATHORNE[1]

[1]GEOMAR Helmholtz Centre for Ocean Research Kiel, Wischhofstrasse 1-3, 24148 Kiel, Germany (*mfrank@geomar.de)

Neodymium (Nd) isotopes and rare earth element (REE) patterns are used as tracers of present day ocean circulation and to fingerprint source materials. We present full water column Nd isotopic compositions and dissolved REE distributions in seawater of the tropical Atlantic Ocean. Samples were collected during the GEOTRACES expedition A11 (R/V Meteor) from Las Palmas (Canary Islands) to Port of Spain (Trinidad and Tobago).

Highly variable REE concentrations and associated REE patterns in surface waters reflect different oceanic provinces and prominent local source provenances, such as volcanic islands and dust particles of continental origin. Generally, concentrations in the eastern basin, in particular in the vicinity of the Canary Islands and off the coast of NW Africa, are higher than in the western basin. In the area of the Canary Islands shale-normalized REE patterns are characterized by a strong increase in concentrations of the heavy REEs relative to the light REEs as a consequence of exchange with the volcanic rocks, while further south comparatively flat REE patterns indicate dust dissolution.

Nd concentrations in surface waters range between a minimum of 14 pmol/kg in low salinity waters (< 33.6 psu) originating from the Amazon river and a broad maximum off NW Africa reflecting the dissolution of Saharan dust. This is also reflected in the dissolved Nd isotope compositions, which range from ε_{Nd} = - 12.7 to - 8.4. The most radiogenic values were measured between Tenerife and Grand Canary and near the Amazon river mouth while the least radiogenic ones are found in the open ocean surface waters off NW Africa, and in the uppermost 100 m of the western basin.

We also present full water column profiles including all major water masses present in the tropical Atlantic Ocean. Southern Ocean sourced intermediate and deep waters are clearly distinct in the eastern and western basins and allow the estimation of mixing proportions between different endmember water masses.

Additional insight into natural $^{185}Re/^{187}Re$ of various materials

A. ZIMMERMAN[1]*, H. STEIN[1,2] AND J. HANNAH[1,2]

[1]AIRIE Program, Colorado State Univ, Fort Collins, CO (*correspondance: aaron.zimmerman@colostate.edu)
[2]CEED Centre of Excellence, University of Oslo, Norway

Following the preliminary work of Zimmerman et al [1] and the impressive results of Miller et al [2], additional investigation into the natural $^{185}Re/^{187}Re$ isotopic ratio supports the notion that variability of the ratio may exist in different geological samples and Re-bearing materials.

Four molybdenite samples, including NIST RM 8599 [3], and AIRIE's Re standard solution (RR-4, prepared from potassium perrhenate), were analyzed for their Re isotopic composition (IC) in triplicate. All samples showed elevated Re IC relative to the "true" value of 0.5974 [4]. The analyses followed standard Re-Os procedures except sample Re was liberated with concentrated HNO_3 in open glass beakers rather than Carius tubes. Anion exchange Re separation followed conversion of the solution to HCl form. Single bead Re clean-up resulted in notable NTIMS signal improvement.

NTIMS multi-collector faraday cup measurements are ruled out as causing elevated ICs as RR-4 loaded directly onto outgassed Pt filaments yields the expected ratio (0.59735±0.00044 1σ stdev, n=6). Excluding two outliers, the mean $^{185}Re/^{187}Re$ is 0.5989±0.0014 1σ stdev (n=16). Interestingly, every sample's IC was above 0.5974 yet there are no systematic correlations between IC and material type or molybdenite geologic setting.

Summarizing the Re IC of the analyzed samples relative to the true value of 0.5974 is difficult because of analytical concerns. The molybdenites selected (save RM 8599) have geologically unusual low Re concentrations between 1ppm and 50ppb. Column chemistry was hampered by extreme Mo:Re and low total Re. RM 8599 and RR-4 amounts were selected to best match the low Re molybdenites. As such, NTIMS signals for all samples were less than ideal. It is therefore difficult to determine whether the elevated Re ICs are analytically robust or biased by anomolous column chemistry and weak signals. Additional analyses using high Re molybdenites along with matching 8599 and RR-4 are in progress to test for biases resulting from low total Re.

Release of engineered nanomaterials from flexible thin-film photovoltaic cells

YANNICK-SERGE ZIMMERMANN[1,2], ANDREAS SCHÄFFER[2], PHILIPPE F.-X. CORVINI[1,3] AND MARKUS LENZ[1]*

[1] Institute for Ecopreneurship, University of Applied Sciences and Arts Northwestern Switzerland, Gründenstrasse 40, CH-4132 Muttenz, Switzerland
[2] Institute for Environmental Research (Biology V), RWTH Aachen University, 52074 Aachen, Germany
[3] State Key Laboratory of Pollution Control and Resource Reuse, School of the Environment, Nanjing University, Hankou Road 22, 210093, Nanjing, China
* (correspondence: markus.lenz@fhnw.ch)

Organic photovoltaic solar cells (OPVs) are a promising renewable energy technology. In consideration of the anticipated forthcoming large-scale production, the environmental impact of OPVs should be benchmarked to commercially available thin film technologies such as CuInGaSe cells (CIGS). Whereas most research focusses on performance of photovoltaics, little is known on the environmental fate and effect of their constituents such as engineered nanomaterials after their life cycle. CIGS rely on hazardous metal(oids) such as Cu, In, Ga, Se, Mo and Cd. However, also OPV – although based on light-absorbing organic molecules – contain metals such as Al, In, and Ag, some of which applied in nanoparticulate form.

For the first time, this study investigates the leaching behavior of engineered inorganic nanomaterials present in OPV and CIGS. Leaching scenarios investigated under environmentally relevant conditions, like exposition to acidic rain and mechanical stress, were carried out for long term. Metal concentrations were determined by Inductively Coupled Plasma Mass Spectrometry (ICP-MS). This allowed the calculation of the predicted environmental concentrations for different scenarios, which were set in relation to corresponding WHO water limits. Furthermore, models for the observed leaching kinetics of the most relevant metals were determined. Eventually, all released inorganic components were investigated by time-resolved ICP-MS in order to distinguish between dissolved and nanoparticulate states. Our results show that after four months, OPV do not pose any risk to the environment regarding their engineered inorganic nanomaterial content, even under most conservative scenarios. On the other hand, high amounts of Mo, Se and Cd were leaching from CIGS. Under the constraints of this study, these would exceed drinking water limits many times.

Highly equilibrated carbonaceous chondrites

J. ZIPFEL[1]*, J.-A. BARRAT[2], CH. GÖPEL[3] AND U. LINNEMANN[4]

[1]Senkenberg Frankfurt, 60325 Frankfurt, Germany (*correspondance: jutta.zipfel@senckenberg.de)
[2]Université de Bretagne Occidentale, 29280 Plouzané Cedex, France (Jean-Alix.Barrat@univ-brest.fr)
[3]IPGP, 75238 Paris, France (gopel@ipgp.fr)
[4]Senckenberg Naturhistorische Sammlungen Dresden, 01109 Dresden, Germany (ulf.linnemann@senckenberg.de)

Most carbonaceous chondrites have primitive, unequilibrated textures of petrologic type 3 and lower. Recently a number of extensively metamorphosed carbonaceous chondrites of types 6 were identified. They have O isotopes similar to CR chondrites and were classified as CR metachondrites [1]. The CR relationship is supported by the similarity in bulk compositions of major elements. The FeO-rich mafic mineralogy (Fa~36) distinguishes these meteorites from CR-chondrites. Northwest Africa (NWA) 6901 and those described by [1] are potentially paired meteorites with identical O isotopic composition, mineralogy, and highly equilibrated texture and old single grain phosphate U-Pb age of 4563 ± 13 Ma [2].

We performed analyses of major and trace elements of bulk NWA 6901 by ICP-AES and ICP-MS [3] and of trace elements of merrilites by LA-ICPMS. Bulk NWA 6901 is different from CR chondrites with depletions of refractory elements (Al, Ca and Sc) and moderately volatile elements (K, Na, Ga, and Zn). The phosphates are strongly enriched in LREE with a positive Ce anomaly, a negative Eu anomaly and a subchondritic U/Th ratio. The pattern is the same as the pattern of bulk NWA 6901. Phosphates of basaltic achondrite NWA 011 have a similar pattern suspected to be caused by terrestrial alteration [4]. The absence of common Pb in single phosphate grains suggest, however, that terrestrial alteration in NWA 6901 is at most minor [2].

The fractionated trace elements of phosphate and bulk NWA 6901 are not in accordance with isochemical metamorphism on the CR parent body and can also not be explained by loss and/or gain of trace element rich partial melts. Chemistry and ^{54}Cr [5] indicate that NWA 6901 is a new type of carbonaceous chondrite derived from a parent body that formed in a chondritic source region unknown so far.

Silver enrichment in rain under different cloud conditions

ASSAF ZIPORI, DANIEL ROSENFELD AND YIGAL EREL*

The Nadine and Freddy Herman Institute of Earth Sciences, the Hebrew University of Jerusalem, 91904 Jerusalem, Israel (*correspondence: yerel@vms.huji.ac.il)

This study follows and records the arrival and activity of AgI in seeded clouds. During four winters while cloud seeding took place, precipitation was collected at three stations in the catchment area of the Sea of Galilee (target stations) and in one station west of the seeding line (control station). Chemical analysis of 23 metals was carried out on more than 4000 rain samples in order to determine the major and trace metal concentrations and enrichment factor with respect to Al (EF), where Al was assumed to represent natural dust. In addition, satellite images were analyzed to characterize the cloud phase (liquid, ice, mixed liquid-ice) and the temperature of the clouds using the EUMETSAT second generation geostationary satellite.

It was found that AgI arrives to the targeted clouds, as indicated by significantly higher EF_{Ag} values there compared with the control station. We found significantly higher EF_{Ag} values in precipitations from mixed-phase clouds compared with precipitation from warm or fully glaciated clouds. This difference was observed only at the target stations and only for Ag (Fig. 1). The observation is consistent with the assertion that AgI contributes actively to the formation processes of precipitation in mixed-phase clouds, where ice nuclei concentrations can be rate determining in precipitation formation. This is also consistent with theoretical predictions about the activity of AgI in clouds.

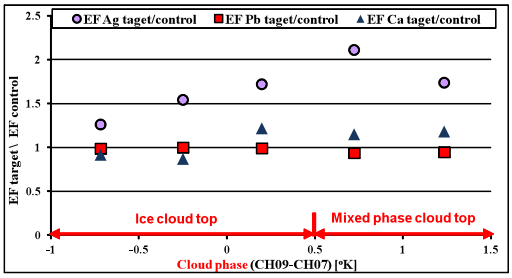

Figure 1: Ratios of EF_{Ag}, EF_{Ca} and EF_{Pb} between the target and the control station at different cloud phase intervals. Liquid clouds > 2, icy clouds ≈ 0.5-0, mixed-phase clouds 0.5 - 1.5. Negative BTD(CH09-CH07) values indicate convective clouds.

Mineralogical and geochemical characteristics of clay deposits from Northwest Gonabad District of clay Deposit (East Iran)

S. ZIRJANIZADEH[1]*, M. H. KARIMPOUR[1] AND KH. EBRAHIMI[1]

[1]Department of geology,Faculty of sciences,Mashhad university, Iran.
(*correspondence: Zirjani38@yahoo.com)

Kaolin deposits, situated approximately northwest of Gonabad (east Iran), have been formed by the intrusion of hydrothermal fluids from granite dike and alteration of rhyolite , dacite and rhyodacite related to the Eocene volcanism [1] . Fore clay deposits have been located in this area. The area is covered by the mikaschist, dacite, rhyolite, trachiandesite, lithic tuff and acidic tuff rocks.

The mineralogical compositions are dominated by quartz, kaolinite, dickite, illite, baidelite and minor phases include chlorite, albite, hematite, montmorilonite, pyrite and gypsum. We analyzed for mineralogical and chemical composition, including the rare earth element contents.

Whole rock chemistry shows that samples rich in SiO_2 and Al_2O_3 . Enrichment of Sr in altered and partially altered rocks relative to fresh volcanic-rock samples demonstrates retention of Sr and depletion of Rb, Ba, Ca, and K during hydrothermal alteration of sanidine and plagioclase within the volcanic units. The chondrite-normalized Rare earth element patterns of the clay deposites show LREE enrichments ((La/Lu)cn = 6.75 to 57.74) and a negative Eu anomaly. The negative Eu anomaly suggests the alteration of feldspar by hydrothermal fluids [2].

The mineralogical composition, REE contents, main elements discrimination diagram and elemental ratios in these deposites suggest a provenance mainly felsic rocks and also, a high amounts of weathering have occurred in Kaolin's source.

Anorthosite dikes from Cyprus: Phase relations in the system $CaAl_2Si_2O_8 – CaMgSi_2O_6 – Mg_2SiO_4$ at 5 Wt.% H_2O

AURELIA ZIRNER[1], CHRIS BALLHAUS[1], CARSTEN MÜNKER[1,2] AND CHRISTIAN MARIEN[2]

[1]Universität Bonn, Germany(zirner.aurelia@googlemail.com)
[2]Universität zu Köln, Germany (c.muenker@uni-koeln.de)

Massive anorthosite dikes are documented for the first time from the Limassol Forest Complex (LFC) of Cyprus, a deformed equivalent of the Troodos ultramafic massif. Both the Troodos and LFC complexes are part of a Cretaceous oceanic crust that formed within a backarc basin 90 Ma ago and was obduced during late Miocene.

From crosscutting relations with the sheeted dike complex, it follows that the anorthosites belong to one of the latest magmatic events on Cyprus. In hand speciment, the rocks appear massive and unaltered, although in thin section magmatic Pl (An_{93}) is partially replaced by Zo. Where magmatic textures are preserved, Pl forms cm-sized, acicular, radially arranged crystal aggregates reminiscent of spinifex textures.

The origin of these anorthosites remains poorly understood. Even though they occcur as intrusive dikes, it is evident they cannot represent liquid compositions, at least under dry conditions. Whole-sale melting of a pure An_{93} would require temperatures in excess of 1450 °C, which is a quite unrealistic temperature of the modern Earth's crust.

We are exploring experimentally if such lithologies can be generated by medium-pressure fractional crystallisation of hydrous basaltic melts followed by decompression-degassing. High pH_2O stabilizes Ol and Spl but tends to suppress Pl, hence may allow the An-component to be accumulated in late-stage melts. Hydrous melts do occur on Cyprus, in form of high-Ca boninites with ~ 5 wt.% H_2O. Experiments are being performed in the Ol-Cpx-Pl-H_2O system, with Ol (Fo_{95}), Pl (An_{93}), and Cpx (Di_{95}) seperates as starting materials. The seperates are ground, mixed in the desired proportions, then equilibrated with 4 wt.% H_2O at 0.5 GPa total pressure from 1000 to 1300 °C in a piston-cylinder press. Aim is to deliniate the An saturation field in the Ol-Cpx-Pl-H_2O system, and assess to what extent Pl can be suppressed as a liquidus phase in a basalt fractionating under hydrous conditions.

Sulphur driven denitrification dominates N-removal in the water column of Lake Lugano

J. ZOPFI[1], C. B. WENK[1], DORA SCHWEIGHOFFER[1], J. BLEES[1], H. NIEMANN[1] AND M. F. LEHMANN[1]

[1] Department of Environmental Sciences, University of Basel, Basel Switzerland; (jakob.zopfi@unibas.ch)

Besides organotrophic denitrification, alternative pathways, such as anaerobic ammonium oxidation (anammox) or sulphide-dependent denitrification are potentially important for the removal of fixed nitrogen from lakes. We identified the dominant N_2 forming processes in the permananetly stratified northern basin of Lake Lugano (Switzerland) using ^{15}N labelling experiments, molecular and cultivation based microbiological approaches.

Potential rate measurements suggest that anammox can contribute up to 30% to total N_2 formation but denitrification remained the dominant process at all depths. Additional incubation experiments with potential substrates for denitrifying bacteria identified sulphide and thiosulphate as important substrates [1]. Enrichment cultures of sulphide dependent nitrate-reducing bacteria were established to determine the products of sulphur and nitrogen transformations, respectively, and for molecular characterisation.

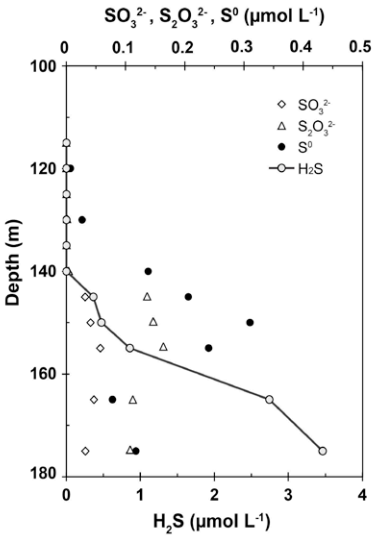

Figure 1: Concentrations of sulphide and sulphur intermediates at the RTZ in the stratified deep northern basin of Lake Lugano

Our study highlights that despite of the mesotrophic nature of the lake and the very low concentrations of sulphur species (Figure 1), water column denitrifications is mainly driven by sulphur compounds rather than organic matter.

Cs and Sr mass transfer constrained via ion beam analysis

B. ZOU[1], T. OHE[2], G.GRIME[3] AND R.WOGELIUS[1]*

[1]Williamson Research Centre, University of Manchester, M13 9PL, UK (*roy.wogelius@manchester.ac.uk)

[2]Tokai University, 259-1292, Japan[3] University of Surrey Ion Beam Centre, GU2 7XH, UK

Micro-Reactor Simulated-Channel (MRSC) methods have been developed to rapidly determine mass transfer coefficients of intact low-permeability rock samples [1,2]. The design uses a thin fluid channel in the centre of the solid system which increases reaction rates due to a high surface area to liquid volume ratio. This enables fast measurements using only small reactor volumes. The MRSC consists of two injection syringe pumps, a reaction unit, an auto sampler, and a drainage tank.Unlike the conventional column method, an intact hard rock sample also produces flat surfaces for direct chemical analysis. ^{90}Sr and ^{137}Cs isotopes are both of great concern in disposal scenarios, with half-lives of approximately 30 years. In the MRSC experiments presented here, aqueous fluids with dissolved Sr and Cs have been pumped through simulated fractures at constant rates. Breakthrough curves were constructed by time resolved analysis of the effluent solution until steady state was observed. Differences between inlet and outlet concentrations are caused by two dominant processes; 1) diffusion into grain boundaries, micropores, and microfractures, and 2) sorption from the simulated fracture onto mineral surfaces. Mass difference is much higher than would be predicted from surface adsorption, and hence it is concluded that appreciable Sr and Cs has diffused into grain boundaries. In order to further constrain the tracer inventory, an analytical regimen was developed using ion beam techniques. This allowed us to fully characterise the reacted surfaces and to carry out depth-profiling. In particular, we designed these measurements to take advantage of the extremely low background radiation levels at the Sr and Cs Kα energies in particle induced X-ray emission (PIXE) analysis in order to accurately quantify Sr and Cs [3]. In addition, the depth profiling capability of Rutherford backscattering spectrometry (RBS) is able to non-destructively constrain diffusion profiles at concentrations down to a few parts per million from areas 1 μm in diameter. Results of these provide critical constraints on mass transfer parameters produced from MRSC experiments.

Concentration and isotopic analysis of soil gas N_2O in a Japanese tea field

YUN ZOU[1]*, YUHEI HIRONO[2], YOSUKE YANAI[2], SHOHEI HATTORI[3], SAKAE TOYODA[4] AND NAOHIRO YOSHIDA[3]

[1]Department of Environmental Science and Technology, Tokyo Institute of Technology, Japan (*correspondence: zou.y.aa@m.titech.ac.jp)
[2]NARO Institute of Vegetable and Tea Science, Japan (hirono@affrc.go.jp, yosukey@affrc.go.jp)
[3]Department of Environmental Chemistry and Engineering, Tokyo Institute of Technology, Japan (hattori.s.ab@m.titech.ac.jp, yoshida.n.aa@m.titech.ac.jp)
[4]Department of Environmental Science and Technology, Tokyo Institute of Technology, Japan (toyoda.s.aa@m.titech.ac.jp)

N_2O is an important trace gas that causes global warming and is indirectly related to destruction of stratospheric ozone layer. Fields planted with tea (*Camellia sinensis*) in Japan have a high potential to emit large amount of N_2O because of the highest level of N fertilizer application. In this study, we focus on the processes leading to high N_2O production in an experimental tea field in Shizuoka, Japan for better arranging N_2O mitigation strategy.

Soil gas samples were collected at four depths in two plots (Plots I and II) at 3 to 7-day interval from May to July, 2012 for concentration and isotopic analysis of N_2O. Surface soils (0-20 cm) were also collected for the analysis of other N-compounds.

Three peaks of N_2O concentration were observed corresponding to fertilization on 8 June and 5 July 2012. Each peak was found after heavy precipitation and a rise in air temperature above 20ºC. The site preference of N_2O (SP, the difference in $^{15}N/^{14}N$ ratio between central (α) and terminal (β) N in $^{\beta}N^{\alpha}NO$) ranged from 0.8‰ to 11.1‰ at the N_2O concentration peaks, suggesting greater (64% to 95%) contribution of bacterial nitrite (NO_2^-) reduction than hydroxylamine (NH_2OH) oxidation or fungal denitrification. However, on one occasion (21 June at 35 cm depth of Plot I) N_2O had relatively high SP value (18.1‰), indicating an increase in production rate of NH_2OH oxidation or fungal denitrification relative to bacterial NO_2^- reduction.

Overall, N_2O in Japanese tea field was mainly produced by bacterial NO_2^- reduction under the effects of fertilization and precipitation in warmer (above 20 ºC) condition.

Clay mineral argon release during frictional shear experiments – Implications for brittle fault dating

H. ZWINGMANN[1]*, S.A.M. DEN HARTOG[2] AND A. TODD[1]

[1]CSIRO ESRE, Bentley, WA 6102, Australia (*correspondance: horst.zwingmann@csiro.au; andrew.todd@csiro.au)
[2]Department of Earth Sciences, Utrecht University, 3508 TA Utrecht, Netherlands (s.denhartog@uu.nl)

Brittle fault zones comprise synkinematic or authigenic clay minerals such as illite, which can be dated by conventional K-Ar or Ar-Ar dating using micro-encapsulation (Zwingmann *et al*., 2010). A pre-requirement for dating authigenic fault illite invokes no inheritence of radiogenic Ar.

The retention of Ar in fine grained clay minerals such as illite, occuring in clay rich fault gouge zones, is difficult to measure in nature. Den Hartog *et al*. (2012) describe friction experiments on fine grained mixtures of illite and quartz, performed with the aim of determining the frictional properties and slip stability under (near) in situ subduction megathrust conditions, i.e. at an effective normal stress of 170 MPa, a pore fluid pressure of 100 MPa at 150-500°C and sliding velocities relevant to earthquake nucleation (1-100 μm/s). These experiments allow investigation of Ar isotope retention and diffusion aspects in artificial gouge samples. We present prelimenary conventional K-Ar age data on four artifically generated illite gouge samples, obtained from frictional shear experiments ranging from 150 to 450°C under the same pressure regime.

The original Rochester shale yields a Silurian age of 421.4 ± 8.4 Ma as described by Folk (1962). Low temperature (150 °C) frictional shearing experiments reduce the age of the artifical gouge to 218.3 ± 5.0 Ma, still containing more than 70% of radiogenic 40Ar. Ar diffusion modeling using a <2 micon clay fraction size indicates neglible diffusion aspects at a temperature of 150 °C. The age data suggests that the frictional shearing of clay gouge affects the clay microstructures and releases radiogenic Ar caused by processes reported in Den Hartog (2012). The 250, 350 and 450°C experiments yield artificial illite gouge ages of 155.0 ± 3.1 Ma, 139.5 ± 2.9 Ma and 74.7 ± 1.5 Ma, respectively. Argon diffusion modeling indicates that diffusion starts to affect the clay mineral gouge ages from 300°C. Further studies are in progress, investigating clay gouge noble gas retention and effects, to constrain timing of fault gouge reactivation in the seismogenic zone.
