The Alpine Fault on the South Island of New Zealand is one of the longest, straightest, and fastest-moving transform faults, with oblique-slip at rates that accommodate over half of the Australia-Pacific plate motion and cause rapid uplift of the Southern Alps. No major earthquakes have occurred on the fault in historic time, but it last ruptured around 1717 AD and is thought to fail in large moment magnitude (M_w>7) to possibly great (M_w>8) earthquakes at ~330 yr recurrence intervals. Rocks southeast of the Alpine Fault are exhumed at rates faster than they can cool, resulting in a 63°C/km geothermal gradient, convective circulation and warm springs without related volcanic activity. Because the seismic cycle is fundamentally controlled by fluids, improved knowledge of fluid circulation in the shallow crust is paramount to understanding earthquake processes on the Alpine Fault.

In the context of the Deep Fault Drilling Project (DFDP), we have investigated gas compositions and noble gas isotopic abundances in spring waters from the vicinity of the fault. Free gas was sampled at four springs, while nine other springs provided water samples that were degassed in the lab. N_2 is commonly the most abundant gas, CO_2 concentrations vary widely from <0.1% to >96%, and CH_4 contributes up to 13%. He concentrations are up to ~500 ppm. $^3He/^4He$ ratios are generally highest (up to 0.81 Ra) close to the fault and decrease to radiogenic values (<0.04 Ra) towards the southeast at distances of a few kilometers from the fault, with two exceptions: Copland Spring (0.42 Ra) is located ~12 km from the fault and exhibits the highest gas flow and the highest CO_2 content of all springs studied in this work. Kotuku Spring, the only location available for sampling on the Australian plate, yields a particularly high $^3He/^4He$ ratio of ~3.1 Ra despite low gas flow and ~17 km distance from the fault. Obviously, mantle fluids can penetrate the thick crust beneath the Southern Alps directly at the fault and may be diverted away from it only where major passageways through the crust exist. It remains to be seen whether the high $^3He/^4He$ ratio of Kotuku indicates a distinct fluid origin on the northwest side of the fault in general or is just a local feature.

Calcium and Oxygen Isotope Fractionation during Precipitation of Calcium Carbonate Polymorphs

A. NIEDERMAYR[1,2], A. EISENHAUER[3], F. BÖHM[3], B. KISAKÜREK[3], I. BALZER[1], A. IMMENHAUSER[1], S.J. KÖHLER[4] AND M. DIETZEL[2]

Different isotopic systems are influenced in multiple ways and amounts by the crystal structure, surface properties, hydration and dehydration processes, deprotonation, adsorption, desorption, isotope exchange and diffusion processes. Herein we studied the structural and kinetic effects on fractionation of stable Ca- and O-isotopes during $CaCO_3$ precipitation in order to evaluate processes controlling their fractionation.

Calcite, aragonite and vaterite were precipitated using the CO_2 diffusion technique[1] at a constant pH of 8.3, but various temperatures (6, 10, 25 and 40°C) and precipitation rates ($10^{1.5}$ to 10^5 μmol h^{-1} m^{-2}).

The precipitation rate effect on fractionation of Ca-isotopes is mainly influenced by the precipitated polymorph. The calcium isotope fractionation between calcite/vaterite and aqueous Ca^{2+} increases with increasing precipitation rate. In contrast the fractionation of Ca-isotopes between aragonite and aqueous Ca^{2+} decreases with increasing precipitation rate. Hence, the influence of precipitation rate on the fractionation of calcium isotopes of aragonite is reverse compared to that of calcite and vaterite. The fractionation of $^{18}O/^{16}O$ between $CaCO_3$ and H_2O decreases with increasing precipitation rate. The latter behaviour is - in contrast to calcium isotope fractionation - similar for all three polymorphs.

Vaterite formation induces lower fractionation of calcium isotopes ($\Delta^{44/40}Ca_{CaCO_3\text{-}aq}$ = -0.10 to -0.55 ‰) compared to calcite (-0.69 to -2.04 ‰) and aragonite (-0.91 to -1.55 ‰). In contrast the fractionation of oxygen isotopes is highest for vaterite, followed by aragonite and calcite at similar precipitation rates and temperatures. Although fractionation of oxygen isotopes is mainly dominated by temperature in our experiments with constant pH, whereas fractionation of calcium isotops is dominated by polymorphism and kinetic processes.

How sandstone mineral surfaces interact with Ca^{2+} and Cl^- ions

A.R. NIELSEN*, K.N. DALBY, N. BOVET, AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*skrupsax@hotmail.com)

Sandstone oil reservoirs form an important global resource. Production with the highest possible yield would extend the resources that are currently accessible with existing infrastructure and postpone the need for developing more risky deep water and high Arctic fields. Enhanced oil recovery (EOR) methods, including flooding with low salinity water, have increased oil recovery rates for sandstone reservoirs, even though the mechanisms responsible are not yet fully understood. Linking reservoir scale studies with investigations carried out at the molecular scale would increase our understanding of such mechanisms and allow EOR methods to be optimised.

In this work, we examined the change in surface composition of two natural sandstones (SS1 and SS2) and the associated extracted clay, during exposure to calcium chloride ($CaCl_2$) solutions at a variety of concentrations. For investigating surface uptake, we used X-ray photoelectron spectroscopy (XPS) on fast frozen samples [1] The sandstones and extracted clay have been thoroughly characterised with X-ray powder diffraction (XRPD) and scanning electron microscopy (SEM) with energy dispersive X-ray spectroscopy (EDXS).

The ratio of Ca/Si and Cl/Si, derived from XPS spectra, show which ions stick to the surface at various Ca concentrations (Figure 1). The SS2 sandstone adsorbed more chloride than calcium, no matter what solution concentrations were used, whereas the opposite was observed for SS1. SS2 also had a higher affinity for adsorption in general than SS1. XRPD patterns confirmed a difference in mineral composition.

We are using the information about responses from natural sandstone and natural clay minerals to design model systems for determining the mechanism behind the oil release that is observed on the reservoir scale in response to low salinity water injection.

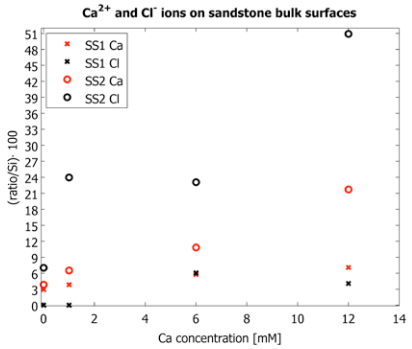

Figure 1: The ratio of Ca/Si and Cl/Si for the two bulk sandstones presented as a function of the calcium concentration of the solution.

Calcite scaling: Growth inhibition by Mg^{2+}, SO_4^{2-} and $Mg^{2+} + SO_4^{2-}$

M. R. NIELSEN*, K. K. SAND AND S. L. S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*mia.rohde.nielsen@nano.ku.dk)

Calcite precipitation in wells, pipes, boilers and the like causes problems for industy. Effective inhibition would save huge amounts of energy and money. Magnesium (Mg^{2+}) is known to poison calcite growth [1-3], so better understanding of how it works could lead to improved scale inhibitors. It has recently been shown that adsorption of both Mg^{2+} and sulfate (SO_4^{2-}) changes calcite surface tension [4-5].

We investigated the effect of each ion singly and in combination by precipitating calcite at room temperature in a constant composition reactor[6]. Calcite precipitated at constant rate, then ions were added and the change in growth rate was monitored with time.

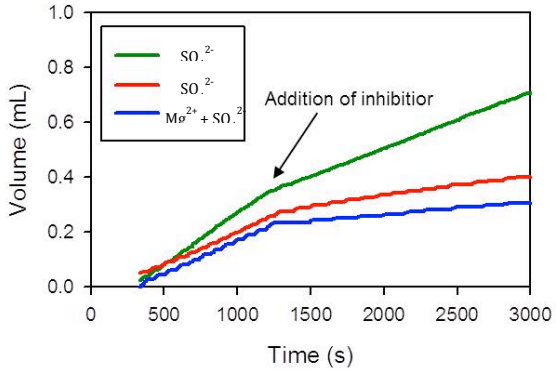

Figure 1. Typical plots for reagent addition versus time. Concentation of the inhibitors was 7.4 mM in all cases

Growth rate for pure calcite ranged from $1.8 \cdot 10^6$ to $6.0 \cdot 10^6$ mol s^{-1} m^{-2}, consistent with previous data. Increased Mg^{2+} concentration correlated directly with increased inhibition. Dissolved Mg^{2+} decreased with growth, sugesting incorporation into the newly formed calcite. Although there is less inhibition by SO_4^{2-} alone than Mg^{2+} alone, when the two are present together, inhibition is stongest (Figure 1).

Toxic effects of butyl elastomers on aerobic methane oxidation

HELGE NIEMANN[1], LEA I. STEINLE[1,2], JAN H. BLEES[1], STEFAN KRAUSE[2], INGEBORG BUSSMANN[3], TINA TREUDE[2] AND MORITZ F. LEHMANN[1]

[1]University of Basel, Dept. of Env. Geosciences, CH (helge.niemann@unibas.ch)
[2]Helmholtz Centre for Ocean Research (GEOMAR), DE
[3]Alfred Wegener Institute, Messtation Helgoland, DE

Large quantities of the potent greenhouse gas methane are liberated into the water column of marine and lacustrine environments where it may be consumed by aerobic methane oxidising bacteria before reaching the atmosphere. The reliable quantification of aerobic methane oxidation (MOx) rates is consequently of paramount importance for estimating methane budgets. A widely used set of methods for measuring MOx rates is based on the incubation of water samples during which the consumption of methane is monitored. Typically, incubation vessels are sealed with butyl rubber stoppers because these elastomers are essentially impermeable for gases at the relevant time scales. We tested the effect of different stopper materials (unmodified- and halogenated butyl rubber) on MOx activity. MOx rates in samples sealed with unmodified butyl rubber were > 75% lower compared to parallel incubations with halogenated butyl rubber seals, suggesting inhibiting/toxic effects associated with the use of unmodified butyl elastomers. In aqueous extracts of unmodified butyl stoppers, we detected various organic compounds including potential bactericides such as benzyltoluenes, phenylalkanes and benzuothiazoles. The inhibition of MOx is most probably caused by organic contaminants that bleed off from the unmodified butyl elastomer into the incubation water.

Multidisciplinary geophysical-geochemical analysis for qualitative renovation by artificial recharge of aquifers (WARBO LIFE)

NASSER ABU ZEID[1] , DANIEL NIETO[2]*, ALESSANDRO AFFATATO [2], LUCA BARADELLO [2,] FLAVIO ACCAINO [2] SALVATORE PEPI [1] , SABRINA RUSSO[1] AND CARMELA VACCARO[1]

[1]Dip. Fisica e Scienze della Terra, Università di Ferrara, Italy
[1] OGS (Istituto Nazionale di Oceanografia e di Geofisica Sperimentale) Borgo Grotta Gigante 42/C - 34010 - Sgonico (TS) – Italy * (dnieto@ogs.trieste.it)

Large areas of the Po Valley proximal to the delta show serious problems related to salinization of the superficial aquifers which are vital for the sustainability of the agricultural activities in the area. Since 2012 the EU life WARBO project activities regards the application of integrated direct and indirect technologies aiming at the monitoring of the possibility to enhance ground water quality in two test sits. One test site is located few km's to the south of the Po River and about 40 km on-shore the western margin of the Adriatic Sea, Northern Italy. In this area, the artificial recharge shall be initiated by flooding an existing lake formed after the termination of pre-existing quarry.

Subsurface geological and hydrogeological model of this test site have been constructed based on through analysis of existing information about surface and subsurface lithology. These were integrated by the acquisition of new geophysical data employing surface and borehole geoelectromagnetic and seismic techniques. The geophysical results helped in the definition of the geohydrogelogical conceptual model. This model, together with the geochemical data, aided in the definition of the possible interactions between surface and ground water bodies. Moreover, the outcomes of the integrated analyses helped in the optimization of the monitoring network.

One of the expected resuts of this project is to succeed in diluting the high salinity of fossil ground water whose presence, surely, contrasts the natural recharge from the Po River. This may be possible by accumulating fresh water in the existing lake. Monitoring activities shall aide in defining the rate of salinisation attenuation in acquifers characerised by modest to low avearage permeabiliy. Understanding the advantages and drawbacks of artificial recharge activites shall help in defining its usefluness or its applicability in other sites having similar characteristics.

Carbon isotope fractionation of injected CO_2 in carbonate reservoirs: Comparison of results from the laboratory and enhanced oil recovery field sites in Alberta, Canada

M. NIGHTINGALE[1]*, B. MAYER[1], M. SHEVALIER[1] C. DALKHAA[1] AND V. BECKER[1]

[1]University of Calgary, Calgary, Canada, T2N 1N4. (*correspondance: night@earth.geo.ucalgary.ca)

Much of what can be surmised about the geochemical reaction of injected CO_2 when sequestered in geological formations has been gleaned from the chemical and isotopic analysis of produced fluids during CO_2 enhanced oil recovery (CO_2-EOR). Carbon isotopes of produced CO_2 have been shown to be a valuable tool for tracing the fate of injected CO_2 [1]. When CO_2 is injected into water bearing carbonate rock, carbon from four distinct sources: 1) injected CO_2, 2) in-situ CO_2, 3) dissolved inorganic carbon (largely bicarbonate) and 4) dissolution of carbonate minerals in carbonic acid, can be expected to contribute to the overall "carbon pool" and may have an impact on the equilibrium carbon isotope ratios of both the produced CO_2 and dissolved inoragnic carbon (DIC). We present the results of chemical and isotopic anaylses of produced CO_2 and DIC before and after the initiation of CO_2 injection at two carbonate hosted CO_2 enhanced oil recovery projects in Alberta, Canada. Results suggest carbon isotope equilibrium is established in a fashion similar to open system carbonate dissolution in shallow environments [2]. In spite of large increases in dissolved bicarbonate attributed to carbonate mineral dissolution, the equilibrium carbon isotope values of the bicarbonate appear to be controlled largely by the injected CO_2 and system temperature. Field observations were verified via a series of laboratory experiments using artificial brines and isotopically distinct CO_2 ($\delta^{13}C$ = -37.5‰) and carbonate rock ($\delta^{13}C$ = +1.2‰). Observed increases in dissolved calcium up to 575 mg/l, and dissolved bicarbonate up to 1500 mg/l, can be attributed to the dissolution of added calcite. The $\delta^{13}C_{HCO3}$ of -28.1‰ at the end of the experiment demostrates the dominance of the CO_2 and sytem temperature (20°C) in determining the $\delta^{13}C$ values of DIC under equlibrium conditions and the "overprinting" of the isotopic signature of the carbon contributed through calcite dissolution.

Magma sources within the Armenian territory since the Jurassic

I. NIKOGOSIAN[1], KH. MELIKSETIAN[2], M.J VAN BERGEN[1], P.R.D. MASON[1] AND G. NAVASARDYAN[2]

[1]Department of Earth Sciences, Utrecht University, Budapestlaan 4, the Netherlands, (iniki@geo.uu.nl)

[2]Institute of Geological Sciences, ANA of Sciences, Yerevan, Armenia, (km@geology.am)

The Armenian Highland forms part of the intensely deformed central segment of the Alpine-Himalayan belt, where fragments of continental blocks of Gondwanaland origin, Mesozoic Tethian island arcs and Late Cretaceous ophiolite sequences constitute a complex geological mosaic. Extensive magmatic activity between the Early Jurassic and Holocene developed under a diversity of geological regimes, ranging between rift and post-collisional settings.

We undertook a detailed geochemical and petrological study of representative, MgO-rich igneous products to explore relationships between magmatism and geodynamics in key areas of the Lesser Caucasus. Samples cover the entire Jurassic-Quaternary time interval, and include picrites, ophiolites, subalkaline and alkaline basalts, dolerites, and shoshonitic-high-K calcalcaline basalts.

Early liquidus assemblages in most of the samples virtually always include high-Fo (>88) olivine that presumably crystallized from (near-)primary mantle-derived melts. Exceptions are low-Fo olivines from the Quaternary Aragats, Gegam and partially Syunik volcanoes that probably crystallized from crust-contaminated AFC melts and/or mixtures of mantle and crust-derived (adakite-type) melts. Spinel inclusions trapped in high-Fo olivines contain variable amounts of Ti, Al, and Cr, that enable us to distinguish the nature of mantle sources involved (MORB-type, OIB-type, subduction-type).

Geochemical signatures of the parental melts were obtained for all studied samples using LA-ICP-MS analysis of melt inclusions trapped in the high-Fo olivines. A wide diversity of (near-) primary melts was found within and between distinct magmatic systems. Where partial melting and secondary effects can be ruled out, much of this variation reflects the amalgam of different mantle-lithosphere domains, which were mobilized in response to the changing geodynamic conditions that have affected the region since Jurassic times.

Multiple origins of carbon in Italian kamafugite melt

I. NIKOGOSIAN, M.J. VAN BERGEN AND S. CHANEVA

[1] Department of Earth Sciences, Utrecht University, The Netherlands (m.j.vanbergen@uu.nl)

Despite ongoing discussion on magmagenesis and geodynamic controls, there are compelling indications that small volumes of kamafugitic magma in the Intra-Apennine Volcanic Province of peninsular Italy were derived from sources that had been affected by (past) subduction of the Adriatic lithosphere. A close association with carbonatitic rocks has posed the question concerning the origin of carbon, which may have been derived from the mantle sources or from interaction with Mesozoic carbonates residing in the crust. We explored the crystallization history of olivines and their melt inclusions, separated from a representative specimen from San Venanzo, which enables us to (1) determine the primary composition(s) of mantle-derived kamafugite melt and (2) to trace the effects of crustal interaction on melt composition and magma evolution. Complex textures of olivine phenocrysts and their trace element compositions provide a framework for the sequence in which melt evolved within a single plumbing system.

Pristine core parts, characterized by high Fo_{93-90}, low CaO, (0.2-0.3 wt.%) and Cr-spinel inclusions (Cr# ~0.7) are considered to have crystallized from primary mantle-derived melt. Compositions of melt inclusions in these cores are consistent with mantle derivation (8-12 wt.% MgO), but span a continuous range between 3 and 9 wt.% K_2O. The K-richest MI have compositions are relatively enriched in Na_2O, P_2O_5 and TiO_2, while the K-poor endmember is characterized by very high CaO contents (up to 21 wt.%). Rim parts show a strong compositional gradient of decreasing forsterite (down to Fo_{70}) and increasing CaO (up to 1.8 wt.%). Profiles of phosphorous contents in the olivines point to steep increases in the rim parts, indicating that they originated as rapid overgrowths onto phenocryst cores. The combined signatures suggest that the rim parts crystallized from an evolved melt that was contaminated through interaction with carbonate-rich lithologies. Fluid inclusions indicate that this interaction occurred at relatively shallow crustal levels (2 – 10km).

From major and elements contents of core-hosted MI we infer that the kamafugite represents an assembly of primary melts with differented compositions, controlled by low-degree melt extraction from a mantle source with mineralogical variations. Our observations are consistent with a mantle source affected by siliceous K-rich and carbonate/apatite-rich metasomatic agents derived from subducted carbonate-bearing metapelites.

Modeling soil structure and nutrient dynamics using the 1D-Integrated Critical Zone Model

N. P. NIKOLAIDIS[1]*, J. VALSTAR[2], E. ROWE[3], K. MOIROGIORGOU[1] AND F.E. STAMATI[1]

[1]Department of Environmental Engineering, Technical University of Crete, Chania 73100, GREECE (*correspondence: nikolaos.nikolaidis@enveng.tuc.gr)

[2]Deltares Soil and Groundwater Systems, Utrecht, The Netherlands

[3]NERC Center for Ecology and Hydrology, Bangor, UK.

Model Development

Soil structure has a strong influence on the physical, chemical and biological processes that take place within the soil, and these processes can in turn influence soil structure. The aim of this work was to develop a tractable and defensible mathematical model, the 1D Integrated Critical Zone (1D-ICZ) Model, that links soil aggregate formation and soil structure to nutrient dynamics and biodiversity. Models of flow and transport (Hydrus 1D); bioturbation; Chemical equilibrium, weathering (SAFE); C/N/P dynamics and soil structure, CAST; and vegetation dynamics, PROSUM, were integrated to formulate the 1D-ICZ Model. This model can simulate and quantify the dynamics of C, N and P sequestration in soils in relation to soil structure and organic matter protection, the effects of exudates and mycorrhizae on nutrient mobilisation and acquisition, above and below ground C stocks including microorganisms, fungi and consumers, and water transformation and filtration in soils.

Model Application Results

Theoretical model simulations will be presented to illustrate the sensitivity of nutrient dynamics to dynamic changes of soil structure due to carbon amendments in the system. The inter-relationships between nutrient dynamics and soil structure dynamics will be elucidated. Soil structure and nutrient content data from cropland to set-aside land conversions will be used to validate the 1D-ICZ model. It will be shown that the 1D-ICZ model can quantify four of the most important soil functions: biomass production, C sequestration, water filtration, and biodiversity and thus be an integral component of soil Life Cycle Assessments and Ecosystem Valuation Analyses by linking inventory data to midpoint indicators for soil functions and services.

Fe^{3+} partitioning systematics between orthopyroxene and garnet in well-equilibrated mantle xenoliths

P. NIMIS[1]*, A. GONCHAROV[2] AND D. IONOV[3]

[1] Dipartimento di Geoscienze, Università di Padova, Italy (*correspondence: paolo.nimis@unipd.it)
[2] Faculty of Geology, Saint-Petersburg State University, Russia (aleksey.g.goncharov@gmail.com)
[3] Université J. Monnet and UMR6524-CNRS, Saint Etienne, France (dmitri.ionov@univ-st-etienne.fr)

Ferric iron to total iron ratios in coexisting orthopyroxene and garnet from eighteen mantle xenoliths from Siberia (Udachnaya, Obnazhennaya) and Mongolia (Dariganga) were measured by ^{57}Fe Mössbauer spectroscopy at room temperature. The xenoliths include both coarse and sheared types and were checked for equilibrium based on textural and compositional criteria. A further check was made through cross-evaluation of thermometric estimates using internally consistent thermometers (cf. [1]). Thermobarometric estimates encompass a large P–T field (1.9–6.4 GPa; 740–1295 °C) relevant to Earth's upper mantle in both on-craton and off-craton settings. The Mössbauer data show that the partitioning of Fe^{3+} between orthopyroxene and garnet is essentially independent of the temperature of equilibration, but varies significantly with pressure. The $(Fe^{3+}/Fe_{tot})_{Grt}/(Fe^{3+}/Fe_{tot})_{Opx}$ ratio increases with pressure and is lower than unity at P < ca. 3.5 GPa and higher than unity at higher pressure. These partitioning systematics imply that thermometers based on Fe–Mg exchange equilibrium between orthopyroxene and garnet will fail at very low and very high pressure if redox conditions in the natural rocks are different from those in the experiments that were used to calibrate the thermometer. In particular, increased bulk Fe^{3+} contents due to more oxidized conditions will lead to over-estimated Opx–Grt temperatures at low P and under-estimated temperatures at high P. Conversely, decreased bulk Fe^{3+} contents due to more reduced conditions will lead to under-estimated Opx–Grt temperatures at low P and over-estimated temperatures at high P. The observed Fe^{3+} systematics may in part explain recognized inconsistencies between two-pyroxene and Opx–Grt thermometry of mantle xenoliths (cf. [1]).

Dynamical and isotopic perspectives on accretion and core formation

FRANCIS NIMMO[1]

[1]Dept. Earth & Planetary Sciences, University of California Santa Cruz, CA 95064, USA (fnimmo@es.ucsc.edu)

Numerical modelling of accretion suggests the following characteristics: Mars-sized bodies can form fast (~1 Myr) but completing an Earth takes longer (10-100 Myr); late-stage impacts can remove (or add) material in a stochastic fashion; the "feeding zone" of a growing planet expands with time. All these characteristics can potentially be quantified using cosmochemical measurements.

Isotopic systems such as Hf-W [1], Pd-Ag [2] and Fe-Ni [3] provide constraints on the timing of core formation. The biggest challenge is to better understand the degree of mantle re-equilibration during large impacts [4]. Re-equilibration occurs at cm-scales during impacts involving Mm-scale objects; it is thus hard to model numerically, but can perhaps be better quantified via laboratory experiments [5]. The effective conditions under which core formation occurred can also be probed with stable Fe or Si isotopes, though the presence of S complicates matters [6].

The bulk compositions of planets may have been affected by late-stage removal of material [7], and spall fragments such as the Moon produced [8]. Models show that smaller surviving bodies show more variability in bulk chemistry and isotopic signatures [9]; larger bodies experience more averaging and are are harder to fragment. Stochastic late impacts may be responsible for the variable amount of "late veneer" apparently added to the terrestrial planets [10].

Feeding zone expansion and the Pd-Ag [2] and I-Xe systems [11] both suggest late impactors are more volatile-rich. Later impactors may also have been more oxidized [12], but recent high-*P* partitioning experiments suggest this is not required [13].

Late-stage impacts probably caused several episodes of regional if not global melting. For both Earth and Mars, mantle convection subsequent to these magma ocean episodes has not been able to erase initial heterogeneities [11,14].

[3] Institute of Geoscience (CSIC, UCM), Madrid, Spain

The formation of biological hard tissues occurs in confined environments within organic matrices and involves the oriented attachment of nanoparticles. Similarities between hydrogels and organic matrices make hydrogels an adequate support for studying biomineralization. In this work the crystallization of $CaCO_3$ in gelatin hydrogels with solid contents ranging between 2.5 and 10 wt% was investigated at 15ºC. Changes in the gelatin concentration correlated with changes in the characteristics of the $CaCO_3$ precipitates, with heavier hidrogels leading to smaller nucleation densities, diminishing proportions of vaterite with respect to calcite and calcite crystals showing smaller sizes, progressively rougher surfaces and more complex morphologies. Moreover, the calcite crystals grown in heavier hydrogels were identified as mesocrystals consisting in assembled nanometric basically equally-oriented rhombohedral subunits separated by small amounts of gelatine (Fig. 1a). Hydrogels with higher gelatin contents were characterized by more complex porosities, which correlated with lower ion difussivities through the hydrogel and higher supersaturations at nucleation (Fig. 1b). These results highlight the connection between medium porosity, supersaturation and mesocrystals formation.

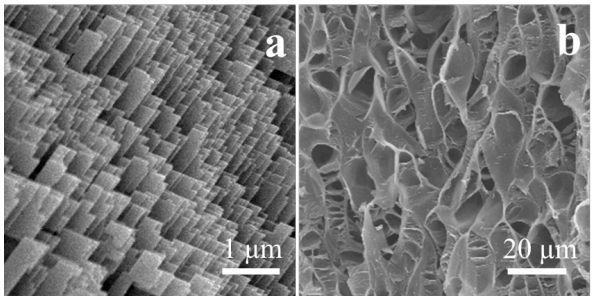

Fig 1. (a) Surface of calcite mesocrystal (10 wt% gelatine hydrogel) (b) Porous structure of a 10 wt% gelatine hydrogel

A Modeling Framework to Predict Changes in Soil Chemistry and Agricultural Return Flow in Seawater Farming of Halophytes

*QINGQIAN NING[1], WAN ABDUL-MATIIN[1] AND FARRUKH AHMAD[1]

[1]Bio-Energy and Environmental Laboratory (BEEL), Water and Environmental Engineering, Masdar Institute of Science and Technology, PO Box 54225, Abu Dhabi, United Arab Emirates. (qning@masdar.ac.ae)

Growing halophyte plants using Integrated Seawater Energy and Agriculture Systems (ISEAS) offers a sustainable solution for the generation of biomass feedstock for carbon neutral biofuels; halophytes neither enter the foodchain, nor do they compete with food-crops for natural resources. One such field demonstration of ISEAS for biomass production to generate aviation biofuels, is planned for the coastal regions of Abu Dhabi, UAE, where it will likely face a number of region-specific soil chemistry and hydogeology challenges not encountered in past demonstrations in Mexico and Eritrea. The unique soil chemistry (evaporite deposits, especially gypsum), and hypersaline coastal hydrogeology of Abu Dhabi will affect long-term halophyte agricultural productivity when Arabian Gulf seawater is applied to coastal soils as part of ISEAS. As an initial phase of the demonstration project, a salt deposition numerical modeling framework was developed to test different seawater loadings onto coastal soils. The aim of this exercise was to predict changes in irrigation return flow and soil chemistry over time in order to establish salt and water balances for sustained operation of the site. These modeling results will be further validated with laboratory lysimeter studies and with field monitoring data collected during one year of ISEAS operation. The results from this study could be used to (i) determine the optimal saline water loading correlating with peak soil salinities that selected halophytes can tolerate, (ii) potential for sodicity of the soil with saline water application, (iii) impacts of land application of saline water on underlying coastal groundwater, and (iv) develop strategies to control soil water activities in favor of halophyte agricultural productivity at ISEAS sites.

Can modern methane events and $\delta^{13}CH_4$ measurements say anything about glacial/interglacial transitions?

EUAN G NISBET[1], DAVID LOWRY[1], REBECCA E. FISHER[1], JAMES L. FRANCE[1] AND REBECCA BROWNLOW[1]

[1]Dept. Earth Sciences, Royal Holloway, Univ. of London, Egham TW20 0EX, UK. (n.name@rhul.ac.uk)

Over the past decade several major excursions, in the southern tropics, mid-latitudes and Arctic, have occurred in the atmospheric methane record. These recent growth rates, though short-lived, are comparable to those seen in the glacial-interglacial transitions. In the tropics recently, transient growth rates in excess of 10 ppb/yr have been observed, with sustained though lower growth rates through 2007-late 2012. This southern tropical event was apparently driven by increased rainfall, not directly by anthropogenic emissions as in the high CH_4-growth events in the 1980s. A brief strong growth event occurred in the Arctic in 2007/8, while high growth in the northern mid-latitudes occurred in 2003 and again in 2009. These latter events may have been partly driven by anthropogenic inputs.

$\delta^{13}CH_4$ studies of sources and polar flights suggest that Arctic and boreal wetlands, not hydrates, have been the dominant regional summer CH4 source in recent years. Hydrate-fed submarine plumes occur but their main near-future impact may be local ocean acidification and deoxygenation. In winter, Arctic anthropogenic emissions likely dominate. These modern changes, and their rapid fluctuations, suggest boreal and tropicla wetland emissions, responding very quickly to warming or cooling, could have dominated the increase in CH_4 at glacial terminations. Modern Atlantic transects and observations also show the importance of distinct air masses in shaping the annual average record.

Tempearture effects on cathodoluminescence of calcite

H. NISHIDO[1], S. NISHIZAWA[1] AND N. KUSANO[1]

[1]Department of Biosphere-Geosphere Science, Okayama University of Science, 1-1 Ridai-cho, Okayama 700-0005, Japan (correspondence: nishido@rins.ous.ac.jp)

Cathodoluminescence (CL) of calcite has been extensively investigated by many researchers, and used for a wide range of geoscientific applications. The CL features are affected by many factors such as activator, sensitizer and quencher of transition metal elements. However, the temperature effects on calcite CL have not been precisely clarified so far. In this study we have quantitatively evaluate temperature quenching effects on calcite CL with various activator concentrations.

Six calcite samples with Mn concetrations of 13, 129, 1259, 3520, 9170, 66500 ppm were selected for CL spectral measurements at various temperatures from −190~25 °C.

CL intensity of low-Mn calcite increases with an increase in sample temperature, but the intensity of medium-Mn calcite shows almost unchangeable at a wide range of temperature. In contrast CL intensity of high-Mn calcite decreases with increasing temperature. These facts imply that temperature effects on calcite CL depend on activator concentrations in calcite, whereas luminescence efficiency generally decreases with rising temperature due to an increase in non-radiative transitions, which has been known as temperature quenching.

A least-square fitting of the Arrhenius plot by assuming a Mott-Seiz model provides an activation energy of 0.04~ 0.07 eV for high-Mn calcite in a temperature quenching process. These values correspond to lattice vibration energy, suggesting that the energy of non-radiative transition might be transferred to lattice as phonon. The result leads that activator (Mn ion) concentration considerably affects temperature quenching effect on CL of calcite.

In situ observation of dehydration and incongruent dissolution of Serpentine (Antigorite) into aqueous fluids

RYO NISHIZAKI AND TATSUHIKO KAWAMOTO [1]

[1] Inst. Geothermal Sci., Graduate School of Science, Kyoto Univ. Kyoto 606-8502, Japan (ryo.nishizaki@gmail.com)

Serpentine plays important roles as triggering earthquakes through its dehydration and controlling the rheological coupling between slab/mantle. We heated a natural polycrystalline antigorite ($Mg_{51}Si_{36}O_{90}(OH)_{66}$) in H_2O in the Basset-type externally heated diamond anvil cell [1]. During 600-620°C, we observed that antigorite slightly dissolved into aqueous fluids and then forsterite started crystallizing under a pressure range from 0.27 to 0.64 GPa. The forsterite grew up to about 30 μm across in an hour. According to the previous studies, a dehydration reaction of antigorite = forsterite + talc + H_2O [2] can occur under the present experimental conditions. Nevertheless, talc was not found in our experiments during 1-4 hours. The experimental duration may be too short for antigorite to dehydrate and nucleate talc. Alternatively our observation indicates that antigorite dissolves incongruently into aqueous fluids at the dehydration reaction in the presence of aqueous fluids.

Takahashi *et al*. [3] conducted shear-sliding tests on antigorite gauge at temperature higher than the stability of antigorite under constant pore water pressure of 30MPa at confined pressure of 0.1GPa. They observe forsterite using SEM and trace amounts of talc using XRD in shear-localized zones. The incongruent dissolution of antigorite in our experiments can explain that the dehydration of antigorite forms forsterite, which can cause strengthening and embrittlement of the gouge even at constant pore water pressure. The talc-dissolved aqueous fluids can be silica-rich, and such fluids can migrate upwards to precipitate talc in the plate boundary [4].

Physiological and isotopic characteristics of nitrogen fixation by hyperthermophilic methanogens: Implication for nitrogen anabolism of the subseafloor microbial communities on the early Earth

MANABU NISHIZAWA[1], JUNICHI MIYAZAKI[1,2], AKIKO MAKABE[3], KEISUKE KOBA[3], AND KEN TAKAI [1,2]

[1] Precambrian Ecosystem Laboratory, JAMSTEC (e-mail: m_nishizawa@jamstec.go.jp)
[2] SUGAR Program, JAMSTEC
[3] Tokyo University of Agriculture and Technology

Hyperthermophilic hydrogenotrophic methanogens are considered to represent one of the most important classes of primary producers in hydrogen (H_2)-abundant hydrothermal environments throughout the history of Earth. Despite extensive studies of methanogenesis, comprehensive research on nutrient anabolism in hyperthermophilic methanogens is limited. This study first investigated the physiological properties and isotopic characteristics of experimental cultures of hyperthermophilic methanogens during the fixation of dinitrogen (N_2), an abundant but less-bioavailable compound in hydrothermal fluids. We found that these hyperthermophilic methanogens actively assimilated N_2 via molybdenum (Mo)-iron (Fe) nitrogenase under broad ranges of Mo and Fe concentrations relevant to present and past oceanic and hydrothermal environments. Furthermore, the methanogens produced more ^{15}N-depleted biomass than that previously reported for diazotrophic photosynthetic prokaryotes. These results indicate that diazotrophic methanogens can be broadly distributed in seafloor and subseafloor hydrothermal environments, where the availability of the transition metals is variable and organic carbon and nitrogen compounds and ammonium are extremely scarce. This perspective may provide key clues to understanding the geological and evolutionary history of the global nitrogen cycle if the nitrogen isotopic ratios of organic matter in the geological records associated with seafloor and subseafloor hydrothermal activities are linked to the potential functions of diazotrophic hyperthermophilic methanogens. The possible emergence and function of diazotrophy coupled with methanogenesis 3.5 billion years before the present may be inferred from the nitrogen and carbon isotopic records of kerogen and fluid inclusions from hydrothermal deposits.

Acid mine drainage (AMD) is a major source of water contamination in metal- and coal-mining districts worldwide. AMD is a natural consequence of mining activity where the excavation of mineral deposits (metal bearing or coal), below the natural groundwater level, exposes sulphur-bearing compounds to atmospheric O_2 and water. The most common reactions that lead to the production of AMD involve the chemical and biological oxidation of metal sulfides contained in mine waste heaps, active or abandoned mine workings, or in tailings piles left over from the processing of sulfide ores. Chemicals used for treating AMD after formation are hydrated lime, pebble quicklime, caustic soda, soda ash briquettes, and ammonia. Each chemical reacts differently with a specific AMD. Therefore, it is essential that each AMD source has be treated and evaluated chemically/physically to determine which is most environmentally sound, efficient and cost effective. In this study a geochemical survey of mine waters discharging in the main mining districts of Tuscany (central Italy) was carried out to establish their geochemical features to provide information on AMD processes at mining-impacted sites in order to supply a background information necessary to the scientists responsible for assessing remediation technologies.

The composition of Mercury's crust from MESSENGER observations

LARRY R. NITTLER[1]*, SHOSHANA Z. WEIDER[1] AND SEAN C. SOLOMON[2]

[1]Carnegie Institution of Washington, Washington DC 20015 USA (*lnittler@ciw.edu)

[2]Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY 10964, USA

The MErcury Surface, Space ENvironment, GEochemistry, and Ranging (MESSENGER) spacecraft has returned a wealth of data since it began orbiting the innermost planet more than two years ago. Imaging observations reveal a surface shaped by widespread volcanism that produced both flood lavas and pyroclastic deposits [1]. Geochemical measurements from X-ray and gamma-ray spectroscopy show Mercury's crust to be chemically distinct from those of the other terrestrial planets and rich in volatile elements [2-4]. Mg/Si ratios are generally higher, and Al/Si and Ca/Si ratios lower than typical crustal materials on other planets; there is no evidence for a lunar-like, feldspar-rich crust. The abundance of sulfur is surprisingly high (~1–4 wt %), which most likely indicates that Mercury formed under highly reducing conditions, and is consistent with the low total surface Fe abundance (1–2 wt %) [4,5]. Correlations between Mg/Si, Ca/Si, and S/Si suggest that MgS and CaS are important crustal minerals. The average K/Th ratio and Na abundance are similar to those of other terrestrial planets, ruling out some high-temperature models of Mercury's formation. The high abundance of volatiles likely plays a key role in the formation of "hollows", enigmatic shallow depressions observed only on Mercury [6]. Substantial chemical heterogeneity is also observed [7,8]: high-reflectance smooth volcanic plains are, on average, enriched in Al, Na, and K and depleted in Mg, Ca, and S, relative to older, darker terrains. The observed compositional variations most likely reflect intrinsic differences in the magmas that produced the surface materials, as well as possible thermal redistribution of K and Na from hot surficial regions to colder ones. The Fe abundance also appears to be heterogeneous on 1000-km scales and is uncorrelated with other elements [5].

Arsenic mobility in limestone and fertiliser-amended tailings

TARYN L. NOBLE[1,3] AND BERND G. LOTTERMOSER[2,3]

[1]School of Earth Sciences, University of Tasmania, Private Bag 79, Hobart, 7007, TAS (Taryn.Noble@utas.edu.au)
[2]Environment and Sustainability Institute, University of Exeter, Cornwall Campus, Penryn, Cornwall, TR10 9EZ, UK (B.Lottermoser@exeter.ac.uk)
[3]Cooperative Research Centre for Optimising Resource Extraction (CRC ORE), Australia

Remediation of acid rock drainage (ARD) through the addition of limestone results in the removal of deleterious metals (e.g. Cd, Cu, Pb) from solution, by mineral precipitation and adsorption reactions as the pH increases. However, arsenic (As) can be mobilised under neutral to alkaline pH conditions due to desorption reactions from different mineral surfaces. Also, the mobility of As is complicated by fluctuations in redox chemistry as well as As desorption in the presence of competitive anions. We investigated the mobility of As at a historic cassiterite tailings deposit (Royal George, Tasmania), where recent remediation efforts by statutory authorities included the application of crushed limestone and phosphate fertiliser pellets to the tailings surface.

Scorodite and iron oxide phases were identified to be the main As-host phases in non-amended tailings. Leaching experiments using different extraction solutions were conducted on amended and non-amended tailings. Results show that As mobility was considerably reduced in near neutral pH, low sulphate extraction solutions for both amended and non-amended tailings. However, a significant proportion of As was mobilised in the amended tailings relative to non-amended tailings, when extraction solutions with high sulphate concentrations were used. Since high dissolved sulphate (>1000 mg/L) waters are present in ARD environments, the application of phosphate fertiliser, in addition to limestone as an amendment strategy, may mobilise As from waste rocks and tailings in the long term. Rehabilitation efforts of As-rich wastes need to consider both the mineralogical siting of As and porewater chemistry.

Trace Element and Isotope Geochemistry of Cretaceous Basalts from Axel Heiberg Island, Arctic Canada

INÊS G. NOBRE SILVA[1]*, VICTORIA PEASE[1] AND GEORGE MORRIS[2]

[1]Dept. of Geological Sciences, Stockholm University, SE-106 91, Stockholm, Sweden (*inobre@geo.su.se)
[2]Geological Survey of Sweden, Box 670 SE-751 28 Uppsala

Cretaceous volcanic rocks related to the High Arctic Large Igneous Province (HALIP) in the Canadian Arctic Islands comprise dykes, sills and lava flows emplaced within the Sverdrup Basin. During an expedition to northwestern Axel Heiberg Island in the summer of 2007, a suite of 114 - 130 Ma basaltic rocks was recovered from the Bukken Fiord region. We present the first geochemical study on 11 of these basalts, including isotopic compositions by MC-ICP-MS (Pb) and TIMS (Sr and Nd).

All samples are tholeiitic. They cover a narrow range of MgO (3.2 to 7 wt%) and SiO_2 (45 to 54 wt%) contents and have high TiO_2 contents that range from 2 to 4 wt%. Trace element ratios of immobile, alteration resistent elements (e.g., Th/Nb, Th/Ta, La/Yb, Zr/Y, Nb/Y) suggest interaction and incorporation of crustal material by an enriched mantle source. The preliminary isotopic compositions of these basalts also support contamination by a crustal component. This is evidenced by their high $^{87}Sr/^{86}Sr$ (0.7036 to 0.7084), $^{206}Pb/^{204}Pb$ (18.5 to 19.1) and $^{208}Pb/^{204}Pb$ (38.2 to 38.9) values despite the acid leaching treatment prior to isotopic analyses to remove the disturbance effects of post-magmatic alteration.

Additional isotopic analysis will further constrain the mantle-crustal components involved in the formation of these basalts and the extent of contamination or assimilation. Integration of these new data with prior HALIP studies will contribute to a better understanding of Cretaceous magmatism during the opening of the Canada Basin.

XAS crystal-chemistry of Fe in mangrove sediments from New Caledonia. Implication for iron biogeochemical cycling

V. NOËL[1,3]*, C. MARCHAND[2], F. JUILLOT[1,2], G. ONA-NGUEMA[1], G. MARAKOVIC[3] AND G. MORIN[1]

[1]IMPMC, Universite Pierre et Marie Curie, 75005 Paris, France (*correspondence: Vincent.Noel@impmc.upmc.fr, Farid.Juillot@ird.fr, Georges.Ona-Nguema@impmc.upmc.fr, Guillaume.Morin@impmc.upmc.fr)
[2]IRD, 98848 Noumea, New Caledonia (Cyril.marchand@ird.fr)
[3]KNS, 98860 Kone, New Caledonia (GMarakovic@koniambonickel.nc)

Mangrove forests are the dominant intertidal ecosystem of tropical coastlines and play a fundamental role in the ecological balance of these areas. They strongly influence the transfer of trace metals between land and sea. In New caledonia, mangroves act as a buffer zone between massive Fe lateritic deposits and a lagoon registered as an UNESCO World Heritage site. Mangroves are composed of different stands, each dominated by a botanical species. Mangrove zonation mainly results from difference in soil elevation, and lenght of tidal immersion, and induces different ecosystem productivity, and redox conditions {1}. As a consequence, it may be responsible for differences in sediment geochemistry, and thus differences in metal speciation and bioavailability {2}.

In the present study, we have determined the distribution and speciation of iron in mangrove sediments in relation with organic content, redox, salinity and botanical gradients. Chemical and mineralogical analyses of mangrove sediment core samples were complemented by direct speciation of Fe using EXAFS spectroscopy. The results obtained show that crystal-chemistry of Fe strongly follows the marked change in sediment redox conditions that range from oxic in surface horizons to anoxic in deep horizons. The Fe-bearing minerals (mainly goethite, with minor amounts of Fe-phyllosilicates) are major phases in the upwards horizons and are inherited from lateritic, then progressively disapear from the surface horizons towards deepest horizons where pyrite forms.

Back to basics: Boron isotopic fractionation in synthetic calcite and aragonite

J. NOIREAUX[1]*, V. MAVROMATIS[2], J. SCHOTT[2], J. GAILLARDET[1], V. MONTOUILLOUT[3], P. LOUVAT[1] AND D. R. NEUVILLE[1]

[1]IPGP, Univ Paris Diderot, Paris, France, (*correspondence: noireaux@ipgp.fr)
[2]GET, Univ Paul Sabatier, Toulouse, France
[3]CNRS-CEMHTI UPR3079, 45071 Orléans France

Boron isotopic fractionation in marine carbonates, such as foraminifera and corals, is dependent on the pH of the seawater in which they form, allowing boron isotopes to be used as a proxy of the ocean-pH. The pH-dependency of the boron isotopic composition in organic calcium carbonates has been confirmed in laboratory environment. This behavior of boron isotopes is classically explained by the incorporation of the borate ion from seawater, whose isotopic composition is a function of its abundance and hence of pH. Modern biologically-precipitated calcium carbonates however display widely spread boron isotopic compositions which can be partially explained by vital effects but do not fit the simple model of preferential incorporation of the borate ion.

In order to better understand the mechanisms responsible for boron isotopic fractionation in calcium carbonates, we precipitated, in laboratory, inorganic calcite, Mg-calcite and aragonite over a wide pH range and performed both isotopic and ^{11}B MAS NMR (Magic Angle Spinning Nuclear Magnetic Resonance) analyses on the solids. Results show that, although δ^{11}B rises with pH for all crystal types, calcite and Mg-calcite display a smaller fractionation (more marked for calcite) with respect to the precipitation solution and a much lesser sensitivity to solution pH than expected. NMR spectra show almost exclusively tetrahedral boron in aragonite but highly variable proportions of trigonal and tetrahedral boron in calcite. We therefore suggest that both borate ion and boric acid are incorporated in calcite and Mg-calcite and that boron is present in both crystalline and non-crystalline sites whereas in aragonite the borate ion is the dominant species, representing over 90% of the total boron. These results overall suggest that aragonite-based calibrations should be favoured in future paleo-pH reconstructions. Calcite-based calibrations require a rigorous characterization via NMR spectroscopy of boron speciation and site occupancy in the crystals.

Impact of calcite precipitation on flow alteration in porous media

CATHERINE NOIRIEL[1], CARL I. STEEFEL[2], LI YANG[2] AND DOMINIQUE BERNARD[3]

[1]Géosciences Environnement Toulouse, Université Paul Sabatier, CNRS, IRD, 14 av. Edouard Belin, F-31400 Toulouse, (catherine.noiriel@get.obs-mip.fr)
[2] Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720, (CISteefel@lbl.gov, lyang@lbl.gov)
[3]Insitut de Chimie de la Matière Condensée de Bordeaux, CNRS, 87, av. du Dr Schweitzer F-33608 Pessac, (bernard@icmcb-bordeaux.cnrs.fr)

One of the major challenges associated with sequestration of carbon dioxide, given the complexity and range of coupled thermal, hydrological, mechanical, and chemical processes involved, is the understanding of geochemical reactivity in the case of long-term sequestration. Mineral trapping involves precipitation of minerals like calcite, which can cause a significant reduction in permeability of reservoirs by altering the shape, size and connectivity of the pores, the roughness of their surface, or by plugging the pore throats.

The effects of calcite precipitation in porous media are evaluated through an experimental and modeling study. Two experiments using cylindrical core packed with glass beads and calcite (Iceland spar) or aragonite (Bahamas ooids) were injected with a supersaturated mixture of $CaCl_2$ and $NaHCO_3$ to induce calcite growth. Bulk rates of precipitation based on the change in aqueous chemistry over the length of the columns are compared with spatially resolved determinations of carbonate precipitation using X-ray synchrotron micro-tomography with a resolution of 4.46 μm. The new crystals are shown to be very different according to the initial mineral surface on which they grow. Results are compared in terms of growth rate, crystal shape, surface area and pore roughness. The impact of crystal distribution on roughness increase and on pore scale flow and permeability is evaluated through numerical modeling. The results are compared with results for several model porous media for which different crystal growth rates were implemented. The effect of differing calcite growth rate laws and surface roughness are compared for cases in which the total porosity change is comparable.

Ten years of ground deformations monitored by the ground-based SAR system on Stromboli volcano and its use in forecasting intense volcanic activity

TERESA NOLESINI[1], FEDERICO DI TRAGLIA[1,2], EMANUELE INTRIERI[1], FEDERICA BARDI[1], FEDERICA FERRIGNO[1], SARA FRANGIONI[1], WILLIAM FRODELLA[1], CARLO TACCONI STEFANELLI[1], LUCA TANTERI[1], CHIARA DEL VENTISETTE[1] AND NICOLA CASAGLI[1]

[1]Dip. Scienze della Terra, Università di Firenze, Via La Pira 4, Firenze
[2]Dip. Scienze della Terra, Università di Pisa, Via Santa Maria 53, Pisa

A Ground Based Interferometric Syntetic Aperture Radar (GBInSAR) system has been installed on Stromboli Volcano since 2003, when on the 30 December 2002, after a major eruptcionan a subsequently large landslide occurred on the NW flank (Sciara del Fuoco, SdF) of the volcano. This GBInSAR is a remote sensing tecnique based on microwaves interferometry that permits the production of 2D displacement maps, called interferograms, with millimetre precision. The apparatus installed on Stromboli, exploits a metric spatial resolution and acquisition frequency of about 11 min. Only the component of the displacement vector to parallel to the line of sight can be assessed.

The investigation conducted by analysis of the GBInSAR data, has permit to divided the crater area and the SdF area in five differents sectors, to better analyze and undestand the behaviour of the volcano flank dynamics.

The GBInSAR installed at Stromboli volcano has been used as a remarkable early-advice tool for mass and gravitative movements on the Sciara del Fuoco. GBInSAR monitoring highlights different deformation patterns, related to the imminent new vent openings. The analysis of the displacement rates in the summit crater area has been used as early warning signal before the occurrence of major explosions and lava emission. Changing in displacement rate registered by the GBInSAR system in the upper part of the volcano, corresponding to the external flank of the summit craters and at the base of the summit area, has been used to forecast the change in the pressure conditions in the shallow plumbing system and the lateral propagation of the conduit-dike system of Stromboli volcano.

Low core-mantle boundary temperature inferred from the solidus of pyrolite

R. NOMURA[1]*, K. HIROSE[1,2,3], K. UESUGI[4], Y. OHISHI[4] AND A. TSUCHIYAMA[5]

[1]Tokyo Institute of Technology (Titech), Tokyo 152-8551, Japan (*correspondence: nomura.r.ab@m.titech.ac.jp)
[2] Earth-Life Science Institute/Titech, Tokyo 152-8551, Japan
[3]IFREE/JAMSTEC, Kanagawa 237-0061, Japan
[4]JASRI/SPring-8, Hyogo 679-5198, Japan
[5]Kyoto University, Kyoto 606-8501, Japan

The solidus of a pyrolite-like composition plays a fundamental role for understanding structure and evolution of the deep Earth, such as temperature profile in the lowermost mantle and melting in the early Earth. Fiquet *et al*. [1] determined the solidus of a pyrolitic composition up to 120 GPa with X-ray diffraction (XRD) measurements using laser-heated diamond anvil cell techniques (LH-DAC). They identified melting by the disappearance of Debye rings of $CaSiO_3$-rich perovskite and/or ferropericlase, however, this melting criteria has a potential to overestimate the solidus temperature due to high temperature gradient along X-ray transmitted axis in LH-DAC.

Solidus temperatures of pyrolitic mantle material were determined by discerning a melting texture from synchrotron dual-energy three-dimensional micro-tomographic images measured at BL47XU of SPring8 [2]. The melting was identified by the existence of (a) round-shaped and (b) iron-enrichd region at the hottest part of the sample. The measured solidus temperature of the pyrolitic material was 3700 K at 135 GPa, which is extensively lower than that of 4200 K at 135 GPa measured by XRD [1]. Since seismic observations suggest that melting of the current lowermost mantle is very localized [3], the solidus of pyrolite set an upper limit to the present temperature at core-mantle boundary below 3700 K.

The subsolidus phase assemblage and the phase transition boundary between $MgSiO_3$-rich perovskite and post-perovskite were also determined near the solidus temperature on the basis of high *P-T* XRD measurements in LH-DAC.

These results have great significance for understanding temperature profile in the lowermost mantle and melting in the early Earth such as volume of basal magma [4] remnants, since these remnants should have lower solidus temperature than that of pyrolite.

A practical constraint on entrainment and condensate evaporation and from aircraft and satellite observations of isotope ratios of water

DAVID NOONE[1]

[1]dDepartment of Atmospheric and Oceanic Sciences and Cooperative Institute for research in Environmental Sciences, University of Colorado, Boulder, CO, 80309-USA (*correspondence: dcn@colorado.edu)

Convective clouds play a significant role in the moisture and heat balance of the tropics. The dynamics of organized and isolated convection are a function of the background thermodynamic profile and wind shear, buoyancy sources near the surface and the latent heating inside convective updrafts. The stable oxygen and hydrogen isotope ratios in water vapour and condensate can be used to identify dominant moisture exchanges and aspects of the cloud microphysics that are otherwise difficult to observe. Aircraft observations show that there is significant disequilibrium between the cloud core and the ambient environment, which allows an estimate of exchange at cloud boundaries that lead to condensate evaporation. Indeed, the mechanisms for condensate evaporation gives a basis for using satellite profiles of D/H isotope ratios to yield estimates of the rate of moistening of the troposphere above the boundary layer. In the western tropical Pacific and over tropical continents in excess of 60% of condensate evaporates into the environment, and is the principal moisture source for tropospheric water. The success of the calculation relies on both an adequate parameterization of the mechanisms driving the water budget, and the use of isotope ratio data to satisfactorily constrain the parameters. The unique information on moisture history provided by the isotope ratio measurements allows assessment of moisture transport that is not otherwise easily observed.

Au mineralization and its relationship with shear zones in senjedeh gold deposit

ZAHRA NOORIAN RAMSHEH*AND MOHAMMAD YAZDI

Department of Geology, Shahid Beheshti University, Tehran Iran* (zn5562@yahoo.com)

Senjedeh gold deposit is located in middle part of the Sanandaj-Sirjan zone, central Iran. It is consist of several gold deposits such as Chah-katoom, Dareh Ashky and Senjedeh. Lithological and stratigraphic investigations show that the geological units in this area include metamorphic rocks (different facies of greenschist to amphibolite schist), silicified and mineralized veins and granitic intrusions. This series have been deformed in effect of tectonic alternating phases and lost their primary sequence and order during late Cretaceous-Tertiary continental collision between the Afro-Arabian and the Iranian micro continent. As a result of these tectonic activities, different rocks fabric has been formed. Based on structural studies, major tectonic structure in this area is shear zones. According to oriented sample studies, some of the fabric features related to shear zone. Ore-mineral assemblages mainly include pyrite and chalcopyrite. Gold mineralization in Senjedeh area occurred in relation to hydrothermal alterations in metamorphic units during to normal faulting. The pervasive alterations in this area are silicification and sulfidation which are responsible of gold mineralization. The field and petrographic studies show a direct relationship between structures and gold mineralization. The petro fabric studies and correlation mineralization direction show that Senjedeh Gold deposit can be an example of orogenic gold deposit in Iran.

Key words: Senjedeh gold deposit, shear zone, Sanandaj-Sirjan zone

Structure-propertie relationship of Na/Ca silicate liquids under pressure by mollecular dynamics simulation

FUMIYA NORITAKE[1]*AND KATSUYUKI KAWAMURA[1]

[1] Okayama Univesity, Okayama, 700-8530, Japan. (*Coresspondence: f.noritake@s.okayama-u.ac.jp)

Peculiar behabiours of physical properties of silicate liquids under high pressure are long standing issue in high pressure earth scinence. For instance, it is well known that shear viscosities of acidic silicate liquids decreases with increasing pressure [1, 2]. In order to explain the softening of silicate liquids at high pressure, several mechanisms have been proposed by various researchers [1, 3]. To investigate the relationship between structure and properties of silicate liquids, we apply the molecular dynamics method to obtain precise information on structures of silicate liquids under high pressure.

Molecular dynamics simulations of $Na_2O \cdot nSiO_2$ and $CaO \cdot nSiO_2$ liquids were performed using the MXDORTO code. The simulated pressure range is from 0.1 MPa to 6 GPa with NPT ensembles and the potential model which well reproduces structures various silicate crystals [4].

In the compression, Si-O and M-O distance remains constant, however Si-Si distances shorten and coordination numbers of O atoms around M atom increase. Adding to those, 3 and 4 membered rings in –Si-O- network decrease with increasing pressure. Those suggest that densification of silicate liquids consist of increasing of flexibility of –Si-O- network, bending of Si-O-Si and increase of coordination number of M atoms. Up to 6 GPa, the decrease of Si-O-Si angle and distrotion of SiO_4 tetrahedra in acidic silicate liquids ($n<3$) are obveously confirmed. Decrease of Si-O-Si angle by densification causes distortion of SiO_4 tetrahedra and weakening of Si-O bonding [5]. These structural change might cause the softening of silicate liquids under high pressure. Deferences between Na and Ca was observed in structure, properties and behaviours of those at hige pressure.

Montmorillonite colloid size heterogeneity – Fractionation and Characterization

K. K. NORRFORS[1]*, M. BOUBY[2], S. HECK[2], N. FINCK[2], R. MARSAC[2], T. SCHÄFER[2]AND H. GECKEIS[2], S. WOLD[1]

[1]Department of Chemistry/Applied Physical Chemistry, KTH Royal Institute of Technology, Teknikringen 30, SE-100 44 Stockholm, Sweden (*correspondence: norrfors@kth.se, wold@kth.se)

[2]Institute for Nuclear Waste Disposal (INE), Karlsruhe Institute of Technology (KIT), P.O. Box 3640, D-76021 Karlsruhe, Germany (muriel.bouby@kit.edu, stephanie.heck@kit.edu, nicolas.finck@kit.edu, remi.marsac@kit.edu, thorsten.schaefer@kit.edu, horst.geckeis@kit.edu)

Highly compacted bentonite is planned to be one component of the engineered barrier system in many spent nuclear fuel final repository designs. The potential release of montmorillonite colloids, acting as carriers, may enhance the transport of radionuclides in case of a leaching canister. During transport, size exclusion/filtration may occur, resulting in migration of specific size fractions only. Therefore, it is necessary to determine the size heterogeneity of the mobile bentonite clay colloid and its radionuclide association.

In this study, unpurified MX-80 bentonite consisting mainly of smectite with impurities of quartz, plagioclase, orthoclase, muscovite as well as calcite/dolomite, gypsum and pyrite, was sedimented in low ionic strength carbonated synthetic ground water (SGW) at 10g/L. Thereafter, seven colloidal suspensions of various size fractions were obtained by sequential and direct centrifugation. Their particle size distributions were measured by PCS and AsFlFFF/UV-Vis/LLS/ICP-MS. The concentrations of colloids and other elements present in the suspensions were measured by IC and ICP-OES. The mineralogical composition was analyzed by XRD.

The mean particle size is decreasing with the number of fractionation steps, from ~500 down to ~50 nm. The presence of predominantly montmorillonite colloids is confirmed by: i) XRD results, for all colloidal fractions and ii) the Si/Al and Al/Mg mole ratios. There is an instant release of Na and SO_4^{2-} to the SGW while adding the bentonite indicating the dissolution of accesory minerals and cation exchange processes. An increasing release of natural ^{238}U with decreasing size fractions (i.e. larger exposed surface area) is evidenced. The results are discussed with respect to the implication on radionuclide speciation and transport.

Activities and volatilities of trace components in CaO-MgO-FeO-Al_2O_3-SiO_2 melts

C.ASHLEY NORRIS AND BERNARD J.WOOD

University of Oxford, U.K., (ashley.norris@earth.ox.ac.uk;berniew@earth.ox.ac.uk)

Knowledge of the activities of trace components in silicate melts is extremely important for addressing such problems as (a) degassing in volcanic systems (b) volatilities in protoplanetary systems and (c) the effect of melt composition on trace element partitioning. Nevertheless these activities are very difficult to measure by conventional phase equilibrium techniques except under circumstances where the metallic element is stable in a readily accessible f_{O2} range[1]. We have modified the "metal-saturation" approach by measuring the partitioning of a large number of elements (V, Cr, Cu, Zn, Ga, Ge, Mo, Ag, Cd, In, Sn, Sb, W, Tl, Pb and Bi) between liquid Fe alloys and liquid silicate at 1.5 GPa and 1650ºC. The data provide activity coefficients for oxide components relative to the activity of FeO, whose partitioning between metal and silicate is also measured. Use of graphite capsules means that the silicate melt composition can be varied over a wide range, but also means that the metal is carbon-saturated, a factor which has a profound effect on the activities of some components (e.g Pb, Ag, W) in the liquid metal.

We find that the activity coefficients of a number of the most important trace components, notably WO_3, MoO_2, GeO_2, $TlO_{0.5}$, $GaO_{1.5}$, $BiO_{1.5}$ and $SbO_{1.5}$ are strongly dependent on melt composition each showing variations of 1-2 orders of magnitude over the accessible range of silicate melt compositions. Values for $CuO_{0.5}$ are in excellent agreement with previous experimental data[2] on Cu-saturated compositions which shows that the method is viable. When combined with thermodynamic data on the gas species we find that volatilities under solar nebula conditions are displaced relative to those of the "conventional" condensation sequence[3].

Geochemical characterization of uranium mill tailings

J. NOS[1]*, A. BOIZARD[2], C. PEIFFERT[2], V. PHROMMAVANH[1], M. CATHELINEAU[2] AND M. DESCOSTES[1]

[1]AREVA Mines – DR&D, 92084, Paris La Défense, France (*correspondence: jeremy.nos@areva.com)
[2] CREGU, 54500, Vandoeuvre-lès-Nancy, France

In France, uranium mines were exploited between 1945 and 2001, leading to the production of 76,000 t of U and 50 Mt of mill tailings stored on 16 storage sites. Studies are being performed to determine the long term behaviour of these storage sites, focusing on the mobility of U and ^{226}Ra.

Following previous work [1] on mill taillings issued from dynamic treatment, coring and sampling were performed in four storage sites, including heap leaching tailings. All the tailings studied come from sulphuric acid treatment of granitic ore. Radio-geochemical variations were assessed through analyses on 10 to 20 samples for each site. Focus was put on the mobility of U and ^{226}Ra by characterizing their granulometric distribution and performing sequential leachings. Concurrently, water-rock interactions were constrained by pore water sampling on one site.

Samples issued from each site feature strong similarities, typical of a mix of tailings and water treatment sludges. Three main mineralogical families are identified: "inherited minerals", intially present in the granitic rock (quartz, micas, K-feldspars, ancillary minerals such as sulfides and oxides), "refractory" U-bearing minerals (uraninite, coffinite) and newly formed minerals. The latter are clay minerals and Fe^{III} oxy-hydroxides (from the alteration of the granite host rock), gypsum (due to reagents input during the ore treatment) and U-phosphates (both inherited and newly formed). Geochemical modellings indicate the presence of soddyite controlling the [U] in the porewater.

The average U content is 100 ppm. The ^{238}U/^{226}Ra disequilibrium is constant in dynamic treatment tailings, consistent with a homogeneous ore treatment and a limited migration of U and Ra. This ratio is more variable in heap leaching tailings, suggesting a heterogeneous ore treatment.

All these results are considered in the modelling of the long term evolution of mill tailings, taking into account the sorption properties of the newly-formed minerals.

The importance of dry deposition in estimating nitrogen input in peat bogs

M. NOVAK[1]*, L. BOHDALKOVA[1], D. FOTTOVA[1], J. CURIK[1], M. STEPANOVA[1], M. DARMOVZALOVA[1] AND F. VESELOVSKY[1]

[1]Czech Geological Survey, Geologicka 6, 15200 Prague 5, Czech Republic (*correspondence: martin.novak@geology.cz)

It has been recently reported that rain-fed peat bogs in pristine areas store more nitrogen (N) than the amount of N that could have been supplied by atmospheric deposition. In such calculations, cumulative input of nitrate and ammonium are compared with the total N content in ^{210}Pb-dated peat cores. We have performed a similar comparison in N-polluted Central Europe. Four sites exhibited 2 – 3 times higher N pool size in *Sphagnum* peat since 1880 than cumulative atmospheric input. This discrepancy might be explained by a large contribution of dry deposition. Dry deposition depends on the surface roughness (leaf area index) and is extremely difficult to measure directly in peatlands. In a first approximation, we have used data on spruce canopy throughfall as a proxy for *Sphagnum* interception of airborne N. At 6 sites of the monitoring network GEOMON, N input via spruce throughfall was smaller than via open area deposition. At another 7 sites, N input via spruce throughfall was slightly higher than via open area deposition (59 vs. 26 kg N ha^{-1} yr^{-1} in Orlicke Mts. was an extreme). It appears that dry deposition may not fully explain excess N in wetland ecosystems.

Comparison of δ^{53}Cr ratios between geogenic and anthropogenic chromium in Central European waters

M. NOVAK[1]*, V. CHRASTNY[1], J. FARKAS[1], T.D. BULLEN[2], E. CADKOVA[1], Z. SZURMANOVA[3], J. TYLCER[3], L. ERBANOVA[1], E. PRECHOVA[1] AND J. PASAVA[1]

[1]Czech Geological Survey, Prague, Czech Republic (*correspondence: martin.novak@geology.cz)
[2]U.S.Geological Survey, Menlo Park, Ca., U.S.A.
[3]AQD-envitest, Ostrava, Czech Republic

$^{53}Cr/^{52}Cr$ isotope ratios can be used to distinguish between geogenic and anthropogenic sources of chromium in surface waters and groundwaters. Often, a multiple-tracer approach is needed. Since 2011, we have monitored Cr concentrations and δ^{53}Cr values in seven different areas of the Czech Republic, Central Europe. At two sites, we sampled first-order streams on ultrabasic (serpentinite) bedrock. At five sites, we sampled shallow groundwater in the vicinity of Cr-processing industrial operations. Water samples were complemented with globally distributed minerals and whole-rock samples. Sofar, we have isotopically analyzed 110 samples. Mean Cr concentrations were 6500 ppb in industrial waters, and 20 ppb in geogenic waters. The range of δ^{53}Cr values increased from minerals/rocks to geogenic and industrial waters. The δ^{53}Cr of solid samples was close to 0 per mil, with isotopically slightly heavier Cr in some serpentinites (+1.1 per mil). The range of δ^{53}Cr of geogenic waters was 4.0 per mil (from -0.1 to +3.9 per mil). The range of δ^{53}Cr of anthropogenic waters was 4.6 per mil (from +1.2 to + 5.8 per mil). In general, Cr in anthropogenic waters was isotopically heavier than Cr in geogenic waters. None of the industrial waters had a δ^{53}Cr close to 0 per mil. Sofar, we have not observed C-isotope indices of natural attenuation of the anthropogenically polluted groundwaters.

Fluvial sediments: Assessment of contamination by trace metals respecting natural variability

TEREZA NOVAKOVA[1,2], TOMAS MATYS GRYGAR[2], MARTIN MIHALJEVIC[1] AND LADISLAV STRNAD[1]

[1]Charles University, Faculty of Science, Albertov 6, 128 43 Prague (*correspondence: Tereza.Novakova@natur.cuni.cz, Mihal@natur.cuni.cz, Lada@natur.cuni.cz)
[2]Institute of Inorganic Chemistry AS CR, 250 68, Rez (Grygar@iic.cas.cz)

According to the latest studies, proper assessment of trace metal contamination levels in fluvial sediments of different rivers necessarily requires individual approaches for each river, according to the local geological proveniences and individual river sedimentation dynamic characteristic.

Such special approach includes sampling respecting floodplain architecture, use of different normalisation elements for each trace metal (e.g., Al, Ti, Rb, Fe) to eliminate highly possible dependence of natural lithogenic background values on lithofacies and finally also use of sufficient method for contamination level assessment.

In this study, comparison of trace elements contamination level (Pb, Zn, Cu, Cr and Ni) of floodplain sediments of five different rivers in Czech Republic (the Berounka, the Jizera, the Morava, the Ohře and the Ploučnice) was done. Floodplain sedimentary profiles were obtained from hand drilled cores, elementary analysis was done by energy dispersive X-ray fluorescence (ED XRF) and by inductively coupled plasma mass spectrometer (ICP MS); cation exchange capacity measurement (CEC) was used for determination of expandable clay mineral content.

Regional lithogenic background values were obtained from “safe” parts of profiles (uniform facies, i.e. no sandy strata, unaffected by reductimorphic processes, unpolluted) and were further used for revelation of potential post-depositional trace elements migrations within profiles and also for determination of anthropogenically contaminated layers.

Elimination of potential influences of lithofacies and also elimination of different provenience influences was allowed by using of carefully chosen normalisation elements for trace elements in the rivers (e.g., Rb normalisation was used for all trace metals in the Morava River sediments or in the case of the Jizera River, Ti normalisation was used for Pb, Zn, Cr and Ni and Rb normalisation for Cu).

The only exception was the upper part of the Ohře River, where no normalisation element was yet established, due to the different proveniences influence and hence simple normalisation could not be used.

The formation of low degree hydrous melts in the Earth's upper mantle

D. NOVELLA[1]*, D.J. FROST[1] AND E.H. HAURI[2]

[1]Bayerisches Geoinstitut, Universitaet Bayreuth, Germany (*correspondence: davide.novella@uni-bayreuth.de)
[2]Carnegie Institution of Washington, DC, USA

Melting processes in the Earth's interior play a crucial role in the chemical evolution of our planet. The presence of low degree, volatile-bearing melts in the deep mantle is supported by the occurrence of volatile-bearing minerals in xenoliths and by geophysical observations. In order to quantify the proportion of melts formed as a function of mantle water content, we have performed a series of crystallization experiments, following a similar methodology to the sandwich technique, where large pools of hydrous melt composition were equilibrated with a complete mantle peridotite phase assemblage. In particular, we determined the chemical composition of these incipient hydrous melts forming at pressures above 3 GPa. Following this approach, we assessed the water content of the low degree melts by mass balance calculation, based on accurate chemical analyses performed on the large portions of melt. The H_2O concentration of the peridotite mineral phases was determined by NanoSIMS analyses in order to obtain information on the partitioning of water between mantle minerals and low degree hydrous melts.

Based on some estimates of the water content of the mantle, a deep onset for the inception of adiabatic melting can also be implied. However, accurate information regarding the chemistry of low degree H_2O-bearing melts is limited to pressures below 3 GPa. This is a consequence of a number of experimental challenges encountered in performing experiments at high pressure within complex systems, such as quench crystallisation and loss of H_2O and FeO from charges. In addition, the small volume of hydrous melts created by plausible mantle H_2O contents at depth creates challenges even for the analysis of major elements. Sandwich experiments are very useful because they permit large proportions of low degree composition melts to be equilibrated with mantle residual assemblages. Large amounts of melt promote crystal growth and facilitate melt analyses.

Using these results the H_2O contents of mineral and melt phases can be addressed as a function of mantle H_2O content. Our results indicate H_2O concentrations in mineral phases that are significantly greater than previous studies performed at similar pressure, temperature and low degree of melting conditions.

Origin of two different zircon types in metabasite veins from the Izera metagranites, West Sudetes, Poland

I. NOWAK[1]* AND M.J. WHITEHOUSE[2]

[1] Institute of Geological Sciences, Polish Academy of Sciences INGPAN, Podwale 75, 50-449 Wrocław, Poland (*correspondence: izanowak@twarda.pan.pl)
[2] Swedish Museum of Natural History, Stockholm, Sweden

In the northern part of the Izera-Karkonosze Massif, which represents the passive margin of the Saxothuringian terrane, c. 500 Ma granites were intruded by a swarm of the WNW-trending subvertical basic veins and then deformed and metamorphosed. Two types of zircon, types I and II, that differ in colour, size, habit and internal structure were identified in six metabasite veins. Colourless, transparent and euhedral, 300 μm sized, CL-bright zircon of type I display inherited old cores as well as c. 500 Ma oscillatory zoned rims. Their U-Pb ages are almost identical with the previously determined intrusion age of a protolith for the Izera metagranites (U-Pb, zircon, 515-480 Ma). Grains of type I show $\delta^{18}O$ (6.2-9.1‰) values and Ti-zircon temperatures (600-780°C) similar to the data from the Izera gneiss zircons. Their REE patterns exhibit a narrow range. Such coincidence indicates that the zircons of type I are probably inherited xenocrysts incorporated into the basic magma via assimilation of material of local granitic crust. Type II zircons, which yield ages of c. 370 Ma, are brown, turbid, subhedral crystals up to 600 μm size, and dark in CL. Their large (c. 2/3 of the grain size), almost homogeneous and microinclusion-rich inner parts are surrounded by thinner oscillatory zoned rims. They display a wide range of Ti-zircon temperatures (630-800°C), variable REE contents and $\delta^{18}O$ (4.5-8.9‰) values. The origin of these brown zircons is ambiguous. Their homogeneous interiors and oscillatory zoned rims indicate growth in a magmatic melt. Grains showing $\delta^{18}O$ from 5.1-5.5‰ present coherent magmatic-style REE patterns with positive Ce and negative Eu anomalies, also indicative of their magmatic origin. However, dark and inclusion-rich centres of type II grains suggest precipitation from hydrothermal fluids, while low $\delta^{18}O$ (4.5-5.0‰) values, incoherent REE patterns, LREE enrichment and a lack of Ce anomaly in many grains suggest interaction of the metabasites with hydrothermal fluids during crystallization of the brown zircons. The results are consistent with type II zircon of crystallizing from a fluid-saturated residual melt or more likely representing magmatic crystals hydrothermally altered by fluids coming from the surrounding metagranites.

Delaminated Lithospheric Mantle and exotic metasomatism beneath East Russia

NTAFLOS TH[1], ASCHCHEPKOV I.[2], KOUTSOVITIS P.[1], HAUZENBERGER A.[3], PRIKHODKO V.[4] AND ASSEVA A.[5]

[1]Dept. of Lithospheric Research, University of Vienna, Austria (theodoros.ntaflos@univie.ac.at)
[2]RAS, Institute of Geology and Mineralogy, Novosibirsk, Russia
[3]Institute für Erdwissenschaften, University of Graz, Austria
[4]RAS, Far-Eastern Branch, Institute of Tectonics and Geophysics, Khabarovsk, Russia
[5]RAS, Far-Eastern Branch, Geological Institute, Vladivostok, Russia

In the back-arc environment of Far East Russia, mantle xenoliths from Sikhote-Alin(KO) and Primorie (SV), Far East Russia are fertile spinel lherzolites with amphibole, phlogopite armalcolite, fassaite and röhnite in some of the studied samples. Though samples from both localities are fertile there is a systematic difference in their fertility. The KO samples have mg# varying from 0.891 to 0.899 and are slightly more fertile than the SV samples that have mg# ranging from 0.898 to 0.904. The cpx REE confirm this trend as the $(La/Yb)_N$ in KO samples range from 0.10 to 1.00 and in SV samples from 0.15 to 1.73.

The clinopyroxene Sr and Nd isotopic ratios range from 0.702599 to 0.703567 and 0.512915 to 513153, repectively, resembling Pacific MORB isotopic ratios.

En route breakdown of diseminated amphibole produces second generation of cpx and olivine and traces of glass as well fassaite and röhnite indicating crystallization at very shallow depths. Melt pockets consisting of Ca-rich glass plagioclase rutile, ilmenite and armalcolite suggest introduction of small amount of an unusual Ti-Ca-rich anhydrous silicate melt at mantle depths.

The lithospheric mantle beneath the studied area represents the residue after partial melting of up to 5% of a primitive mantle. Despite the fact that the studied area experienced several subducting episodes, the lithospheric mantle appears to be unaffected from the upwelling fluids/melts of the subducted slab(s). Since there is no indication for plume activity, and/or evidence for refertilization, it is likely that the lithospheric mantle has been delaminated as the result of tectonic events (lithospheric attenuation, inverse tectonic) associated with the subduction processes and that the studied spinel lherzolites represent upwelling asthenosphere.

Resilience Biomimcry model for natural disturbance scenarios

NUNES L[1] AND NAROG M[2]

[1]Luisa Nunes, ESACB/CEABN, Qta Sra Mercules, 6000 Castelo Branco Portugal,(lfnunes@ipcb.pt)
[2]Marcia Narog, USDA Forest Service, Pacific Southwest Research Station, Riverside, CA, mnarog@fs.fed.us

Mobile links are 'keystone' organisms that move among habitats and provide essential ecosystem functions such as pollination, seed dispersal, or nutrient translocation. After disturbance, some ecosytem functions may become disrupted or may disappear altogether. Much like similar habitats joined by corridors, the mobile links connect areas that may be widely separated spatially or temporally. Species strategies and interactions must be reconfigured after disturbance based on residual organisms and any altered environmental constraints. Reassemblage of organisms might be based on an ecological memory that contributes and leads to the recovery of the affected area. This ecological memory is the complex network of species and their relations with each other and the environment.

Based on the renewal cycle of Holling, we developed a biomimicry resilience model that identifies recovery strategies inspired by opportunistic species colonization, their accumulation and storage of resources and the reorganization phases to a new stability.

We studied and characterized which interactions take place within and between disturbed and undisturbed areas that facilitate proliferation, regeneration and nutrient translocation. The resilience model also considered limitations such as distance from source areas, availability of dispersal agents and suitability of the disturbed environment.

This resilience model was created to help understand natural recovery processes that can be emulated after disturbances and applied to human community disaster planning.

Probing paleoearthquakes with *in situ* U-Pb SHRIMP-RG analyses of fault-related opals

PERACH NURIEL[1]*, KATE MAHER[1]J AND DAVID M. MILLER[2]

[1] Department of Geological and Environmental Sciences, Stanford University, CA 94305, US (*correspondence: perach@stanford.edu, kmaher@stanford.edu)

[2] U. S. Geological Survey, 345 Middlefield Road, MS-973, Menlo Park, CA 94025, USA (dmiller@usgu.gov)

In the past decade U-Pb and U-series dating techniques have been successfully applied to opals from arid regions, providing important temporal constraints on paleohydrology, paleoclimate, and depositional environments. In particular, the use of *in situ* SHRIMP-RG (Sensitive High Resolution Ion Microprobe – Reverse Geometry) dating techniques has been demonstrated to resolve mixed multiage problems that arise from slow-growth or multi-stage growth at the sub-millimeter scale. Building upon these advances, we apply *in situ* SHRIMP-RG dating methods to fault-related opal precipitates taken from seismically active fault zones with the aim of dating brittle deformation events. The Mojave Desert fault segments within the Eastern California Shear Zone (ECSZ) are ideal faults to investigate the long-term history because of the need for improved constraints on the timing of fault initiation and the observed discrepancy between long-term and short-term estimates for strain accumulation rates.

We analyzed fault-related opal samples from five different fault exposures within the Camp Rock and the Cave Mountain fault systems. Millimeter size fragments of fault-related opal, occurring as fault coating, filling or fault-breccia cement, were imaged using cathodoluminescence and backscattering electron microscopy in order to identify distinct phases of opal associated with specific syntectonic microstructures. Sub-samples within each phase are then targeted with multiple SHRIMP-RG analyses (<50 μm in diameter) to allow the construction of $^{238}U/^{208}Pb$-$^{206}Pb/^{208}Pb$ and/or Tera-Wasserburg U-Pb isochrons. Of the 30 distinct phases that were identified, 10 were successfully dated, providing U-Pb ages with $2\sigma \leq 10\%$ and MSWD between 0.42 and 1.8. The most important factors for successful age determinations were low amounts of common Pb, high U concentrations (between 50 and 1300 ppm) and heterogeneities within each phase. Ages range from 1.45 to 0.58 Ma and coeval ages are clustered into several periods during this time interval, suggesting periods of enhanced fault activity. Additional analyses of syntectonic opals, taken from several sites and from additional faults segments can constrain the long-term deformational history and contribute to our understanding of how strain is distributed both locally (within a specific structure) and regionally (within different fault systems) over a geological time scale.

U-series isotopes as tracers of particles fluxes and deposition rates of Heinrich layers H2 and H1 from a core raised off Hudson Strait

L. NUTTIN* AND C. HILLAIRE-MARCEL

GEOTOP research centre, Université du Québec à Montréal, Montreal, Canada (correspondence: lanuttin@gmail.com)

A ~9 m-long core was retrieved from the lower Labrador Sea slope (2674 m water-depth), approximately 180 km off the Hudson Strait shelf edge. It yielded a high resolution record of recent detrital carbonate (DC) sedimentary pulses from the Hudson Strait outlet of the Laurentide ice sheet, assigned to "Heinrich events" H2 and H1. These fine carbonate-rich layers (calcite/dolomite ~ 2.5) originated from glacial erosion of Paleozoic rocks in Hudson Strait and Ungava Bay. The coarse sediment fraction content of the layers suggest intense iceberg calving at the ice-stream edge, while sub-glacial meltwater flushing over the Hudson Strait sill carried fine silt-sized, carbonate-rich glacial flour to the shelf edge. Such suspended sediment pulses led to the spreading of turbidites into the deep Labrador Sea. These layers are characterized by a ^{234}U deficit (vs ^{238}U) and by very low ^{230}Th excesses corrected from decay to the time of deposition $(^{230}Th_{xs})_0$. These low values indicate extremely fast deposition. Inventories of $(^{230}Th_{xs})_0$ were used to estimate durations of ~1.28 and ~1.99 ka respectively for H2 and H1, relative to estimates of ~1.15 and ~2.12 ka from calibrated ^{14}C ages on planktic foraminifers. Another DC-layer was deposited at ~8.3 cal ka BP, during the final drainage of Lake Agassiz. Above, high $(^{230}Th_{xs})_0$ activities but low $^{230}Th_{xs}$-fluxes point to some ^{230}Th-focussing with enhanced biogenic carbonate fluxes, under a stronger Western Boundary Undercurrent influence leading to the winnowing of slope sediments, thus reduced sedimentation rates at the site. $^{231}Pa/^{230}Th$ ratios are used to further document sedimentary regimes at the site.

Carbonate mineralization in shallow Lake Balaton

I. NYIRŐ-KÓSA[1], É. TOMPA[1], Á. ROSTÁSI[1], T. CSERNY[2] AND M. PÓSFAI[1]*

[1]Dept. of Earth & Env. Sci., Univ. Pannonia, Veszprém, 8200 Hungary, (*correspondence: mihaly.posfai@gmail.com)
[2]Geol. Geophys. Inst. Hungary, Stefánia 14, H1143 Budapest

Calcite precipitates in hardwater lakes as a result of CO_2 consumption by algae through photosynthesis. Lake Balaton has a large surface area (~600 km^2) but an average depth of only ~3.5 m. Its sediment is dominated by carbonate minerals, including Mg-calcite that precipitates from lakewater, aragonite from shells, diagenetic 'protodolomite' and allochtonous calcite and dolomite [1]. We studied various aspects of carbonate formation relevant for the biogeochemical cycles in the lake: the relationships between Mg-content, crystal structure, particle size and morphology, the potential autochtonous formation of dolomite, the roles of organisms in nucleating and reprocessing mineral matter, and the association of P with the carbonate minerals.

Both sediment cores and freshly precipitated material were collected, either by placing sediment traps under the ice (in order to avoid the resuspension of sediments by wind-driven turbulence) or by filtering lakewater. Mg incorporation into calcite was studied by X-ray powder diffraction analysis of d(104) spacings. Particle morphologies, microstructures and compositions were observed using scanning and transmission electron microscopies. The Mg content of calcite increases from west to east in the lake, reflecting a gradient in water composition. Mg-calcite particles are elongated, few μm-large aggregates in which the crystallites occur in a consensus crystallographic orientation. Smaller, euhedral dolomite crystals also occur in the sediment traps; in places their cell parameters slightly differ from those of stoichiometric dolomite. Concerning the roles of organisms in mineral precipitation, no evidence has been found for the microorganism-assisted nucleation of Mg-calcite; however, the reprocessing of mineral matter by filtering organisms (zooplankton and mussels) typically produces pellets of several hundred μm in size that are major constituents of the sediment. Studies are in progress to map the distribution of P in the various carbonate minerals, and to explore the origin of the dolomite that has anomalous lattice prameters [2].

Paleoclimatic changes across the Cretaceous-Paleogene boundary: Geochemical reconstructions from Seymour Island, Antarctica

CHARLOTTE L. O'BRIEN[1]*, STUART A. ROBINSON[1], DAVID B. KEMP[1,2], J. ALISTAIR CRAME[3], JANE E. FRANCIS[4], DANIEL J. LUNT[5], JON R. INESON[6], ROWAN J. WHITTLE[3] AND VANESSA BOWMAN[4]

[6]Geological Survey of Denmark and Greenland, Copenhagen, Demark

The Cretaceous-Paleogene (K-Pg) boundary, ~66.0 Ma, marks the most catastrophic global extinction event of the past 100 Myr and is well documented in both terrestrial and marine biotic records. Although the K-Pg mass extinction occurred at a time when the Earth's climate operated under greenhouse conditions, the specific climatic and environmental changes associated with this event remain poorly understood. Shallow marine sediments exposed on Seymour Island, Antarctica (paleolatitude ~65°S) provide one of the most expanded K-Pg successions known. Moreover, the high latitudes represent areas of significant climatic importance due to polar amplification of global warming.

We first present a low resolution MBT/CBT (methylation of branched tetraethers/cyclisation of branched tetraethers) continental temperature reconstruction that indicates a persistent cool temperate climate (11.4 ±5 °C) on the Antarctic Peninsula during the latest Cretaceous to early Paleogene. The addition of a higher resolution study across the K-Pg boundary is then used to investigate short-term paleoclimatic and paleoenvironmental perturbations, using MBT/CBT, BIT indices and biomarker abundances. Integration of these data with paleontological and paleobotanical datasets allows us to reconstruct the response and recovery of high latitude terrestrial and marine environments to the K-Pg global extinction event.

Reaction mechanisms, pathways, and transport in anaerobic abiotic and microbial U(IV)-oxide dissolution studies

PEGGY A. O'DAY[1]*, MARIA P. ASTA[1], MASAKAZU KANEMATSU[1,2], CARL STEEFEL[2] AND HARRY R. BELLER[2]

[1]University of California, Merced, CA 95343 USA (*correspondence: poday@ucmerced.edu)
[2]Lawrence Berkeley National Laboratory, Berkeley CA USA

Applications of combined thermodynamic-kinetic descriptions to mineral-water interface processes that include chemical reactivity, microbial metabolism, and physical transport are challenged by the need to bridge differences in spatial and temporal scales for multiple, competing reactions. Even in simplified systems, formulation of reactive-transport model descriptions requires parameterization that must aggregate the details of molecular-scale reactions and microbial catalysis to some extent. Investigations of the oxidative dissolution of biogenic U(IV)-oxide (nominally UO_2(s)) under anaerobic conditions by either chemical oxidants (nitrate or nitrite) or by *Thiobacillus denitrificans*, a chemolithoautotrophic bacterium that catalyzes anaerobic, nitrate-dependent U(IV) and Fe(II) oxidation, are used to examine coupled and competing oxidation-reduction processes in flow-through column experiments. Abiotic oxidation of UO_2(s) in the presence of nitrate under anaerobic conditions is slow but faster than control experiments of non-oxidative dissolution. Abiotic UO_2(s) oxidation by nitrite is significantly faster by several orders of magnitude. In the presence of *T. dentrificans* and dissolved nitrate, higher rates of dissolved U release were observed compared with abiotic controls, suggesting that *T. dentrificans* catalyzed the oxidative dissolution of UO_2(s) in addition to the abiotic oxidation pathways. X-ray spectroscopic characterization of reaction products indicates solid-associated oxidized U(VI) that is retained in the column. Analysis of local atomic structures shows formation of U-oxo molecular moieties within or on particle surfaces that are similar but not identical to aqueous or sorbed uranyl species, suggesting mostly surface particle oxidation rather than detachment and re-adsorption of uranyl in the column. Reactive transport modeling incorporating thermodynamic solubility, irreversible overall abiotic and biotic kinetic reactions, and uranyl sorption can simulate effluent U concentrations for a small amount of UO_2(s) oxidation relative to total mass, but calculations are sensitive to particle surface area.

Remediation Strategies for Redox-Active Elements Using Combined Experimental, Spectroscopic, and Computational Approaches

PEGGY A. O'DAY[1]*, SUSANA SERRANO[1] VIRGINIA ILLERA[1] AND DIMITRI VLASSOPOULOS[2]

[1] School of Natural Sciences, University of California, Merced, CA 95343, USA (*correspondence: poday@ucmerced.edu)
[2] Anchor QEA, LLC. Portland, OR 97204, USA

Contaminants such as arsenic (As), mercury (Hg), and other redox-active elements pose particular challenges to remediation because of their ability to readily change oxidation state and speciation at surface conditions from coupled microbial-abiotic processes that are spatially and temporally dynamic. A variety of *in situ* sediment or soil amendment treatments, whether added directly to geomedia or emplaced within barriers or caps, can sequester and stabilize contaminants in place in order to reduce their ability to partition to water or biota, their toxicity, and their potential for transport. Computational approaches such as thermodynamic-kinetic reaction path and reaction transport models capable of simulating biogeochemical, speciation, partitioning, and transport processes are valuable tools for assessing remediation effectiveness when constrained by spectroscopic and experimental investigations of laboratory and field systems. The contrasting chemical behavior and exposure pathways of As and Hg illustrate how remediation approaches using amendments or sediment caps can be optimized by minimizing the concentration of specific chemical species associated with maximum health risk. For As, inorganic arsenite ($As^{III}(OH)_3$) is the most toxic form and human exposure is typically through drinking water. Combined field, laboratory, and modeling studies show that sorption or amendment sequestration of arsenate (As(V)) under oxic conditions, or precipitation of solid As sulfides under anaerobic conditions, are most effective for limiting concentrations of dissolved arsenite. For Hg, remediation should target reduction of net methylation of inorganic Hg to methylmercury, which results primarily from bacterial sulfate reduction in anaerobic environments and is the first step in Hg bioaccumulation. Approaches such as sediment chemical amendments or caps can reduce methylation by limiting bioaccessibility of inorganic Hg through solid encapsulation or irreversible sorption, reducing the total concentration of dissolved sulfide species, buffering system oxidation potential above sulfate reduction, and/or buffering pH at circumneutral or above.

Biogenic Influence on Sea-Spray Aerosol and its Impacts

C.D. O'DOWD*, A. VAISHYA, J. OVADNEVAITE, J. BIALEK, S.G. JENNINGS AND D. CEBURNIS

School of Physics and Centre for Climate and Air Pollution Studies, Ryan Institute, National University of Ireland Galway, University Road, Galway, Ireland (*correspondence: Colin.Odowd@nuigalway.ie, aditya.vaishya@nuigalway.ie, jurgita.ovadnevaite@nuigalway.ie, jakub.bialek@nuigalway.ie, gerard.jennings@nuigalway.ie, Darius.Ceburnis@nuigalway.ie)

Marine aerosol, whether primary or secondary, comprises both inorganic and biogenic organic components. Although primary sea-spray mass is dominated by super-micron sea-salt, the sub-micron sizes dominate the sea-spray number concentration leading to important contributions to both direct and indirect radiative effects [1,2]. The relative contributions of sea-salt and primary organic matter to sub-micron sea-spray has been shown to be influenced by biogenic productivity in oceanic waters, with the organic mass fraction ranging from 10% under low biological activity, to 90% under high activity [3, 4]. The organic enrichment reduces the spray's hygroscopicity [4]; however, there is a dual-state effect leading to hygroscopicity flipping between a high hygroscopicity to low hygroscopicity as the organic matter volume fraction exceeds ~50%. The effect leads to a ~3-fold reduction in scattering enhancement as a function of increasing relative humidity and potentially a reduction in the radiative impact of sea-spray from -6.5 Wm^{-2} to -1 Wm^{-2} under wind speeds of 20 m s^{-1}.

Effects of subduction-related melt extraction on Iapetus Ocean mantle

B.O'DRISCOLL[1]*, R.J. WALKER[2], J.M.D. DAY[3] AND J.S. DALY[4]

[1]School of Physical and Geographical Sciences, Keele University, Keele, UK (*correspondence: b.o'driscoll@keele.ac.uk)

[3]Geosciences Research Division, Scripps Institution of Oceanography, La Jolla, CA, USA
[4]UCD School of Geological Sciences, University College Dublin, Dublin, Ireland

Ophiolites enable assessment of the causes and length-scales of mantle compositional heterogeneity because field-based observations can be coupled with geochemical investigations of upper mantle lithologies resolved relative to the petrological Moho. The ~497 Ma Leka Ophiolite (Norway) comprises a section of early-Palaeozoic (Iapetus) oceanic lithosphere with well-exposed mantle and lower crustal sections and remarkably low degrees of serpentinisation (≥20%). The Leka upper mantle section is heterogeneous at the cm-to-m scales, manifested by abundant dunite lenses and sheets in harzburgitic host-rock, especially within ~500 m below the Moho. Abundant chromitite (≥60 vol.% Cr-spinel) and pyroxenite lenses and layers also occur in the uppermost 200-300 m of the mantle section.

The array of mantle lithologies on Leka is considered to have developed during fluid-assisted melt extraction in a supra-subduction zone (SSZ), offering an opportunity to interrogate the nature of Os isotope and HSE abundance heterogeneities developed in such rocks and circumventing, at least in part, the effects of serpentinisation. Initial results show that the Os isotope compositions of the Leka peridotites are quite consistent, with a range of γOs_{497Ma} of -1.57 to +4.43, and Os concentrations ranging from 1.4-24.8 ng g^{-1} Os, for eleven harzburgites and dunites. Given the similarity between Leka peridotites and estimates of Os isotopic composition and HSE abundances in the oceanic mantle (e.g., from abyssal peridotites), we see scant evidence for modification of these elements by SSZ fluid or melt-rock interactions. Comparison of the Leka data with mantle peridotite data from the (~492 Ma) Iapetan ophiolite exposed on the Shetland Islands (Scotland) [1] implies that on ocean-basin scales, SSZ fluid/melt interactions may only play a limited role in processing the HSE in already strongly depleted mantle.

Earth's Hadean crust: Insights from the Nuvvuagittuq Greenstone belt

J.O'NEIL[1], R.W. CARLSON [2] AND M. BOYET [3]

[1] Depart. of Earth Sciences, Univ. of Ottawa, Ottawa, Canada
[2] Carnegie Institution of Washington, Washington DC, USA
[3] Laboratoire Magmas et Volcans, Clermont-Ferrand, France

The Hadean Eon is still poorly understood due to the scarcity of preserved samples. Most of what we know of early crustal evolution comes from the Hadean Jack Hills detrital zircons. Despite the fact that their host rock has been destroyed, the isotopic composition of these zircons points to a basaltic protocrust reworked to form multiple generations of TTG-like crust. With a minimum age of 3.8 Ga, the Nuvvuagittuq Greenstone Belt (NGB), represents an ideal terrain to investigate early Earth's crustal evolution. Rocks from the NGB show considerable variability in $^{142}Nd/^{144}Nd$ ($\mu^{142}Nd$ = +8 to -18) that can only be produced during the Hadean. The correlation observed between the $^{142}Nd/^{144}Nd$ and the Sm/Nd ratios of the dominant mafic lithology called the Ujaraaluk unit is consistent with their formation between 4.3 and 4.4 Ga. This age, however, has been challenged because the oldest U-Pb ages on zircons from the NGB felsic rocks are ~3.8 Ga. An alternative model suggests mixing of mantle-derived melts in the Eoarchean with some hypothesized reservoir enriched in incompatible elements during the Hadean to produce the ^{142}Nd deficits of the NGB rocks. This conclusion, however, is not supported by our latest ^{176}Lu-^{176}Hf / ^{142}Nd data. Here we present a summary of the geology and geochronology of the NGB and discuss the alternative models of Eoarchean or Hadean age for the belt. We used long-lived and short-lived isotopic systematics ($^{147,146}Sm$-$^{143,142}Nd$, ^{176}Lu-^{176}Hf) for all NGB lithologies including mafic and felsic rocks as well as combined Pb-Hf in zircons to understand the evolution of the NGB and the formation of Earth's early crust. Our data suggest that the protolith of the Ujaraaluk unit includes both tholeiitic and calc-alkalic mafic volcanic rocks originally erupted in the Hadean. Reworking of this basaltic precursor over several hundred million years in the Eoarchean produced TTG-type magmatism. If the Ujaraaluk unit is interpreted as Eoarchean, then one must hypothesize the existence of a Hadean enriched component that has identical compositional and isotopic characteristics to the Ujaraaluk as the source of the low ^{142}Nd in both some Ujaraaluk and the NGB TTG suite. We suggest instead that the Ujaraaluk unit is a Hadean mafic protocrust and may therefore represent the first crust to stabilize after the moon-forming impact and be the closest analogue to the primordial crustal source of the Jack Hills zircons.

What does Hadean mantle mixing tell us about Hadean geodynamics?

CRAIG O'NEILL[1], VINCIANE DEBAILLE[2] AND BILL GRIFFIN[3]

[1]CCFS, Macquarie University, (craig.oneill@mq.edu.au)
[2] Université Libre de Bruxelles,(vdebaill@ulb.ac.be)
[3]CCFS, Macquarie University, (bill.griffin@mq.edu.au)

A hot Hadean mantle is suggested from high internal heat production, high rates of impact bombardment, and significant primordial heat from accretion. Consequently, extremely high internal temperatures argue for low internal viscosities, and extremely vigorous mantle convection. Mixing in such high-Rayleigh number convective environment should have efficiently remixed or erased chemically heterogeneous mantle anomalies on timescales of less than 100Myr.

However, platinum group elements concentrations in Archaean komatiites, purported due to the later veneer of meteoritic addition on the Earth, only achieve current levels at 2.7Ga – indicating a time lag of almost 1-2Gyr in mixing this material thoroughly in the mantle. ^{142}Nd and ^{182}W isotope studies also indicate that heterogeneous mantle domains survived, without mixing, for over 2Gyr – at odds with mixing rates expected.

Here we suggest the surface tectonic regime may have significantly retarded mixing efficiency in the Hadean. A number of lines of evidence suggest episodic resurfacing in the Archaean, and extrapolating back to Hadean times implies the Hadean was characterized by long periods of tectonic quiescence (albeit violently volcanic). We explore mixing times in 3D spherical-cap models of mantle convection, which incorporate vertically stratified and temperature-dependent viscosities. We show that mixing in stagnant lid regimes can be over an order of magnitude less efficient than mobile lid mixing, and for plausible Rayleigh numbers and internal heat production, the lag in Hadean convective recycling can be explained. This explanation not only explains the long-lived ^{142}Nd and ^{182}W anomalies, but also 1) posits an explanation for the delay between accretion of the late veneer – between 4.5-3.8Ga on a stagnant surface – and its fully mixed signature apparent in elevated PGEs in 2.7Ga komatiites, and 2) provides an explanation for the 400Myrs of immobility of the mafic protolith from which the Jack Hill zircons were sourced, and 3) retards early heat loss from the mantle, providing a solution to the "Archaean thermal catastrophe" of parameterized Earth evolution models.

The effects of silicate melt composition and sulfur on the solubilities of PGEs in silicate melts

HUGH ST. C. O'NEILL[1]

[1]Research School of Earth Sciences, The Australian National University, Canberra, ACT 0200, Australia (hugh.oneill@anu.edu.au)

Experimental studies of PGE solubilities at conditions directly relevant to natural basaltic melts are difficult because the low solubilities are often masked by variable amounts of micronuggets suspended in the melts. Experiments in simple haplobasaltic melts appear to establish that solubilities at low pressures are less than ~1 ng g^{-1} at typical terrestrial oxygen fugacities and temperatures, raising questions as to how PGEs are transported from the mantle and concentrated into economic ore deposits. The applicability of the simple system experiments is sometimes queried because, it is claimed, missing ingredients like Fe or S might enhance solubilities. To address this issue directly, the effect of melt composition on Ir and Pd solubilities has been determined at ambient pressure. Samples were equilibrated in a 1-atm. gas-mixing furncace using Ir and Pd metal loops, quenched to glasses and analysed by laser ICP-MS (detection limits < 1 ng g^{-1}), with EMPA for major elements and sulfur. The compositional dependence was studied first at high temperatures (1500ºC for Ir and 1400ºC for Pd), which reduces the micronugget problem, and compositions least affected by micronuggets were then selected to measure the effects of T and fO_2. For Ir, ~ 40 melt compositions in CaO-MgO-Al_2O_3-SiO_2±FeO± Fe_2O_3±Na_2O±TiO_2 were investigated. The results show that Ir dissolves only as Ir^{3+} over the experimentally accessible range of fO_2, and solubilities are simply related to the melt composition through its optical basicity. The effects of FeO and Fe_2O_3 are small but individually resolvable: fO_2-corrected solubility decreases as Fe_2O_3 replaces FeO. High Fe or Ti suppresses micronuggets. As regards sulfur, Ir solubility is too low for any effect to be seen at the fO_2s needed to achieve measurable S^{2-} in the melt in 1-atm experiments. Pd dissolves as Pd^{1+} with some Pd^{2+} at higher fO_2, in agreement with literature results. The effect of melt composition on Pd solubility is much less than for Ir, and is not related to any simple compositional variable. To investigate the effect of S quantitatively, experiments on the solubility of Ru (as Ru^{3+}), which is ~ 50 times more soluble at a given fO_2 than Ir, were undertaken using a high Fe-Ti picritic composition at 1500ºC to eliminate micronuggets, in olivine capsules. Only a small effect was observed despite ~1000 μg g^{-1} S^{2-} in the melt.

Archean lithospheric mantle: The fount of all ores?

*SUZANNE Y. O'REILLY[1], W.L. GRIFFIN[1], G.C. BEGG[1,2], N.J. PEARSON[1] AND J.M.A. HRONSKY[1,3].

[1]CCFS/GEMOC, Macquarie University, Sydney, Australia (*correspondence: sue.oreilly@mq.edu.au)
[2]Minerals Targeting Intl., 17 Prowse St., W. Perth, Australia
[3]Western Mining Services (Aust.) Pty Ltd, 17 Prowse Street, W. Perth, WA 6005, Australia

Magma-related ore systems form economic deposits that underpin our human civilisation. The magmas related to metallic element redistribution derive from the asthenosphere, then traverse and interact to varying degrees with the subcontinental lithospheric mantle (SCLM). Convergent geochronology datasets of Hf isostopic model ages for zircons and Re-Os model ages for mantle sulfides, reinforced by other geochemical and tectonic criteria, indicate that over 70% of the SCLM and its overlying crust (now mostly lower crust) formed at about 3.5 Ga, probably in a global overturn event that marked a change in Earth's fundamental geodynamic behaviour. This primitive SCLM, the roots of the Archean cratons, was geochemically highly depleted, and subsequently played a major role in crustal metallogeny for many ore types. *Firstly*, the high degree of buoyancy of this ancient SCLM relative to the asthenosphere, due to the Mg-rich and Fe-poor composition, results in persistence today of low-density, rheologically coherent Archean domains (including relict blobs in rifted ocean basins [1]) and commonly, preservation of old crustal domains (the "life-raft" model). *Secondly*, the enduring (and volumetrically dominating) Archean lithospheric mantle domains represent a reservoir for metasomatic enrichment over their 3.5 billion year history, creating a potentially metallogenically fertile mantle impregnated with critical elements (including Au, Cu, Ni? and platinum group elements [2]). *Thirdly*, the formation of Archean cratons provide an architectural lithospheric mantle-scape of regions with contrasting rheology, composition and depth penetration. The cohesive Archean domains control magma and fluid pathways around their margins, and may act as both sinks and sources for ore-forming elements depending on the geodynamic evolutionary stage. *Fourthly*, if this first stabilisation of lithospheric mantle at 3.5 Ga signalled the end of an overturn regime (either uniquely, or intermittent with subduction), then long-lived tectonic regimes conducive to mineralising systems (e.g. back-arc basins, passive margins, cratonic boundaries) became available.

[1] O'Reilly *et al*. (2009), Lithos, 112, 2, 1043-1054. [2] Zhang *et al*. (2008), E. Sci Rev 86, 145-174.

P-T modeling reveals juxtaposition of units within the Gruf Complex (Central Alps) during orogenesis.

J. OALMANN[1], A. MÖLLER[2] AND R. BOUSQUET[3]

[1,2]Department of Geology, University of Kansas, USA, (joalmann@ku.edu, amoller@ku.edu)
[3]Institute of Geosciences, Christian-Albrechts-Universität zu Kiel, Germany, (bousquet@min.uni-kiel.de)

Equilibrium assemblage diagrams calculated with Theriak-Domino are used to constrain peak P–T conditions of sapphirine granulites and migmatitic paragneisses. Residual orthopyroxene + garnet + sapphirine + sillimanite granulites record peak conditions of 900–960°C at 8–10 kbar. Subsequent UHT decompression to <8 kbar produced cordierite coronae around peak minerals. Complex compositional zoning patterns in garnet porphyroblasts suggest no diffusional equilibration at peak conditions and thus a short-lived UHT event. Muscovite-bearing and muscovite-free paragneisses reached peak conditions of 650–700°C and 700–750°C, respectively, at ≤7.5 kbar. The paragneisses contain no evidence for UHT metamorphism. The different peak conditions suggest that peak metamorphism of the granulites and paragneisses occurred at different crustal levels. The granulites and associated charnockites were subsequently juxtaposed against the paragneisses and associated orthogneisses along mylonitic shear zones.

Ages of zircon rims in granulites suggest they underwent UHT metamorphism at ≥32.7±0.5 Ma (Liati & Gebauer, 2003, *SMPM*). Variably deformed aplite and pegmatite dikes crosscut all other rock types and are deformed within the mylonitic contacts between the granulite–charnockite and paragneiss–orthogneiss units (Galli, 2010, PhD thesis, ETH Zürich). The dikes crystallized at ≤30 Ma, suggesting juxtaposition occurred between 33 and 30 Ma, coeval with crystallization of the Bergell tonalite–granodiorite. By c.24 Ma, the granulites and thus the entire Gruf Complex cooled below the U-Pb closure temperature of rutile (Oalmann *et al*., 2011, Goldschmidt abstract), coinciding with crystallization of the Novate S-type leucogranite and the latest, undeformed dikes.

UHT metamorphism coincides with the transition from (U)HP to Barrovian metamorphism in the Central Alps. Therefore, heat for UHT metamorphism likely resulted from asthenospheric upwelling after slab breakoff. Exhumation and juxtapostion of units within the Gruf Complex was likely related to the emplacement of the Bergell intrusion.

Isotope effect in the formation of solid water by surface reactions at 10 K

YASUHIRO OBA, NAOKI WATANABE AND AKIRA KOUCHI

Institute of Low Temperature Science, Hokkaido University, JAPAN. e-mail:((oba@lowtem.hokudai.ac.jp)

D/H ratio of water in molecular clouds (MCs) is often 2-3 orders of magnitude higher than that of terrestrial ocean water ($D/H \sim 1.56 \times 10^{-4}$). Such a significant deuterium enrichment often observed not only for water but also organic compounds like formaldehyde and methanol in MCs [1] cannot be explained by the gas-phase fractionation only. It is at present widely recognized that grain-surface reactions are crucial for the formation and deuterium enrichment of those molecules.

Among various reactions proposed, the reaction $OH+H_2 \rightarrow H_2O+H$ is considered to have a significant contribution (>70%) to H_2O formation in dense MCs [2] where the typical temperature is ~10 K. It is therefore reasonable to assume that deuterated water like HDO could also be formed by the similar surface reactions such as $OH+D_2 \rightarrow HDO+D$ and $OD+H_2 \rightarrow HDO+H$. In the present study, we performed laboratory experiments on the formation of water (H_2O, HDO, or D_2O) by reactions of OH/OD with H_2/HD/D_2 on a solid substrate at 10 K.

Experiments were performed under ultra-high vacuum conditions ($\sim 10^{-8}$ Pa). OH or OD radicals were produced by the dissociation of H_2O or D_2O in microwave-induced plasma and coolded to 100 K. Each radical was codeposited with H_2, HD, or D_2 on a substrate at 10 K.

We found that all reactions studied occur on the substrate at 10 K. However, the reaction efficiency was clearly different between H- and D-atom abstraction reactions from H_2 , HD, or D_2. The former reactions (e.g. $OH+H_2 \rightarrow H_2O+H$) were about 10 times more efficient than the latter (e.g. $OH+D_2 \rightarrow HDO+D$). The difference in efficiency is derived from the different effective masses of reactions. The efficiency does not depend on the kind of hydroxyls (OH or OD) but only on that of atoms abstracted.

The present study suggests that one of the important factor to control the D/H ratio of water in MCs is OD/OH ratio. If OD and OH were produced by D- and H-addition to O atoms on grains, respectively, atomic D/H ratio in MCs would be crucial for constraining the D/H of water in MCs.

Distribution of iron (II) in the Northwestern Pacific

H. OBATA[1], S. TAKAHASHI[1], T. GAMO[1] AND J. NISHIOKA[2]

[1] Atmosphere and Ocean Research Institute, University of Tokyo, Chiba 277-8564, Japan

[2] Institute of Low Temperature Science, Hokkaido University, Hokkaido 060-0819, Japan

Iron is an essential micronutrient for marine phytoplankton and its availability affects marine primary production in the ocean. Among iron species in seawater, Fe(II) is readily bioavailable form for phytoplankton, but its distribution is not clearly revealed. In this study, the distribution of Fe(II) along the 160° E line in the Northwestern Pacific was investigated. Seawater samples were collected during the R/V Hakuho-maru cruise (6 July – 3 August, 2012) with acid cleaned X-Type Niskin samplers deployed onto a CTD-CMS. Dissolved Fe(II) was determined quickly after sampling onboard the ship with luminol chemiluminescence method [1].

We observed the Fe(II) maximum (6 – 54 pM) in the oxygen minimum zone (OMZ) commonly. Dissolved oxygen concentrations were 14 - 58 μM in the OMZ, where in-situ Fe(III) reduction did not occur. During the remineralization process of biogenic particles, Fe(II) was probably released and / or produced in the reducing conditions within the settling particles [2].

A top-sealed plastic tube with a diameter of ca. 15 cm had been buried ca. 70 cm deep vertically at the base of La Fossa volcano, Vulcano island, Italy, next to the front of the obsidian flow. The tube had been filled with layered rock and quartz wool to condense vapors emanating from the soil. At ca. 75 cm below the surface the sample had been exposed to vapors from Sept. 2005 to April 2006. The leached sample had not been in touch with the ground. 2 other glass wool cushions (ca. 10 cm thick, uncompacted) had been underneath to minimize capillary effects. A rock wool layer not touching ground revealed nucleated sylvite (KCl ~10 μm in size) and barite ($BaSO_4$ ~5-10 μm in size) crystals by SEM/EDS in its basal portion. Other very small (< 2 μm) particles were observed on the rock wool fibers but we could not identify them because they were suddenly volatilized by the electron beam. The bright appearance in backscattered images suggests that these particles may be metal compounds. The nucleation of sylvite and barite documents the presence of ions. Leaching of the quartz wool at room temperature with deionized H_2O and ICP-MS analysis documented 4 groups of elements: 1. positive signal: Mg, K, Ca, Cr, Mn, Ni, (Ba); low to moderate volatility at magmatic conditions. 2. unclear signal: Al, Si, P, Fe; low volatility at magmatic conditions. 3. no signal: V, As, Se, Mo, Co. As, Se, Mo, V are considered to be highly volatile, Co got a low volatiliy. 4. positive signal: Cu, Zn, Cd, Sn, Pb, W; high volatility at magmatic conditions. Leaching with nitric acid documented also V and Fe, and produced higher values for all elements, except K and Sn. This experiment documents for the first time an unknown element transport by vapors/gases through a volcanic edifice interacting with hydrothermal and magmatic gases. More information can be found at http://www.iugg2007perugia.it/webbook/

Volatiles in arrojadite: combining single-crystal XRD and FTIR microspectroscopy

R. OBERTI [1]*, G. DELLA VENTURA[2], F. BELLATRECCIA[2] AND F. RADICA[2]

[1] CNR-IGG, UOS Pavia, Italy,(oberti@crystal.unipv.it)
[2] University of Roma Tre, Rome, Italy

Arrojadites are complex phosphates typically found in granitic pegmatites or hydrothermal veins, although their occurrence in metamorphic rocks suggests wider conditions of formation. Re-examination by EMP, LA-ICP-MS and single-crystal XRD analysis of a set of samples from various occurrences lead to revise the structure, the formula and the nomenclature of the group [1,2]. The correct structural model for arrojadite implies three OH-groups: two of these (W1 and W2) have similar local environment (they bridge three octahedra), crystallographic orientation and hydrogen-bond system. W3 is connected with the apical oxygen of a newly defined tetrahedron in the structure, and is involved in a bifurcated hydrogen bridge with surrounding oxygen atoms. Raman spectra reported in [1] show two higher-frequency, intense and convoluted bands which were assigned to specific local environments of W1 and W2; an additional low-frequency, broad and weak feature in the spectra could not be assigned with certainty. We report in this work on a FTIR study of various samples studied in [1,2]. Chemical zoning of the volatile components was checked by FTIR imaging using an FPA detector fitted on a Bruker Hyperion 3000 microscope. In contrast with the Raman spectra, the FTIR patterns show a very intense and broad absorption extending from 3500 to 2900 cm^{-1}. Single-crystal XRD has shown that F is ordered at the W1 site, and this generates a significant modification of the FTIR pattern, as observed on holotype fluoro-arrojadite-(BaFe) from Sidi Bou Kricha (Morocco).

The FTIR spectrum of holotype arrojadite-(KNa) from Rapid Creek shows also an intense doublet at 3190-3087 cm^{-1} which can be assigned to NH_4^+ groups, as later confirmed by EMPA. The orientation of the absorber (i.e. the O-H bond) with respect to the crystallographic axis can be determined from polarized-light measurements along the principal optical direction [4]. In all the samples, no evidence of molecular water is present in the NIR 4000-6000 cm^{-1} region.

Rare Earth Elements in the sediments of Lake Baikal

L. M. OCH[1]*, B. MÜLLER[1], A. ULRICH[2†], A. VOEGELIN[3], A. WICHSER[2], E. A. VOLOGINA[4] AND M. STURM[3]

[1] Eawag, Swiss Federal Institute of Aquatic Science and Technology, CH-6047 Kastanienbaum, Switzerland (*correspondance: lawrence.och@eawag.ch)

[4] Institute of the Earth's Crust, Siberian Branch of the RAS, Irkutsk, 664033, Russia

Lake Baikal is the deepest and oldest lake on Earth. However, the biogeochemical cycling of major and trace elements in this oligotrophic lake and its watershed have received relatively little scientific attention. The Rare Earth Elements (REEs), in particular, have gained importance as powerful tracers of chemical processes on the Earth's surface as they form a relatively coherent group of elements with, nonetheless, sensible differences among them. Cerium (Ce) and Europium (Eu), for example, are the only REEs which exhibit redox-sensitivity. The present study offers an overview over the REE chemistry in Lake Baikal and its catchment area and more specifically their distribution in five short sediment cores distributed across the Lake at different depths whereby we analysed and discussed normalised REE patterns and their consequential Ce, Eu and gadolinium (Gd) anomalies. We found that, while particulate REE concentrations are mainly influenced by processes above or near the surface of Lake Baikal, such as the development of a widespread negative Ce anomaly, early diagenetic chemical activity is best reflected in the dissolved fraction of the REEs, where their complexation with inorganic and organic ligands plays an important role in addition to adsorption onto metal oxides and clay minerals. A further extraordinary feature found within the lake's sediments are highly positive Eu anomalies, which are otherwise rare in sedimentary systems, in particular within Fe- and Mn-oxide accumulations buried within the reducing part of the sediment. Eu anomalies correlate with elevated barium (Ba) contents which are likely associated with phosphates and/or manganese oxides and we argue that Eu substitutes for Ba. Furthermore, while the Ce and Eu anomalies are formed within the watershed and the sediment respectively, the omnipresence of positive Gd anomalies in the sediment and the pore waters can be traced back to the atmospheric input into the lake.

Uptake of radiocesium by crops from soils contaminated by the Fukushima Accident

K. ODA[1]*, Y. MURAMATSU[1]*, T. OHNO[1], T. KOBAYASHI[2] AND S. FUJIMURA[2]

[1]Depertment of Chemistry, Gakushuin University, Mejiro 1-5-1, Toshima, Tokyo, 171-8588, Japan (*correspondence: 12142005@gakushuin.ac.jp, yasuyuki.muramatsu@gakushuin.ac.jp)
[2]Fukushima Agricultural Technology Centre, Koriyama, Fukushima, 963-0531, Japan

Cs-137 ($T_{1/2}$; 30.1 y) and Cs-134 ($T_{1/2}$; 2.06 y) were released by the accident of Fukushima Daiichi NPP and agricultural fields in Fukushima prefecture were widely contaminated. More than 2 years after the accident, some crops exceed the guideline for radiocesium (100 Bq/kg) and the mechanism of higher uptake is poorly understood. We investigated radiocesium and stable element concentrations in rice plants and komatsuna (a leafy vegetable) grown in soils which were collected from the contaminated fields in Fukushima Prefecture. We discuss mechanisms of radiocesium transfer with special reference to the soil characteristics in this study.

Cultivation experiments using soil that was contaminated with radiocesium were carried out in Fukushima Agricultural Technology Centre and the radiocesium concentrations of both soil and plant samples were determined by a Ge-detector at Gakushuin University. The plants were cultivated in Wagner pots (3 L) in a greenhouse.

As a results, the highest values for transfer coefficient were observed in crops grown in brown forest soils, while the plants cultivated in gray lowland soil showed the lowest values. In order to compare soils with different radiocesium levels, we collected them from the top layer with high radiocesium concentrations (upper 5 cm) and from the underlying soil with lower concentrations (5–15 cm). We cultivated komatsuna and found that the transfer coefficients of plants grown in the underlying soils are greater than those of komatsuna planted in the surface soils. This might be related to the speciation of radiocesium in the soils. Deeper layers may have more labile, plant-available radiocesium, while less labile particulate-bound radiocesium from the accident may be more common in the surface soils.

Additionally, we have also carried out stable element analysis (including Cs) in crops and soil extracts to examine whether there is any correlation between the transfer factor of radiocesium and that of stable elements.

Assessment of Groundwater Quality in some parts of Southwestern Nigeria

*ODUKOYA ABIODUN MARY[1] AND LANIYAN TEMITOPE[2]

[1]Department of Geosciences, University of Lagos, Nigeria (*correspondence: mabiodun@unilag.edu.ng)
[2]Department of Geology, Olabisi Onabanjo University, Ago Iwoye, Nigeria.

One hundred and twenty samples from groundwater were collected at Ago Iwoye, Oru and Ijebu Igbo, Southwestern Nigeria. The purpose was to establish preliminary baselines for these constituents in the ground water of the study area and also to determine the quality. The analysis of trace elements and cations in water were carried out using inductively coupled plasma optical emission spectrometry (ICP-OES at Acme, Ontario Canada. Concentrations of 34 elements which include trace and major elements such as Al, As, B, Ba, Be, Ca, Cd, Ce, Co, Cr, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Ni, P, Sb, Se, Si, Te, Ti, Tl, U, V, W and Zn were determined. Trace elements like Si, Bi and Ti were below detection level of 0.05ppb,0.05ppband 10ppb respectively for all the samples. As, Be, Cd, Cr, Cu, Mn, Se and Zn were below Maximum Contamination Level (MCL) of EPA 2012 for all the samples. Al, Br, Fe, Mn, Ni, Pb, Sb were above the standard and generally pose health or environmental hazard for most of the samples with the following ranges <1-2686ppb, 5.48-2199.35ppb, <10-22450ppb, <0.05-52.8ppb and 0.09-11.64ppb respectively. The pollution index among all sites varied from 0.075 to 6.26 and exceeded the acute and chronic effect levels proposed by the United States Environmental Protection Agency in 2007.

Production of S-MIF Signatures during Photochemistry of Biogenic Volatile Sulfur Compounds: A Potential Marker for Marine Stratospheric Sulfur Aerosol Layer

HARRY ODURO[1] AND SHUHEI ONO[1]

[1]Department of Earth, Atmospheric, and Planetary Sciences, MIT, 77 Massachussetts Avenue, Cambridge, MA 02139-4307, USA. E-mail: (Hoduro@mit.edu)

Sulfur mass-independent fractionation (S-MIF) has been reported for UV-photochemistry SO_2 and CS_2 but not for OCS and H_2S. These experimental observations have been linked to S-MIF signatures observed in sedimentary sulfides and sulfates of Archean and Early Palaeoproterozoic age, and have been used as evidence for a low-pO_2 atmosphere on the Early Earth. Although biogenic methylated sulfur compounds is important in atmospheric sulfur cycles today, multiple-S isotope effects of photochemistry of dimethylsulfide (DMS), dimethyldisulfide (DMDS), dimethyltrisulfide (DMTS), and episulfides (e.g., ethylene sulfide (ES)) have not been reported. Characterizing multiple sulfur isotope effects during photochemistry of these organic sulfur compounds may be used to study the fate for marine biogenic sulfur, particularly DMS photochemistry, which is the most abundant biogenic sulfur gas in our present atmosphere.

We will report that broadband UV-photolysis of DMS, DMTS, and ES using a Xenon-Arc lamp produced S-MIF signals with magnitudes of $\Delta^{33}S$ up to +2.9 ‰ and $\Delta^{36}S$ up to +0.9 ‰ for the solid aerosol sulfur products with significant changes in $\delta^{34}S$ fractionations up to +7.1‰. UV-photolysis experiments with water vapor produced relatively small to no S-MIF signals in some of their oxidation products (e.g., sulfate and sulfonic), which may likely result from HO_x oxidation reactions via direct or indirect photodissociation reactions of; $O_2 \rightarrow O + O$, and $H_2O + O \rightarrow 2HO$. These biogenic gases undergo a rapid oxidation when emitted to the present day atmosphere, and its oxidation products can be transferred above the tropopause and contribute to stratospheric cloud-condensation nuclei (CCN). Our results suggest that the production of S-MIF could be potentially possible even in today's atmosphere containing biogenic sulfur gases. We hypothesize that these S-MIF signals can be used as a marker to identify the source of sulfur aerosols where biogenic sulfur constituents affect radiative forces.

What can spectral properties of SNCs and Martian surface tell us about crust-mantle system evolution?

A. ODY[1]*, F. POULET[2], D. BARATOUX[3], J.-P. BIBRING[2], M. TOPLIS[3] AND C. QUANTIN[1]

[1]LGLTPE, 69622 Villeurbanne, France (*correspondence: anouck.ody@ias.u-psud.fr)
[2]IAS, 91405 Cedex Orsay, Fran
[3]Observatoire Midi-Pyrénées, 31400 Toulouse, France

The SNC meteorites are the only samples of Mars available for analysis on Earth, providing unique insights into the formation and evolution of the Martian crust-mantle system. However, the absence of identified source regions and the debate surrounding the age of shergottites limits exploitation of the mineralogical and geochemical information provided by these rocks. With this in mind, a comparison between the near-infrared (NIR) spectral properties of the SNCs and spectra of the Martian surface from the NIR imaging spectrometer OMEGA/MEx has been made. We show that shergottite spectra are comparable to those of early Hesperian volcanic provinces such as Syrtis Major, consistent with an age of these meteorites more ancient than the Amazonian [1]. This result is largely controlled by the fact that the pyroxene mineralogy inferred for Hesperian terrains is comparable to that of the basaltic shergottites.

Additional constraints on the formation and evolution of the crust-mantle system can be provided by the study of olivine, which is a precious marker of magmatic processes. The global distribution of olivine as seen with OMEGA shows that olivine is mainly associated with three different geological settings [2]: (1) ejecta around the Hellas basin with an intermediate to forsteritic composition suggesting a Mg# >50 for the excavated upper mantle, (2) large impacts and crustal outcrops that argue for olivine in deeper sections of the crust in the form of cumulates or alternatively in a global layer of older (early Noachian) rocks, (3) early Hesperian lava flows throughout the Martian surface suggesting a planetary event of olivine-enriched fissural volcanism. In contrast, olivine is not detected in Noachian terrains that formed the major part of the southern highlands. This fact could be related to an evolution in magma composition or in the degree of olivine fractionation between these two epochs.

These results will be discussed in light of the predictions of petrologic models for the formation and evolution of the Martian crust-mantle system [3,4].

Reversibility of calcium and magnesium isotopic signatures during ambient temperature fluid-carbonate mineral interaction

E. H. OELKERS[1]*, P. POGGE VON STRANDMANN[2], U.-N. BERNINGER[1] AND V. MAVROMATIS[1]

[1]GET, CNRS, UMR 5563, Toulouse, FRANCE
(* corresponding author, oelkers@get.obs-mip.fr)
[2]Earth Sciences, University of Oxford, Oxford OX1 3AN UK

The interpretation of mineral isotopic signatures in low temperature fluid-rock systems commonly relies on the assumption that they remained unchanged since their precipitation over geologic time, despite potentially being out of isotopic equilibrium with their co-existing fluids (e.g. the use of carbonate isotopic compostions to deduce paleo temperatures). Similarly, fluid compositions are frequently interperted assuming that isotopes are conservatively transferred from minerals to fluids as they dissolve.

In an attempt to test such assumptions, we have dissolved both calcite and hydromagnesite ($Mg_5(CO_3)_4(OH)_2*4H_2O$) in closed-system reactors from far to near to equilibrium conditions in aqueous $NaHCO_3/Na_2CO_3$ solutions at constant pH from 6.5 to 9. Ca and Mg were strongly fractionated during the stoichiometic dissolution of these minerals; in each case the fluid is significantly isotopically heavier than the dissolving mineral. For example, calcite dissolution at pH ~6.8 yielded a fluid phase that was ~0.65‰ heavier than the dissolving mineral during the 3 days required to attain equilibrium. Correspondingly, the calcium in the solid phase became ~0.14‰ ligher during this experiment. Isotope fractionation during stoichiometric dissolution is interperted to stem from the two way transfer of material to and from the mineral as equilibrium was approached, consistent with the concept of microreversibility. Preliminary mass balance calculations suggest that more than 20% of the Ca contained in the calcite present in this experiment must have passed through the fluid phase to attain this degree of fractionation. Similarly, hydromagnesite dissolution at ~pH 8.4 yielded a fluid phase that was ~0.3‰ heavier than the dissolving mineral during the 3 days required to attain equilibrium. In some cases, the isotopic composion of the fluid continues to evolve after the mineral attained elemental equilibrium. These observations clearly contervene the concept of conservative isotopic mass transfer during mineral dissolution and questions the degree to which mineral isotopic signatures can be preserved in low temperature systems.

Using coupled Fe-Mg chemical and isotopic diffusion profiles to model magma residence times of crystals

M. OESER[1,*], S.WEYER[1], R. DOHMEN[2], I. HORN[1] AND S. SCHUTH[1]

[1]Leibniz Universität Hannover, Institut für Mineralogie, Callinstr. 3, 30167 Hannover, Germany (correspondence: m.oeser@mineralogie.uni-hannover.de)

[2]Ruhr-Universität Bochum, Institut für Geologie, Mineralogie und Geophysik, Universitätsstr. 150, 44780 Bochum, Germany (ralf.dohmen@rub.de)

Recent studies have shown that chemical diffusion at magmatic temperatures generates Fe and Mg isotope fractionation in olivine that exceeds potential equilibrium isotope fractionation by an order of magnitude [1,2]. Accordingly, diffusion-generated Fe-Mg chemical zoning in olivine should be coupled with Fe-Mg isotopic zoning. In this case, magma residence times of crystals can be derived by adequate modeling of both, chemical and isotopic zoning.

This approach has been tested on olivine grains in basaltic rocks from the Massif Central volcanic region (France). Large, chemically zoned olivines were analyzed by femtosecond laser ablation MC-ICP-MS. With this technique an external precision of ±0.10‰ (2 SD, based on replicate analyses of glass standards) can usually be achieved for both δ^{56}Fe and δ^{26}Mg.

Several olivines show significant Fe-Mg isotopic zoning (of up to 1.5‰ for δ^{56}Fe and up to 0.8‰ for δ^{26}Mg) that is coupled with the chemical zoning (i.e. Mg#). Furthermore, the zoning profiles of δ^{26}Mg and δ^{56}Fe are negatively correlated. This strongly indicates that the observed zoning was generated by diffusion of Fe into and Mg out of the olivine during magma evolution (e.g. [3]). Simplified and independent modeling of Fe- and Mg- chemical and isotopic zoning was used to estimate the duration of Fe-Mg inter-diffusion between crystal and melt, which may reflect the residence time in a magma chamber before eruption [4]. Our results point to minimum magma residence times between 0.5 and 10 years, which is similar to the short timescales determined by diffusion modeling of chemical gradients in olivines hosted in basaltic lava flows from Mt. Etna [5].

A major focus of our project is to apply our developed technique to olivine crystals in MORBs to improve our knowledge on magma evolution at mid-ocean ridge settings. Olivines from the Mid-Atlantic Ridge and the Costa Rica Rift show both normal zoning and reverse zoning of forsterite (up to 4 mole percent). Fe-Mg isotopic profiles will be determined to prove whether the chemical zoning was generated by diffusion and thus provides information on magma residence times of these olivines.

The transport of toxic elements in river affected by acid thermal water and effect of dam against elemental distributions

Y. OGAWA[1], D. ISHIYAMA[1], N. SHIKAZONO[2] AND N. TSUCHIYA[3]

[1] Center for Geo-Environmental Science (CGES), Graduate School of Engineering and Resource Science, Akita University, Akita010-8502, Japan (*correspondence: y_ogawa@gipc.akita-u.ac.jp)

[2] Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Kanagawa 223-8522, Japan

[3] Graduate School of Environmental Stidies, Tohoku University, Miyagi 980-8579, Japan

Acid waters accompanied by mining activities commonly cause environmental problems worldwide. The same is true for the acid thermal waters. The Shibukuro and Tama rivers in Akita Pref., northeast Japan, were one of the most contaminated river system in Japan due to discharge of the the Tamagawa thermal water. This thermal water has being neutralized before inflowing into this river system. The Tamagawa Dam was constructed, and the man-made lake is also contributing dilution of acidic river water. In this study, we investigated the changes in physico-chemical status of As, Cd and Pb originated from the Tamagawa thermal water and their fractionation during river transport.

The geochemical behaviors of As and Pb are mainly controlled by the pH-dependent sorption onto ferric and aluminum solid materials. At upstream region, As tends to be sorbed onto bedrocks and the suspended hydrous ferric oxide (HFO) during river transport. The suspended HFO sorbing As is transported to man-made lake, and the most As originated from the Tamagawa thermal water settled onto the lakebeds. Due to the pH increase, Pb is considerably removed at this lake, although the Pb spread toward the downstream is not completely suppressed. On the other hand, Cd sorption onto both Fe and Al solid phases is not observed in the entire study reach, but Cd concentration is diluted at the lake.

Downstream from the Tamagawa Dam, paddy fields are widely distributed. Accordingly, it is concluded that the Tamagawa Dam plays environmentally important role for not only the neutralization of acid thermal water but also the dilution of toxic elements and/or suppression of their spread.

Biomineralization of jarosite by *Purpureocillium lilacinum*, an acidophilic fungi isolated from Río Tinto

M. OGGERIN [1]*, F. TORNOS [1], N. RODRÍGUEZ [1], C. DEL MORAL [2], M. SÁNCHEZ-ROMÁN [1] AND R. AMILS [1,2]

[1] Centro de Astrobiología, INTA-CSIC, 28850 Torrejón de Ardoz, Madrid, Spain (*presenting author:oggerinom@cab.inta-csic.es)

[2] Centro de Biología Molecular Severo Ochoa, CBMSO (CSIC-UAM), Madrid, Spain (correspondence: ramils@cbm.uam.es)

Río Tinto (Huelva, Southwestern Spain) is an extreme environment with a remarkably constant acidic pH and a high concentration of heavy metals, conditions generated by the metabolic activity of chemolithotrophic microorganisms thriving in the rich complex of the Iberian Pyrite Belt (IPB).

In this study, we report the specific biomineralization of (hydronium)-jarosite, an iron sulfate mineral that appears in abundance on Río Tinto banks by an acidic fungal isolate, *Purpureocillium lilacinum*. Different fungal species were isolated from Rio Tinto; characterized, cultured and tested for their ability to promote the formation of jarosite. Of the 10 strains tested, only *P. lilacinum* was able to produce jarosite. The biomineral was characterized by X-Ray Diffraction (XRD) and its formation was observed with high-resolution transmission electron microscopy (TEM) and scanning electron microscopy (SEM) coupled to Energy-dispersive X-ray spectroscopy (EDX) microanalysis.

Jarosite began to nucleate on the fungal cell wall, even on dead cells (although with much less efficiency). Also extracellular polymeric substances (EPS) released by the fungus could serve as nucleation sites for this biomineralization process. Our model proposes the creation of Fe^{3+}/Fe^{2+}-rich microdomains in the cell walls of *P. lilacinum* that induce the supersaturation and precipitation of jarosite. This change in the proportions of reduced and oxidized iron species, can be produced by the electrostatic interaction between soluble ferric iron and the negatively charged groups of the fungal cell wall, acting as nucleation sites for mineral precipitation according to previous studies [1].

The occurrence of *P. lilacinum* in an ecosystem with high concentrations of jarosite strongly suggests that might participate actively in the formation of this mineral in the river banks.

The biological control on the atmospheric pCO_2 level through geologic time

HIROSHI OHMOTO[1] AND ANTONIO C. LASAGA[2]

[1]NASA Astrobiology Institute and Dept. of Geosciences, Penn State University, University Park, PA 16802, USA. (hqo@psu.edu;) [2]Geokinetics, 213 E. Mitchel Av., State College, PA 16803, USA;(hlb2@psu.edu)

Here we constrain the atmospheric pCO_2 levels during the evolution of the Earth's biosphere through pre-biotic, anaerobic, pre-plant aerobic, and plant stages based on the BLAG-type geochemical modeling of CO_2 cycling. We have developed a new set of equations considering: (i) the flux and fate of CO_2 and reduced volcanic gases; (ii) the biological influence of soil formation; (iii) the cycling of phosphorus-bearing compounds; (iv) the C/P ratios of kerogen; (v) the burial efficiency of organic matter in sediments; (vi) the weathering efficiency of kerogen; (vii) the production efficiency of biogenic CH_4; and (viii) the formation of organic haze in the atmosphere and the deposition of haze-C in sediments. Our modeling suggests that the atmospheric pCO_2 remained at > 100 PAL during most of the pre-biotic-, anaerobic-, and pre-plant aerobic stages. No additional greenhouse gases (e.g., CH_4, H_2) were necessary to maintain a warm Earth under a faint young Sun. A transition of the biosphere caused a drastic change in the atmospheric pCO_2 level: a drop from >1,000 to ~100 PAL due to the development of an anaerobic world; a rise from ~100 to ~1,000 PAL during the anaerobic to aerobic transition; and a drop from ~20 to ~2 PAL due to the development of the plant world. Fluctuations in the soil-forming land area profoundly affect the climate of the Earth. Continental breakup would result in a global cooling event, while the formation of supercontinents would result in global warming.

Ocean-pH evolution and weathering conditions during the Ediacaran: Insights from B, Sr & Li isotopes at the Gaojiashan Section, South China

FRANK OHNEMUELLER [1,*] ANETTE MEIXNER [1] ANTONIA GAMPER [2] AND SIMONE A. KASEMANN [1]

[1] Dept. of Geosciences, University of Bremen, Leobener Str., D-28359 Bremen, *(fohnemueller@marum.de)
[2] Museum für Naturkunde, Invalidenstr. 43, D-10115 Berlin

The Ediacaran to Cambrian transition was a decisive time in Earth history since substantial changes in ocean-atmosphere interactions, climate, tectonics and bio-geochemical processes catalyzed the advent and radiation of metazoa. In this study, we investigate the boron, strontium and lithium isotope records of the Algal Dolomite, Gaojiashan and Beiwan Members (all Dengying Formation) at the Gaojiashan section (551-542 Ma) in south-western Shaanxi, South China to gain detailed insights into changing ocean-pH and weathering conditions. The 65 m thick carbonate-siliciclastic Gaojiashan Section is located at the north-western margin of the Ediacaran Yangtze-platform. Sedimentary data suggest a near shore shallow water setting that is exceptionally well preserved and only present in this part of the platform. Carbonate sedimentation is influenced by continuous detrital input presumably from a pro- and retrograding delta front.

In the upper part of the Gaojiashan Member, a negative $\delta^{13}C$ and $\delta^{11}B$ anomaly is unveiled with nadirs down to ~ -7‰ for carbonate carbon and -2‰ for boron, respectively. In total, the excursion comprises a shift of -13‰ for $\delta^{13}C$ and -12‰ for $\delta^{11}B$ which equals a decrease of ~ 1.5 pH units. At the same time, Sr isotopes display a positive excursion ($^{87}Sr/^{86}Sr$ 0.7085 to 0.7110) indicating a time of enhanced weathering through relative sea-level fall. To further assess the continental silicate weathering flux, Li isotopes have been analysed.

If we accept that those changes in the isotope pattern and ocean geochemistry are of primary origin, it needs to be discussed whether a (temporarily) restricted environment or open-ocean conditions are recorded. In view of the pronounced negative $\delta^{13}C$ anomaly it must also be considered that the Precambrian-Cambrian boundary interval is recorded in the uppermost Gaojiashan Member and the overlying sediments already belong to early Cambrian strata.

Determination of ^{129}I by ICP-MS/MS; it's application to Fukushima soil samples

TAKESHI OHNO[1], YASUYUKI MURAMATSU[1], SHOICHI TOYODA[1] AND HIROYUKI MATSUZAKI[2]

[1] Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro 1-5-1, Toshima-ku, Tokyo, Japan, 171-8588,(takeshi.ohno@gakushuin.ac.jp)
[2] Department of Nuclear Engineering and Management, School of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, Japan, 113-8656

The accident at the Fukushima Daiichi nuclear power plant (FDNPP) resulted in a substantial release of radioiodine and radiocesium into the environment. The distribution of radiocesium has been studied. On the other hand, ^{131}I could only be determined within a couple of months, due to its short half-life (8 days), resulting in a lack of data on the deposition of this nuclide. Another iodine isotope, ^{129}I (half-life: 1.57×10^7 y), was released simultaneously with ^{131}I. To reconstruct the early distribution of ^{131}I, ^{129}I has been used as a tracer. The determination of ^{129}I in Fukushima soils is of importance to investigate the distribution of radioiodine released from the FDNPP.

Recent advances in ICP-MS/MS (Agilent 8800) have enabled us to determine the long-lived radionuclide ^{129}I in soil samples. The ICP-MS/MS has an additional quadrupole mass filter, situated in front of the reaction cell, which allows only the analyte mass to enter the cell. Therefore, polyatomic interferences, such as $^{127}IH_2^+$ generated in the cell, can be reduced. In this study, we measured ^{129}I in samples collected from an orchard in Koriyama-shi (about 60 km from the FDNPP). The measured $^{129}I/^{127}I$ ratios in the samples by ICP-MS/MS are consistent with the value determined by AMS within the analytical error, suggesting the applicability of this method to measurements of ^{129}I in Fukushima soils. We also examined the depth distributions of radioiodine and radiocesium in the orchard. Sampling was carried out in April 2011 and July 2012. Our results demonstrate that, in April 2011, more than 80% of the radioiodine was distributed in the upper 4 cm of the soil column in the orchard. About one year after the accident, the proportion of the inventory in the upper 4 cm was about 60%, indicating 20% of the radioiodine had transferred to the lower part of the column. On the other hand, no significant change was observed in the depth distribution of radiocesium. This result suggests that it is difficult to use radiocesium as a tracer of ^{131}I released from the FDNPP.

Influence of depth on soil organic matter characteristics: An ultrahigh resolution mass spectrometry study

TSUTOMU OHNO[1]*, IVAN J. FERNANDEZ[2], RACHEL L. SLEIGHTER[3] AND PATRICK G. HATCHER[3]

[1]Department of Plant, Soil, & Environmental Sciences, University of Maine, Orono, ME 04469-5722. *(correspndence: ohno@maine.edu)

[2]School of Forest Resources, University of Maine, Orono, ME 04469-5722.(ivanjf@maine.edu)

[3]Department of Chemistry and Biochemistry, Old Dominion University, Norfolk, VA 23529.(rsleight@odu.edu,) (phatcher@odu.edu).

The characterization of soil dissolved organic matter (DOM) is a fundamental challenge given its diversity, chemical complexity, and importance in many vital ecosystem processes. We analyzed podzolic B horizon soil collected at multiple depths from the Bear Brook Watershed in Maine (U.S.A.) to study changes in soil DOM chemical properties with depth using ultrahigh resolution mass spectrometry.

The results show that for the B horizon-derived DOM, the Aromaticity Index (A.I.) decreases with depth, indicating that the more aromatic components of DOM are preferentially being removed either through sorption with surface functional groups and/or microbial processes. Also with increasing B horizon depth, the van Krevelen diagram classified protein- and lipid-like DOM components (those that are aliphatic) increase in relative content. Increases in these chemical classifications have been linked to microbial processes.

Soil Horizon	A.I. > 0.5	A.I. > 0.67	VKD % Proteins	VKD % Lipids
B 0-5 cm	19.5	5.3	24.0	0.2
B 5-10 cm	14.3	2.5	26.0	0.4
B 10-15 cm	11.2	1.2	26.9	0.7
B 15-20 cm	11.2	1.8	29.0	0.6
B 20-25 cm	9.1	0.6	30.9	0.8
B 25-50 cm	9.2	0.7	31.8	1.2

Table 1: Influence of soil depth on DOM chemical properties of soils from a reference hardwood stand.

The results are consistent with the hypothesis of Kaiser and Kalbitz [1], who suggested that near-surface DOM is more related to plant-derived molecules, while DOM at depth has a greater content of microbially-derived molecules.

[3]Fukushima U., Fukushima, Fukushima 960-1296, Japan

The nuclear accident at the Fukushima Daiichi Nuclear Power Plant (FDNPP) occurred as a consequence of the massive earthquake and associated tsunami that struck the Tohoku and north Kanto regions of Japan on 11 March 2011. A series of hydrogen explosion was occurred from 13 March to 15 March at the units 1, 2, and 3. The release rate of ^{137}Cs on 15 March is estimated between 10^{12} and 10^{15} Bq/h [1]. This fallout radioactive Cs were dispersed from FDNPP to ocean [1,2] and land [1]. Some of the released radiocesium was deposited on the area located north-west direction from FDNPP. We should elucidate the migration behavior of radiocesium in environments.

Local area distribution and relocation of radiocesium in trees has been studied by measuring its spatial distribution on/in trees using autoradiography analysis. The samples of trees were collected on the places located between 4 and 55 km from FDNPP at approximately 2, 8, 20, and 22 months after the accident. The autoradiography analyses of *Cryptomeria japonica*, *Torreya nucifera*, and *Thujopsis dolabrata* var. *hondae* collected on approximately 2 and 8 months after the accident showed that radiocesium was mainly distributed as like spots on the branches and leaves of the trees emerged before the accident, and was little detected in new branch and leaves emerged after the accident. On the contrary, radiocesium was detected at the outermost tip of branches in the trees collected after 20 months of the accident. *Morus alba* collected after 22 months contained radiocesium in and outside of the stem, even though no radiocesium was detected in the root, strongly suggesting that some radioacesium was translocated from the outside stem to inside. These results indicate that distribution of radiocesium deposited on/in the trees has been gradually changed with time in the scale of the year.

Leakage behavior of gases to bottom water through sediment layers with gas-hydrate stable conditions

T. OHSUMI[1]*

[1]Dept. Chem., Tokai University, Kita-Kaname, Hiratsuka 259-1292, Japan (*correspondence: ohsumitk@ohsumi-jp.com)

The water under the main thermocline in the Japan Sea is a single water mass referred to as the Japan Sea Proper Water (JSPW). It can be defined as having temperature below 2.0°C, salinity above 34.0. It is known that wintertime air-sea interaction in the Japan Sea, enhanced by outbreaks of dry and cold air masses from the Eurasian continent, generates the JSPS characteristic water mass through deep convection.

Below 10 °C, carbon dioxide hydrate is stable over the pressure of 4.4 MPa. In the Japanese archipelago side of the Japan Sea basin, the area with a water depth from 200 m to 1000 m is several tens thousand square kilometers, which is attractive for the CO_2 storage in the sub-seabed geological formations with at least 10^{11} tons of CO_2 storage capacity; in the process of upward migration, the leaked CO_2 would have much chance of hydrate formation reaction *in situ*.

While the most famous natural analog is the CO_2 seapage in mid-Okinawa Trough backarc basin found by Sakai *et al*. [1], the recently-found seafloor methane hydrate outcrops occurring on the top of the CH_4 plume in the sediment layers [2] also provides an insight into the leakage mechanism for liquid CO_2.

Gaseous CH_4 plume will be self-sustaining by its dry-out effect in the sediment and be hence developping its size as large as of several hundred meters in diameter [2], which would enhance the mixing of gas with the ambient water to make hydrate crystal growing effectively. The key is the low density of CH_4 hydrate (less than 1.0) that brings about buoyant behavior of the hydrate solid out of the bottom sediment into the overlying water column in the long run. On the contrary, liquid CO_2 might not make a gaseus plume due to its higher solubility in water and small upward migration driving force. The upward migration path could be like a dispersed mesh network in shape, partly due to the increased density of the interstitial water in contact with liquid CO_2 (*i.e*., partial molar volume of CO_2 gas in aqueous solution is *ca*. 32cm^3/mol). Self sealing of the laeked CO_2 *in situ* is probably effective, if there exist no fractures or conduits in the sediment layers.

The spatial distribution of chalcophile elements in terrestrial and marine areas of Japan

A. OHTA[1]* AND N. IMAI[1]

[1]Geological Survey of Japan, AIST, Tsukuba 305-8567, Japan; a.ohta@aist.go.jp

The Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, has conducted research on the spatial distribution of 51 elements (Geochemical Maps) both in terrestrial and marine environments [1]. Japan is surrounded by vast sea, so it is important to know the spatial distribution patterns of elemental concentrations comprehensively in land and sea. This project is intended: 1) to elucidate background of elemental abundance in terrestrial and marine areas; 2) to find mass transport from land to sea or in marine environment; and 3) to estimate diffusion processes of pollutants.

Chalcophile elements such as Cu, Zn, As, Cd, Sb, Hg, and Pb are highly enriched in stream sediments associated with metalliferous deposits and anthropogenic activity. However, coastal seas sediments that were supplied by rivers flowing through metalliferous province are not significantly enriched in these elements. We assumed that the sulfide ores are oxidized, consequently releasing heavy elements in river water during transportation. However, Zn and Pb are exception. The high concentration areas of these elements are found both in terrestrial area associated with metalliferous deposits and the adjacent coastal sea area. It is possible that aqueous Zn and Pb released through oxidation process of sulfide are derived to coastal seas and sorbed on the sediment surface.

The influence of anthropogenic activity on geochemical maps is different from the case of metalliferous deposit. The concentrations of chalcophile elements are elevated in both the metropolitan area and adjacent inner bay. Chalcophile elements are enriched in the inner bay but poor in the outer bay. The spatial distributions suggest that the contaminated materials remain in the bay without extending to the outer sea. It is probable that the estuarine circulation prevents fine particles associated with chalcophile elements from reaching the outer sea because it flows from the outer sea to the bays.

Modeling fluid migration in deep crust with modeled permeability based on wettability and energy consideration

J. OHTA[1]* AND T. TOKUNAGA[2]

[1]Department of Systems Innovation, University of Tokyo, Tokyo 113-8656, JAPAN (*correspondence: 7394793531@mail.ecc.u-tokyo.ac.jp)

[2]Department of Environment Systems, University of Tokyo, Chiba 277-8563, JAPAN

Under the high-temperature and high-pressure system in deep crustal setting, it is considered that fluid flows through deformative polycrystalline solid [1]. Here, the solid–liquid dihedral angle which express the wettability of the system is considered to be an important factor in determining internal pore structure, and hence, permeability [2, 3]. The pore structure is formed so as to satisfy texturally and energetically stable conditions under certain dihedral angle and fluid fraction [2, 3].

We constructed a permeability model to formulate a relationship among dihedral angle, permeability and fluid fraction by taking into consideration the textural and energetic conditions. The model is based on the assumption that there exists a fluid fraction to minimize grain boundary interfacial energy under certain dihedral angle [3]. We calculated the fluid fraction and the permeability under the "minimum" interfacial energy condition as a function of dihedral angle. The generalized permeability was described as functions of the permeability and the fluid fraction under the "minimum" interfacial energy condition.

We numerically calculated fluid migration processes by applying the modeled permeability to the governing equations formulating both solid deformation and fluid flow through polycrystalline solid. We found that fluid fraction increased with decreasing permeability in the case that the change of dihedral angle was inversely proportional to depth. By setting the solid bulk/shear viscosity to be 10^{20} Pa•s, fluid fraction showed repeated fluctuation. Consequently, intervals with relatively high fluid fraction were formed. Moreover, flow regime drastically changed depending on the solid bulk/shear viscosity. Our result emphasizes the importance of wettability and spatial heterogeneity of deep crust on the fluid flow processes.

[4]Institute for Material Research, Tohoku University, Sendai 980-8577, Japan

Water circulation in global Earth is one of the most important issues in geodynamics, because water can affect the physical properties including rheological property of the Earth's materials [1]. Several hydrous minerals in subducting slabs work as water carriers or reservoirs under the conditions of the upper mantle and transition zone [2]. However, it has been debated whether water can be transported into the lower mantle and core [2]. Dehydrated water in subducting oceanic crusts by decomposition of lawsonite may be trapped as a pore fluid because of a high wetting angle between garnet and water, thus resulting in coexistence of water and aluminous $MgSiO_3$ perovskite, which is the major mineral in the subducting oceanic crust [3]. Here we report a new mechanism for water transport into the lower mantle and core, i.e., a reaction between aluminous perovskite and water to form alumina-depleted perovskite and δ-AlOOH [4] along the slab and mantle geotherms under the lower mantle conditions. δ-AlOOH coexists with the aluminous $MgSiO_3$ perovskite and post-perovskite phases in the $MgSiO_3$–Al_2O_3–H_2O system along the slab and mantle geotherms in the lower mantle. Chemical analysis of these phases revealed that the perovskite and post-perovskite phases were depleted in Al_2O_3. Our results demonstrate the coexistence of alumina-depleted $MgSiO_3$ perovskite or post-perovskite phase and Mg, Si-bearing δ-AlOOH phase in wet slabs subducting in the lower mantle. Thus, Mg, Si-bearing δ-AlOOH phase thus formed transports hydrogen into the core-mantle boundary (CMB) region.

Micro-scale sensor array-enabled hot spring mapping

J. OILER[1]*, E.L. SHOCK[1], H.E. HARTNETT[1] AND H. YU[1]

[1]Arizona State University, Tempe, AZ 85287, USA (*correspondance: joiler@asu.edu)

Micro-scale temperature and electrical conductivity sensor arrays were fabricated. The linear temperature array consisted of 15 temperature sensors with separations of 1 cm. The linear conductivity array consisted of 5 conductivity sensors with separations of 1 cm. Both arrays were deployed in hot springs at Yellowstone National Park, USA. At one site, two geochemically different hot spring outflow channels converged. One channel was acidic (pH ~3.3, temperature ~36 °C, conductivity ~900 µS/cm). The second channel was alkaline (pH ~7.8, temperature ~60 °C, conductivity ~4200 µS/cm). Where the two streams mixed, visually distinct bands of photosynthetic pigments were observed that were not seen elsewhere in either stream.

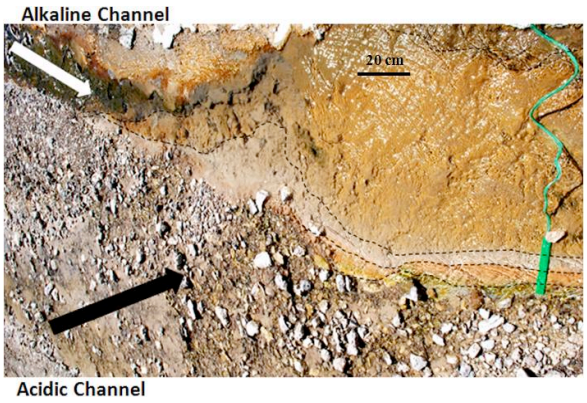

Figure 1: Photograph showing the confluence of two hot spring outflow channels. Where the alkaline channel (top – white arrow) and the acidic channel (bottom – black arrow) mix, bands of color are observed. The location between colors is assisted with dashed lines.

More than 700 temperature and 90 conductivity measurements were taken within the mixing zone using the arrays. Extremely high spatial resolution mapping of temperature and conductivity in the mixing zone was performed. The temperature color map traces out distinct regions that match the shape and width of many of the photosynthetic pigment bands. Furthermore, the temperature data were used to predict the conductivity at a higher sampling density than was measured, providing a new technique for mapping conservative constituents at high spatial resolution in mixing zones.

Development of ETV-MC-ICPMS technique for W isotope analysis

*SATOKI OKABAYASHI[1], SHUHEI SAKATA[1] AND TAKAFUMI HIRATA[1]

[1] Laboratory for Planetary Sciences, Kyoto University, Kyoto, Japan, (correspondance: okabayashi-s-aa@kueps.kyoto-u.ac.jp)

Hf-W chronometer is based on the negative beta-decay of r-process nuclide ^{182}Hf to ^{182}W with a half-life of 8.9 ± 0.1 Myr [1]. Hafnium is strongly lithophile elements, whereas W is moderately siderophile elements, and therefore, it has been well recognized that the Hf-W age provided critical information about the timing of metal-silicate differentiation (core formation) processes at the early stage of the planetary formation. Moreover, both the Hf and W is strongly refractory elements, the Hf-W age can reflect the timing of condensation or segregation of the metallic nuggets from chondritic reservoir at the early sequence of the solar system.

In this study, we have developed a new sample introduction system using an electrothermal vaporization (ETV)-MC-ICPMS technique in order to measure the isotope ratio from ng-amount of W. Compared to the conventional nebulization sample introduction technique, the ETV technique has significantly higher sample introduction efficiency. ETV-ICP technique has been accepted as a one of the most powerful tool to measure the small sample sizes[2]. With the conventional ETV system, despite the better sample introduction efficiency could be achieved, signal stability for the refractory elements, including W, was deteriorated. To obtain stable signal intensity profiles for W isotopes, He, instead of Ar, was used as carrier gas.

In our experiments, W sample in 0.5 - 1.0 μL of 2wt% HNO_3 solution was loaded onto a Re filament. The filament was set into the small glass chamber (~25 mL), and then, temperature of the Re filament is controlled by the incident current (0 – 4 A) under the He gas. W signal was observed at ~1100ºC. Compared to Ar gas environment, W signal stability was dramatically improved under the He gas condition. W standard solution (JMC22841) was measured several times, and the obtained ^{182}W/^{184}W ratios were 0.864691 ± 0.000024 from 75 ng W (n = 9) and 0.864693 ± 0.000044 from 25 ng W (n = 9) (corrected using exponential law using ^{186}W/^{183}W = 1.9859 [3]). In this presentation, ^{182}W/^{184}W ratios obtained from meteorite samples will be discussed.

Laboratory experiments on the effect of microbial activities on iodine speciation in seawater

N. OKABE[1]*, Y. MURAMATSU[1] AND S. AMACHI[2]

[1]Gakushuin University, 1-5-1 Mejiro, Toshima-ku, Tokyo 171-8588, Japan (*correspondence:12242003@gakushuin.ac.jp)

[2]Chiba University, 648 Matsudo, Matsudo-shi, Chiba 271-8510, Japan

In seawater, iodine concentration is relatively constant (0.3 – 0.5 micro M). However, chemical forms of iodine are known to be variable and there are species of iodide (I^-), iodate (IO_3^-) and organic iodine. Due to the oxic condition in seawater, iodate is thermodynamically stable and it is dominant. In surface seawater, iodide which is a reduced form, also exists, due to presence of microorganisms, e.g. nitrate-reducing bacteria which reduce iodate to iodide (Tsunogai and Sasa, 1969; Amachi *et al*. 2007). In our previous study on the speciation of iodine in pore water of marine sediments, we found the dominant species was iodide. This was explained by the anoxic condition created by the effect of microorganisms in the sediments.

In this study, we used seawater samples collected from to site on Pacific Coast such as Numadu (Suruga Bay) and Odaiba (Tokyo Bay). The samples were introduced into 50 ml glass vials after following treatments; autoclaving, filtering or addition of antibiotic substances together with unfiltered fresh samples. They were incubated under light and dark conditions at 25 ºC in a laboratory. The chemical forms of iodine were determined over time using HPLC-ICP-MS.

Analytical results showed that the concentration of iodide increased and that of iodate deceased with time under light condition. This result agrees with increased iodide proportion reported in the euphoric zone. However, under dark condition, no obvious changes of iodine chemical forms were observed.

In seawater samples that were either sterilized by autoclaving or filtering, chemical forms of iodine did not change as much. These findings indicate the role of microorganisms on the transformation of iodine species.

Calcite and Chalk: Differences in Vapour Adsorption Behaviour

D.V. OKHRIMENKO*, K.N. DALBY, L.L. SKOVBJERG, N. BOVET, M.P. ANDERSSON, M.H.M. OLSSON AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*denisokr@nano.ku.dk)

Calcite is a common mineral, widely used in industry and important in environmental processes. It is the main component of chalk and limestone, which serve as natural reservoirs for water and oil. Understanding adsorption energetics and wetting properties of calcite surfaces is important for developing remediation strategies for aquifers, for improving oil recovery, for minimising risk in CO_2 storage and for optimising industrial processes. We have compared the adsorption properties of synthetic calcite with those of chalk samples, composed of biogenic calcite.

We measured the heat of adsorption for water and several alcohols, from the gas phase, and determined the surface energy in order to learn more about the surface properties of these samples. XPS (X-ray photoelectron spectroscopy) was used to monitor changes in chalk surface composition when the organic content was decreased by extraction with CH_2Cl_2/CH_3OH. The affinity for vapour of polar longer chain organic compounds (e.g. alcohols) was higher for synthetic calcite than for chalk, giving enthalpies of adsorption typical for chemisorption (˃100 kJ/mole). DFT/MD (density functional theory and molecular dynamics) simulations showed that the alcohols formed structured monolayers on calcite and that dispersive lateral interactions between the CH_2 tails of the adsorbed molecules contributed as much as 60% of the overall adsorption energy. Such behaviour was not observed for the chalk samples. Alcohol vapours adsorbed to chalk with lower binding energy (˂80 kJ/mole), showing a distribution of adsorption energies typical for heterogeneous surfaces. After partially removing organic contamination by extraction, water and ethanol adsorption experiments showed that surface energy, mainly the dispersive component, increased. This increase might be a response to the low polarity of surface sites generated during extraction and could be connected to the presence of nanoscale clay lamellae, already seen using AFM (atomic force microscopy) chemical force mapping [1]. However, the response could also result from increased lateral interactions between the CH_2 tails of alcohols adsorbed on the calcite surface of the chalk.

Theory on thermodynamic constraints on biogeochemical diversity

J.G. OKIE[1]*, P. CANOVAS[1] AND E.L. SHOCK[1]

[1]School of Earth and Space Exploration, Arizona State University, P.O. Box 8714004, Tempe, AZ 85287. USA. (correspondence: Jordan.Okie@asu.edu)
(Peter.Canovas@asu.edu, Everett.Shock@asu.edu)

Understanding geographic patterns of biological and geological diversity is central to ecology, evolution, biogeography, and many areas of geology. The number of energy-yielding reactions—geochemical catabolic richness—imposes fundamental constraints on the number of energy-yielding reactions harnessed by a living system—the biogeochemical catabolic richness—which in turn can influence organism and ecosystem function and taxonomic diversity. Theory on geochemical and biogeochemical catabolic richness is lacking, despite its relevance to understanding evolutionary and macroecological patterns of functional and metabolic diversity. A system's potential biogeochemical catabolic richness is the number of chemical reactions having energy-yields above some A_{min} required to make the reaction useful as an energy source. We develop general mathematical theory based in thermodynamics and theoretical geochemistry showing how potential biogeochemical catabolic richness of a reaction system involving a given chemical species depends on temperature, pressure, concentration, A_{min}, and the frequency distribution of the species' stoichiometric coefficients for the reactions. We then apply the theory to reactions involving H+ to provide mathematical predictions of how the community's potential biogeochemical catabolic richness is a function of temperature, pH, and A_{min}. We find that the theoretical predictions closely matched empirical richness patterns of hot springs at Yellowstone National Park. The developed theory elucidates the degree to which various physicochemical variables can influence biogeochemical richness, and may have implications for patterns of functional, taxonomic and phylogenetic diversity in microbial communities.

H_2, CH_4 and NH_4 formation through low temperature water-rock reactions in ultramafic rock

OKLAND, I., THORSETH, AND I.H., PEDERSEN, R.B.

Centre for Geobiology/ Department of Earth Science, University of Bergen, Allegaten 41, N-5007 Bergen, Norway. e-mail:(Ingeborg.Okland@geo.uib.no)

H_2, CH_4 and NH_4 are electron donors potentially important for chemolithothrophic microorganisms in subsurface endolithic communities. High-temperature formation of H_2 and CH_4 in ultramafic systems is well studied. Knowledge of low-temperature processes, and the effect of ferrous secondary minerals are however limited. Here we explore the formation of these species during experimental low temperature (25°C) alteration unaltered, medium altered and highly altered dunite from continental sites.

H_2, CH_4, NH_4 and NO_3 were detected in the fluids in all three setups. We suggest that H_2 results from reduction of water due to oxidation of Fe(II) released from olivine in unaltered dunite, from brucite and olivine in medium altered dunite, and from brucite and serpentine in highly altered dunite. CH_4 may result from abiotic methanogenesis or dissolution of CH_4 containing fluid inclusions. The N-species were most likely absorbed to serpentine in the altered dunite, while the source for unaltered dunite is probably explosives used during mining.

The results indicate that water-rock reactions in medium and highly altered ultramafic rocks can provide reduced species potentially supporting microbial communities in low-temperature subsurface environments in ophiolites and near seafloor parts of ultramafic oceanic lithosphere.

The Greater Caucasus represents a Phanerozoic collisional orogen which is formed along the Euro-Asian continent South margin and is expended over 1200 km between the Black and Caspian Seas. The Kakheti segment is located on the eastern part of the Greater Caucasus southern slope and is mainly formed of folded Lower Jurassic clay-shales and basic volcanic-sedimentary formations, which according to geophysical data, are located on oceanic or transitional crust (Morariu, Nouval, 2009). The complex of these rocks is intersected by Middle-Upper Jurassic gabbroic, dioritic, quartz- dioritic and felsitic intrusions which caused intensive hydrothermal silicification, sericitization and ore mineralization of the fractioned host rocks (Okrostsvaridze *et al*., 2012).

The above mentioned ore mineralization was studied by supported of Georgian National Science Foundation grant (#GNSF/ST09-1071-5-150). Metals chemical analyses more than 300 ore samples were carried out in the laboratory of ACMELABS (Canada, Vancouver), using ICP-MS, by 3B, 14B, F5 and 1F15 methods.

Our research showed that ore mineralization processes genetically are related to postmagmatic events of Middle-Upper Jurassic intrusive magmatism in the Caucasus Kakheti segment. Two mineralization zones - the Northern and the Southern are distinguished here. The Northern one is mainly distinguished by pyrite-polymetallic mineralization, where content of Pb and Zn sometimes is >10000 g/t, Co - varies between 40-295 g/t, and Ag – 5-95 g/t intervals. Au doesn't have an industrial concentration (0.01-0.05g/t) in this zone. The Southern mineralized zone is represented by copper-pyrrhotitic ores, where Cu concentration sometimes is >10000 g/t, and Au reaches industrial concentrations (0.1-3.1 g/t). At the last stage of ore mineralization, at some areas of the South mineralized zone Th and Bi concentrations are detected, which genetically should be related to carbonate hydrotherms. In these rocks Th content varies from 40 to 120 g/t, and Bi – from 200 to 800 g/t, but near the Gelia ore zone concentration of Th reaches 3842 g/t, and Bi - 4806 g/t (Okrostsvaridze *et al*., 2011).

Sr stable isotopic anomalies in primitive meteorites and chondrules

WATARU OKUI[1]*, TETSUYA YOKOYAMA[1], MASAOI UNO[1], HIKARU IWAMORI[1] AND EIICHI TAKAHASHI[1]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology. (*:okui.w.aa@m.titech.ac.jp)

Chondrules are one of the main constituents of chondrites (CC: 15-60 vol.%, OC: 60-80 vol.%, EC: 60-80 vol.%). The identification of chondrule formation mechanism is an important clue to understand how Solar System precursor solids formed, were transported, and mixed in the nebula. Interpritations of chondrules' origins are still controversial, however, particularly because chondrule bulk compositions have a large variation in their chemical composition. In this study, we tackle this issue by analyzing highly precise Sr isotope compositions in chondrules with a variety of chemical compositions that were separarted from multiple chondrites.

Chondrules were separated by a freeze-thaw method or sampled from sliced specimens by using a micro milling system (Geomill 326, Izumo) [1]. We followed the sample digestion procedure of [2]. Sr isotopic measurements were carried out by TIMS (Triton plus at Tokyo Tech). The $^{84}Sr/^{86}Sr$ ratios are reported in $\mu^{84}Sr$ units, which are 10^6 relative deviations from the average of NIST 987 Sr.

The $\mu^{84}Sr$ values in two Allende (CV3.6) chondrules (+140 ppm, +130 ppm) are greater than those of bulk Allende (+70 ppm). This result suggests that the matrix components have $\mu^{84}Sr$ values lower than bulk Allende, because CAIs also have $\mu^{84}Sr$ values greater than the bulk. This is supported by a previous study [3] reporting that Allende acid leachate #1, where matrix component is dominant, had a $\mu^{84}Sr$ value lower than the bulk Allende (+35 ppm). Our new data would suggest that Allende chondrules are also isotopically distinctive carriers for Sr along with presolar grains and CAIs. This strongly argues against the genetic linkage between chondrules and matrix components in a single meteorite. On the contrary, $\mu^{84}Sr$ values in chondrules from Sahara 97072 (EH3) and Sahara 98175 (LL3.5) are not resolvable from those in the bulk rock of their host meteorite.

For Allende, we propose that X-wind model is one of the conceivable processes to concurrently induce large scale migration of chondrules and Sr isotopic anomalies between chondrules and matrix. In contrast, chondrules from ordinary and enstatite chondrites have formed locally and did not undergo large scale migration in the solar nebula before they formed parent body with matrix.

Delineating biotic and abiotic carbonaceous material in the Apex chert

ALISON OLCOTT MARSHALL[1]*, JAN JEHLICKA[2], JEAN-NOEL ROUZAUD[3] AND CRAIG P. MARSHALL[1]

[1] Department of Geology, University of Kansas, Lawrence, KS 66045, USA
(* Correspondance: (olcott@ku.edu)

[3] Laboratoire de Géologie, UMR CNRS 8538, Ecole Normale Supérieure, 24 Rue Lhomond, 75231 Paris Cedex 5, France

The Apex chert in Western Australia has been the center of many debates about whether these rocks contain unambiguous evidence of the early biosphere. Originally, these rocks were described to contain cyanobacterial microfossils [1] although later studies have described these features as having a morphology [2] and mineralogy [3] inconsistent with life. Additionally, these rocks contain carbonaceous material (CM) of unknown origin. This CM as been described by some as being of abiotic catalytic origin [2], and by others as biogenic [4]. Although Raman spectroscopy is not sufficient in and of itself to determine the source of CM, including whether it is biogenic [5], we recently used Raman spectroscopy in a paragenetic framework to demonstrate that the CM is from at least two separate populations [6]. Here we show using high-resolution transmission electron microscopy (HRTEM) that the CM found in the Apex chert exhibits at least four different microtextures. As different types of CM have different carbon crystallinities, the sources of these microtextures can be determined, revealing CM produced by processes such as abiotic catalytic synthesis, meteoritic input, and biological synthesis. These four populations of CM, combined with the geological history of the area, reveals over a billion years of fluid mixing and CM redeposition. Our study reveals that while care should be taken when interpreting bulk chemical data in samples from the Apex chert, HRTEM can offer the ability to delineate biogenic CM from abiotic CM in Archean sedimentary sequences.

Mg-isotopic evidence for CBb chondrule formation by condensation from an impact plume

M. B. OLSEN[1], M. SCHILLER[1] AND M. BIZZARRO[1]

[1]Centre for Star and Planet Formation, National History Museum of Denmark, University of Copenhagen, Copenhagen 1350 DK. E-mail: (mia.b.olsen@snm.ku.dk)

Chondrules are millimeter-sized spherules formed as molten droplets and are a major constituent of chondrite meteorites. Using U-corrected Pb-Pb dating, it has been showen that chondrule formation started contemporaneously with calcium-aluminium-rich inclusions (CAIs) and lasted several Myr [1]. Of interest are chondrules from the CB group, which in contrast to typical chondrules have exclusively non-porphyritic textures and magnesium-rich compositions. Their formation is believed to have occurred >5 Myr after CAIs, that is, much later than most chondrules. Based on these observation, it has been suggested that CB chondrules formed from a plume produced by an impact between planetary embryos after dust in the protoplanetary disk had largely dissipated [2]. However, late formation of these objects in a disk environment cannot be excluded [3]. Here, we use high-resolution Al-Mg isotope measurements to explore the formation mechanism(s) of CBb chondrules.

We selected ten skeletal chondrules from the CBb chondrite Hammadah al Hamra 237 and determined their Mg isotope compositions and $^{27}Al/^{24}Mg$ values using methods described in [4]. The chondrules show variability in the mass-dependent $\mu^{25}Mg$ component (from -86±15 ppm to 292±7.1 ppm relative to Earth's mantle) that is correlated to their $^{27}Al/^{24}Mg$ ratios in a manner consistent with a condensation origin. Using a kinetic fractionation law (β=0.511) to determine the mass-independent $\mu^{26}Mg^*$ values results in a negative correlation in $\mu^{26}Mg^*$ and $^{27}Al/^{24}Mg$ space, establishing that the $\mu^{25}Mg$ variability was not imparted by kinetic processes. Instead, using the experimentally determined fractionation factor of β=0.514 [5] returns a single $\mu^{26}Mg^*$ population with an uncertainty that is comparable with the external reproducibility of our method (~2.5 ppm). These data indicate that CBb chondrules formed by condensation from a isotopically homogeneous reservoir >4.7 Myr after formation of canonical CAIs. The Mg-isotope composition of CBb chondrules are thus supportive of the giant impact scenario for the the formation of CB chondrites.

Effects of pH and ionic strength on the surface charge density of self assembled monolayers (SAM)

M.H.M. OLSSON*, M.P. ANDERSSON, J. MATTHIESEN AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*mats.olsson@nano.ku.dk)

The properties of a surface depend very much on its surface charge density and polarity. Charged or highly polar surfaces are usually water wet and interact strongly with polar molecules. In some cases, such surface-organic affinities enhance organic compound adsorption. Surface charge density is therefore also important in making our society more sustainable through, for example, designing new material properties, filtering drinking water, ensuring safe CO_2 storage and enhancing oil recovery. We used ionizable COOH-terminated self assembled monolayers (SAM) to investigate the effect of solvent pH and ionic strength on surface charge density. We set up three different models for the effective charge-charge interaction between neighboring COO^- groups and calculated the fraction of deprotonated SAMs for various ionic strengths (figure).

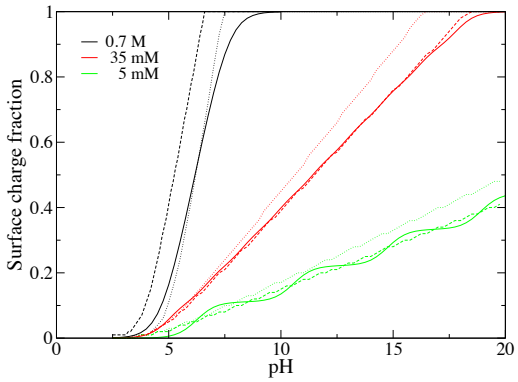

Figure: Titration curves predicted using the three models for three values of ionic strength.

The effective pK_a value of the SAM increases substantially from the monomer value at low salinity because of the increased charge-charge interaction between neighbors. As ionic strength decreases, the titration curves become flatter and deviate significantly from the standard Henderson-Hasselbalch expression. With these simulations, we obtain contour plots of the surface charge density at any pH and ionic strength. The simulations are nicely consistent with data from atomic force microscopy (AFM) chemical mapping.

Biogeochemistry of Acidic lakes in the Iberian Pyritic Belt

E. O. OMOREGIE[1]*, E. SANTOFIMIA[2], E. LÓPEZ-PAMO[2], G. WEGENER[3], M. E. BÖTTCHER[4], P. ESCHER[4], U. STRUCK[5], Á. AGUILERA[1] AND R. AMILS[1,6]

[6]CBM-SO, Autonoma University of Madrid, Spain (ramils@cbm.uam.es)

The Iberian Pyritic Belt is one of the largest pyrite deposits on Earth. The exposure and subsequent oxidation of sulfide containing ores, resulting from mining activities, has lead to the formation of acid mine drainage (AMD) in this region. Acidic, metal contaminated lakes, which often form as result of the inundation of mine pits are a substantial hazard in this region. For this reason the hydrochemistry of these systems has been the subject of several studies. However, there is very little known about the sediments in these lakes and the role of benthic-pelagic coupling for these systems. We conducted an interdisciplinary study that combined geochemical, stable isotope (H, O, C, S), and microbiological tools to develop a biogeochemical model for three pit lakes: Concepción, Nuestra Señora del Carmen, and Tharsis Filón Centro.

Consistent with the oxidation of sulfide minerals, mixolimnion pH of these lakes ranged between 2 and 3, with enhanced concentrations of dissolved elements, such as SO_4^{2-}, As, Fe, Al, Mn, and Zn. ORP ranged from +600 to +400 mV and Fe(III) dominated iron speciation within these zones. In general, Fe(II), CO_2, CH_4 and pH increased in the monimolimnion of all lakes. Additionally, Eh decreased in these zones. In the sediments, pH ranged from 4 to 6 and ORP from -200 to +100 mV. Moderate sulfate reduction rates of up to 60 nmoles $SO_4^{2-}cm^{-3}d^{-1}$ were measured in the sediments. CO_2 and CH_4 concentrations were enhanced compared to the water column. 16S rRNA gene analysis revealed the presence of sulfate reducing bacteria as well as a broad spectrum of other bacteria, and archaea commonly associated with acidic sedimentary environments. Our results indicate that the sediments act as concentrators for organic material, resulting in microbial activity that enables the increase in pH of the sediments and bottoms waters of the lakes.

Effect of hydroxycarbonate green-rust particle size on ferrous denitrification

G. ONA-NGUEMA[1], D. GUERBOIS[1], P. MAFFIOLI[1], V. NOEL[1], J. BREST[1] AND G. MORIN[1]

[1]Institut de Minéralogie et de Physique des Milieux Condensés (IMPMC), Environmental Mineralogy group, UMR 7590 UPMC-CNRS, Campus de Jussieu – 4 place Jussieu 75005 Paris (*correspondence:georges.ona-nguema@impmc.upmc.fr, delphine.guerbois@impmc.upmc.fr, priscilla.maffioli@impmc.upmc.fr, vincent.noel@impmc.upmc.fr, jessica.brest@impmc.upmc.fr, guillaume.morin@impmc.upmc.fr)

Green-rusts are mixed Fe(II,III) layered double hydroxides commonly found in anoxic zones of natural environments such as sediments and hydromorphic soils, in which they control the concentration of dissolved iron in the soil solutions. In such anoxic environments, green-rust minerals play an important role in the biogeochemical redox cycling of Fe, and can affect the speciation and mobility of many organic and inorganic contaminants. Therefore, an improved understanding of the processes and/or parameters controlling the formation and growth, the particle sizes and reactivity of green-rust in natural and engineered systems may help to better managing contaminant fate. Indeed, previous laboratory studies have reported that synthetic green-rusts are capable of reducing for instance nitrate [1] and nitrite [2], selenate [3], chromate [4], Ag(I), Au(III), Hg(II) [5] and halogenated hydrocarbons [6].

In the present study, we have prepared synthetic Fe(II,III) hydroxycarbonate green-rusts [GR(CO_3)] under various conditions, using various chemical procedures. Among the abiotic GR(CO_3) obtained from these synthesis pathways, the most stable were aged, leading to significant particle growth. The reactivity of nano-sized and micro-sized GR(CO_3) was studied in the presence of either nitrite or nitrate. X-ray diffraction and scanning electron microscopy were used to characterize solid phases of time-series samples obtained after interaction with nitrite or nitrate and show major influence of the particle size on the mass balance and the kinetics of the redox reactions investigated.

Quantitative color mapping of a brown altered granite by means of dark field reflection visible micro-spectroscopy

C. ONGA[1]* AND S. NAKASHIMA[1]

[1]Department of Earth and Space Science, Osaka University, Toyonaka, 560-0043, Japan
(*cresppondence: chieonga@ess.sci.osaka-u.ac.jp)

Reddish brown zones often extend from fractures toward interiors of granites (Fig.1a). Such colored zones are considered to be due to the presence of iron (hydr)oxides formed by weathering and/or hydrothermal alteration. However, their chemical forms and distributions have not been well characterized by conventional analytical methods.

In this study, microscopic visible dark field reflectance spectroscopy equipped with a color mapping system has been developed and applied to a brown-colored Rokko granite sample (Fig.1b). Sample reflectance spectra show similar features to goethite, lepidocrocite and ferrihydrite. Raman micro-spectroscopy on the granite sample surface confirm the presence of these minerals. L*a*b* color values (second CIE 1976 color space) were determined from the sample reflection spectra.

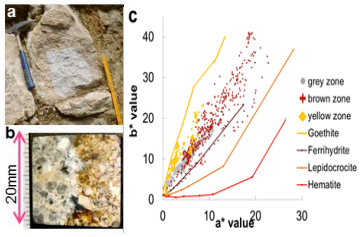

Figure 1: Brown-colored Rokko granite (a) and its hand specimen with a brown front (b). Color values by microscopic visible reflectance spectra in the a*-b* diagram (c).

Grey, yellow and brown zones of the granite show different L* a* and b* values. In the a*-b* diagram (Fig.1c), a* and b* values in the grey and brown zones are between the goethite and ferrihydrite trends, but their values in the brown zone are larger than those in the grey zone. The yellow zone shows data points close to the goethite trend. Iron (hydr)oxides rich areas can be visualized by means of large a* and b* values in the L*, a* and b* maps. The visible dark field reflectance spectroscopy with the color mapping system can be an useful method for studying distribution of colored-minerals such as iron (hydr)oxides.

Phase transformation in Fe_2SiO_4 at high pressure and high temperature

S. ONO[1]

[1]JAMSTEC,, Yokosuka 237-0061, Japan (sono@jamstec.go.jp)

Olivine, $(Mg,Fe)_2SiO_4$, is the most abundant mineral in the upper mantle. The iron content in olivine varies with depth because of chemical interactions with other mantle phases and determining the phase diagram of the polymorphs of the Fe_2SiO_4 end-member is important for precise modeling of the Mg_2SiO_4-Fe_2SiO_4 system. With pressure and temperature increase, Fe_2SiO_4 fayalite transforms into a spinel phase. The transition pressure from olivine to spinel phase has been confirmed to be around 5 GPa at high temperatures by previous experimental studies. However, the values of these *dP*/*dT* slopes scatter from 2.5 to 4.5 MPa/K. This phase boundary has been used as a pressure calibration point at high temperatures in high-pressure experiment. Therefore, the precise phase boundary of Fe_2SiO_4 needs to be determined.

The starting material was Fe_2SiO_4 fayalite, synthesized from a starting mixture composed of finely powdered Fe_2O_3 and SiO_2. High-pressure X-ray diffraction experiments were performed using a multi-anvil high-pressure apparatus, and was combined with a synchrotron radiation source located at the KEK and SPring-8 facilities in Japan. In our experiments, pressure was applied to the sample by generating a press load. The sample was then quickly heated until it reached the desired temperature for a given press load. After reaching the required temperature, we performed *in situ* measurements using the synchrotron X-rays and the heating temperature was maintained for 1-3 h. At the end of the experimental runs, the sample was quenched by cutting off the electrical power. This heating procedure was the same as that used in typical quench experiments.

We report on the disputed issue of the *dP*/*dT* slope of the olivine-spinel transition in Fe_2SiO_4, and establish the phase boundary with improved accuracy using our pressure and temperature data. We performed approximately 25 experimental runs to investigate the phase boundary between the olivine and spinel structures. The gradient of *dP*/*dT* of the phase boundary was positive.

P (GPa) = 0.5(3) + 0.0034(3) x T (K).

The boundary determined in this study is in general agreement with those reported in previous quench or *in situ* high-pressure experiments. However, the *dP*/*dT* slope was more positive than that in the previous *in situ* experiment.

Clumped Methane Isotopologue ($^{13}CH_3D$) Thermometry of Geological Methane by Tunable Mid-Infrared Laser Spectroscopy

SHUHEI ONO[1], BARBARA SHERWOOD LOLLAR[2], ELIZA HARRIS[1], BARRY MCMANUS[3], MARK ZAHNISER[3] AND DAVID NELSON[3]

[1]Department of Earth, Atmospheric and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, MA. (sono@mit.edu)

[2]Department of Earth Sciences, University of Toronto, Toronto, ON, Canada

[3]Center for Atmospheric and Environmental Chemistry, Aerodyne Research, Inc., Billerica, Massachusetts, USA

We have developed a tunable laser mid-infrared spectroscopy instrument to measure four isotopologues of methane including clumped isotopologue, $^{13}CH_3D$. Precise measurements of $^{13}CH_3D$ abundance will add another critical dimension to resolve biogenic and abiogenic sources of methane in the marine and continental deep subsurface, and the atmosphere.

The new spectrometer houses two quantum cascade lasers that are tuned to a series of well resolved fundamental absorption lines in the 8 μm wavelength region. One laser measures absorption lines for $^{12}CH_3D$, $^{12}CH_4$, and $^{13}CH_3D$, and the other $^{12}CH_4$ and $^{13}CH_4$. Precisions (1σ) are 0.1‰ for the ratio $^{13}CH_4/^{12}CH_4$ and $^{12}CH_3D/^{12}CH_4$, and 0.3 ‰ for the ratio $^{13}CH_3D/^{12}CH_4$, evaluated by comparing two methane cylinder samples. Accuracy of the technique is assured by comparing $\delta^{13}C$ and δD values measured by a conventional isotope-ratio mass spectrometer.

The abundance of $^{13}CH_3D$ is expected to reflect the temperature at which methane is thermally equilibrated, according to the isotope exchange reaction:

$$^{13}CH_4 + {}^{12}CH_3D \leftrightarrow {}^{13}CH_3D + {}^{12}CH_4$$

The equilibrium constant for this reaction approaches unity at very high temperatures (>1,000K). At low temperature, the above equilibrium constant deviates from unity, reaching values of 1.0066, 1.0050, 1.0011 at 0, 100 and 400 °C, respectively. Therefore, the precision of 0.3 ‰ would permit a temperature estimate of ±10°C for methane formed or scrambled at 25°C. The measured 'clumped isotope temperature', however, is expected to be be biased when mixing of two or more sources of methane occur due to some non-linearity in the ratio $^{13}CH_3D/^{12}CH_4$ upon mixing. We will discuss some preliminary data and the potential of this new approach to delineate deep subsurface methane sources and their role in the deep carbon cycle.

Meteorite impact, volcanism, and radiolarian faunal turnover recorded in the Upper Triassic of Japan

T. ONOUE[1,*], H. SATO[2], T. NOZAKI[3], J. KURODA[3] AND K. SUZUKI[3]

[1]Kumamoto University, Kumamoto 860-0862, Japan (*correspondence: onoue@sci.kumamoto-u.ac.jp)
[2]Kyushu University, Fukuoka 812-8581, Japan (3SC12024G@s.kyushu-u.ac.jp)
[3]Japan Agency for Marine-Earth Science Technology (JAMSTEC), Yokosuka 237-0061, Japan

The Late Triassic was characterized by several marine and terrestrial biotic turnover events prior to the end-Triassic mass extinction. The causes of the end-Triassic mass extinction and these Norian to Rhaetian biotic turnover events are still the subject of debate. Catastrophic processes such as widespread eruption of the Central Atlantic Magmatic Province (CAMP) flood basalts and extraterrestrial impacts have been proposed to account for the biotic turnover events [1, 2]. Here, we report a marine osmium (Os) isotope record reconstructed from an Upper Triassic bedded chert succession in Japan, which accumulated on the paleo-Pacific deep seafloor. We also analyzed the extinction patterns of Late Triassic radiolarian species from the bedded chert succession with the marine Os isotope record.

The Os isotope data show an abrupt and marked negative excursion from an initial Os isotope ratio of ~0.477 to unradiogenic values of ~0.127 in a claystone layer within a middle Norian bedded chert (~215 Ma), indicating the input of meteorite-derived Os into seawater [3]. A gradual decrease in $^{187}Os/^{188}Os$ ratio during the Rhaetian (201–210 Ma) is considered to have been closely linked to the CAMP volcanic event [4]. An analysis of radiolarians provides no indication of a mass extinction event across the claystone layer and during the CAMP volcanic phase. However, a significant faunal turnover occurred at ~1 Myr after the impact event. Biostratigraphic analysis shows that 20 radiolarian species became extinct at this level in the chert. It is possible that the impact triggered the extinction of these 20 species, though the direct cause of their extinction remains uncertain.

The influence the stoichiometry of arsenopyrite on the impurity density

V. ONUFRIENOK *, A. SAZONOV AND A. NIKIFOROV

Siberian Federal University, Krasnoyarsk, Russia (*correspondence: VOnufriynok@yandex.ru)

The chemical composition of arsenopyrite FeAsS may differ in detail from one deposit to another, from one deposition stage to another in a given deposit, and even from the outer parts of a single grain towards its interior. Based on a comprehensive analysis of the crystal structure, chemical and phase composition of the analytical expressions for the calculation of the impurity density in the arsenopyrite received. The algorithm for calculating the impurity density structures such as NiAs proposed Onufrienok (Onufrienok *et al*., 2012). To calculate the density impurities into arsenopyrite was amended. The impurity density for the impurity atoms cobalt Co, copper Cu, nickel Ni and gold Au is calculated separately. Specimens for investigated from the deposit Panimba Krasnoyarsk region. Studies have been conducted on ~65 samples from different mines. One such series is presented in Table 1

Table 1: Results of the microprobe analysis (α) and the results calculations of the density impurity (β) into the arsenopyrite.

Because of the large scatter of the experimental points should speak not about dependencies but only a trend. As it is shown in the table, tendency to increasing of the density impurities with increasing nonstoichiometry is installed. Stoichiometric composition should be considered when the ratio (As + S)/Fe is equal to two. Decreasing this ratio impurity density tends to decrease. Statistical analysis of all samples (~65) confirmed the findings.

Marine Cements and the Late Cretaceous to Cenozoic History of Magnesium, Srontium, and Calcium in the Ocean

BRADLEY OPDYKE[1], RYAN OWENS[1], JEREMY CAVES[2], PAUL WILSON[3] AND ANDRE DROXLER[4]

[1]The Research School of Earth Sciences, The Australian National University
[2]Environmental Earth System Science, Stanford University
[3]Ocean & Earth Science, National Oceanography Centre, Southampton University of Southampton
[4]Earth Science, Rice University

Relatively unaltered 'pristine' marine cements from neritic environments are recognised as some of the best known proxies for recording marine chemistry through geologic time. Unfortunately, due to their metastable nature they are rarely preserved in the rock record. We have been fortunate enough to recover two examples of such cements from ancient reef environments; one from Site 877 of Leg 144 of the Ocean Drilling Program and one from a RV Melville survey in the Gulf of Papua in 2004. Both were preserved because they were tightly cemented on rapidly subsiding reef platforms and not subject to meteoric diagenesis.

The ODP sample is Maastrichtian in age and the Gulf of Papua sample is from the Early Miocene. These two time intervals represent extremes in the history of strontium incorporation into shallow water depositional environments. During the Late Cretaceous scleractinian corals (which take up large quantities of strontium into their skeletons) were relatively rare, whereas the Early Miocene represents the acme of modern style coral reef growth, with scleractinian corals abundant.

The marine cements record an Early Miocene strontium concentration that is a third of the Late Cretaceous value. Strontium concentrations are similar to or lower than comparable Holocene cements. Magnesium-calcium ratios drop to approximately 3.6 for the Early Miocene and near 2 in the Late Cretaceous. Mass balance of calcium fluxes through over the past 100 million years indicate that the alkalinity has not changed dramatically over this interval. If we hold this total relatively constant then these data confirm previously documented trends in magnesium calcium ratios and for the first time document a significant increase in strontium concentrations in the oceans of the Late Cretaceous relative to the late Cenozoic values.

Changing riverine silicon isotope delivery to the ocean over glacial-interglacial intervals? Evidence from glaciated basaltic terrains

OPFERGELT S.[1,2], BURTON K.W.[1,3], POGGE VON STRANDMANN P.A.E.[1], GISLASON S.R.[4] AND HALLIDAY A.N.[1]

[1] Department of Earth Sciences, University of Oxford, United Kingdom
[2] Earth and Life Institute, Université catholique de Louvain, Belgium (sophie.opfergelt@uclouvain.be)
[3] Now at Department of Earth Sciences, Durham University, United Kingdom
[4] Institute of Earth Sciences, University of Iceland, Iceland

The marine primary production is dominated by diatoms which largely depend upon the riverine silicon delivery to the ocean. In paleoreconstruction of Si utilisation by diatoms, a constant Si isotope input from the continent to the ocean is generally assumed. In this study, glacier-fed and direct runoff rivers draining basaltic catchments in Iceland display significantly different dissolved Si isotope compositions, with lighter values ($\delta^{30}Si$ = +0.17±0.18‰) associated with the high physical erosion rates in glacial rivers, and heavier values ($\delta^{30}Si$ = +0.97±0.31‰) associated with lower physical erosion rates and enhanced formation of secondary minerals in direct runoff rivers. The riverine Si isotopic compositions correlate with those of Li and provide evidence of a climatic dependence that is likely to have led to glacial-interglacial differences in the isotopic composition of Si delivered to the oceans. Based on existing $\delta^{30}Si$ from diatoms in a sediment record from the Southern Ocean, the interpretation of changes in Si utilisation between the Last Glacial Maximum (LGM) and the early Holocene is revisited accounting for changing Si isotope delivery to the ocean over glacial-interglacial intervals. The results are consistent with a lower Si utilisation during the LGM (53±5%) relative to the Holocene (88±5%). During the LGM, Si utilisation values are slightly higher when allowing for changing Si isotope input to the ocean (53±5%), than when a constant Si isotope input is considered (42 to 47±5%). This study suggests that changes in Si isotope delivery to the ocean should be accounted for in the precise reconstruction of ocean Si utilisation and primary productivity over glacial-interglacial timescales.

Cold-water coral biomineralization in high resolution

OPPELT, A.[1]*, AND ROCHA, C.[1]

[1] Biogeochemistry Research Group, Department of Geography, School of Natural Sciences,Trinity College Dublin, Ireland (*correspondence: oppelta@tcd.ie)

Deep-sea scleractinian skeletons are primarily precipitated along a longitudinal growth axis but also expand radially forming layers. A LA-ICP-MS track at a resolution of 15 µm across radial layers revealed sharp peaks in U^{238} concentrations and almost perfect antithetical behaviour of Mg^{25} and U^{238} (fig. 1). The peaks are preceeded by slightly offset minima in Ba^{137} which generally follows Mg for most of the growth. Uranium peaks align with the last precipitates of visible layers before the onset of the next (often white) layer and increase of U^{238} values.

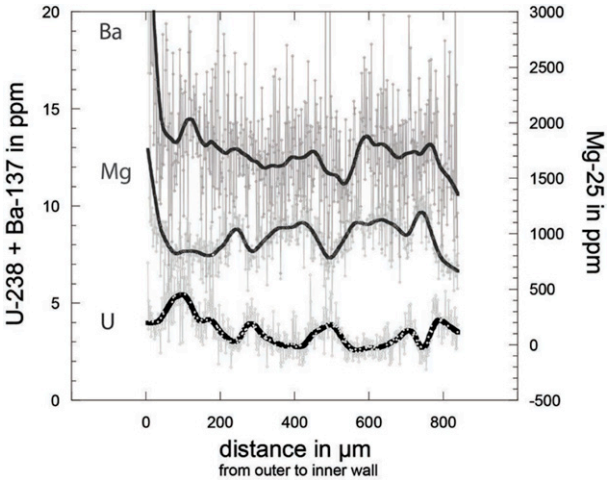

Figure 1: Ba, Mg and U concentrations (weighted at 8%) across the coral wall from outside (left) to inside (right).

The strong antithetical behaviour of U^{238} and Mg^{25} and the known negative correlation of U/Ca concentrations in corals and CO_3^{2-} in seawater [1] invite an interpretation as variations in growth rates in the corals. The short steep increases in U^{238} concentrations will be discussed as phases of low CO_3^{2-} and Mg^{2+} availability, and accordingly lower growth rates. The U peaks are preceeded by minima in Ba^{137} which functions as a nutrient proxy [2]. Repeating peaks in Barium might connect variations in growth rate with regular nutrient input from surface primary production or nepheloid layers. $\delta^{13}C$ ratios will be included in those discussions.

[5]Global Undersea Research Unit, University of Alaska Fairbanks, Monterey, CA, USA; (wheat@mbari.org)

Oceanic crust is the largest potential habitat for life on Earth and may contain a significant fraction of Earth's total microbial biomass, yet little is known about the form and function of life in this vast subseafloor realm that covers nearly two-thirds of the Earth's surface. A deep biosphere hosted in subseafloor basalts has been suggested from several lines of evidence; yet, empirical analysis of metabolic reaction rates in basaltic crust is lacking. The first measure of oxygen consumption in young (~ 8 Ma) and cool (<25 ºC) basaltic crust is calculated from modeling oxygen and strontium profiles in basal sediments collected during Integrated Ocean Drilling Program (IODP) Expedition 336 to 'North Pond', a sediment 'pond' on the western flank of the Mid-Atlantic Ridge (MAR). Dissolved oxygen concentrations increased towards the sediment-basement interface, indicating an upward diffusional supply from oxic fluids circulating within the crust. Furthermore, evidence of biological carbon fixation in basalt biofilms comes from stable isotope incubations, with implications for carbon cycling in oceanic crust. Long-term microbiology experimentation in crustal subseafloor observatories at the Juan de Fuca Ridge flank and at North Pond are poised to yield exciting new discoveries about the dynamics of microbial activity and community structure in the crustal subsurface.

Newly revealed NNW shift of granitic magmatism during Mid-Miocene period, Kyushu, Japan

YUJI ORIHASHI[1], HIRONAO SHINJYOE[2] AND RYO ANMA[3]

[1]Earthquake Research Institute, the University of Tokyo (oripachi@eri.u-tokyo.ac.jp)
[2]Tokyo Keizai University (shinjoe@tku.ac.jp)
[3]Graduate School of Life and Enviromental Sciences, University of Tsukuba (ranma@sakura.cc.tsukuba.ac.jp)

Mid-Miocene granitic plutons, related to subduction of young Shikoku Basin of the Philippne Sea (PS) plate after immediate clockwise rotation of SW Janpa, are spoladically but widely distributed along the Nankai Trough in the outer zone of SW Japan (e.g., [1]). Kyushu Island is located on western part of the outer zone. This study newly determined precise U-Pb ages for felsic dikes and granitic bodies of six locations; Tanegashima, Yakushima, MinamiOsumi, Osuzuyama, Takakumayama and Okueyama, by using LA-ICPMS technique [2]. The obtained U-Pb ages ranged from 15.6 Ma to 13.7 Ma and showed negative correlation to their distances from the Nankai Trough (see below figure). Shift rate of the granitic magmatism is 4.6 cm/year with NNW direction, which is almost same to that of recent plate movement of the PS plate (4.8 km/year). Considering that the shift rate is reflected to the subduction of the PS plate, the subdction angle in Mid-Miocene is estimeted as ca. 17 degree, which is almost same to that of recent PS plate on Shikoku Island. In Kyushu Island, however, the recent angle becomes max. 60 degree and Plio-Quaternary arc volcanism makes apparent volcanic front. This suggests that the PS plate during Mid-Miocene period has been shallowly subducted and subsequently slab rollback has been occurred due to slab-pushing caused by latteral flow of ashenospheric upwelling of the Ryukyu Trough [3] and/or other unknown tectonic events.

Authigenic carbonates as dynamic microbial ecosystems: expanding views of methane cycling in the deep sea

VICTORIA J ORPHAN[1]*, JEFF MARLOW[1], DAVID CASE[1], JOSH STEELE[1], WIEBKE ZIEBIS[2], SHAWN MCGLYNN[1], GRAYSON CHADWICK[1], ANDREW THURBER[3] BEN GRUPE[3] AND LISA LEVIN[3]

[2]University of Southern California, Los Angeles, CA USA
[3]Scripps Institute of Oceanography, University of California, San Diego, CA, USA

Sulphate-dependent anaerobic oxidation of methane (AOM) is the dominant sink for methane along continental margins, oxidizing significant fraction of methane in anoxic sediments prior to its release to the hydrosphere. The alkalinity generated during this process frequently results in the precipitation of δ^{13}C-depleted authigenic carbonates, which vary in morphology, size, and mineralogy, ranging from micritic cements and cm-sized concretions to massive 'chemoherm' structures, mounds, and pavements that can cover hundreds of square meters. These methane-derived structures often persist long after the flux of methane subsides, with remnant methanotrophic biomarkers recovered from paleo-seep carbonates dating back to the Paleozoic. While these authigenic carbonates have long served as important indicators of methane seepage, they are frequently discussed as passive recorders of prior seep activity, rather as than an active microbial habitat. Using a combination of molecular and geochemical analyses, rate measurements, stable isotope labelling experiments and nanoscale secondary ion mass spectrometry (nanoSIMS), we examined the potential for these systems to sustain active methanotrophic microorganisms and documented changes in the microbial community associated with areas of active methane venting and sites of low methane flux. Here we demonstrate that authigenic deep-sea carbonates 1) host abundant methanotrophic archaea and sulphate-reducing bacterial consortia, 2) are actively oxidizing methane 3) are capable of growth and incorporation of methane into biomass 4) provide a unique habitat and food source for seep-associated meio- and macrofauna. Seafloor calcite and dolomite incubations, transplant experiments and *in situ* collections of carbonates show differences in the dominant methanotrophic archaea (ANME-1 vs. ANME-2) and methane-oxidation rates related to levels of methane seepage and possibly mineralogy, with viable endolithic methanotrophic archaea and above background levels of methane-oxidation documented in authigenic carbonates well outside areas of visible methane seepage. Together, this data indicate that authigenic carbonates are living and actively evolving ecosystems and represent a previously underappreciated sink for methane.

Measurement of light extinction by single aerosol particles

A.J. ORR-EWING*, J.S. WALKER, A.E. CARRUTHERS, B.J. MASON AND J.P.REID

School of Chemistry, University of Bristol, Bristol BS8 1TS, UK (*correspondence: a.orr-ewing@bris.ac.uk)

Cavity ring-down spectroscopy (CRDS) is increasingly being used to determine extinction of light by ensembles of aerosol particles, either in the laboratory or in field measurements. Under controlled laboratory conditions, with size-selection of the aerosol particles prior to CRDS detection, extinction efficiencies and refractive indices can be determined. However, the precision and accuracy of such ensemble measurements are limited by a number of factors inherent in the experiments [1,2]. One significant source of uncertainty is the distribution of sizes of the aerosol particles passing through the differential mobility analyser employed as the size-selecting device.

We have therefore developed a CRDS-based method to determine the optical cross sections and extinction efficiencies of *single* aerosol particles of diameter ~ 1 μm or less. A Bessel beam optical trap is used to confine and manipulate the position of the single aerosol particle. Particles smaller than 1 μm can be captured indefinitely and we have demonstrated the ability to study processes that change the size or refractive index, such as the evaporation of volatile components or the uptake of water. The measured extinction induced by the particle depends on the position of the particle within the cavity [3,4], so fine positional control is required. Results will be presented for a number of aerosol particle compositions. For example, the variation in extinction efficiency of a single trapped sodium chloride droplet with relative humidity agrees very well with predictions from Mie scattering theory. The advantages of single-particle over ensemble measurements will be discussed.

Temperature reconstruction for the last 1000 years at WAIS-Divide, Antarctica, from inert gas isotopes and borehole temperature.

ANAIS J. ORSI[1] AND JEFFREY P. SEVERINGHAUS[2]

[1]Scripps Institution of Oceanography, UCSD, 9500 Gilman Drive, La Jolla, CA 92093-0244, USA, (aorsi@ucsd.edu)
[2]Scripps Institution of Oceanography, UCSD, 9500 Gilman Drive, La Jolla, CA 92093-0244, USA, (jseveringhaus@ucsd.edu)

West Antarctica is warming, but it is not clear yet whether it is abnormal, in the context of natural background variability. The amplitude of natural climate variability on multi-decadal timescales remains poorly quantified, but it is essential to our understanding of the significance of the warming of the last 50 years.

Here, we present a 1000-year temperature record at WAIS-Divide, in the center of West Antarctica, reconstructed from the combination of inert gas isotopes from the ice core and borehole temperature measurements. Borehole temperature provides an absolute estimate of long-term trends, while noble gases track decadal to centennial scale changes. This method provides a temperature reconstruction that is independent of the water isotope of the ice, and allows us to improve our understanding of water isotopes as a temperature proxy at this site.

We found that the "Little Ice Age" cold period of 1400-1800 was 0.52°C colder than the last century, and that 50 to 100 year variability is on the order of 0.5 to 1°C.

[3] College of Earth, Ocean, and Environment, University of Delaware:(jfbiddle@udel.edu)

Microbial community metabolism in the marine subsurface likely plays an important role in global biogeochemical cycles but deep biosphere activities are not well understood. Illumina sequencing of community messenger RNA was performed to obtain the first subseafloor metatranscriptome from anaerobic Peru Margin sediment up to 159 meters below seafloor. Metabolic reconstruction indicates anaerobic metabolism of amino acids, carbohydrates, and lipids are dominant processes, and profiles of dissimilatory sulfite reductase transcripts are consistent with sulfate concentration profiles. Moreover, cell division transcripts across all three domains of life increase where peaks in microbial abundance are observed in subseafloor sulfate-methane transition zones. These data support calculations and models of subseafloor microbial metabolism, and represent the first holistic picture of deep biosphere activities. Furthermore, an investigation of eukaryotic 18S rRNA revealed active Fungi across a range of marine subsurface provinces. Subseafloor fungal populations exhibit statistically significant correlations with total organic carbon, nitrate, sulfide, and dissolved inorganic carbon suggesting environmental selection of active Fungi in the marine subsurface.

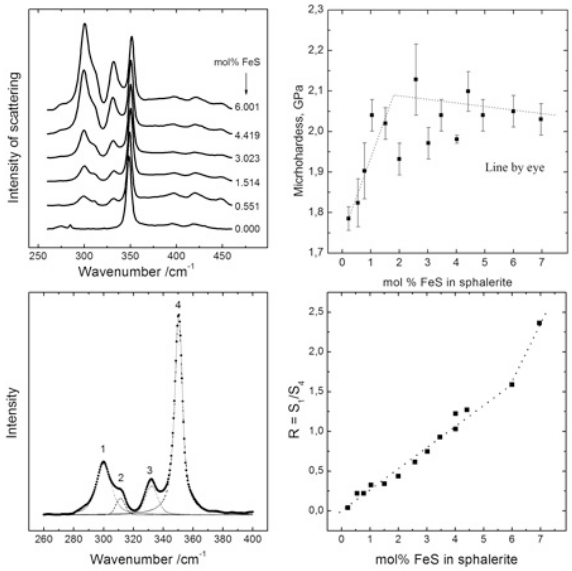
Raman Spectra And Microhardness Of Sphalerite Solid Solutions ZnS·FeS

OSADCHII E.G.[1]*, BONDARENKO G.V.[1], CHAREEV D.A.[1] AND OSADCHII V.O.[2]

[1] Institute of Experimental Mineralogy RAS, Chernogolovka, Russia (*correspondence: euo@iem.ac.ru)
[2] Moscow State University, Geological Department

Synthesized sphalerite solid solutions ($Fe_xZn_{1-x}S$) in the range 0 <mol % FeS <50 with compositional step 5 have been studied with the use of Raman spectroscopy. The main objective of these experiments was to learn how the iron content of sphalerite affects the Raman spectra [1].

Raman intensities over the whole range of concentrations suggest a structure change in the rather narrow region of mole fractions of FeS between 0.15 and 0.25. Currently special attention was paid for compositions 0≤mol% FeS≤ 6 (15 samples, gas transport and average diameter of crystals 1 mm) where microhardnes (HV) grows extremely from 1.7 to 2.1 GPa. In this composition area additional peak 310 cm^{-1} appears that might be due to cluster forming process in sphalerite lattice. The ratio of intensities of Raman lines 295 and 345 cm^{-1} can be used for the compositional analysis of sphalerite.



This study was supported by Grant RFBR 13-05-00405.

The Aerosol Radiative Forcing in East Asia (A-FORCE) aircraft campaign was conducted over East Asia in March-April 2009 [1]. We examined vertical transport mechanisms of black carbon (BC) aerosols and their transport pathways over East Asia in spring using the modified version of the CMAQ model and simulating the A-FORCE aircraft campaign. Comparisons of the model results with the A-FORCE observations show that the model reproduces relatively well the vertical distributions of mass concentration and transport efficiency of BC, including their latitudinal gradients and dependences on precipitation that air parcels had been experienced during transport. During the A-FORCE period, we find two types of pronounced upward mass fluxes of BC from the planetary boundary layer (PBL) to the free troposphere (FT) over northern-eastern and inland-southern China. The major uplifting mechanism of BC over northern-eastern China is the cyclones with modest amounts of precipitation. Cumulus convections and orographic lifting along the high-altitude mountains play an important role for the upward transport of BC to the FT over inland-southern China, in spite of the large amounts of precipitation. In addition to the outflow in the PBL over the midlatitude, the upward transports over northern-eastern and inland-southern China, followed by the westerly transports in the lower and the middle FT, respectively, make major contributions to the exports of BC from East Asia to the Pacific in spring.

Precipitation and stability behaviour of calcium sulfate: the role of salinity temperature and reaction time

M.OSSORIO[1], A.E.S. VAN DRIESSCHE[1], P. PÉREZ[2] AND .M. GARCIA-RUIZ[1]

[1]LEC, IACT, CSIC-U.Granada, Spain. (mercedes@lec.csic.es, sander@lec.csic.es, jmgruiz@ugr.es)

[2]Depart. Fisica general, U. Habana, Cuba, (pvperez@uci.cu)

A marked inconsistency exists between the phase diagram of calcium sulfate and its crystallization behaviour [1]. To gain a better understanding on the precipitation dynamics and stability region of each phase (gypsum, bassanite and anhydrite), a series of precipitation experiments were carried out from 40 to 120 ºC, at three salinities (0.8, 2.8 and 4.3 M NaCl) and different reaction times (from 2 min up to 10 months).

Salinity and temperature strongly influence the type and stability of the precipitate. No primary anhydrite precipitation occurs and with increasing salinity bassanite precipitation prevails and its stability is strongly enhanced (up to 10 months at 80 ºC). Phase transition occurs through dissolution of the less stable phase and subsequent recrystallization of the more stable phase. This process is controlled by the differences in surface free energy and step kinetic coefficients between the three phases [2-4].

Testing the "deep-basin high-rank gas machine" hypothesis

CHRISTIAN OSTERTAG-HENNING[1]

[1]Federal Institute for Geosciences and Natural Resources, Hannover, Germany (correspondence: (Christian.Ostertag-Henning@bgr.de)

During the past decade the interest in a more detailed understanding of processes during gas and oil formation has been spurred by growing importance of gas and oil from unconventional reservoirs, e.g. shale gas and shale oil as well as deep basin-centered gas. In addition to the classical view of mainly first-order reactions for the inorganic formation of hydrocarbon gases by thermal cracking of bitumen or kerogen, several researchers have put forward avenues to explain some not accounted for observations in hydrocarbon occurrences, molecular or isotopic compositions. These hypotheses always include a geologic component not considered in most kerogen/bitumen pyrolysis studies: The presence and role of water [1], the possible catalytic activity of mineral surfaces [2], the importance of metals in aqueous fluids, the metastable equilibria of hydrocarbons and more oxidized organic compounds in pore-fluids in the subsurface – and the role of minerals as part of pore-fluid redox- or pH-buffers [3]. Price [4] combined many of the aforementioned hypotheses in calling for a "deep-basin high-rank gas machine".

A broad study to produce a consistent data set of HC formation rates and elemental transfer reactions in the gas-fluid-rock system at elevated pressures and temperatures is ongoing at the BGR. By using different experimental facilities for maturation of organic matter from small gold capsules to Dickson-type flexible gold-titanium cells in high-pressure reactors to large diameter high pressure reactors for heating/expulsion tests on core material several key questions are being addressed.

The experiments with source rock material of natural maturity series allowed the detailed comparison of effects of natural medium-temperature/high-pressure maturation in the sedimentary basin to artificial high-temperature/high-pressure maturation in the lab. Interestingly, a clear depiction of the predominance of different processes – e.g. thermal cracking, oxidation reactions to less reduced organic compounds, dehydrogenation by cyclization and aromatization - is visible in the data sets. The comparison of sets of experiments with the identical amounts of source rock material with/without the admixture of different mineral standards – e.g. carbonate, pyrite, montmorillonite – yielded clues about the role of certain mineral surfaces for catalytic oxidation/dehydrogenation/hydrogenation and fluid buffering. Using organic model compounds with isotope labels added to the source rocks clearly identified pathways of hydrocarbon gas formation – and the production of more oxidized organic compounds.

Anaerobic methane oxidation in the water column of the eutrophic sub-alpine Lake Zug (Switzerland)

K. OSWALD[1,2]*, J. MILUCKA[3], M.M.M. KUYPERS[3], B. WEHRLI[1,2] AND C.J. SCHUBERT[1]

[1] Swiss Federal Institute of Aquatic Science and Technology (Eawag), CH-6047 Kastanienbaum, Switzerland (*correspondence: kirsten.oswald@eawag.ch)

[2] Swiss Federal Institute of Technology (ETH), CH-8092 Zürich, Switzerland

[3] Max Planck Institute for Marine Microbiology, 28359 Bremen, Germany

Anaerobic oxidation of methane (AOM) remains only partially understood in freshwater environments. Water column field investigations suggest that AOM could be mediated via other pathways, i.e. denitrification or metal oxide reduction, in lakes [1, 2], as opposed to its marine counterpart, where AOM proceeds via SO_4^{2-} reduction [3].

The potential for AOM was assessed in the water column of the eutrophic sub-alpine Lake Zug, situated in Central Switzerland. Through geochemical profiling and flux calculations of the relevant factors, the oxic/anoxic transition zone and anoxic depths, showing favorable conditions for AOM, were identified. At these selected depths, incubation experiments were carried out with ^{13}C-labelled methane to determine methane oxidation rates, simultaneously in-situ available electron acceptors were monitored. Fluorescence in-situ hybridization targeting Group I and II as well as anaerobic methanotrophs was carried out at the incubation depths. Furthermore, functional gene analysis for particulate (*pmoA*) and soluble methane monooxygenase (*mmoX*), both essential for aerobic methanotrophs, and methyl coenzyme M reductase (*mcrA*), an indicator for anaerobic methanotrophs, was completed.

Preliminary experiments show that AOM rates are one order of magnitude higher (~600 $nM \bullet d^{-1}$) than aerobic rates (~40 $nM \bullet d^{-1}$). Highest rates occur at depths, which are devoid of oxygen. First results are still inconclusive as to which electron acceptor is responsible for AOM, however, SO_4^{2-} does not appear to contribute substantially. Hybridization techniques confirm the presence of Type II alpha-proteobacterial methanotrophs as well as Group I and II methanotrophs.

Although the temporal change in trace element concentrations in Banded Iron Formations (BIFs) can be useful in reconstructing Earth's Precambrian surface environments and associated biological activity, BIFs from various sedimentary settings, particularly of Archean age, will be investigated to increase our understanding of these environments. In this study, we investigated geological, petrographic and geochemical characteristics of ferruginous rocks deposited in a shallow water environment in the Moodies Group, in the Barberton Greenstone Belt, South Africa. Samples were obtained from an outcrop in the Moodies Hills Block and at a cross cut in the Sheba mine.

The petrographic relationships between hematite and magnetite in the samples resemble those observed in typical oxide-type BIFs. Geochemical data show that Fe and Cr are enriched relative to Ti in the ferrouginous rocks. Although various detrital minerals are observed, including detrital quartz, the proportion of refractory elements and rare earth element (REE) patterns show that the sediment was predominantly derived from felsic rocks. Therefore, the results of geochemial analyses of these rocks indicate that both Fe and Cr are chemical precipitates or of an early digenetic origin. Oxygen isotope analyses of individual chromite grains by Secondary Ion Mass Secrtometry (SIMS) reveal they are depleted in ^{18}O compared to previously reported values for magmatic chromite, indicating that the chromite was formed under sub-magmatic temperatures (e.g., hydrothermal). Therefore, our detalied petrographic and geochemical investigations of the chemical and clastic sedimentary rocks show that some geochemically important elements (i.e., Fe, Cr, and U) were already mobile and fixed in a shallow water environment at 3.2 Ga.

Dissolution of Amorphous Silica in the Presence of Ca^{2+} and Mg^{2+} at pH 6 and 9

EMI OTSU, MAYUMI ETOU, YOSHIHIRO OKAUE AND TAKUSHI YOKOYAMA*

[1]Department of Chemistry, Faculty of Science, Kyushu University, 6-10-1, Hakozaki, Higashi-ku, Fukuoka, 812-8581, Japan

Silica dissolves into natural waters as monosilicic acid ($Si(OH)_4$) through an break of siloxane bonds by attack of water molecule. Factors controlling the silica dissolution reaction are important subject in geochemistry to elucidate circulation of silicon in hydrosphere. Especially, because an alkaline and alkaline earth metal ions exsist abundantly in natural water, the effect of these metal ions on the dissolution of silica has been investigated and the acceleration of the dissolution of silica has been reported[1-4]. However, the acceleration mechanism of dissolution of silica by cations has been uncertain even at present. In the previous studies, only the variation of silicic acid concentration was mainly examined. No researcher has been investigated quantitatively the behavior of cations during the dissolution reaction. The purpose of this study is to elucidate the effect of Ca^{2+} and Mg^{2+} on the dissolution of silica from both the variation of silicic acid concentration with time and behavior of Ca^{2+} and Mg^{2+}.

From the behavior of Ca^{2+} and Mg^{2+} during the dissolution of silica, it was revealed that the acceleration mechanism of each metal ion was clearly different by reaction pH. At pH 9, the dissolution of silica is controlled by the interaction between Ca^{2+} and Mg^{2+} and silicic acid: the formation of Ca^{2+}-silicic acid complex and of an insoluble magnesium silicate-like structure. Although no adsorption of Ca^{2+} and Mg^{2+} ions occurred at pH 6, the dissolution of silica was accelerated. This may be caused by attack of water molecules to siloxane bonds hydrated to Ca^{2+} and Mg^{2+} ions due to fast exchange reaction with the bulk water near the surface of silica.

[5] SPring-8/JASRI, Japan

In-situ observation of plagioclase crystals in synthetic basalt by using micro-tomography beam lines at SPring-8, is supported from two previous experimental studies realized on same run charge [1,2]. It is here proposed to quantify crystal agglomeration and connectivity (touching crystals/non touching crystals) during crystallization and also to improve corrections applied in 2D CSD. By using micro-tomography beam lines and softwares (©Slice and ©Blob3D), three-dimensional images of the run products at a resolution of 2.74 μm are created. Size and shape evolution during cooling are clearly outlined by variation of the shape factor. A first comparison between 2D/3D CSD shows similarity in the CSD morphology. The connectivity (Fig. 1) between plagioclase crystals increases very rapidly with a ratio of 0.2 to 0.4 in the early stages of crystallization (5% plagioclase crystals) to 1 for 20-25 % of plagioclase crystals in the late stages. Processes of crystals agglomeration do not appear of major importance compared to connected crystals that form a continuous 3D network. This early crystal network strongly influences magma rheology.

Marine aerosol activation to CCN and cloud formation

J. OVADNEVAITE*, G. MARTUCCI, D. CEBURNIS, J. BIALEK AND C.D. O'DOWD

School of Physics and Centre for Climate and Air Pollution Studies, Ryan Institute, National University of Ireland Galway, University Road, Galway, Ireland (*correspondence: jurgita.ovadnevaite@nuigalway.ie; giovanni.martucci@nuigalway.ie, Darius.Ceburnis@nuigalway.ie, jakub.bialek@nuigalway.ie, Colin.Odowd@nuigalway.ie)

Marine aerosol occurring in cloud condensation nucleus (CCN) sizes suggest that it may contribute notably to the CCN population [1, 2], but further cloud droplet number concentration (CDNC) would strongly depend on the ambien (cloud) conditions, such as avialable water content, supersaturation and competition between the CCN of different composition [3]. Since the global importance of marine aerosol particles to the cloud formation was postulated several decades ago [4], it has progressed from the evaluation of the nss-sulphate and sea salt effects to an acnowledgement of the significant role of organic aerosol [5]. It was demonstrated that primary marine organics, despite its hydrophobic nature, can possess the high CCN activation efficiency, resulting in the efficient cloud formation [6]. Here we show the relationship between the marine boundary layer aerosol composition, CCN activation and CDNC for different aerosol and ambient conditions. We investigate the activation of sea spray composed of the sea salt and externally mixed with nss-sulphate as well as the sea spray highly enriched in organics, stressing the importance of the latter to the formation of the cloud droplets. We also explore the suitability of existing theories to explain the different composition marine aerosol activation to CCN and resulting CDNC.

Dating zircons from volcanic ash beds in sedimentary successions: magmatic crystallization vs. ash deposition

M. OVTCHAROVA[1]*, U. SCHALTEGGER[1], N. GOUDEMAND[2] AND H. BUCHER[2]

[1]Earth and Environmental Sciences, University of Geneva, Switzerland,(maria.ovtcharova@unige.ch*)
[2]Institute and Museum of Paleontology, Zurich, Switzerland

Detailed calibration of the Late-Middle Triassic time-scale requires precise and accurate age determinations from volcanic ash beds within biostratigraphically well dated marine sedimentary sections. High precision CA-ID-TIMS U-Pb zircon dates on volcanic zircon have been used to quantify and calibrate different stratigraphic schemes across the Early-Middle Triassic boundary in South China. Despite an optimal control on the continuity of the stratigraphic record and on the accuracy of analytical procedures, some single ash-beds from the Monggan Wantuo section (Luolou Fm., NW Guangxi, S. China) yield ages that are too old and contradict the stratigraphic succession. How can we improve the confidence in the interpretation of zircon dates as proxies for the age of deposition of these ash beds?

We dated 15 individual ash beds within the 15m Wantuo Mongan section, applying CA-ID-TIMS techniques on a number of single grains for each sample. In 13 out of 15 ash beds zircon dates are following the stratigraphic succession within analytical uncertainty (from the late Early Triassic Luolou Formation – 248.08 ± 0.12 Ma. to the Middle Anisian Transition Beds – 246.43 ± 0.17 Ma). The zircons from two intermediate volcanic ash beds within the Transition Beds at the Early/Middle Anisian boundary yield well clustering $^{206}Pb/^{238}U$ dates at 247.10 ± 0.15 and 247.35 ± 0.11 Ma, clearly indicating that the zircons in this magma batch were crystallizing over a long period of time or remobilized from deeper levels within the same magmatic system. The problem of recurrent zircon dates in a sedimentary succession is common and can only be discovered by sufficiently dense sampling and a sufficient number of data for each ash bed.

We have to keep in mind that for the correct interpretation of dates in stratigraphic sections interlayered with fossil-bearing rocks we need; i) at least one single well preserved stratigraphic section with sufficient chronological control (biochronology and/or chemiostratigraphy) to guarantee that the stratigraphic succession is accurately known; ii) volcanic ash beds that are undisturbed (no volcanosedimentary material, no sedimentary reworking); (iii) sufficient sample and data density to be able to distinguish between magmatic and sedimentary signals coded in the crystallization ages of zircon.

The Thrym Complex of southeastern Greenland: Evolution of Ni-Cu-sulfide mineralization in the lower crust

J.OWEN[1]*, L. BAGAS[1], J. KOLB[2], M. L. FIORENTINI[1], B. M. STENSGAARD[2] AND N. THEBAUD[1]

[1]CET/CCFS, The University of Western Australia, Perth, Australia (*owenj03@student.uwa.edu.au)
[2]Geological Survey of Denmark and Greenland, Copenhagen, Denmark

The Thrym Complex of southeastern Greenland forms part of the North Atlantic Craton and is characterized by migmatitic orthogneiss, narrow bands of mafic granulite, ultramafic rocks, paragneiss, and alkaline-carbonatitic intrusive rocks. The narrow bands of mafic granulite are interpreted as tectonically emplaced gabbroic rocks exposed from the lower crust.

The two main styles of mineralization locally observed in the Thrym Complex are: (1) disseminated sulfides associated with mafic and ultramafic locally granoblastic-decussate rocks; and (2) remobilised sulfides concentrated in amphibolite-greenschist facies shear zones. This mineralization observed differs from typical orthomagmatic Ni-Cu-sulfide occurrences common in the upper crust in that there is no evidence for significant contamination by a crustal sulfur source. Furthermore, no trans-lithospheric structure for the emplacement of the mineralization is apparent.

The sulfide mineralization in the Thrym Complex may represent the root of such a system or the result of a similar magma being emplaced in the lower crust in an area lacking such a fluid-pathway. Mantle-sourced magma emplaced at pressure-temperature conditions in the lower crust would maintain or achieve sulfur-saturation more easily than magma emplaced in the upper crust [1]. As such, there may be no need for interaction with crustal material for the formation of sulfide mineralization in lower crustal settings.

Trace metal drawdown during a Cretaceous oceanic anoxic event: Implications for global redox conditions

J.D. OWENS[1]*, C.T. REINHARD[2] AND T. W. LYONS[1]

[1]University of California, Riverside, Riverside, CA, USA, (jowens@student.ucr.edu, timothyl@ucr.edu (* presenting author)

[2] California Insitute of Technology, Pasadena, CA, USA, (reinhard@caltech.edu)

The global redox state of the oceans during periods of widespread organic-carbon deposition is an essential part of our understanding of Earth's important climatic feedbacks. The Cretaceous is renowned for several global organic-carbon burial events marked by coeval positive carbon isotope excursions now widely known as oceanic anoxic events (OAEs). Here we present a high-resolution compiled data set from Demerara Rise spanning the Cenomanian-Turonian boundary event (~93.9 Ma) or OAE 2, which shows a dramatic drawdown of redox sensitive trace elements. Organic carbon contents are high throughout the entire section analyzed, and, importantly, Fe speciation implies the locality was dominantly euxinic (i.e., anoxic and sulfidic bottom waters) before, during, and after the event. Molybdenum (Mo) and vanadium (V) are effective paleoredox proxies for tracing oceanic euxinia and anoxia, respectively. The drawdown of Mo coincides with the onset of OAE 2, suggesting a global expansion of reducing and sulfidic conditions. Significantly, though, the drawdown of these two redox sensitive elements is offset by 100 kyr, with V preceding Mo. The decline in V enrichment prior to Mo implies an expansion of low oxygen but non-euxinic conditions prior to the OAE. Numerical geochemical box modeling for Mo suggests that euxinia must have covered >2% but <10% of the global seafloor to explain enrichments that were only 25% of those seen before and after the event. Mo and V drawdown may have impacted the nitrogen cycle and thus patterns of primary production, and this feedback may have contributed to the termination of the OAE.

Chemical compositions of soluble aerosols around the last termination in the NEEM (Greenland) ice core

[6] British Antarctic Survey, Cambridge, CB3 0ET, UK

The polar ice cores provide us with reconstruction of past atmospheric aerosols. Soluble aerosols in both Arctic and Antarctic ice cores are well discussed by using the proxy of ion concentration/flux, however, there are few studies about chemical compositions of soluble aerosols in ice cores. Using sublimation method [1], here we show differences in the compositions of sulfate and chloride aerosols around the last termination in the NEEM ice core.

A total of 43 samples were distributed from NEEM ice core section from 1280 to 1580 m. Soluble aerosols were extracted from the samples by sublimation system [1]. Constituent elements and diameter of each non-volatile particle were measured by SEM-EDS. By using a method in ref. [2], we assumed chemical compositions of sulfate and chloride aerosols.

We divided the last termination into 4 stages by focusing on the temperature; Holocene, Younger Dryas (YD), Bølling-Allerød (B-A) and Last Glacial Period (LGP), and compared the mass ratio of sulfate and chloride aerosols in each stage. During the cold stage in YD and LGP, $CaSO_4$ accounted large percentage of sulfate aerosols. On the other hand, during the warm stage in Holocene, Na_2SO_4 accounted large percentage of sulfate aerosols. In B-A, percentage of Na_2SO_4 is almost as same as that of $CaSO_4$. Since $CaSO_4$ is considered to be formed at first among sulfate salts in the atmosphere, these results is probably controlled by Ca^{2+} concentration. Mass ratio of $NaCl/Na_2SO_4$ decreased from LGP to Holocene (Fig. 2f), which indicate that sulfatization of NaCl increased toward Holocene.

Geochemistry and Petrology of the Tımar basaltic volcanism in the northeast of Lake Van

VURAL OYAN[1]* MEHMET KESKIN[2 A] AND YAVUZ ÖZDEMIR[3]

[1]Yüzüncü Yıl University, Faculty of Architecture and Engineering, Department of Mining Engineering Van, Turkey.
[2] Istanbul University, Faculty of Engineering, Department of Geological Engineering Istanbul, Turkey.
[3] Yüzüncü Yıl University, Faculty of Architecture and Engineering, Department of Geological Engineering Van, Turkey.

Timar Pliocene basaltic volcanism in the northeast of the Lake Van Basin erupted from local central eruption centers. Products of basaltic volcanism in the Timar region are covered by younger lavas of Late Pliocene Etrüsk volcanics and Quaternary basalts in age. Available K-Ar ages [1] indicate that basaltic volcanism observed in north and southeast of the Etrüsk volcano erupted in a period between 4.90 and 4.50 Ma corresponding to Zanclean (Pliocene). Alkaline-subalkaline basalts and hawaiites consist of olivine, augite, titanoaugite and plagioclase phenocrysts and micro-phenocrystals. The groundmass of these lavas contains the microcrystals of the same mineral assemblages and volcanic glass. They display porphyritic, glomeroporphyritic, intersertal and hyalopilitic textures.

Results of our FC, AFC and EC-AFC modelings indicate that the Timar basaltic lavas were slightly influenced by crustal contamination and fractional crystallization. MORB patterns of corrected data to MgO 9% show that some HFS elements such as Nb and Ta are depleted relative to LIL and LREE (La-Ce). This findings imply that Timar basaltic volcanism could have been derived from a mantle source with a distinct subduction component.

Results of our melting models indicate that the Timar basaltic rocks were derived from both shallow and deep mantle sources with different melting degrees ranging between 0.8 - 5 %. The percentage of spinel seems to have increased in the lerzolitic mantle source of the basaltic lavas. Accordingly, chemical character of the lavas turned from alkaline to subalkaline in time. We argue that the temporal increase of spinel contribution and the melting degree in the mantle source region was responsible for transition from alkaline to subalkaline character in the lava chemistry in time.

Conditions for Proterozoic anoxic and non-sulfidic ocean: Constraints from a marine biogeochemical cycle model

K. OZAKI[1]* AND E. TAJIKA[2]

[1]Atmosphere and Ocean Research Institute, University of Tokyo, Chiba 277-8561, Japan (*correspondence: ozaki@aori.u-tokyo.ac.jp)
[2]University of Tokyo, Chiba 277-8561, Japan (tajika@k.u-tokyo.ac.jp)

Understanding the Earth's oceanic redox evolution in response to several environmental conditions is one of the fundamental topics in the Earth science. Accumulating geochemical records, such as iron speciation and molybdenum geochemistry, reveal large spatial heterogeneity of Proterozoic ocean redox chemistry; anoxic and non-sulfidic (i.e., ferruginous) conditions had been prevailed throughout the Proterozoic, and sulfidic conditions might have covered only a small portion of the seafloor. However, the atmospheric oxygen level (pO_2) in the Proterozoic has not been well constrained, and it remains unclear exactly what biogeochemical conditions are necessary to explain such redox structure in the Proterozoic ocean interior.

Here, we try to constrain the conditions for Proterozoic ocean redox structures by use of a marine biogeochemical cycle model in which C-N-P-O-S coupled biogeochemical cycles are taken into account. The results of systematic sensitivity experiments regarding pO_2 and chemical weathering rate on land demonstrate that the conditions for pervasive euxinia are very limited, and widespread ferruginous condition would be an inevitable consequence of low pO_2 and high pyrite burial efficiency during the Precambrian. Sulfidic waters would be restricted in near-shore regions where riverine sulfate flux is sufficient to stimulate the sulfate reduction. We also found that other environmental factors affecting long-term oceanic redox state (e.g, sea-level stand, settling rate of marine snow in water column) do not change above biogeochemical consequences.

These quantitative results would provide insight into further understanding of the Earth's rdox history and its stabilization mechanism(s) from a perspective of the biogeochemical dynamics. We also propose that shelf euxinia still has a significant impact on the availability of redox-sensitive, bioessential trace metals, and therefore would provide a linkage between evolution of ocean oxidation state and biological innovation.

Igneous and impact processes on a ureilite parent body inferred from Y-983890 polymict ureilite

SHIN OZAWA[1], AKIRA YAMAGUCHI[1] AND HIDEYASU KOJIMA[1]

[1]National Institute of Polar Research, Tokyo 190-8518, Japan (ozawa.shin@nipr.ac.jp)

Ureilite is the second largest group of achondrites. They are largely divided into two types: monomict and polymict. Most ureilites are monomict ureilites, whereas polymict ureilites are relatively rare. Polymict ureilites are polymict breccias containing lithic clasts and mineral fragments of various lithologies [1]. Therefore, it provides valuable information about igneous and collisional processes on ureilite parent bodies. Yamato (Y-) 983890 is a recently classified new polymict ureilite [2]. In this study, we conducted careful petrographic observations on this new polymict ureilite.

Y-983890 consists of lithic clasts and mineral fragments which show a large variety of lithologies. Most of them are monomict ureilite-like materials. They consist of coarse-grained (up to 1 mm) olivine and/or pyroxene (pigeonite, orthopyroxene, and minor augite) with interstitial dark carbonaceous materials and/or graphite. The chemical compositions and Fe/Mg-Fe/Mn relations of olivine and pyroxene are consistent with those of monomict ureilites [3].

Non-monomict ureilite-like materials include feldspathic clasts, dark clasts, a chondrule fragment, and others. We identified several distinct feldspathic clasts. They show different igneous textures and different chemical compositions of constituent minerals (feldspar and pyroxene). Some of the feldspathic clasts are considered to be basaltic counterparts complementary to monomict ureilites (ultramafic residues). The dark clasts consist of fine-grained phyllosilicate-rich matrices with variable amounts of opaque minerals such as magnetite and sulfides (pyrrhotite, pentlandite). These dark clasts mineralogically resemble the matrices of CI carbonaceous chondrites. A chondrule fragment was also identified. It shows a barred olivine chondrule texture. The chemical composition of the olivine is in the range of that of H chondrite. The dark clasts and the chodrule fragment are considered to be fragments of impactors collided with the parent body of Y-983890.

Organic geochemical characteristics of the coaly Miocene units in the Şahinali (Aydın) region, Büyük Menderes Graben, Turkey

ORHAN ÖZÇELIK[1]*, MEHMET ALTUNSOY[1], SELIN HÖKEREK[1], NESLIHAN ÜNAL[1] AND NAZAN YALÇIN ERIK[2]

[1]Department of Geological Engineering, Akdeniz University, 07058 Antalya, Turkey (*correspondence: oozcelik@akdeniz.edu.tr); (altunsoy@akdeniz.edu.tr; selinhokerek@akdeniz.edu.tr; nunal@akdeniz.edu.tr)

[2]Department of Geological Engineering, Cumhuriyet University, 58140 Sivas, Turkey (nyalcin@gmail.com)

In the Şahinali (Aydın-Turkey) region the Miocene units consist of conglomerate, coal, clayey coal, sandstone, siltstone, claystone, clayey limestone and silicalimestone. Total Organic Carbon (TOC) values in these units range between 0.11-38.13 %. Rock-Eval analyses on core samples with the highest TOC values give hydrogen index (HI) values from 60-566 mgHC/gTOC and oxygen index (OI) values from 31-245 mgCO_2/gTOC. The organic matter can be classified as Type II and III kerogen on the modified van Krevelen diagram. Tmax values vary between 338 and 429 ^{0}C, with an average of 413 ^{0}C indicating the diagenesis stage. Based on the microscopic studies, organic matter is composed of predominantly autochthonous algal and amorphous material, with a minor contribution of terrestrial material. The average vitrinite reflectance value is 0.35 %. Vitrinite reflection index and Tmax values indicate that the organic matter is immature. Biomarker characteristics also verify these results. 8α (H)-22, 29, 30-trisnorhopane Ts/(Ts+Tm) ratio is 0.85. This value indicates immature (Ts/Tm>1) organic matter, while C32 22S/(22S+22R) ratio is determined to be 2.56. Diasterane/sterane ratio is generally low in immature sediments - between 0.08-0.71 in the samples- in spite of the lithology effect. The thermal process is evaluated through the biomarker data during the coalification, and the moretane/hopane ratio shows immaturity and early maturity. One of the maturity parameters derived out of C29 regular sterane is 5α (H), 14β (H), 17β (H) C29 sterane and 5α (H), 14α (H), 17α (H) C29 sterane (αββ/αββ+ααα) ratio which is less than 1 in the samples (0.23-0.31). C23/C24 and C28/C29 ratios are between 0.61-2.86 and 0.71-2.95 respectively. 20(S)/(20S+20R) and ββ/(ββ+αα) sterane ratios indicate immature stage. Oleananes type biomarkers were determined to be 5.52-6.51 derived from the angiosperms. This might indicate angiosperm abundance under deposition conditions.

Effect of Magma Mixing on the evolution of the intermediate members of Süphan Volcanics: Eastern Turkey.

YAVUZ ÖZDEMİR[1]* NİLGÜN GÜLEÇ[2] AND JON BLUNDY[3]

[1]Yüzüncü Yıl University, Department of Geological Engineering Van, Turkey.
[2] Middle East Technical University, Department of Geological Engineering, Ankara, Turkey.
[3] University of Bristol, Department of Earth Sciences, Bristol BS8 1 RJ, UK

The Süphan stratovolcano, representing one of the major eruption centers of the post-collisional volcanism in eastern Anatolia, Turkey, consists of lava flows, domes and pyroclastics ranging in composition from basalts to rhyolites. Geochemical data reveal transitional mildly alkaline to calc-alkaline character for the eruptive products. Ar-Ar age data and published K-Ar data from different levels of the volcanostratigrafic succession yield a range of 0.76-0.06 Ma. Mineral chemistry and textures indicate that magma mixing played an important role on the chemical diversity of Süphan volcanics [1]. Intermediate members of the volcanism show a wide range of mineral compositions, for pyroxenes, olivine and plagioclase, that are intermediate between those of basalts and rhyolites. Mineral thermometry of these rocks also yields a wide range of temperatures intermediate between rhyolite (~750 °C) and basalt (~1100 °C). Geochemical modeling [2] of major element compositions suggests that relatively mafic (SiO2 ≤ 55wt %) and SiO_2 rich (SiO2>~65 wt %) members of the Süphan volcanics evolved at moderately hydrated (H2O=1 wt %) and QFM (quartz-fayalite-magnetite) conditions at 2-4 kbar pressure. On the other hand, most of the lavas with SiO_2 contents between ~ 57 - ~65 wt % are products of isobaric-isenthalpic mixing of 70% basaltic trachyandesitic magma (at 1100 0C) and 30 % rhyolitic magma (at 900 0C) at a crustal pressure of 0.5 kbar.

Trace Elements in the Environment at the Site of probable Underground Building in the Nizhnekansky Rock Massif (Siberian Craton)

ANDREY OZERSKIY[1] AND DMITRIY OZERSKIY[2]

[12]Krasnoyarskgeologia Co., Carl Marx Str., 62, Krasnoyarsk, Russia, 660049 (ozerski@krasgeo.ru)

Trace elements were investigated along with geological exploration of the rock massif for underground isolation of radioactive wastes. Perspective site of rock massif is mainly formed by archaean gneisses with dykes of gabbros or dolerites. Exploration methods included well boring up to 700 m in depth, hydrogeological pumping, geophysical and environmental surface researches etc. Bedrocks (205 samples), soil (50) , subsoil (50), bottom sediments (25), and natural taiga's vegetation (15) were sampled for environmental analysis. The samples were tested by atomic absorption spectroscopy (AAS), ICP MS and partially chemical methods.

Searching correlations between different environmental systems and spatial distribution we defined two main types of trace elements, that differ on its' origin. The first type named as *autochtonous* originated from parent bedrock. The second type named as *allochtonous* derived to industrial emissions. In turn, both types are subdivided into some groups that are characterized by different conditions of migration and concentration.

Inert elements (Be, Ga, Mo) have approximately equal concentrations in all searched systems. Cerium and lithium form a group named *immobile in bedrock*, both two elements were detected only in bedrock. A more widespread group, *passive migrating to soil*, is characterized by largest concentrations in rocks. Ba, Co, Cu, La, Pb, Sc, Sn, Ti, Y, Yb, Zn form this group.

The group of elements *active migrating to soil* has two sources of its origin: autochtonous and allochtonous. These elements have the largest concentrations in soils. Autochtonous elements derivated from bedrocks are Ag, B, Cr, Ge, Nb, Ni, V, Zr. The source of Mn, Sr, and P is a fly ash, emitted by power and heating plants of the Krasnoyarsk, situated about 60-80 km to southwest.

Only one element, cadmium, is *accumulated in surface landscapes*. It was found in vegetation and bottom sediments but never in bedrock and soils. It may be also the result of industrial emission.

Primordial noble gas in the Solar System

M. OZIMA[1] AND B. MARTY[2]

[1]University of Tokyo, Tokyo 113-0033, Japan (*correspondence: ezz03651@nifty.ne.jp)
[2]CRPG-CNRS, Univérsite de Loraine, BP 20, 54051, Vandoeuvre, France (bmarty@crpg.cnrs-nancy.fr)

The solar noble gases, especially their isotopic compositions, are crucial reference parameters in discussing planetary evolution. Either Solar wind noble gas (SW) or Q-component in primitive meteorites, both widely occurring in the early solar system with very uniform isotopic composition (except for Q-Ne), has been regarded to represent the primordial solar noble gases. Curent conventional practice is to assume the SW noble gases as the proxy of the solar noble gas [e.g.1]. However, on the basis of noble gas isotopic systematics based on noble gas isotopic data in various planetary objects, Ozima *et al* [2] concluded that Q-noble gas represented the solar noble gas, from which SW-noble gas was fractionated (30.3‰/amu at mass number 16). Here, we propose a new noble gas isotopic reference paramters for the primodial solar system with special refernce to the neon isotopic ratio in the Earth, and discuss their implications on the evolution of terrestrial planets.

The primordial $^{20}Ne/^{22}Ne$ value in the Earth is still an enigma, but a common assumption is to asign the SW ratio of $^{20}Ne/^{22}Ne = 13.8$ [e.g.1]. However, we infer from the above noble gas systematics [2] that $^{20}Ne/^{22}Ne$ in Q-noble gas, namely the solar $^{20}Ne/^{22}Ne$, was close to 13.0. The ratio is almost identical with the in-situ observed ratio in the Jovian atmosphere [4], a likely locale for the primordial noble gas in the early solar system. Moreover, recent Ne isotopic ratios deduced from some mantle-derived materials such as basaltic glasses from Iceland [1] and Devonian plutonic rocks [5] showed the indigenous mantle component of $^{20}Ne/^{22}Ne = 13.0$. The result would require revision of some of widely held Earth evolution models based on the conventional noble gas reference.

Heavy and Precious Metal Prospecting Using With Geophysical Methods in The Ophiolitic Rocks Exposed Bozkır (Konya-Turkiye) and Hatıp-Çayırbağı (Meram-Konya-Turkiye) Regions.

ALICAN ÖZTÜRK[1]*AND AHMET. BAYKAL[2]

[1] [1]Selcuk University, Ge ological Engineering Department, Konya, Turkey (correspondence: acan@selcuk.edu.tr
[2] Yapıray Railway Construction Systems Industry&Trade Inc.

In this study, ore deposit prospecting on the ophiolitic rocks exposed in the Bozkır (Konya) and Hatip-Çayırbağı (Meram-Konya) regions were realized using with the geological, geophysical and geochemical methods.

In the Bozkır region; emplacement age is Upper Cretaceous of Bozkır Unit and located as allochthonous on the underlying rocks . Bozkır Unit is represented by mainly Bozkır Ophiolitic Melange and Boyalıtepe Group. Although Bozkır ophiolitic Melange consist of serpentinite, gabbro, dunite, diabase, spilitic basalt and deep-sea sediments, Boyalıtepe Group made up of different lithological featured limestones (Mahmuttepe, Kuztepe, Soğucak and Erenlertepe limestones). In the Miocene time Kızıltepe Volcanics cuts and exposes above mentioned units. Gündüğün formation placed uncomformably over all of the older units at the topmost of the sequence.

In the Hatip-Çayırbağı Region; basement of the sequence is represented by Upper Triassic- Upper Cretaceous aged Lorasdağı Formation and Midostepe Formation. These units were covered Upper Cretaceous Hatip Ophiolitic Complex and Çayırbağı Ophiolite. Upper Miocene-Lower Pliocene Ulumuhsine Formation unconformably lies over the older units.

Chemical analysis of the rock and plaser samples derived from both two areas were run on the major oxides, trace elements, platinium group metals and rare earth elements and statistical interpretations were performed.

Different units of both two areas were tried to be determined by using rezistivity as an electrical geophysical method. With this aim three-point in the Bozkır region and four-point in the Hatip-Çayırbağı region investigated using with vertical electrical sounding (VES). As a result of the obtained data of VES in the Bozkır Region; hydrothermal permeable metal-rich and magnetite-rich altered gabbro and spillite siliceous levels were determined formations. In the Hatip Region silica levels and also magnetite and chromite-rich serpentinite formations have been identified [1].

The geochemical evolution of lateral and vertical direction of Delihalil volcano (Yumurtalık, Turkey)

ALI ÖZVAN[1]* [A] AND VURAL OYAN[2]

[1]Yuzuncu Yıl University Department of Geological Engineering 65080 Van, Turkey (*Correspondance:aliozvan@yyu.edu.tr)

[21]Yuzuncu Yıl University Department of Mining Engineering 65080 Van, Turkey

The study area, located between Ceyhan and Osmaniye in Southerh Turkey, is surrounded by pyroclastics and lavas of Delihalil volcano. The lateral and vertical composition of these lavas are different. Basaltic lavas have different shapes as porous and masive in this region. Generally, porous basalt is seem on surface. Geochemical evolution of the Delihali basaltic volcanism in the vertical direction was investigated in this study.

Delihalil volcano and other young volcanics in study region erupted from late Pliocene to historical time along the NE-SW trending left lateral Yumurtalık fault zone in southern Turkey which is characterized by alkali olivine basalts on surface [1]. These lavas were drilled up to 20 m depth at different points. Core samples were taken to determine the vertical compositon of lavas.

These lavas are composed of olivine, plagioclase, augite and titanoaugite crystals and display porphyritic to aphyric textures. The basaltic lavas display transitional characteristics from alkaline to subalkaline and are basanite, alkali basalt and subalkali basalt. MORB pattern of the basaltic lavas imply that basanitic and basaltic lavas erupted from Delihalil volcano could have been derived from a mantle source like within plate. LREE of the most primitive lavas display strong enrichments relative to HREE and MREE on Chondrite-normalized spider diagrams. This finding indicates the presence of garnet in the mantle source.

A partial melting model was conducted to evaluate partial melting processes in mantle source of the basanites and basalts in the Delihalil volcano alkaline volcanism. Results of this study suggest the presence of both strongly garnet and slightly spinel peridotite in the source, a partial melting degree of 0.1-3 % and mixing of the derivative melts from them in the genesis of the mafic basanitic and basaltic lavas.

Synthesis and characterization of K-zeolites by the use of a diatomite

C. PACE[1], D. NOVEMBRE[1]* AND D. GIMENO[2]

[1]Dipartimento di Ingegneria e Geologia, Università degli Studi G. D'Annunzio, Chieti Scalo 66100, ITALY (*correspondence: dnovembre@unich.it)

[2]Depart. de Geoquímica, Petrología i Prospecció Geològica, Facultat de Geologia, Universitat de Barcelona, 08028, SPAIN (domingo.gimeno@ub.edu)

Hydrothermal crystallization of K-zeolites (K-F and W-Merlinoite type) from gels obtained by the use of k-aluminate and naturally derived k-silicate is here achieved. The use of an inexpensive natural rock ("Tripoli" siliceous rock from Crotone, Italy) reduces the high costs of the usual industrial synthesis protocols and favours the exploiting of the same natural material. Chemical treatments were performed on the opaline siliceous rock, whose composition resulted in quartz, amorphous opaline silica, clay minerals and a minor amount of calcite [1], in order to obtain K-silicate. A first attack with nitric acid to eliminate the calcitic and carbonatic fraction and Fe and Mn oxides, was followed by a treatment in an alkaline bath (KOH 10%) to induce the solubilization of the siliceous fossil fraction and the production of the K_2SiO_3 solution. The second reagent, potassium aluminate, was achieved by the mixing of potash

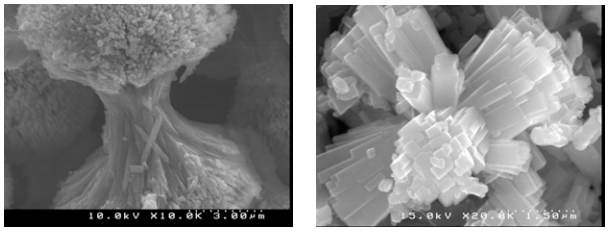

Figure 1: Left: W-Merlinoite type zeolite; right: K-F zeolite.

(20%) with $Al(OH)_3$ (65%). Five series of synthesis were performed inside autoclaves at a temperature of 150°C and ambient pressure by varying the ratio of the silicatic and aluminatic solutions. Infrared and X-ray spectroscopy, thermo diffraction, nuclear magnetic resonance ^{29}Si, structural refinement together with high temperature diffraction textural, chemical, and physical characterization give values comparable to those proposed by literature.

Environmental diversity of denitrification

LAURA A. PACE[1], JAMES HEMP [2], RANJANI MURALI[3], ROBERT B.GENNIS[3] AND WOODWARD W. FISCHER[2]

[1]University of Utah (laura.a.pace@gmail.com)

[2]California Institute of Technology (jim.hemp@gmail.com)

[3]University of Illinois at Urbana-Champaign

The modern nitrogen cycle is a complex web of microbially mediated redox reactions found in both oxic and anoxic environments. Recently, the breadth of microbial roles in the nitrogen cycle has expanded substantially, with the discovery of both new metabolisms (ANAMMOX; anaerobic oxidation of methane coupled to denitrification), and novel organisms performing known reactions (ammonia oxidation in Archaea). Here we use metagenomics, coupled with biochemical and physiological experiments, to identify new enzyme families able to catalyze nitric oxide reduction. These results greatly expand the known diversity of organisms capable of performing denitrification, suggesting also that this metabolism is more widespread than previously recognized.

Nitric oxide reduction is catalyzed by enzymes from the heme-copper oxidoreductase (HCO) superfamily. The superfamily is extremely diverse, with members playing crucial roles in both aerobic and anaerobic respiration. It is currently divided into two reaction classes; oxygen reductases and nitric oxide reductases. The oxygen reductases are terminal enzymes in aerobic respiratory chains, and are able to conserve energy in a proton electrochemical gradient. The nitric oxide reductases (NOR) catalyze the reduction of nitric oxide to nitrous oxide ($2NO + 2H^+ + 2e^- \rightarrow N_2O + H_2O$) in microbes capable of denitrification, and are not known to conserve energy.

The HCO superfamily currently consists of three oxygen reductase families (A, B and C) and two NOR families (cNOR and qNOR). We used metagenomics and comparative genomics to discover at least seven new families capable of nitrogen cycle reactions. Five of these families (eNOR, bNOR, sNOR, gNOR, nNOR) catalyze nitric oxide reduction. The two other families are predicted to perform reactions new to the superfamily; nitric oxide dismutation ($2NO \rightarrow O_2 + N_2$) and nitrous oxide reduction ($N_2O + 2H^+ + 2e^- \rightarrow N_2 + H_2O$). All sequenced ammonia-oxidizing bacteria have the sNOR family, whereas the gNOR family is specifically found in environments where sulfide oxidation is coupled to denitrification. The eNOR and bNOR families have proton channels, which allow them to conserve energy, enabling these microbes to extract more energy from denitrification. Significantly, according to metagenomic data, the eNOR family appears to be the most common NOR found in Nature.

Hydrogen diffusion in Ti-bearing forsterite

PADRON-NAVARTA J.A.[1,2], HERMANN J.[3], AND O'NEILL H.S.C

[1]Géosciences Montpellier, CNRS-UM2, Montpellier, France.
[3]Research School of Earth Sciences, ANU, Australia.

Migration of point defect in ferromagnesian silicates controls the transport properties of the Earth's mantle. The geodynamic and chemical evolution is dictated by the influence of "water" (more specifically hydrogen) on the physical properties of olivine $(Fe,Mg)_2SiO_4$, which dominates the mineralogy of the upper mantle. The presence of hydrogen significantly modifies the timescale of diffusion, plastic deformation and other transport properties in olivine such as electrical conductivity or the attenuation of seismic waves. In order to understand all these processes it is essential to unravel the diffusivity of hydrous defect in nominally anhydrous minerals (NAMs). We report a new experimental approach to study hydrogen diffusion in forsterite containing key hydrous defects relevant for the upper mantle.

Synthetic titanium-bearing forsterite crystals containing 308 ± 20 ppm wt. H_2O were heated at 1273 K, 1173 K and 1073K during 296, 432 and 1304 h (ca. 1.8 months) respectively. The temporal evolution of individual peak heights related to hydroxyl (OH) stretching vibration in the infrared spectra was measured. OH-stretching bands assigned to titanium clinohumite point defects, silicon and magnesium vacancies and defects associated to trivalent cations show contrasting behaviors with time. Two different parts are distinguished during the dehydroxylation process: (1) hydrous defects related to trivalent cations and Mg-vacancies early disappear followed by hydrous defects related to Ti and Si-vacancies with a diffusion coefficients one order of magnitude slower than previously reported. The first part of the dehydroxylation is associated to the precipitation of an oriented Ti-rich phase; (2) In the second part of the dehydroxylation process, a concentration of 39-46 ppm wt. H_2O (exclusively related to Si-vacancies) is reached and remains constant until the end of the experiment. We suggest that this is related to a very slow diffusivity of Si-vacancies when other type of defects are lacking. Hydrogen extraction in forsterite and likely in other NAMs is thus far more complex than previously assumed. Unraveling these complex processes are crucial to understand the deep Earth's water cycle.

Fluorine, Cl, Br & I in serpentinites

LILIANNE PAGE* AND KEIKO HATTORI[1]

[1]Dept. Earth Sci., Univ. Ottawa, Ottawa, Canada, K1N 6N5
(*correspondance: lpage097@uottawa.ca)

The abundance of F, Cl, Br and I in serpentinites were examined to evaluate their behaviour in subduction zones. Samples include (1) unmetamorphosed, obducted hydrated abyssal peridotites, (2) subducted abyssal peridotites to depth of ~30 km, (3) forearc mantle serpentinites from shallow depth (<30 km) and (4) mantle wedge serpentinites from ~140 km depth in the Himalayas. Samples (1,2,3) from Dominican Republic are composed of lizardite (low temp. serpentine). The Himalayan samples consist of antigorite (high temp. phase). Abyssal peridotites contain high (<530 ppm) Cl but they lose Cl during their subduction. In the mantle wedge, elevated (<880 ppm) Cl in shallow serpentinites suggests transfer of Cl from subducting slab to the overlying mantle wedge. Lower Cl values (≤50 ppm) in deep mantle wedge serpentinites indicate loss of Cl either by pressure increase or transition from lizardite to antigorite. The Br/Cl ratios for obducted abyssal peridotites are comparable to that of seawater, confirming their serpentinization on or near the ocean floor. Bromine appears to mimic Cl in its behaviour; abyssal peridotites partially lose Br during subduction and there is high Br content in shallow mantle wedge serpentinites. However, the degree of Br loss is less than that of Cl with increasing depth, as illustrated by the elevated Br/Cl ratio (<12 $x10^{-3}$) in the deep mantle wedge. Hydrated abyssal peridotites contain relatively high I/Cl ratios up to 240 times seawater. Our results are consistent with data from sea floor serpentinites [1]. The content of I remains relatively constant during their shallow subduction. In the mantle wedge, shallow and deep forearc serpentinites contain similar amounts of I, indicating retention of I during the lizardite to antigorite phase transition.

Fluorine shows significantly different behaviour from the other halogens. The content of F is low (≤20 ppm) in abyssal peridotites, as expected from low F content in seawater. Upon shallow subduction, F content increases in hydrated abyssal peridotites, likely incorporated from shallow water sediments. Similar F-enhancement is observed for shallow forearc peridotites. Fluorine is further enriched in deep mantle wedge peridotites (<160 ppm) by incorporating F released from slabs and sediments.

Serpentinites likely contribute to the transfer of F and I into the deep mantle, whereas Br and Cl likely have shallow cycles in subduction zones.

Primary and secondary biomass burning aerosols determined by factor analysis of H-NMR spectra

M. PAGLIONE[1]*, S. DECESARI[1], L. GIULIANELLI[1], E. TAGLIAVINI[2], R. HILLAMO[3], S. CARBONE[3], S. SAARIKOSKI[3], E. SWIETLICKI[5], S. FUZZI[1] AND M.C. FACCHINI[1]

[1]CNR-Institute of Atmospheric Sciences and Climate(ISAC), Bologna, Italy (*correspondence: m.paglione@isac.cnr.it)
[2]Dept. of Chemistry, University of Bologna, Bologna, Italy (emilio.tagliavini@unibo.it)
[3]Finnish Meteorological Institute, Air Quality Research, Helsinki, Finland (risto.hillamo@fmi.fi)
[4]Div. of Nuclear Physics-Dept. of Physics, Lund University, Sweden (erik.swietlicki@pixe.lth.se).

Discovery of Secondary Organic Aerosol (SOA) formation in biomass burning plumes leads to the question whether oxidized fraction of biomass burning aerosol is rather of secondary instead of primary origin and what are chemical compositions of oxidized biomass burning POA and SOA.

In the frame of EUCAARI project proton-nuclear magnetic resonance (H-NMR) spectroscopy was applied to investigate the functional group composition of fresh and aged biomass burning aerosols during an intensive field campaign carried out in spring 2008 at a Po Valley rural station, Italy. Factor analysis applied to set of NMR spectra was used to apportion wood burning and other OC source contributions, including aliphatic amines. Comparison between NMR results and those from parallel high resolution aerosol mass spectrometry (HR-Tof-AMS) measurements shows only a partial overlap between NMR and AMS factors relating to fresh biomass burning. The comparison between the two techniques substantially improves when adding factors tracing possible contributions from biomass burning SOA. The chemical composition of such secondary combustion aerosols was shown to be markedly different from that of the corresponding POA and, at the same time, was not represented by most common organic tracers used to apportion biomass burning POA. NMR results, in fact, show that fresh wood burning is composed of polyols and aromatic compounds, with a sharp resemblance with wood burning POA obtained from smoke chambers, while aged samples are depleted of alcohols and are enriched in aliphatic acids with a smaller contribution of aromatics. Factor analysis applied to NMR proven to be able to overcome the main drawbacks of methodologies relying on molecular tracer analysis and could be profitably used for the identification of SOA fractions.

Loss of Volatile Elements After the Moon-Forming Giant Impact

K. PAHLEVAN[1], S. KARATO[1] AND B. FEGLEY[2]

[1]Dept. of Geology and Geophysics, Yale University, USA
[2]Dept. of Earth & Planetary Sciences and McDonnell Center for Space Sciences, Washington U. St. Louis, USA

Among the most striking observations made of the Apollo samples is the relative dearth of volatile elements observed in the lunar material [1], including moderately volatile elements that condense from the solar nebula at relatively high (T > 1,000 K) temperatures. Although such an observation is generally thought to be consistent with the energetic events associated with a giant impact, no quantitative chemical and dynamical scenario has been put forward to explain it.

The energy released in the Moon-forming giant impact is sufficient to melt and partially vaporize both the Earth and the impactor. The timescale to eliminate this heat by radiation is ~10^3 years [2]. Hence, the Earth-Moon system is expected to be in a molten, partially vaporized state for the first thousand years after the giant impact. This stage of the evolution may permit the loss of volatile elements via selective partitioning of elements into a vapor phase followed by phase separation of the lunar material. It has been known for decades that H – in molecular form – is gravitationally unbound in the circumterrestrial lunar disk [2]. However, no process is known that can separate the light, unbound vapor species from the heavier molecules of the silicate vapor atmosphere on the relevant timescales.

Here, we investigate a new possibility: redistribution of elements in the proto-lunar disk. Because the Moon accretes from the outermost regions of the proto-lunar disk, it may inherit a composition distinct from that of the inner disk which accretes back onto the Earth. We will present model calculations that explore physical and chemical conditions necessary for the Earth-ward transport of volatile elements in the proto-lunar disk and present the consequences of such a redistribution process. Such an approach has the potential not only to explain the abundances and isotopic composition [3] of lunar volatiles but also to permit the observed abundances to be used to yield insight into the largely unknown processes accompanying lunar origin.

Distribution of dissolved neodymium isotopes across the southern South Pacific

KATHARINA PAHNKE*AND CHANDRANATH BASAK

Max Planck Research Group for Marine Isotope Geochemistry, Institute for Chemistry and Biology of the Marine Environment (ICBM), University of Oldenburg, Oldenburg, Germany (*correspondence: kpahnke@mpi-bremen.de)

The South Pacific is an important area of bottom and intermediate water formation, and a key location for the communication of the Pacific with the Indian and Atlantic Ocean basins. Despite its importance for the global ocean, the South Pacific is largely understudied with respect to the distribution of trace elements and their isotopes, and in particular neodymium isotopes ($^{143}Nd/^{144}Nd$, expressed in ε_{Nd}), for which only a limited database exists in the southeast Pacific [1].

Here we present dissolved Nd isotopes from 11 stations across the South Pacific between South America and New Zealand and between 46°S and 69°S. The transect samples South Pacific water masses east and west of the Pacific-Antarctic Ridge and north and south of the circum-Antarctic frontal system, affording insight into the spatial variation of the Nd isotopic composition of different water masses. We observe a clear difference in ε_{Nd} between bottom waters in the western basin within the Deep Western Boundary Current (ε_{Nd} = -9) and the eastern basin just north of the Ross Sea (ε_{Nd} = -7), suggesting that Antarctic Bottom Water from different source regions carries different isotopic signatures. Notably, bottom water formed in the Ross Sea (RSBW) can also be distinguished from overlying Circumpolar Deep Water, making ε_{Nd} a useful tracer for past changes in RSBW export into the southeast Pacific. Most profiles further show a shift towards less radiogenic ε_{Nd} at the depth of Upper Circumpolar Deep Water (UCDW) that is associated with a salinity maximum in the Southern Ocean. This negative shift is consistent with a higher component of unradiogenic North Atlantic Deep Water ($\varepsilon_{Nd} \approx -13$) in UCDW. The results provide a good basis for an improved understanding of the distribution of Nd isotopes in the Pacific Ocean, and for the use of ε_{Nd} as a tracer of past circulation changes.

High Precision measurements of sub nanogram levels of neodymium measured as NdO^+ using Phoenix X62 Thermal Ionization Mass Spectrometer

ZENON PALACZ[1], DAVID BURGESS AND JEREMY INGLIS[1]

[1]Isotopx, Unit 1A Milbrook Court, Middlewich, Cheshire, CW10 0GE.

We have analysed sub nanogram amounts of the JNd-I Neodymium standard as NdO^+ using the Phoenix X62 TIMS. Samples were loaded on single Re filaments with a TaF_5 activator. Ion/Atom detection efficiency increases with decreasing sample size, with efficiencies of up to 30% attained for sample sizes between 500 and 50pg. For sample sizes of 1-10ng efficiencies are about 10%. Similar efficiencies are also observed for Sr. The maximum detection efficiency is close to the transmission of the spectrometer, and that the TaF_5 activator is producing nearly 100% ionization off the filament for small samples of Sr and Nd, which have similar ionization potentials of 5.2 and 5.5eV respectively. This is much higher (by more than an order of magnitude) than Sr and Nd^+ without the TaF_5 and probably indicates an increase due to close coupling with the very high work function fluorine atom. Using static multicollection and $1e^{11}$ ohm resistors, the reproducibility of $^{143}Nd/^{144}Nd$ remains better than 20ppm 1RSD for sample sizes down to 100pg. It is possible that using a higher gain resistor will improve this since ion intensities for $^{143}Nd^{16}O$ are only 50mv.

Soil aggregate-scale chemical gradients resulting from coupled biogeochemical and transport processes

CÉLINE PALLUD[1]* AND MATTEO KAUSCH[1]

[1]Environmental Science, Policy and Management (ESPM),University of California, Berkeley, USA(*correspondence: cpallud@berkeley.edu)

A continuing challenge in environmental science is to understand and predict how concentrations of nutrients and contaminants vary over space and time in natural systems. Within soils, biogeochemical processes controlling elemental cycling are heterogeneously distributed owing partly to the physical complexity of the media. Structured soils are composed of individual aggregates that form a network of interconnected microenvironments. The aggregate scale (mm-cm) is of particular interest due to the sharp transition in pore size between the aggregates themselves and the macropores surrounding them. The objective of this study is to investigate the coupling of physical (transport) and biogeochemical processes that affect small-scale iron transformations and that control selenium sequestration within soils.

We present a combined experimental and modelling study on single artificial soil aggregates assessing the biogeochemical processes governing transformations of redox sensitive elements (iron and selenium) in a complex but controlled setting representative of natural systems. Circumventing byproduct accumulation and substrate exhaustion common in batch systems and avoiding the poor physical analogy to aggregated soils of homogenously packed columns, our novel experiments mimic soils using constructed cm-scale aggregates in flow-through reactors, which results in diffusively and advectively controlled regions. A newly developed reactive transport model is used to delineate transport regimes, identify reaction zones, and estimate kinetic parameters and reaction rates at the aggregate scale.

Overall, our findings demonstrate significant aggregate-scale variations in biogeochemical processes and consequent distribution patterns of solid phases within soils. We show that those chemical gradients are mainly controlled by diffusive mass-transfer limitations of both solute delivery to the aggregates and metabolite removal from the aggregates. This highlights the importance of appreciating the spatial connection between reaction and transport fronts and of obtaining information on transport-limited, intra-aggregate biogeochemical dynamics to better understand reactive transport of redox-sensitive species in structured soils.

Formation of chondritic meteorites

H. PALME

Sektion Meteoritenforschung, Forschungsinstitut und Naturmuseum Senckenberg, Senckenberganlage 25 D-60325 Frankfurt, Germany (palmeherbert@googlemail.com)

More than 99% of the mass of the solar system is in the Sun. The chemical composition of the Sun and similar stars is well known from absorption line spectroscopy. The Sun has about equal numbers of Mg, Si and Fe atoms. Planetesimals with these characteristics are parental to primitive, undifferentiated or chondritic meteorites. Bulk Earth, Venus and Mars also have approximately solar ratios of Mg, Si and Fe. CI-chondrites match solar abundances to within a few percent. Small deviations from solar abundances in other groups of chondritic meteorites reflect nebular processes prior to accretion to larger objects: (a) Loss or gain of refractory phases (Ca, Al, Ti), (b) variable accumulations of forsteritic olivine and (c) of metallic FeNi and (d) incomplete sampling of volatile elements. In addition, large variations in oxygen contents are observed. Each chondrite group is formed from a comparatively small isolated nebular reservoir [1].

On a cm scale chondritic meteorites are chemically uniform [2]; on a mm scale and below they are extremely variable. Chondrules, mm sized once molten silicate droplets, and fine grained matrix are two major components of chondrites. They are chemically complementary: The low average Fe/Mg and Si/Mg of chondrules is balanced by higher atomic ratios in matrix yielding the chondritic bulk composition. Both components must have formed from a single solar-like reservoir [3]. This is an important often neglected constraint for chondrule formation models. The reason for the enormous chemical variability of chondrules is unclear. Yet, the bulk composition of primitive chondrites requires that it must have been established in a closed reservoir of chondritic composition.

Each chondrite group has its own stable isotope signature [4]. The Earth and the other planets were built of a series of chondritic planetesimals. But stable isotopes indicate that the presently known population of chondrite parent bodies did not significantly contribute to the Earth [5].

The chemical composition of the Earth

H. PALME[1] AND H.ST.C. O'NEILL[2]

[1]Sektion Meteoritenforschung, Forschungsinstitut und Naturmuseum Senckenberg, Senckenberganlage 25, 60325 Frankfurt /Main, Germany, (palmeherbert@googlemail.com),
[2]Research School of Earth Sciences, Australian National University, Canberra ACT, 0200 Australia

The composition of the Earth is derived from ultramafic rocks, samples from the Earth's mantle in a variety of geologic settings [1]. The high Mg, Ni and PGE contents, chondritic Ni/Co ratios, unfractionated compatible refractory elements (Yb/SC), chondritic Na/Mn ratios etc. support a primitive mantle origin, affected only by core formation and loss of a small fraction of partial melt, which may have occurred before final accretion of the Earth [2,3]. From a detailed comparison with chondritic meteorites it is concluded that the bulk Earth composition is not CI chondritic (i.e. precisely solar) but has similarities to the chemical composition of the CV group of carbonaceous chondrites: (a) Enrichment of refractory elements, (b) bulk Earth Mg/Si ratio, assuming 7 % Si in the core, (c) similar patterns of moderately volatile elements as CV (d) depletion of Mn and other moderately volatile elements shortly after the first solids had formed in the solar nebula (based on ^{53}Cr). Despite chemical similarities Earth does not mach CV precisely: (a) Earth has excess Fe, (b) Earth is more depleted in volatiles than CV chondrites (d) the stable isotopic composition of several elements in the Earth is similar to ordinary chondrites and even closer to enstatite chondrites but different from carbonaceous chondrites [4]. However, enstatite chondrites have very different chemistry and are not good candidates for the Earth. It seems impossible to make the primitive upper mantle from a high Si, low Al source. As chemistry and stable isotopes are decoupled similarities of in stable isotopes have limited significance: Isotopically main group pallasites fit with the non-carbonaceous chondrites while Eagle Station pallasites are close to carbonaceous chondrites [4]. Considering chemistry and stable isotopes one has to conclude that Earth is made of a variety of chondritic meteorites, different from known groups of chondrites.

The role of tephra diagenesis in the carbon cycle

M.R. PALMER[1]*, T.M. GERNON[1] AND SHIPBOARD SCIENTISTS OF IODP LEG 340[2]

[1]School of Ocean & Earth Science, University of Southampton, European Way, Southampton SO14 3ZH,UK (*correspondance: pmrp@noc.soton.ac.uk)
[2](http://iodp.tamu.edu/scienceops/expeditions/antilles_volcanism_landslides.html)

Most volcanoes are located close to the oceans. Hence a high proportion of the 10^{15} g/yr of tephra that is created by subaerial volcanism ends up in marine sediments, such that tephra comprises ~25% of Pacific Ocean sediments. In addition, individual massive explosive eruptions have covered large areas of the globe during Earth history. Given that fresh tephra is highly reactive when exposed to seawater it is important to consider the implications of this flux of material to the oceans.

We hypothesise that tephra deposition in the oceans may influence the ocean-atmosphere carbon cycle through the following mechanisms: (1) Leaching of tephra deposited in surface waters may cause increased productivity (and drawdown of atmospheric CO_2) via addition of nutrients to Fe-limited areas. (2) Deposition of tephra in sediments leads to rapid depletion of dissolved O_2 in pore waters, thus enhancing organic carbon preservation in underlying sediments. (3) After tephra deposition, bioturbation mixes the upper tephra surface with background sediments. Tephra contains reactive Fe phases that are known to complex organic carbon in non-volcanic sediments and enhance organic carbon preservation. (4) As the tephra layer is buried deeper, it moves into zones of CH_4 and alkalinity production. Alkalinity (and oxidised CH_4) diffuses into the overlying tephra where it encounters high dissolved Ca levels from Ca-Mg exchange during tephra diagene-sis, leading to precipitation of calcite cements that effectively sequester CO_2 produced from organic carbon and form a further barrier to downwards diffusion of oxidising species.

We review here the evidence supporting each of these processes and indicate times and places in Earth history when they have played a particularly important role.

Coherent pyroxene-akimotoite phase transformation in NWA 5011 shocked chondrite

E. PÁL-MOLNÁR[1]*, SZ. NAGY[1], K. FINTOR[1], I. GYOLLAI[2] AND ZS. BENDŐ[3]

[1]University of Szeged Department of Mineralogy, Geochemistry and Petrology, Szeged, Hungary (*correspondence: palmolnare@gmail.com)
[2]University of Vienna, Vienna, Austria
[3]Eötvös Loránd University, Budapest, Hungary

Introduction

Akimotoite is a major constituent phase through Earth's transition zone [1]. Up to now this phase transition has been observed as incoherent nucleation and growth in and around opaque shock melt veins [2]. In this abstract we are reporting the possible first coherent pyroxene-akimotoite transformation along the cleveages of pyroxene.

Results and Discussion

The NWA 5011 shocked chondrite consists of shock veins in various thickness and chondrules. A mixed-type pyroxene chondrule (approx. 1 mm in diameter) contains numerous subchondrules observed in the sample. One of the subchondrules exhibits dense cleavage network in which the angle between two cleavage plains is nearly right (87°). Therefore this orientation of crystal face is {110}. The BSE-images revealed that plain of cleveages enriched in Fe and it shows microgranular texture. However, the microgranular character is slightly overhanging from the original boundary of cleavages to the host grain area. The thickness of "overhanged" transition area is observed up to 0.5μm, and parallel to the direction of cleavages. In some areas between the cleavages incoherent pyroxene-akimotoite phase transformation occurs. Raman spectra have been collected along the cleavage, which confirmed the pyroxene-akimotoite phase transition. The Fe-enrichment in cleavage is possible due to weathering processes, or melting and subsequent metal-sulfide formation. The most characteristic feature of the Raman spectra is the presence of main vibrations of ringwoodite and stishovite besides akimotoite peaks. This feature confirms that inside the fragments far from boundary of shock melt veins lower *P-T* regime transformation products in the $Mg_4Si_4O_{12}$-$Mg_3Al_2Si_3O_{12}$ system can survive due to the fast temperature drop. This suggests subsequent evidence for high P-T regime change in shock melt veins within a small affected area.

[2]Laboratoire de Sciences de la Terre, Ecole Normale Supérieure de Lyon, France

Subducted mid-oceanic ridge basalts (MORB) are likely to be important components of the lower mantle. As a consequence of plate tectonics, basaltic oceanic crust is subducted into the mantle introducing chemical heterogeneity. Compared to average peridotitic mantle, MORB are enriched in silicon, aluminium, calcium and alkalis. At lower mantle conditions, experimental studies have shown that subducted MORB comprises more than 20 % of an aluminium rich phase, the so called NAL (new aluminium phase) phase. Evidence for the existence of the NAL phase has been observed in sublithospheric diamonds, where composite multiphase inclusions have been found with similar bulk compositions to NAL. If present, NAL will be a contributor to the bulk elastic properties of the lower mantle and knowledge of its elasticity is crucial for investigating the consequences of subducted crust for the seismology of the mantle.

NAL crystallising in MORB form complex solid solutions and have the general formula $XY_2Z_6O_{12}$ where X is a large monovalent or divalent cation (Ca^{2+}, K^+, Na^+), Y a middle-sized cation (Mg^{2+}, Fe^{2+} or Fe^{3+}), and Z a small sized cation (Al^{3+} and Si^{4+}). Here we report the crystal structure refinement of NAL synthesized at lower mantle conditions with a composition close to that expected to crystallise in a subducting slab. We also report for the first time its full elastic tensor experimentally determined by Brillouin scattering spectroscopy at room and high pressure. We complement these experimental results with first-principles calculations, performed using density-functional theory and density-functional perturbation theory.

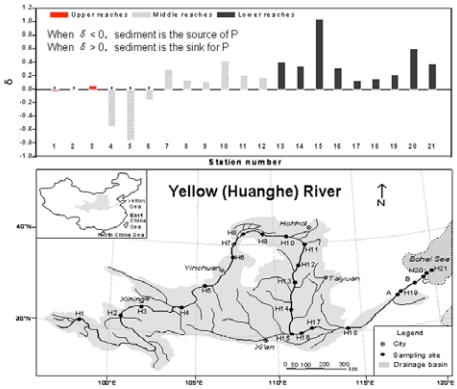
[3]Charney school of Marine Scinces, Haifa University, Haifa, Israel

While the importance of phosphorus (P) as a limiting nutrient is well established, the understanding of global scale control on P cycling in continents and how these affect riverine P fluxes is still incomplete. P in water and sediment in the Huanghe was measured for 21 stations from the source to the Bohai Sea. The average total particulate matter (TPM) increased from 40 mg/L (upper reaches) to 520 mg/L (middle reaches) and 950 mg/L in lower reaches of the river. Although there was considerable nutrient pollution, the dissolved PO4 concentration remained low (0.32-0.58 μmol/L) due to adsorption on particles. The P removed was mainly due to the high TPM rather than the surface activity of the particles since they had low labile Fe and low affinity for P. The sediment was a major sink for P in the middle to lower reaches but not in the initial upper to middle reaches. TPM has been reduced by more than 10-fold due to artificial dams over the last decades. Experimental modeling revealed that TPM of 1 g/L was a critical threshold for Huanghe below which most of the P input to the river can no longer be removed by the particles where eutrophication may occur. These findings provide realistic representations of particle control on riverine P fluxes which can be used in coupled land-ocean modeling in global biogeochemical P cycling.



Nd-Sr Isotopic Constraints on the Source of the Hexi Corridor Loess

PAN YAODONG[1] RAO WENBO[1] AND WU WEIHUA[2]

[1]Institue of Isotope Hydrology, Hohai University, Nanjing, 210098, China.(Panyaodong612@163.com)

[2]Institute of surficial geochemistry, Nanjing University, Nanjing, 210093, China

Analysis and Comparison

The loessial soil is very important for habitants in the Hexi Corridor, North China. However, knowledge on the loess source of this region is uncertain till now. In order to answer this question, Sr-Nd isotopic comparisons between the loess of the Hexi Corridor and surface sediments of surrounding areas are conducted in this study.

River sediments from the Qilian mountian are collected for isotopic analysis of their fine-grained fractions in this study. The measured $\varepsilon_{Nd}(0)$ values vary from -11.84 to -11.95 with $^{87}Sr/^{86}Sr$ ratios from 0.7196 to 0.7388 □As listed in Table 1□.

According to topographical and meteorologic data, the Badain Jaran desert, the Qaidam desert, the Taklimakan desert, the Gurbantunggut desert and Rivers of the Qilian mountains might be potential sources to supply fine-grained fractions for the loess formation in the Hexi Corridor. $\varepsilon_{Nd}(0)$ values and $^{87}Sr/^{86}Sr$ ratios of fine-grained fractions vary from -7.4 to -10.2 and from 0.7132 to 0.7174 for the Badain Jaran Desert, from -10.0 to -10.5 and from 0.7166 to 0.7187 for the Qaidam Desert, from -9.5 to -11.7 and from 0.7136 to 0.7171 for the Taklimakan Desert, from -1.2 to -3.3 and from 0.7113 to 0.7136 in the Gurbantunggut Desert, respectively [2].

Results and Conclusion

Isotopic compositions of the Hexi Corridor loess are distinctly different from those of the Badain Jaran Desert, the Qaidam Desert and the Gurbantunggut Desert, but are roughly similar to the Taklimakan Desert and river sediments of the Qilian mountian. Due to the stability of Sr-Nd isotopes in the surficial process [3], the geochemical similarity of the loess in the Hexi Corridor with the fine-grained fractions of the Taklimakan Desert and river sediments of the Qilian mountian indicates the two areas might be main sources of the Hexi Corrdior loess.

Region	Type	Grain size	$\varepsilon_{Nd}(0)$	$^{87}Sr/^{86}Sr$
Qilian Mts.	River sediment	<75μm	-11.84	0.7335
			-12.95	0.7338
			-12.15	0.7196
			-11.96	0.7222

Molecular level characterization of methyl sugars and other carbohydrate compounds in marine high molecular weight dissolved organic matter (HMWDOM)

C. PANAGIOTOPOULOS[12]*, D.J. REPETA[3], L. MATHIEU[12], J-F. RONTANI[12] AND R. SEMPERE[12]

[1]Aix-Marseille Université, Mediterranean Institute of Oceanography (MIO), 13288, Marseille, Cedex 9, France; [2]Université du Toulon, CNRS/INSU, IRD, MIO UM 110, 83957 La Garde, France (*correspondance: christos.panagiotopoulos@univ-amu.fr)
[3]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA (drepeta@whoi.edu)

Dissolved organic matter (DOM) is an active component of the carbon cycle however its chemical composition, fate, and sources are poorly understood. Approximately 30% of surface DOM can be sampled by ultrafiltration, and thereby concentrates the high molecular weight DOM fraction (HMWDOM > 1kDa)[1]. Previous studies have shown that most HMWDOM is comprised of carbohydrates (acylated carbohydrates or APS), but only a minor fraction of the carbohydrate has been identified at the "molecular level" (as monosaccharides after hydrolysis, *i.e.* fucose, rhamnose, arabinose, galactose, glucose, mannose, and xylose). The discrepancy between NMR derived estimates of HMWDOM carbohydrate (50-70% C) and molecular level analyses (10-20% C) has not been explained, and no new sugars have been identified in HMWDOM in about 10-15 years[2].

Here using ultrafiltration, silver cation preparative chromatography, and GC-MS we identified 50 novel sugar compounds after hydrolysis of the HMWDOM. Sugars were identified using chemically synthetized sugar standards and mass spectra data available in literature. Our results showed that mono- and di- methylated hexoses; mono- and di-methylated pentoses; mono- and di- methylated 6-deoxysugars, as well as heptoses, methylated heptoses, 3,6-dideoxysugars and 1,6 anhydrosugars (*i.e.* levoglucosan, galactosan, and mannosan) are components of HMWDOM, which may explain in part the low apparent yields of sugars recovered by molecular level (HPLC) analyses compared to NMR estimates.

Our results also indicated that the above compounds accounted 2-3% of the APS in surface/deep waters and their diversity decreased with depth. The high diversity of mono- and di- methylated hexoses in the surface sample most likely suggests an algal and/or bacterial source, while the high abundance of methylated 6-deoxy hexoses in the deep sample points toward a important bacterial contribution.

[3]Depto. Química Inorgánica y Orgánica, Univ. Jaén, E-23071, Spain
[4]BRIDGE, Geographical Sciences, University of Bristol, UK

Numerous transient hyperthermals have been identified in Earth history, and most are associated with a sharp negative carbon isotope excursion (CIE). The CIEs indicate that rapid global warming was at least partly caused by the release of reduced carbon, with methane hydrates, peat deposits and permafrost all being proposed as sources. Much work on hyperthermals, and especially the Paleocene-Eocene Thermal Maximum (PETM), illustrates that rapid global warming caused dramatic changes in the hydrological, erosional and weathering regime. These changes were associated with a marked increase in the mobilisation and transport of soil and terrestrial vegetation, and it is likely that under a warmer climate state at least some of this OM was oxidised, providing a positive feedback on global warming. Here, we present evidence that even reduced carbon reservoirs that are generally perceived as recalcitrant (i.e. kerogen) are also mobilised during such events.

Kerogen inputs to marginal marine sediments increased dramatically during both OAE1a and the PETM. This is documented by a shift in biomarker (sterane and hopane) assemblages from thermally immature to mature signatures over short stratigraphic scales. This is indicative of mixing of two distinct organic matter sources, most likely a source contemporaneous with sediment deposition and another older, reworked source. These observations confirm that an increase in hydrological energy during hyperthermals was sufficient to markedly and widely increase sedimentary rock erosion. We suggest that this strong response was particularly due to rapid deviation from steady state conditions. Moreover, erosion and chemical weathering are generally coupled and even ancient kerogens have been shown to be highly oxidisable during shale weathering; thus, these events were likely associated with kerogen oxidation. Although unlikely to have been a major source of additional reduced carbon (<10% of the CIE), this work highlights the potential lability of all organic matter pools during rapid climate change events.

Anomalous lithospheric and geodynamical evolution of the southern part of Vindhyan basin, central India

O.P. PANDEY, NIMISHA VEDANTI* AND RAVI PRAKASH SRIVASTAVA

CSIR-National Geophysical Research Institute, Hyderabad, India (*correspondence: nim.ved@gmail.com)

Introduction

Tectonically active sickle shaped Vindhyan basin is considered the largest intra-cratonic Proterozoic sedimentary basin in peninsular India that covers an area of about 200,000 sq.km. It is well known for diamond occurrences. Possibility of hydrocarbon potential has led to a surge in various kinds of geological and geophysical investigations during recent times. An attempt has been made here to synthesize seismic, gravity [1,2] magnetotelluric, geothermal and borehole geological data, which throws a new light into the crustal and upper mantle evolution of this basin.

Significant Results

The southern part of this basin appears to have undergone episodic thermal interactions between crust and hot underlying mantle, which induced magmatism, upwarping and erosion followed by crustal rifting and sedimentation. Seismic data reveals that as much as 10-15 km crustal exhumation may have taken place beneath this region. Almost 5 to 6 km thick Proterozoic sediments have deposited over exhumed high velocity middle crust in the Jabera basin. A high heat flow of almost 80 mW/m^2 has also been estimated for this region, which indicates presence of extremely high Moho temperature and mantle heat flow. Lithosphere has been found to be extremely thin at about 50 Km below Jabera basin. In some geo-tectonic segments, granitic-gneissic upper crust has been totally eroded due to sustained exhumation of deep seated mafic rocks. A 5-10 km thick retrogressed metasomatically altered layer with significantly reduced velocities consequent to interaction with hydrothermal and other mantle fluids, has also been delineated at around mid to lower crustal transition. There is a possibility that this region may have been under the influence of a super mantle plume around 1.1 Ga.

Atmospheric Evolution and Chemical Aging of Combustion Organic Particulate Matter

SPYROS N. PANDIS[1], NEIL M. DONAHUE[2] AND ALLEN L. ROBINSON[3]

[1]Department of Chemical Engineering, University of Patras, Greece (spyros@chemeng.upatras.gr)
[2]Department of Chemical Engineering, Carnegie Mellon University, USA (neil.donahue@andrew.cmu.edu)
[3]Department of Mechanical Engineering, Carnegie Mellon University, USA (allen.robinson@andrew.cmu.edu)

Organic particulate material has been traditional classified as either primary or secondary with the primary component being treated as nonvolatile and inert. Laboratory and field studies during the last decade, demonstrate that primary combustion aerosol is highly dynamic, consisting of mostly semi-volatile material that moves between the gas and particulate phases in the atmosphere and at the same time is oxidized forming a variety of oxygenated products. This oxidation can lead to both lower volatility material through functionalisation but also to smaller lower volatility molecules through fragmentation. A unifying framework for the description of all organic components based on their volatility distribution and oxygen content (the two-dimensional volatility basis set) can be used for the treatment of a wide range of processes affecting organic aerosol loadings and composition in the atmosphere. This modeling framework is combined with emission characterization studies, laboratory smog chamber studies, and field measurements to simulate the atmospheric evolution of these organic emissions. Applications of this modeling framework to major urban areas (Paris and Mexico City) and continental Europe, where major field campaigns have recently taken place are used to provide insights about our understanding (or lack thereof) of the corresponding physical and chemical processes.

Ore genesis of the Longshan Sb-Au deposit, Hunan, China: Evidence from fluid inclusions

M. ZHANG[1], B. PANG[1]*, D. YANG[2], X. LIU[1] AND B. WANG[1]

[1]Guilin University of Technology, Guilin, 541004, China (*correspondence: pbc@glut.edu.cn)
[2]Guangzhou Institute of Geochemistry, Guangzhou, 510640, China (yds1019@gig.ac.cn)

The Longshan gold-antimony deposit is one of the typical Sb-Au associatioins in Hunan province, China. The mineralization is related to NWW and NNE trending fault systems and hosted within gravel sandy slate in Jiangkou Formation of Sinian System. Gold occurs mainly in cracks in stibnite, pyrite and arsenopyrite, or in the contact area of these three minerals and gangue minerals, or enclosed by stibnite. From a limited number of hydrogen and oxygen isotope data, some previous workers proposed that the ore-forming fluid was predominantly meteoric in origin. In contrast, we argued that metamorphic fluid is an alternatively likely source of the ore-forming fluid based on a preliminary study of fluid inclusion microthermometry and Raman spectrum.

Mineralization and paragenesis of the Longshan deposit can be divided into three stages as follows based on geology and petrography of the deposit: Qz + Py +Asp +Au (stageⅠ); Qz + Py +Asp + Sb + Au (stageⅡ) ; Qz + Sb + Cal (stageⅢ). StageⅡ is the mainest ore-forming stage accounting for approximately 82% of ore reserves. Primary inclusions in quartz from stageⅡ ores are mainly mixed aqueous-gaseous fluid inclusions (H_2O–NaCl–CO_2-other gases). Pure liquid and pure gaseous can be occasionally observed. For mixed aqueous-gaseous fluid inclusions, two or three phases can be observed at room temperature: a bubble of carbonic vapor suspended in aqueous liquid, or a double bubble in which a bubble of carbonic vapor is enclosed by a bubble of carbonic liquid suspended in aqueous liquid. The size of inclusions ranges from 2.31μm to 12.89μm, mainly 3μm to 7μm. These inclusions exhibit relatively variable vapor to liquid ratios (5-25%, mostly 10-15 percent vapor by volume), and have homogenization temperatures ranging from 235℃ to 320℃. Two-phase inclusions show a wide salinity range of 0.18-9.85wt% NaCl equiv, with most data clustering around 3-8 wt% NaCl equiv. By contrast, three-phase inclusions have a lower range in salinity (1.42-2.2 wt% NaCl equiv). Trapping pressure estimated from three-phase inclusions is up to 135MPa, suggesting that antimony-gold mineralization occurred at the depth of approximately 7.7km. Laser Raman Spectrum analysis for two-phase of CO_2-H_2O inclusions indicate the existence of minor N_2 and C_2H_6 besides CO_2. Physical and chemical characteristics of fluid inclusions suggest that the Longshan Sb-Au deposits may have resulted from metamorphic fluids.

Mafic potassic volcanics from the Altiplano, South America: Indication of a dynamic A-type magma source under construction?

M. J. PANKHURST[1,2]*, B. F. SCHAEFER[2] AND S. P. TURNER[2]

[1]School of Earth and Environment, University of Leeds, Leeds,UK (*correspondence: m.j.pankhurst@leeds.ac.uk)
[2]GEMOC, Macquarie University, Sydney, Australia

Small volume monogenetic mafic volcanoes, erupted onto the Altiplano (active orogenic platuea) during the Neogene to Quaternary, display high K, F, Ga/Al and low Ca relative to typical basalts. These characteristics match key chemical affinities of post-orogenic A-type granite magmas.

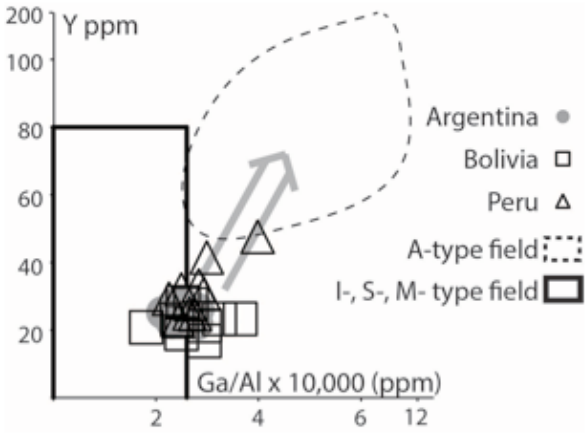

Figure 1. Geochemical affinites between orogenic mafic volcanics and A-type granites. Arrow indicates liquid evolution involving plagioclase and clinopyroxene from a deep crustal reservoir stacked with mantle-derived, low degree partial melts into the A-type field.

New geochemical data and Sr, Nd and Hf isotopic ratios of these Altiplano volcanics are consistent with a petrogenetic model that involves iterative low-degree partial melting regimes within underlying metasomatised aesthenospheric and lithospheric mantle. We consider generation of such melts to be widespread and significant, since the same signatures are observed across ~1750 km of strike length and are not restricted to a specific time period. Their small individual erupted volumes suggest ascending batches are subject to efficient cooling and stalling at deeper levels. Therefore it is plausible they may be vastly underrepresented at the surface, and difficult to directly detect by geophysical methods. Second order convections within the mantle during downwelling/delamination of lithosphere may account for the production and emplacement of these magmas. We propose that the generation of these melts during orogenesis contributes chemical and isotopic signatures to subsequent post-orogenic magmas, via their iterative pooling and crystallisation within the lithosphere.

LREE-rich beach sands from Sithonia Peninsula (Chalkidiki, Greece)

A. PAPADOPOULOS[1]*, G. CHRISTOFIDES[1], G. PE-PIPER[2] AND A. KORONEOS[1]

[1]Department of Mineralogy, Petrology, Economic Geology, Aristotle University of Thessaloniki, 54124, Thessaloniki, Greece (*correspondence: argpapad@geo.auth.gr, christof@geo.auth.gr, koroneos@geo.auth.gr)

[2]Department of Geology, Saint Mary's University, Halifax, Nova Scotia, B3H 3C3, Canada (gpiper@smu.ca)

Beach sands, being the weathering products of the adjacent Sithonia Plutonic Complex [1], have been studied for their heavy mineral and LREE content. For the mineral separation, the 125-500 μm grain-size fraction, accounting for 90.6-95.4 wt % of the whole sample, was used. Among the samples collected, three are particularly enriched in heavy minerals.

Heavy liquid (tetrabromoethane, 2.967 g/mol) and a magnetic separator were employed to determine the wt % heavy fraction and the heavy magnetic and non-magnetic fractions of the whole sample (Table 1). The heavy magnetic fraction (<0.8 amp at cross and logitudinal settings of 10º) contains epidote, allanite, biotite and hornblende, while the heavy non-magnetic fraction (>0.8 amp at same settings) contains zircon, monazite, apatite and sphene.

	Heavy fraction	Heavy magnetic fraction	Heavy non-magnetic fraction
S1	85.3	50.6	34.7
S2	26.8	16.0	10.8
S3	56.4	51.6	4.8

Table 1: Heavy, heavy magnetic and non-magnetic content (wt % relative to the bulk sample).

The content of the studied samples in LREE and Y is particularly high (Table 2). This is attributed mainly to the presence of monazite, allanite and to a lesser extent epidote.

Organic matter oxidation and authigenic rhenium in late Eocene pelagic sediments

FRANCOIS PAQUAY*[1] AND GREG RAVIZZA[1]

[1]Geology & Geophysics, SOEST, University of Hawaii, Manoa, Honolulu HI 96822 USA. ravizza@hawaii.edu, (correspondance: paquay@hawaii.edu)

Poor organic carbon preservation in the deep sea during Eocene warmth suggests an important change in the carbon cycle during greenhouse episodes [1]. An expected consequence of this phenomenon is that Eocene pelagic sediments should be more reducing than similar modern sediments. Measured Re concentrations demonstrate significant authigenic Re-enrichment, up to 30X average crustal concentrations, associated with very low total organic carbon (TOC; <0.2%) in late Eocene sediments from ODP Site 1090 (42°54.8′ S, 8°53.9′ E) on the Agulhas Ridge in the South Atlantic. Using measured $^{187}Re/^{188}Os$ ratios to correct for ^{187}Re decay since sediment deposition yields initial $^{187}Os/^{188}Os$ ratios that are similar to contemporaneous seawater, requiring that Re enrichment occurred during or soon after sediment deposition. Therefore these data provide strong evidence of a brief episode (a few hundred kyr) of reducing conditions. Integrating Re-Os results with previously published data [2,3] constraining paleoredox (U, U/Al) and paleoprodictivity (biogenic Ba, organic carbon and reactive phosphorus) highligts several important aspects of the reduced interval of this record. Re (ppb)/TOC % (up to 55) are among the highest reported to in recent marine sediments. The zone of elevated Re is not clearly associated with evidence of elevated paleoproductivity, suggesting that decreased in oxygen penetration depth is more likely to be due to lower bottom water oxygen, than an episode of elevated organic matter flux to the sediment water interface. Although U/Al ratios are modestly elevated across the interval with elevated Re, average Re/U (15 ng/μg) ratios are much higher than in most modern reducing sediments and higher than expected if both elements are enriched via diffusion across the sediment water interface and reductively fixed at the same depth. We suspect that elevated Re/U is the result differing reduction mechanisms within sediment pore waters. In total, these results provide empirical evidence that Re is a uniquely powerful paleoredox tracer in organic-poor, pelagic sediments.

Major and trace elements composition of basalts from ultramafic and volcanic seafloor. Southwest Indian Ridge (61 to 67°E)

MARINE PAQUET*[1], MATHILDE CANNAT[1], CÉDRIC HAMELIN[2], MANUEL MOREIRA[1] AND DANIEL SAUTER[3]

[1]Institut de Physique du Globe de Paris, France (*paquet@ipgp.fr)
[2]Centre for Geobiology, University of Bergen, Norway
[3]Institut de Physique du Globe de Strasbourg, France

Our study area is located on the ultra-slow Southwest Indian Ridge, east of the Melville Fracture Zone, between 61 and 67°E. This part of the SWIR has a very low magmatic supply, and the axial lithosphere is thick. The melt distribution is very heterogeneous with volcanic areas and areas of ultramafic seafloor where plate separation is accomodated by large offset normal faults [1]. The ultramafic rocks are locally overlain by a thin veneer of basalt. Basalts samples have been dredged on these two types of seafloor during the EDUL (1997) and SMS (2010) cruises. We use the major and trace elements composition of these basalts to discuss the magmatic plumbing system of this very low melt supply ridge.

Most basalts from ultramafic seafloor areas have higher Na_2O and TiO_2 contents at a given MgO, and higher Zr/Y and Sr than those from volcanic seafloor. These differences could be explained [2] by a lower degree of partial melting of the mantle source for ultramafic seafloor basalts. However, the lower CaO content of most ultramafic seafloor basalts suggests larger amounts of early fractionation of clinopyroxene [3] from the melts feeding ultramafic areas. This early clinopyroxene fractionation could also partly explain the Na_2O and TiO_2 trends, but not the Zr/Y trend. Our data therefore suggest that both the melting regime and the magma plumbing system producing the two groups of basalts are different. $(La/Sm)_n$ ratio and REE spectra point to a similar source for the two groups of basalts, possibly a refertilized depleted mantle [4]. One dredge in volcanic seafloor stands out with a depleted LREE spectrum, low $(La/Sm)_n$ and very high MgO content. This dredge could be interpreted as resulting from very low degree of melting of a non-refertilized residual mantle domain.

Early Solar System ^{87}Rb-^{87}Sr Chronology

R. PARAI[1]*, S. HUANG[1] AND S. B. JACOBSEN[1]

[1]Dept. of Earth and Planetary Sciences, Harvard University, 20 Oxford St., Cambridge, MA 02138, USA. (*email: parai@fas.harvard.edu)

The long-lived ^{87}Rb-^{87}Sr system provides a useful chronometer for early Solar System events. Due to differences in the volatility of Rb and Sr, $^{87}Sr/^{86}Sr$ ratios record information about condensation and volatile depletion in the early Solar System. Thus, high-precision analysis of Rb-Sr systematics in Solar System materials such as calcium-aluminum inclusions (CAIs), meteorites and lunar rocks provide insight into processes that shaped the early Solar System, including the formation of Earth's Moon.

Recent studies have argued for a late formation of the Moon based on Sm-Nd and U-Pb systematics [e.g., 1-2], but have avoided use of Rb-Sr chronometry due to possible disturbance of the Rb-Sr system. However, a chronology may be constructed based on relative variations in initial $^{87}Sr/^{86}Sr$ in Solar System materials, rather than absolute ages derived by the Rb-Sr isochron method. For Rb-poor samples such as Moore Co. plagioclase, Angra dos Reis, Juvinas and the lunar anorthosite 60025, corrections for radiogenic ingrowth are small, and variations in resulting initial $^{87}Sr/^{86}Sr$ may be interpreted to reflect differences in the timing of separation from an evolving solar nebula [e.g., 3-5]. Based on a compilation of literature Rb-Sr data measured in various laboratories over the course of decades, Halliday and Porcelli [6] computed a young Sr model age for lunar formation of 90±20 Myr after the formation of CAIs. However, from the fact that 60025 has an initial $^{87}Sr/^{86}Sr$ between the basaltic achondrite best initial and Angra dos Reis [3-4], it appears that 60025 must be essentially as old as these meteorites, requiring a very old age for the Moon (<30 Myr after CAIs).

In order to determine an internally-consistent Sr model age of lunar formation, we undertake precise Sr isotopic measurements in a comprehensive suite of early Solar System materials in a single laboratory. We also develop a Sr double spike method to distinguish any non-radiogenic isotopic anomalies [e.g., 7,8] and thus further refine our chronology.

Pore scale heterogeneity in the reactive surface area of rocks

ALICIA PARBHOO[1]*, PETER LAI[1,2] AND SAMUEL KREVOR[1,2]

[1]Department of Earth Science & Engineering, Imperial College London, London UK (*correspondence: ap3409@ic.ac.uk)

[2]The Qatar Carbonates and Carbon Storage Research Centre at Imperial College London, London UK

There are major knowledge gaps in the ability to characterize reactive transport in porous media at scales larger than individual pores. This precludes prediction of the field-scale impact of geochemical processes on fluid flow [1]. This is a source of uncertainty for CO_2 injection, which results in a reactive fluid-rock system, particularly in carbonate rock

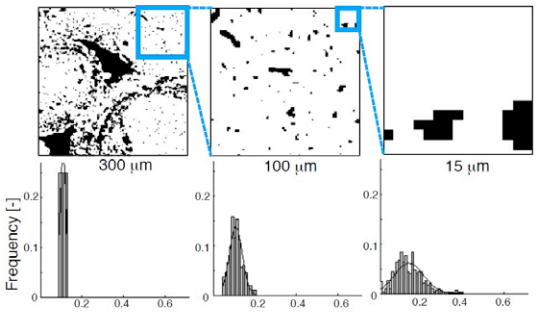

Figure 1: Ratio of surface area to pore volume [m^2/m^3] in an Indiana limestone at various length scales.

reservoirs. A potential cause is the inability of the continuum approach to incorporate the impact of heterogeneity in pore-scale reaction rates. This results in part from pore-scale heterogeneities in surface area of reactive minerals [2,3].

In this study we have created µm resolution 3D images of 3 sandstone and 4 carbonate rocks using x-ray microtomography. Using in-house image processing techniques we quantified the surface area from the images. This quantification was validated against N_2 BET surface area and He porosity measurements of the imaged samples. Distributions in reactive surface area were constructed by calculating surface areas in thousands of randomly selected subvolume images of the total sample (Fig. 1), each normalized to the pore volume in that image. Berea sandstone was far less heterogeneous and has a characteristic pore size at which a surface area distribution may be used to quantify heterogeneity. In carbonates, heterogeneity is more complex and surface area must be characterized at multiple length scales for an accurate description of reactive transport.

Termination and hydration of Forsterite (010) and Diopside (010) surfaces

CHANGYONG PARK AND HONGPING YAN[1]

[1]HPCAT, Geophysical Laboratory, Carnegine Institution of Washington, Argonne, IL 60439, USA, (cpark@ciw.edu)

The hydrous alteration of ultramafic rocks has been paid much attention for its attribution to the abiogenic hydrocarbon generation from crystalline rocks. The molecular processes at the interface of water and those mineral surfaces, however, have not been described. We use in-situ high-resolution X-ray reflectivity to examine the forsterite (010) and diopside (010) surfaces in water. By modelling the electron density profile in the surface normal direction and fitting the measured data with least-square method, the atomic structures of hydrated single crystal surfaces could be depicted. We found, for the forsterite surface polished with alumina colloidal suspension under acidic environment (pH 3.5), a homogeneous termination with about half of the surface magnesium depleted and replaced with possibly a water species. In contrast, the forsterite surface polished with silica colloids under basic condition (pH 9-10) does not show such homogenous surface, but substantial morphological difference from the alumina-polished surface is observed by Atomic Force Microscopy measurement. The difference indicates the importance of solution chemistry to constrain the surface reactivity and dissolution mechanism. On the other hand, the diopside (010) surface is a naturally grown surface, which shows qualitatively identical features in its termination plane and the first adsorbed water electron density profile compared to those of the forsterite (010) surface. This similarity indicates common features in the hydration structure of these mineral surfaces, although the silicate compositions and structures are quite different.

Quantifying trace element distributions in agate banding by LA-ICP-MS

C.-S. PARK[1]*, Y. KIM[2], H. S. SHIN[1], K. YI[1] AND H. OH[1]

[1]Korea Basic Science Institute, Ochang 368-883, Korea (*correspondence: cspark@kbsi.re.kr)

[2]Chungbuk National University, Cheongju 361-763, Korea

Samples

Agates are banded forms of microcrystalline chalcedony often forming spectacular, colorful geodes or veins. Two analyzed agates are characterized by the rhythmic banding of redish and bluish layers, respectively, ranging in width about 50 mm. Boundaries between each layer are well distinguished by the slight contrasting in color. The color of agates can vary with the species and concentration of trace elements. Agates thus can provide direct visual evidence for correlations in concentrations among trace elements and between trace element concentrations and color contrasts.

Analytical methods

X-ray mapping was carried out using a Shimadzu EPMA 1600. Subsequent quantitative mapping was performed using a NewWave 213 nm Nd:YAG laser ablation system attached to a Thermo X2 quadrupole ICP-MS, with instrument settings at 11 J/cm^2 for energy density, 10 Hz repetition rate, 55 μm beam size, 60 μm spacing between adjacent line scans, and 10 μm/s scan speed. The oxidation rate was controlled below 1%. NIST612 glass was used as the external standard, and ^{29}Si as the internal standard, assuming stoichiometric quartz. Data reduction was carried out using Iolite software.

Results

Among 9 trace elements including Al, Ca, Co, Fe, Ti, Cr, Mn, Cu and Ni. Al and Fe are the most abundant, up to ~5000 ppm in red agate and up to ~500 ppm in blue agate, whereas concentrations of other elements are less than 400 ppm. All the quantitative elemental maps except Cr and Ni show that trace elements are concentrated in the boundaries between each layer. Quantitative Al and Fe maps show a harmonious behaviour of Al and Fe in red agate, but an antithetic relationship in blue agate. The Al and Fe distribution patterns in red agate are reproduced in the Al Kα and Fe Kα X-ray maps, but not clear in blue agate. All the above results suggest that quantitative elemental maps using LA-ICP-MS are previleged to visualize trace elements distributions.

Pb and stable Pb isotopes in sediments of the eastern coast of the Yellow Sea

JONG-KYU PARK[1], MAN-SIK CHOI[1], Dongjun Chang[1], Sojeong Park[1] AND DHONG-IL LIM[2]

[1]Chungnam National University, Daejeon, Korea (aska4332@naver.com), (mschoi@cnu.ac.kr), (zzung1009@nate.com)

[2]Korea Institute of Ocean Science and Technology, Geoje, Korea. dlim@kiost.ac

In order to investigate the distribution and sources of Pb in coastal sediments in the Yellow Sea, 88 surface sediments were collected and analysed for Pb concentration (1M HCl leached and residual fractions) and stable Pb isotopes (^{207}Pb/^{206}Pb, ^{208}Pb/^{206}Pb) using MC-ICP-MS.

Leached Pb concentration varied in the range of 3.8-28.8mg/kg (mean 11.3mg/kg) and showed the highest concentration in the fine-grained sediments and seemed to be associated with Fe oxide/hydroxide. Pb concentration in the residual fraction showed 2.6-18.1mg/kg (mean 11.1mg/kg) range and higher concentration in coarse-grained sediments, which indicated that high Pb were resulted from K-feldspar abundant in sand, which were consistent with the previous study[1].

^{207}Pb/^{206}Pb and ^{208}Pb/^{206}Pb varied in the range of 0.844-0.851 and 2.102-2.118, respectively. Pb isotope ratios decreased from the northern part toward the southern part. Based on the ratio-ratio plots and ratio- the inverse of Pb concentration plots, the spatial distribution of isotopes were resposible for the mixing between materials borne from Korean rivers (the Han and Geum)[2] in the northern part, and the mixing between the Geum River borne sediments and offshore sediments [2]in the southern part.

An investigation of transboudary particulate matter over northeast Asia

M. E. PARK[1], C. H. SONG[1]*, R. S. PARK[1], J. LEE[2], S. J. LEE[1] AND J. KIM[3]

[1]School of Environmental Science and Engineering, Gwangju Institute of Science and Technology, Gwangju, Korea (*correspondence: chsong@gist.ac.kr)
[2]Goddard Space Flight Centre, NASA, Greenbelt, MD, USA
[3]Department of Atmospheric Science, Yonsei University, Seoul, Korea

CMAQ modeling was conducted for a period of 1 April to 31 May, 2011, in order to assess the impacts of Long-Range Transport (LRT) events on the particulate matter (PM) concentrations over northeast Asia. Meanwhile, a Korean geostationary satellite, Communication, Ocean, and Meteorological Satellite/Geostationary Ocean Color Imager (COMS/GOCI)-retrieved data were also used in this study to overcome the temporal limitation of the Low Earth Orbit (LEO) satellites. The LEO pass over the region of interest once a day (or several days), although these has been mainly applied to investigate the characteristics of AOD over northeast Asia. The GOCI-retrieved AOD products were obtained through Yonsei aerosol retrieval algorithm and CMAQ model simulations considered dust and biomass burning emissions and their transports. The CMAQ-calculated AOD was then improved by integrating hourly GOCI-retrieved AOD via a data assimilation technique for the purpose of producing more accurate AOD products over northeast Asia. It clearly showed the several long-range transport events of the small- and large-scale AOD plumes from Central East China (CEC) to the Korean peninsula. In addition, according to statistical analysis of the assimilated AOD for the LRT and non-LRT events at five AERONET sites, the average AOD increased by LRT events was found to be 0.40 above the background AOD value of 0.24.

Contribution of ammonium nitrate to aerosol optical depth and direct radiative forcing by aerosols over East Asia

RAE S. PARK, SO J. LEE, SUNG-K. SHIN AND CHUL H. SONG*

School of Environmental Science and Engineering, Gwangju Institute of Science and Technology (GIST), Gwangju, 500-712, Korea (rspark28@gmail.com, *correspodence to chsong@gist.ac.kr)

This study focused on the contribution of ammonium nitrate (NH_4NO_3) to aerosol optical depth (AOD) and direct radiative forcing (DRF) by aerosols over an East Asian domain. In order to evaluate the contribution, CTM-estimated AOD was combined with satellite-retrieved AOD, utilizing a data assimilation technique, over East Asia for the entire year of 2006. Using the assimilated AOD and CTM-estimated aerosol optical properties, the DRF by aerosols was estimated over East Asia via a radiative transfer model (RTM). Both assimilated AOD and estimated DRF values showed relatively good agreements with AOD and DRF by aerosols from AERONET. Based on these results, the contributions of NH_4NO_3 to AOD and DRF by aerosols (Φ_{AOD} and Φ_{DRF}) were estimated for four seasons of 2006 over East Asia. Both Φ_{AOD} and Φ_{DRF} showed seasonal variations over East Asia within the ranges between 4.7% (summer) and 31.3% (winter) and between 4.7% (summer) and 30.7% (winter), respectively, showing annual average contributions of 15.6% and 15.3%. However, these contributions can be even larger in the locations where NH_3 and NO_x emission rates are strong like the Central East China (CEC) region and Sichuan basin. For example, both Φ_{AOD} and Φ_{DRF} over the CEC region range between 6.9% (summer) and 47.9% (winter) and between 6.7% (summer) and 47.5% (winter), respectively. Based on this analysis, it was concluded that both Φ_{AOD} and Φ_{DRF} cannot be ignored in East Asian air quality and radiative forcing studies, particularly during winter.

Tracking changes in ocean redox during the PETM using Cr isotopes

I.J. PARKINSON*[1,2], S.K. DIXON[2], P. SEXTON[2], M.A. FEHR[2], R.H. JAMES[3] AND C.L. PEACOCK[4]

[1]School of Earth Sciences, University of Bristol, BS8 1RJ, UK. (*correspondence: Ian.Parkinson@bristol.ac.uk)
[2]Department of Environment, Earth and Ecosystems, The Open University, MK7 6AA, UK.
[3]School of Earth and Environment, University of Leeds, LS2 9JT, UK.
[4]Marine Geosciences, National Oceanography Centre, Southampton, SO14 3ZH, UK.

Previous deoxygenation events in the geological record may provide insight into the dynamics of changing oxygen levels in the Earth's oceans already underway[1]. The Palaeocene-Eocene Thermal Maximum (PETM) at ~55Ma is a ~150 kyr period of intense global warming with evidence for at least local-scale, ocean oxygen depletion[2,3]. To track seawater oxygenation during the PETM, we use the stable Cr isotope composition of marine carbonates, a new palaeo-redox proxy, which hasshown potential when applied to modern and ancient carbonates [4,5].

Here we present δ^{53}Cr, trace element and REE data of foraminifera through the PETM interval from DSDP Site 401 (North East Atlantic), hosting exceptionally well-preserved foraminifera. ~150 mg of foraminifera were taken from the 63-150μm size fraction and species count data indicate that the relative proportions of dominant species do not change significantly over the event[6]. Systematic changes occur in Cr concentration and δ^{53}Cr throughout the event with a positive δ^{53}Cr excursion of 1.7‰ coincident with the onset of the negative δ^{13}C excursion. This reflects an increased reduction of Cr(VI) and thus a change to more reducing conditions in the water column at the onset of the event. Chromium concentrations of the foraminifera decrease leading into the PETM, and do not recover, indicating either a reduction in seawater Cr concentrations, a change or a change in Cr geochemical cycling during the event.

New Zircon U-Pb and Hf-isotope data of the Birimian Terrane of the West African craton

LUIS A. PARRA[1]*, MARCO L. FIORENTINI[1], ELENA BELOUSOVA[2], ANTHONY I. S. KEMP[1], JOHN MILLER[1], T. CAMPBELL MCCUAIG[1] AND NURU SAID[1]

[1]Centre for Exploration Targeting, ARC Centre of Excellence for Core to Crust Fluid Systems, School of Earth and Environment, The University of Western Australia., Perth, WA, Australia. (*Correspondance:20835812@student.uwa.edu.au)
[2]ARC National Key Centre for Geochemical Evolution and Metalogeny of Continents, ARC Centre of Excellence for Core to Crust Fluid Systems, Department of Earth and Planetary Sciences, Macquarie University NSW, Australia.

In order to explore whether the West African Craton was formed by the accreation of Archean terranes [1], zircons from 22 igneous rocks collected from across SW Mali and Burkina Faso were recently dated using SHRIMP and analysed for in-situ Lu-Hf isotopes by laser ablation MC-ICPMS. The SHRIMP ages for the samples range from 2195 Ma to 2074 Ma. The intrusion ages suggest two domains: (1) SW Mali where the dated samples range between 2130-2074 Ma; and (2) Burkina Faso with ages between 2195-2100 Ma.

The εHf in zircons at the inferred emplacement age ranges between 0 and 7.5. Three εHf groups can be broadly correlated with age groups: (1) εHf<3, ages 2130-2074Ma; (2) 3<εHf<5, ages 2170-2115 Ma; and (3) εHf> 5, with ages 2195-2140 Ma. Combined, the U-Pb and Hf isotope data define two major periods: (1) an alternation between increasing and decreasing Hf values with decreasing U-Pb ages between 2195-2140 Ma; this reflects periods of addition of juvenile magmas and reworking of slightly older crustal material; and (2) falling Hf values with decreasing U-Pb ages 2140-2074 Ma. Slightly higher εHf values are observed towards the end of this period. These trends imply the dominance of reworking of slightly older crustal material.

This new insight into the architecture and evolution of the WAC suggests that the craton was formed mainly by the assembly of juvenile material with sporadic episodes of reworking. This conclusion, along with that of a study conducted in the northern portion of the craton [2], helps to constrain the poorly understood tectonic history of the Birimian period of West Africa.

In situ U-Pb dating of carbonate by LA-ICP-(MC)-MS and ID-TIMS

R.R. PARRISH[1], M. HORSTWOOD[2], W AUSTIN-GIDDINGS[3], N.M.W. ROBERTS[4], D. CONDON[5] AND T.RASBURY[6]

An easily applicable method to provide absolute age constraints in carbonate has proved elusive except in unusually favourable materials. U-Pb dating of carbonate has so far been restricted to ID-TIMS methods that involve analysis of larger volumes. Unfortunately there is currently no a priori way to know if a sample has a viable U/Pb ratio, and many carbonates are not datable. The challenge is to find a rapid method to date materials in situ by identifying suitable materials (low common Pb, >0.3ppm U), finding the higher-U and highly radiogenic subzones zones that are key to precise ages, so that a substantial robust age on material can be put in a sedimentary or other geological context. Materials of interest include calcite veins in structurally relevant fractures, cements, diagenetic calcite, primary biogenic carbonate, speleothems, lake sediments, tufas and paleosols, etc.

We have successfully adapted LA-ICP-(MC)-MS zircon methods by using a well characterized 254±6 Ma (95% confidence) calcite standard (dated by ID-TIMS at NIGL and Stony Brook) to correct the measured U/Pb ratio for matrix effects. This approach allows in situ U-Pb dating with uncertainties as little as ±4% at 95% confidence with minimal sample consumption, supplemented by ID-TIMS data as appropriate. We have dated samples with average uranium concentrations (0.4-5 ppm) such as speleothems, paleosols, tufa, marine cements (in ammonite chambers), calcite veins from fractures etc. The age of dated materials is as young as 250ky, the latter U-Pb dates agreeing with U-series dating after correcting for U activity. For Quaternary materials beyond the range of U-series, we measure residual disequilibrium of U to make corrections for initial U activity ≠ 1. We have found that our LA-ICP-MS in situ method has distinct advantages over ID-TIMS in its sub-sampling power. Examples of these applications will be presented. This new area of geochronology is likely to grow rapidly in the future.

Long-term residual alteration rates of synthetic basaltic glass

B. PARRUZOT*, P. JOLLIVET AND S. GIN

CEA Marcoule, DEN/DTCD/SECM/LCLT, BP 17171, 30207 Bagnols sur Cèze CEDEX, France.
(*correspondence: benjamin.parruzot@cea.fr)

Laboratory measured residual rates

Basaltic glasses are considered as good analogues to nuclear glasses [1]. However, if forward alteration rates and mechanisms are well-known [2], long-term alteration rates need to be determined in order to deepen this analogy.

We performed batch experiments at high surface-to-volume ratio (high reaction progress) on a Li- or B-doped synthetic tholeiitic basaltic glass at 90°C and 30°C during 1000 days. After 182 days, the rates did not evolve significantly. When considered constant with respect to time, the mean residual rates were 1.2×10^{-5} $g.m^{-2}.d^{-1}$ and 3.9×10^{-6} $g.m^{-2}.d^{-1}$ at 90°C and 30°C, respectively.

The alteration layer was a dense amorphous gel in which some crystalline clayey sheets may be found. Its porosity was sufficient to allow water and Si to pass through. At the alteration layer/solution interface, low density poorly crystalline clays had precipitated.

Comparison to naturally altered samples

The measured alteration rates indicate a drop of 4 to 5 orders of magnitude when compared to forward alteration rate and 1 order of magnitude inferior to the rates at higher progress of reaction reported by Técher *et al* [3]. This is 10 times higher than the drop between initial and residual rates observed on the SON68 nuclear glass [4].

These values were extrapolated both in temperature (to 5°C with an Arrhenius law) and in time resulting in a value comprised between 0.1 and 0.6 $\mu m/10^3$ y. This result is comparable to naturally altered samples showing a similar alteration layer (i.e. non-zeolitized samples) whose alteration rate is comprised between 0.1 and 10 $\mu m/10^3$ y [3].

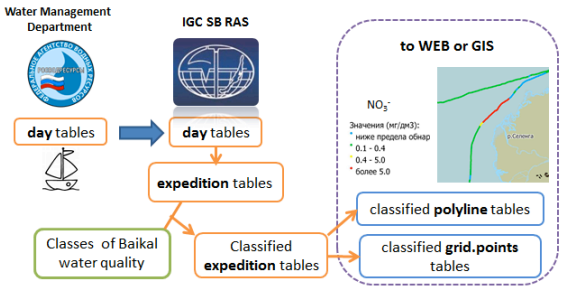
Spatial database for the hydrochemical monitoring of Lake Baikal

A. PARSHIN, S. SHESTAKOV AND K. CHUDNENKO

Vinogradov Institute of Geochemistry SB RAS, Russia. (correspondence: sarhin@geo.istu.edu)

Lake Baikal is a unique geosystem requiring its preservation in its original form. Since 1965, environmental monitoring of Baikal water is based on researching physical and chemical parameters. Currently used two types of sensors: ship-based measurement systems and analysis of water samples in chemical laboratories. To solve the problems of environmental control, the investigators from IGC SB RAS in cooperation with specialists of Russian Water Management developed a distributed spatial database, to provide the task of collecting, storing, analyzing, interpreting and reporting monitoring data.



In the ship-based part of the database is stored the information coming from the chemical analyzers. This data aggregates with the coordinates in the tables "day", which are transmitted to the data center IGC SB RAS. "Day" tables forms the "expedition" tables. After that, the data is subjected to automatic classification based on the tables of regional classes of water quality "background concentrations-MPC" [1]. Classes are the result of specialized four-year study of Lake Baikal hydrochemistry.

Collected database currently contains more than 2.5 million georeferenced sampling points. For fast display of such data on the web and GIS interfaces require additional treatment. Geodata are transformed into two types of tables: the point of sampling, calculated on the regular network, and sample profiles presented in the form of classified polylines. These tables are linked to the thematic geoportals intended for informing involved agencies, interested professionals and ordinary citizens.

Geologic carbon storage (GCS) in saline formations may induce increased dissolution of many metals including arsenic from reservoir rock minerals and from caprock and overlying rock minerals, in case of leakage of CO_2 or CO_2-saturated brine. Preliminary experiments on metal mobilization on carbonate rocks upon contact with CO_2-saturated brine have indicated arsenic release in excess of the U.S. EPA standards for drinking water. The most common sources of arsenic in sedimentary geologic formations are arsenopyrite (FeAsS) and arsenian pyrite. This study aims to determinine the maximum long-term dissolution rates of arsenopyrite under a range of conditions representative of deep and shallow geologic formations. For this purpose, a small-scale flow-through system was developed and used to simulate the dissolution of arsenopyrite under a wide range of temperature, pressure and solution chemistry conditions. The effects of flow rate, pressure and different oxidants on arsenopyrite were separately tested. The dissolution studies focused on determining the mineral dissolution rate based on total As release with the system at steady state operation. However, measurements of Fe and S were also collected for comparison with previous studies. The dissolution rate computed from steady state As concentrations resulting from reaction of the mineral with 10^{-4} M Fe^{3+} as oxidizing agent at ambient conditions was $10^{-8.3}$ mol/m^2s, which is comparable to reported rates of arsenopyrite dissolution rates under similar conditions. Ongoing dissolution experiments with CO_2-saturated NaCl solution at high pressure and temperature show the effect of CO_2 and brine on the release of As.

Dissolution of geologically stored CO_2 in brines of saline geologic formations may lead to a change in pH and brine composition which may subsequently increase the dissolution rates of reservoir and cap rocks. Dissolution of minerals induces the release of various metals that may participate in subsequent dissolution and precipitation reactions, and that may be of concern if reacted formation fluids migrate out of the target storage zone. The objective of this study is to study the release of As and Fe, present in the reservoir and cap rocks of the Lower Tuscaloosa reservoir. XANES analysis of the samples indicated a relationship between As and Fe in these samples. To assess the potential release of As and Fe, and to measure the effect of CO_2 on their release rates, dissolution experiments were conducted with caprock and reservoir rock samples obtained at different depths. The dissolution was studied at representative conditions of the reservoir (i.e. 60 °C, 100 bars, synthetic brine of 1.4M NaCl) utlizing a small-scale flow-through system. The dissolution was conducted with deoxygenated 1.4M NaCl solution for 10 hours prior to CO_2 injection into the NaCl solution. The solution chemistry was defined pre- and post-CO_2 injection by ICP-MS analysis. Accordingly, rock samples were analyzed pre- and post-CO_2 injection by XRD and SEM. Preliminary dissolution experiments showed that upon CO_2 injection, rates of metal release increased significantly before reaching a new equilibrium (Figure 1).

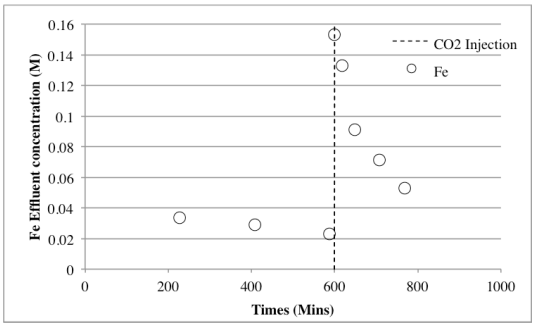

Figure 1. Effluent Fe concentration (M) with time at T=60 °C, P= 100 bar with 1.4 M NaCl. CO_2 injection after 10 hours.

Filling in the juvenile magmatic gap: evidence for continued Paleoproterozoic plate tectonics during the Great Oxidation Event

C.A. PARTIN[1]*, A. BEKKER[1], P.J. SYLVESTER[2], N. WODICKA[3], R.A. STERN[4], T. CHACKO[5] AND L.M. HEAMAN[5]

Despite several decades of research on the growth of the continental crust, it remains unclear whether the production of juvenile continental crust has been continuous or episodic in the early Precambrian. Models for episodic crustal growth have gained traction recently through compilations of global U-Pb zircon age abundance spectra interpreted to delineate peaks and lulls in crustal growth through geologic time. One such apparent trough in zircon age abundance spectra between ~2.45 and 2.22 Ga is thought to represent a pause in crustal addition, resulting from a global shutdown of magmatic and tectonic processes [1]. The ~2.45 - 2.22 Ga magmatic shutdown model envisions a causal relationship between the cessation of tectonism and accumulation of atmospheric oxygen over the same period. Here, we present new coupled U-Pb, Hf, and O isotope data for detrital and magmatic zircon from the western Churchill Province and Trans-Hudson internides of Canada, covering an area of approximately 1.3 million km^2, that demonstrate significant juvenile crustal production during the ~230 million-year interval, and thereby argue against the magmatic shutdown hypothesis. Uninterrupted plate tectonics between ~2.45 and 2.22 Ga would have contributed to efficient burial of pyrite and organic matter and the consequent rise in atmospheric oxygen documented for this time interval.

Microthermometric and Raman analysis of fluids that interacted with variably graphitic pelitic schist in the Dufferin Lake zone, south-central Athabasca Basin: Implications for graphite loss and uranium deposition

MARJOLAINE PASCAL[1]*, KEVIN ANSDELL[1], IRVINE R. ANNESLEY[1], MARIE-CHRISTINE BOIRON[2], TOM KOTZER[3], DAN JIRICKA[4] AND MICHEL CUNEY[2]

[1]University of Saskatchewan, Saskatoon, Canada, (* presenting author: mjp313@mail.usask.ca, kevin.ansdell@usask.ca, ira953@mail.usask.ca)
[2]Georessources, Vandoeuvre-lès-Nancy, France, (marie-christine.boiron@univ-lorraine.fr, michel.cuney@univ-lorraine.fr)
[3]Cameco Corporation, Saskatoon, Canada, (Tom_Kotzer@cameco.com)
[4]D.E Jiricka Enterprises, (djiricka@sasktel.net)

The Athabasca Basin (Canada) contains the highest grade unconformity-type uranium deposits in the world. Underlying the sedimentary rocks of the basin in the Dufferin Lake zone are variably graphitic pelitic schists; altered to chlorite and hematite, and locally bleached near the unconformity (Red/Green Zone: RGZ) during paleoweathering or later fluid interaction.

Fluid inclusions (FI) were examined in quartz veins, using microthermometry and Raman analysis, to characterize and compare the different fluids that have interacted with the RGZ and the graphitic pelitic schist. The inclusions appear to be secondary, which is compatible with quartz veins from deformation zones.

Monophase vapor are the dominant type of FI in the graphitic pelitic schist, whereas aqueous two-phase (L+V) and three-phase (L+V+Halite) FI occur in the RGZ. The temperature of ice melting of aqueous fluid inclusions from the RGZ are between -23 and -26°C, which suggests a salinity of 34wt% using the H_2O-NaCl-$CaCl_2$ system. The temperature of homogenization (TH) varies mainly between 90 and 170°C. The temperature of dissolution of halite (190-200°C and 210-220°C) yields a salinity of about 32wt% eq. NaCl for the paleofluid. In the graphitic pelitic schist, all FI homogenize into the vapor phase. The CH_4 dominant fluid has a TH between -81 and -74°C. The N_2 dominant fluid has a TH between -152 and -100°C. Some contain CO_2 and traces of H_2S. The aqueous fluid is interpreted to be the regional basinal fluid. The monophase vapor FI could be the break down of graphite to CH_4 and associated feldspars/micas to NH_4 and N_2; three possible reductants for uranium mineralization.

Zn-Pb-Fe sulfide formation in Grieves Siding peat, Tasmania

R. PASCUAL[1]*, V. KAMENETSKY[1], K. GOEMANN[2], T. NOBLE[1] AND N. ALLEN[3]

[1]School of Earth Sciences and CODES, University of Tasmania, Hobart, Tasmania 7001 (*correspondence: Richelle.Pascual@utas.edu.au)
[2]Central Science Laboratory, University of Tasmania, Hobart, Tasmania 7001
[3]14 Station Lane, Exton, Tasmania

Aqueous aluminosilicate colloids in mineral formation had been studied in hydrothermal systems, but little is known in low temperature environments. The Grieves Siding Zn-Pb rich peat was investigated to understand the role of organic matter and colloids in the transport and formation of metal-bearing minerals at ambient conditions. The peat samples revealed pronounced enrichment in Zn (up to 28.6 wt%), Pb (up to 3.8 wt%) and other metals. Highly unusual assemblages of sulfides, carbonates, phosphates, oxides, sulfates, silicates, native metals and inorganic carbon were identified in addition to the ubiquitous organics. Dominant sulfide is ZnS with minor PbS and FeS_2. ZnS commonly exhibits colloform texture appearing like schalenblende at smaller scale. The banded ZnS incorporates O (up to 18.5 wt%), Al (up to 4 wt%) and Pb (up to 2.3 wt%), as well as minor (<0.5 wt%) Si, Cd, Fe, As, Ag, and Ni. Carbon is also present. The banding indicate variability in the distribution of Al, O and occasionally C, relative to Zn and S. Dark bands corresponds to an elevated concentration of Al, O and C whereas light bands are linked to diminishing abundance of Al-O-C and prevalence of Zn-S. Sulfate reduction by bacterial action is implicated in the formation of the sulfides. Metal-rich aqueous aluminosilicate colloid precursor to colloform ZnS is possibly produced from the bioweathering of silicates. Organics may also have participated in the transport, deposition and retention of the metals in the peat.

Thermogenic hydrocarbons in Mid Ocean serpentinites

V. PASINI[12]; D. BRUNELLI[13] AND B. MÉNEZ[2]

[1]Università di Modena e Reggio Emilia, L.go St. Eufemia 19, 41100 Modena, Italy.
[2]Institut de Physique du Globe de Paris, 1, rue Jussieu - 75238 Paris cedex 05, France
[3]Istituto di Scienze del Mare – CNR, Via Gobetti 101, 49100 Bologna, Italy

The progressive hydration of mantle-derived peridotites is known to support deep microbial ecosystems unrelated to photosynthesis. Relics of endogenic, microbiologically-driven, carbon accumulations have been recently discovered strictly associated to hydrogarnet minerals in serpentinized rocks coming from the MAR 4-6 °N region [1]. The presence of this colonization suggests that the serpentinization byproducts can constitute a valuable source of carbon and metabolic energy for microorganisms held deep in the oceanic lithosphere. We have decided to re-investigate the recently described relics of deep microbial ecosystems to study its fate through ageing and thermal degradation. A set of high resolution micro-imaging techniques (HRTEM, Raman and Fourier-transform infrared microspectroscopy, and STXM at the carbon K-edge) have been applied to characterize the organic carbon speciation and its spatial distribution at the micrometer scale. Our data show that the biologically derived organic matter colocalized with the hydrogarnets has experienced thermal degradation and aromatization while a light fraction constiting of C_6-C_{10} aliphatic compounds associated to carboxylic functional groups wet the surrounding bastite and the late vein network.
Ecosystem-hosting serpentinites can thus be seen as source rocks generating deep thermogenic hydrocarbons which then migrate upward and mix with the complex pool of organic compounds discharged at hydrothermal vents.
This work shows how a combination of complex biological and geochemical processes contribute to the hydrothermal carbon cycle at Mid Ocean Ridges.

Novel Method for Compound Specific Stable Isotope Analysis of contaminated groundwater across the sediment-water interface

ELODIE PASSEPORT[1], KATRINA CHU[1], GEORGES LACRAMPE COULOUME[1], RICHARD LANDIS[2], EDWARD J. LUTZ[2], E. ERIN MACK[2], KATHRYN WEST[3], AND BARBARA SHERWOOD LOLLAR[1]

[1]Dept. of Earth Sciences, University of Toronto, 22 Russell Street, Toronto, ON M5S 3B1, Canada
[2]Dupont Corporate Remediation Group, Glasgow 300, Newark DE 19714-6300, USA
[3]URS Group, Newark DE 19714-6300, USA

Chlorinated benzenes are toxic contaminants frequently identified in groundwater. Because a variety of bacteria are able to conduct reductive dehalogenation of these compounds, Monitored Natural Attenuation (MNA) is a potentially effective technique for groundwater remediation. Here, we evaluate the potential for Compound Specific Isotope Analysis (CSIA) to detect *in situ* biodegradation of chlorinated benzenes in a historically contaminated site. Groundwater samples were collected during three sampling campaigns in 2009 and 2012 along a contaminant plume that discharged to surface water until a sheet pile barrier was installed in December 2008 and controlled the release. A passive sampling "peeper" method for conducting microscale CSIA sampling at the groundwater - sediment pore water interface, was also tested for its suitability for CSIA.

In the highest concentration zone, the most ^{13}C-depleted carbon isotopic signatures for dichlorobenzenes (DCBs) and 1,2,4-trichlorobenzene (1,2,4-TCB) were measured ranging from -32.4 ± 0.5‰ to -29.6 ± 0.5‰. Downgradient of the plume, moderate (2 to 4 ‰, 1,4-DCB and 1,2,4-TCB) to large (10 ‰, 1,2-DCB) enrichments in the heavy stable carbon isotope were observed with values as enriched as -27.9 ± 0.5‰ (1,4-DCB), -20.5 ± 0.5‰ (1,2-DCB), and -28.2 ± 0.5‰ (1,2,4-TCB) in 2009. A similar trend was confirmed in 2012. The most enriched values were measured close to the groundwater / sediment pore water interface where high microbial activity may have been responsible for biodegradation. A novel method for sampling for CSIA via peeper diffusion sampler with a polysulfone membrane showed promise for collecting chlorinated benzene-bearing water samples without significantly affecting contaminant isotope signatures. This new approach will be used to extend the current field investigation by measuring CSIA trends at a fine spatial resolution across the sediment - pore water interface.

Triple oxygen isotope compositions of late Cretaceous dinosaur eggshells and implications for atmospheric carbon dioxide

BENJAMIN H. PASSEY[1]*, HUANTING HU[1], SHAENA MONTANARI[2], SHUNING LI[1] AND NAOMI E. LEVIN[1]

[1]Johns Hopkins University, Department of Earth and Planetary Sciences, Baltimore, MD 21218, USA
[2]American Museum of Natural History, Sackler Institute for Comparative Genomics, New York, NY 10024, USA
*(correspondence: bhpassey@jhu.edu)

It has recently been proposed that the triple oxygen isotope composition of minerals that incorporate oxygen from atmospheric O_2 is related to atmospheric carbon dioxide levels [1,2]. The mechanism is mass independent transfer of ^{17}O and ^{18}O from O_2 to O_3 and CO_2 during photochemical reactions in the stratosphere, leading to negative $\Delta^{17}O(O_2)$ values, and positive $\Delta^{17}O(O_3)$ and $\Delta^{17}O(CO_2)$. The effect is enhanced by the carbon cycle: the residence time of O in the CO_2 reservoir is far shorter than that of O in the O_2 reservior, leading to preferential sequestration of positive $\Delta^{17}O(CO_2)$ anomaly to the biosphere + hydrosphere, and hence buildup of negative $\Delta^{17}O(O_2)$ anomaly in the atmosphere. This effect increases with increasing atmospheric CO_2 concentration.

Biominerals forming in equilibrium with body water sample the atmospheric $\Delta^{17}O(O_2)$ signal owing to metabolism ($CH_2O + O_2 \rightarrow CO_2 + H_2O$) [2]. We have developed a method that allows for high precision measurement (±0.02‰ 1σ) of $\Delta^{17}O$ of CO_2 (and hence $CaCO_3$, including eggshell) using a scheme where O in CO_2 is converted to O in H_2O by reduction with H_2. The H_2O is then fluorinated to yield O_2 suitable for mass spectrometry. We apply the method to late Cretaceous (Campanian and early Maastrictian) dinosaur eggshell from Mongolia [3], as well as modern ostrich eggshell. The $\Delta^{17}O$ values of CO_2 extracted from dinosaur eggshell, ~ -0.15 to -0.27‰ (relative to $\lambda = 0.528$), are similar to the observed range for modern ostrich (~ -0.21 to -0.25‰), suggesting that atmospheric CO_2 levels, or operation of the global carbon cycle and stratospheric photochemistry, or both, were not drastically different during the late Cretaceous compared to today. This generally agrees with results from the paleosol carbonate CO_2 barometer [4] and carbon cycle models [5].

Determination of probabilistic Kd values for radionuclides in French rivers using a speciation code

L. MARANG (1), P. CIFFROY(1), AND L.PASTOR(1)

(1) EDF, Division Recherche et Développement, Département Laboratoire National d'Hydraulique et Environnement, 6 quai Watier, 78401 Chatou, France (Lucie.pastor@edf.fr)

Environmental risk assessment of radionuclides (RN) depends to a great extent on modelling their fate and mobility based on solid-liquid partition coefficient (Kd). To take into account the variability of many environmental factors that influence the Kd value (pH, nature of particles…), Kd can be expressed as a probability density function (PDF). Several databases containing Kd values have been referenced and a weighted bootstrapping procedure was set up in order to built PDF for environmental conditions. However the relevance and robustness of PDF depends on the number of Kd values in the database. Also, different values of Kd can be used for a specific RN at a specific site (depending on the database used), which can indeed lead to major differences in the results.

The objective of this study is to define a new methodology to calculate site specific Kd values for French rivers. This is particularly interesting when a limited number of Kd value is available in the literature (chromium and nickel for instance). This method is based on a predictive chemical speciation calculation. So far, multi-linear regression models were favoured to predict Kd values. The observed field-based partition coefficient can be counter-intuitive because of the competiting roles played by the solid and dissolved organic matter. Recently, new models have become available that can adequately describe metal ion binding to DOC, POC, clays and oxides: the NICA-isotherms [1], the CD-Music model. These new models have been shown to give good predictions of the behaviour of contaminants even in heterogeneous systems characteristics of the natural environment.

To validate this approach, *in-situ* experiments will be conducted as part of the COPA project (funded by NEEDS Environnement), focussing on the major RN released by the French nuclear power plants (NPP) (^{110m}Ag ,^{58}Co, ^{60}Co, ^{54}Mn, ^{63}Ni, ^{134}Cs, ^{137}Cs, ^{125}Sb). First, a steady-state approach will consist in studying the suspended particulate matter and the dissolved fractions collected at the SORA station on the Rhône River (France) since 2005 to extract annual averages or change in comportment during hydrological events (floods, low water periods, controlled released by NPP). Then, a specific and planned release from a NPP will be studied to better assess the non steady-state behaviour of a chosen RN through time and distance from the source.

The detailed methodology as well as preliminary results will be presented here.

Extraterrestrial mechanism of kimberlite emplacement

MARIUSZ PASZKOWSKI[1] AND JERZY W. MIETELSKI[2]

[1]Institute of Geological Sciences PAN, Senacka 1, Kraków, Poland, ndpaszko@cyf-kr.edu.pl
[2]Institute of Nuclear Physics PAN, Radzikowskiego 152, Kraków, Poland, jerzy.mietelski@ifj.edu.pl

The most popular model of kimberlite formation combines "magma needle" concept with massive degassing which is suppose to form extremely narrow and long pipe which is then filled up with kimberlite matter originating from the mantle and some xenoliths dropped into formed vain from the surface. This class of models left some researchers unconvinced. The pipe must be formed rather rapidly, otherwise it will be blocked in the deep rocks due to high pressure there, moreover there will not be diamonds presents since in slow decompression they will go into graphite. The energy which form the pipe in thermodynamic process must be also dispersed. Thus some other models are formed which includes explosion of reactive gases or electrical force as an additional factor, including near passage of extraterrestrial charged body. We propose another concept: the kimberlite pipe is formed by an impact of small, macroscopic, ultra dense object which existence was proposed in 1984 as a kind of dark matter. Such objects can be present in jets of accretion discs of a black hole and originate from destruction of neutron star during its impact onto black hole or are remains from Big Bang era. The 1 mm^3 volume of such matter can have mass of 10^5t . If it has speed of 400 km/s the kinetic energy is $8*10^{21}$J. On the other hand, the energy which is needed to heat up a 1 m^2 surface tunnel across whole globe to the temperature of about 1 million K is on the order of magnitude of 10^{20}J. This shows that such ultra dense object may have enough kinetic energy to cross whole globe. At such speeds crossing will take several seconds. The shock wave will heat up the formed plasma tunnel but the degassing will remove all materials from it leaving relatively cold straight vain which can be filled by mantle material and xenoliths. We propose that reality of such scenario can be verified by measurements of the isotopic abundances of the elements in the walls of kimberlite on the side of country (host) rock: the neutrons produced from nuclear reactions during whole process will influence the isotopic abundances, and this influence will decrease with the distance from the center of the pipe. Therefore we propose undertaking of such isotopic studies outside the kimberlite pipes in host rocks.

The stable isotopic composition of carbon monoxide from Greenland firn air samples collected at NEEM

CO plays an important role in tropospheric chemistry. Precise measurement of its isotopic composition from the past is useful in constraining individual source and sink processes and thus its global cycle. High volume air samples from the NEEM EU 2008 S4 & NEEM 2009 S2 boreholes were measured for mole fractions, $\delta^{13}C$ and $\delta^{18}O$ of CO on a continuous-flow isotope ratio mass spectrometric (CF-IRMS) system. This system extracts the CO from the air sample (100 mL-200 mL of air required), converts the CO to CO_2 using Schütze reagent and transfers the CO_2 (derived from CO) via an open-split to the IRMS for isotope analysis. The results are qualitatively similar to the ones published in Wang *et al* [1] but also show differences that will be investigated by firn modelling.

Plio-Pleistocene alkaline basalts have brought upper mantle xenoliths to the surface at five different locations within the Carpathian-Pannonian region.

After a thorough sampling and detailed petrographic examination, in addition to the dominant lherzolite xenoliths, several wehrlite xenoliths were recognized that show unique modal composition and textural characteristics. Based on the major element geochemistry of the rock-forming minerals, significant Fe and Mn enrichment in olivines, Ti, Al and Fe enrichment in clinopyroxenes, and Fe and Ti enrichment in spinels was observed compared to compositions of common lherzolite xenoliths.

Many silicate and sulfide melt inclusions were observed in the clinopyroxene and olivine from the wehrlite xenoliths. The sulfide mineralogy was consistent with other sulfides found in the upper mantle, however, sulfides in these wehrlite xenoliths show higher Fe and lower Cu concentrations relative to the lherzolite hosted sulfides.

Five representative wehrlite xenoliths from different localities have been selected for a detailed silicate melt inclusion analysis using LA-ICP-MS. The results show an incompatible element enrichment compared to the host mineral, especially in LIL elements (e.g. Ba, Sr, Pb) and in HFS elements (e.g. Th, U, Nb, Ta, Zr, and Ti).

Based on this detailed study, wehrlite xenoliths are interpreted to be products of a process called stealth mantle metasomatism, whereby the metasomatizing agent is a mafic melt with high MgO/FeO ratio, which is different from the host alkaline basalt.

Resolving s- and r-process presolar carriers using Ba-isotope anomalies in FUN CAIs, bulk meteorite samples, and Ivuna acid leaches

C. PATON*, M. SCHILLER AND M. BIZZARRO

Centre for Star and Planet Formation, Natural History Museum of Denmark, University of Copenhagen, Copenhagen DK-1350 Denmark (*Correspondence: chadpaton@gmail.com)

Resolvable nucleosynthetic anomalies are well documented for a number of nuclides (e.g., ^{54}Cr, ^{26}Al; ^{84}Sr; [1,2,3]). Remarkably, correlations exist between a number of these nuclides [1,2], despite originating from different stellar sources and being hosted in multiple presolar carriers. Such correlations are most readily explained by one of two contrasting processes: Variability due to incomplete mixing of differing components, either because of a late injection of anomalous material [4] or physical differences such as grainsize; or alternatively a process that unmixed carriers in a previously homogenised disk (e.g., thermal processing) [1]. Understanding the cause of these correlations is thus a necessary step in deciphering the information they preserve.

We have developed protocols for high-precision Ba-isotope measurement on a Triton thermal ionisation mass spectrometer. Barium has the advantage of having pure p-process (130 and 132), pure s-process (134 and 136), and mixed s- and r-process isotopes (135, 137, 138). By using protocols that allow measurement of the p-process isotopes (despite their very low abundances), we are thus able to identify distinct s- and r-process carriers.

Results from an acid-leach of the Ivuna CI chondrite and two newly measured FUN CAIs (KT-1 and STP-1) allow us to clearly distinguish separate s- and r-process carriers. Our leaching experiment indicates an acid resistant host for the s-process (presumably SiC), whereas the r-process carrier is not resolved by leaching, suggesting parent-body alteration of the original carrier. Despite these physical differences, our FUN CAI data indicate an absence of both carriers, which is difficult to reconcile with a late injection scenario. In combination with data from "canonical" CAIs and chondrites it can be shown that these two carriers behaved independently during early solar system formation.

Deepwater Horizon spill effects on fish otoliths by LA-ICP-MS

W. PATTERSON III[1] K. MCLACHLIN[2] R.W. HUTCHINSON [3A] AND C.J.P O'CONNOR[1]

[1]University of South Alabama and Dauphin Island Sea Lab, 101 Bienville Bvld, Dauphin Island AL 36528
[2]ESI Inc, 685 Old Buffalo Trail, Bozeman MT 59718 (mclachlink@esi.com)
[3]ESI Europe LTD, 8 Avero Court, Ermine Business Park, Huntingdon Cambridgeshire PE296SX

The Deepwater Horizon oil spill that occurred in 2010 released an estimated 4.9 million barrels of oil into the Gulf of Mexico. This study uses laser ablation mass spectrometry (LA-ICP-MS) to measure the effects on the otoliths of multiple populations and species affected by the spill to different degrees. Otoliths are often used as ecological markers due to their fast speed of growth, which makes them sensitive to environmental changes.

LA-ICP-MS offers a precise means of directly measuring elemental heterogeneity across a sample that is impossible with aqueous methods. This study utilizes an XYR shutter to further increase the spatial resolution. A NWR193 laser ablation system fitted with a fast washout TruLine cell and attached to an Agilent 7700s is used to track elemental tracers such as V and Ni from the oil through the otolith to determine how the oil was incorporated and test for earlier exposures.

Reactive transport modeling to assess geological CO_2 storage via mineral carbonation in peridotite

AMELIA PAUKERT[1]*, JUERG MATTER[1,2], PETER KELEMEN[1] AND ERIC SONNENTHAL[3]

[1]Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, USA (* apaukert@ldeo.columbia.edu)
[2]Ocean and Earth Science, National Oceanography Centre Southampton, University of Southampton, UK
[3]Earth Science Division, Lawrence Berkeley National Lab, Berkeley, CA, USA

In situ mineral carbonation is a mechanism for safely and permanently storing CO_2 by converting it to carbonate minerals in geologic formations. Reactive silicate formations with high concentrations of divalent cations (e.g., Mg^{2+}, Ca^{2+}, or Fe^{2+}) have an enormous capacity to sequester CO_2: the mantle peridotite in the Samail Ophiolite, Oman alone could sequester $30x10^{12}$ tons of CO_2 [1]. However, the accessible capacity may be much lower, as CO_2-water-rock interaction is limited by porosity, permeability, and reactive surface area, which are relatively low in fractured-rock aquifers such as in peridotite. Sustained mineral carbonation will also depend on how these hydrogeological factors evolve with reaction progress- carbonating peridotite involves a volume increase of over 40%, so secondary mineralization could clog the existing porosity and permeability, and could armor unreacted peridotite from further carbonation. Alternatively, stresses from volume increase could cause fracturing, creating new permeability, porosity, and reactive surface area. This reactive cracking would allow the carbonation front to continue propagating into the formation. Completely carbonated peridotites in Oman are proof that the carbonation reaction can proceed to completion, given the right conditions [1].

Here we present a reactive transport model of *in situ* mineral carbonation in peridotite to help determine ideal carbonation conditions and how they can be met within the confines of an engineered geological CO_2 storage project. The model is constrained by geochemical and hydrogeological data for peridotite aquifers in the Samail Ophiolite collected over five field seasons. It includes reaction kinetics, non-isothermal multiphase flow, and CO_2 injection scenarios to evaluate how to optimize carbonation by adjusting different parameters (formation temperature, fluid pCO_2, injection rate and temperature, etc.), and estimate what extent of carbonation is realistic for a CO_2 storage project employing *in situ* mineral carbonation in peridotite.

Simulating Arctic Mixed-Phase Clouds with Aerosol-Dependent Ice Nucleation and Ice Nuclei Depletion

M. PAUKERT* AND C. HOOSE

IMK-AAF, Karlsruhe Institute of Technology (KIT), 76344 Eggenstein-Leopoldshafen, Germany (*correspondence: marco.paukert@kit.edu)

Arctic stratus clouds frequently consist of long-lived supercooled liquid layers which precipitate ice. Depending on the partitioning of liquid water and ice, they modify the radiation budget at ground levels [1].

In semi-idealized simulations with a cloud-resolving model, we investigate for which concentrations of ice nucleating aerosols (here: mineral dust and ice-active bacteria) a stratiform supercooled liquid cloud remains stable, i.e. maintains an approximately constant liquid water path and ice water path over several hours. For this purpose, the ice nucleation scheme in the COSMO model has been replaced by an ice nucleation active site density approach for immersion freezing [2], relating the ice nuclei number to the temperature and to the aerosol surface area based on results from laboratory experiments. In addition, depletion of ice nuclei is taken into account, assuring that only entrainment of fresh aerosol particles or further cooling of an air parcel leads to the formation of ice crystals. The model is applied to the simulation of a cloud which was observed during the ISDAC campaign [3].

The evolution of the liquid/ice partitioning in the cloud is highly sensitive to both the vertical velocity distribution, the ice crystal growth parameterization and the ice nuclei concentration. It is found that both dust and bacteria concentrations need to be several orders of magnitude higher than our initial assumptions based on typical background values to reach the transition from the growing to the glaciating state through immersion freezing.

Annual Rainfall Proxy Records from Soda-straw Stalactites

BENCE PAUL[1]*, HELEN GREEN[1], RUSSELL DRYSDALE[2], JON WOODHEAD[1], JANET HERGT[1], JOHN HELLSTROM[1] AND JOL DESMARCHELIER[3]

[1]School of Earth Sciences, The University of Melbourne, Parkville, VIC Australia, (*correspondance: bpaul@unimelb.edu.au)

[2]Melbourne School of Land and Environment, The University of Melbourne, Parkville, VIC Australia

[3]Glass Expansion 15 Batman Street, West Melbourne, VIC Australia,(jdesmarchelier@geicp.com)

We present a reconnaissance study of the use of soda-straw stalactites (straws) as palaeoclimate proxies. Straws are a previously under-utilised, yet potentially promising, source of such data that may provide intra-annual rainfall records of up to 1000 years, depending on growth conditions. In this contribution we investigate the structure and formation of straws and look at some issues that may affect the reliability of these records. We use laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) trace element analysis to document surface contamination features that have the potential to obscure annual trace element variations, and discuss a simple method to reveal the underlying layering. We also use LA-ICP-MS to map the two-dimensional trace element distribution in straws. This internal structure reveals broad layers with relatively higher Sr, Mg and Ba contents, compared to narrow, trace-element-poor winter layers. These layers are widest at the outside edge of the straw, narrowing and becoming almost parallel on the interior of the straw.

Based upon these observations, we present a model for the formation of visibly layered straws, where rapid degassing of CO_2 from the drip extending below the straw forms the wider outer layers. In the example presented, summers are defined by increased layer widths and higher trace element contents relative to winter layers. In palaeoclimate studies, where such annual variations can be used to construct time-lines, we suggest that, ideally, the outer-most surface of the straw be analysed where the trace element content difference is greatest and layering is widest.

We also present the trace element profile of the terminal phase of a straw, where layer widths decrease and trace element contents increase. The features described are likely representative of soda-straw responses to drought-induced decreases in percolation water, and may be used to recognise droughts from the pre-instrumental period. We also discuss initial modelling of results from another straw that records annual layers from 1996 to 1780.

Lead isotopes and concentrations in the South Atlantic from the UK GEOTRACES transect along 40°S

M. PAUL[1], T. VAN DE FLIERDT[1], M. REHKÄMPER[12], D. WEISS[1], M. LOHAN[3] AND G. M. HENDERSON[4]

[1]Imperial College London, London, SW7 2AZ, UK (m.paul@imperial.ac.uk)
[2]Natural History Museum, London, SW7 5BD, UK
[3]University of Plymouth, Plymouth, PL4 8AA, UK
[4]University of Oxford, Oxford, OX1 3AN, UK

Documenting the distributions of trace elements and their isotopes (TEIs) in the ocean and understanding the processes responsible for these distributions is one of the overarching goals of the ongoing GEOTRACES program [1]. The marine geochemical cycle of lead (Pb) has been extensively influenced by anthropogenic activities since the mid-19th century and, in particular, by the use of leaded gasoline [2]. The characteristic isotope fingerprint of different anthropgoenic sources, combined with the short residence time of Pb in the ocean, makes the Pb isotope system a unique source tracer and monitor of ocean circulation [3].

We here present new results from two UK GEOTRACES cruises (D357 and JC068), forming a South Atlantic transect along 40°S. Seawater samples were analysed using a TIMS double spike methodology developed at Imperial College London. This method allows precise measurements for small seawater samples (2L) of both Pb concentrations and isotopic ratios, including the minor isotope ^{204}Pb.

Lead concentrations are generally higher in surface waters (15 to 35 pmol/kg) than in deep water (5 to 15 pmol/kg), and are higher in water depths associated with North Atlantic Deep Water (NADW) than in intermediate waters sourced from the south. The highest Pb concentrations can be found in surface waters close to the South African continent. Lead isotopic compositions clearly support the identification of the major water masses in the region. Excluding coastal areas, surface waters are characterized by ^{206}Pb/^{204}Pb ratios of 18.15 to 18.30, which is distinct from the ^{206}Pb/^{204}Pb ratios of 17.95 to 18.05 characteristic of AAIW. Deep waters usually display higher isotopic ratios with the most radiogenic ^{206}Pb/^{204}Pb ratios of 18.54 being observed at 4500 m depth (Antarctic Bottom Water).

Searching radiation-resistant microorganisms in high-Mn sites

IVAN G.PAULINO-LIMA[1]*, KOSUKE FUJISHIMA[2], JESICA U. NAVARRETE[3] AND LYNN J. ROTHSCHILD[4]

[1]NASA Ames Research Center (*correspondence: ivan.g.paulinolima@nasa.gov)
[2]NASA Ames Research Center [kosuke.fujishima@nasa.gov]
[3]University of California Santa Cruz [junavarr@ucsc.edu]
[4]NASA Ames Research Center [lynn.j.rothschild@nasa.gov]

Recently, several physiological parameters have been described to play a role on radiation resistance [1, 2]. In particular, a strong positive correlation has been demonstrated between intracellular accumulation of manganese and high resistance to radiation in several biological models [3]. However, the question of the evolution of radiation resistance has never been studied using an approach of environmental microbiology. In order to tackle this problem, soil samples were collected from different locations: (i) a manganese mine in Arizona, (ii) the Atacama desert, Chile, and (iii) the Moffett Field campus, CA. Samples were submitted to UV-C irradiation (300 J/m2) and resistant microorganisms were selected from three different culture media: Marine Agar, LB (Sigma) and R2A (Difco). All isolates were molecularly identified by PCR of the 16S rRNA gene. Each isolate was then subjected to another round of UV-C irradiation and classified according to their tolerance. Survival curves were performed in triplicate for the most resistant isolates and their intracellular Mn/Fe ratio was determined by ICP-MS. UV-resistant isolates have Mn/Fe ratios around two orders of magnitude higher than UV-sensitive ones. Three isolates are more resistant than *Deinococcus radiodurans* to UV-C irradiation, and show a higher Mn/Fe intracellular ratio. A better characterization of these isolates is currently in progress. Access to microbial resources in soils enriched in manganese will be essential for the development of new products and processes for application in various fields of knowledge. The discovery of radiation-resistant microorganisms naturally occurring in manganese-enriched sites will have a profound impact on several lines of research, including future space exploration.

Dolomite in microbial mats from sabkha (Qatar): insights from combined Raman-Atomic Force Microscopy study.

C. PAULO[1] AND M. DITTRICH[1]

[1]University of Toronto Scarborough, 1265 Military Trail, Toronto, ON, Canada, M1C 1A4 (*correspondence: mdittrich@utsc.utoronto.ca)

The formation of dolomites has been reported in the extreme environment of Arabian Gulf sabkhas (Illing, Wells *et al* 1965). Many of the sites are characterized by extensive growth of cyanobacterial mats. Carbonates precipitation at low-temperature appears to be impacted by microbial extracellular polymeric substances (EPS) (Dupraz *et al* 2005). Cyanobacteria are key producers of EPS, but so far no information has been gathered on their involvement in dolomite precipitation.

The first objective of this study was to gain insights into the spatial distribution of cyanobacterial EPS and dolomite in different sediment layers of Khor Al-Adaid sabkha (Qatar) Secondly, this project aims to characterize microbial mats in respect of organic and inorganic components on a molecular level. For this purpose, *in-situ* 2D Raman spectroscopy and Atomic Force Microscopy (AFM) were used. Additionally, samples have been anazysed with scanning electron microscopy (SEM) and X-ray difraction (XRD),.

Our results showed that Raman fingerprints of dolomite (~1098,~725 and 300cm^{-1}), cyanobacterial EPS (~1130-1148 cm^{-1}) and carotenoids (1507 and 1000cm^{-1}) are widely distributed in the top 2 cm of the sabkhas sediments. The mineralized EPS have been observed by SEM analysis, and dolomites have been identified by means of XRD.

2D chemical imaging of sediment layers, spectroscopically characterized minerals and organic matter of microbial origins at high spatial resolution. Raman mapping identified small dolomite clusters (<2um) embedded in a dense cyanobacterial EPS matrix. Therefore, our data provide evidence for an interaction between cyanobacterial molecules, especially EPS, and dolomite in the sabkhas top sediments. This study demonstrated that Raman mapping is a robust and sensitive technique for acquisition of *in situ* information from complex biofilm-minerals samples.

High-pressure amphibolite facies metapelites of Carrancas *Klippe*, Southern Brasília Belt, Brazil

M. PAVAN[1,2 A] AND R. MORAES[1]

[1]Geosciences Institute, University of Sao Paulo, Brazil (mauriciopsilva@usp.br; moraes@igc.usp.br)
[2]CPRM – Geological Survey of Brazil, São Paulo, Brazil

The Carrancas *Klippe,* is composed from base to top by a pure to micaceous quartzite, grading vertically to a staurolite-garnet-chloritoid-chlorite phyllite or porphyroblastic kyanite-staurolite-garnet schist, depending on the conditions of metamorphism. The metamorphism recorded in these rocks increases to the southeast, from upper greenschist facies to transition of amphibolite to eclogite facies, as a result of the development of Brasilia Belt. Metamorphism was modeled using THERMOCALC, via pseudosections and optimal geothermobarometry. In Estancia Hill, rocks of top portion had peak metamorphic conditions calculated as 10.0 ± 1.7 kbar and 577 ± 8 °C and for Bicas Hill, lower rocks, metamorphic peak conditions were attained at 12.9 ± 1.0 kbar and 608.5 ± 19.5 °C, with retro-metamorphism taking place at 7.0 ± 2.2 kbar and 541.5 ± 25.5 °C. The mineral paragenesis of the studied samples are typical of the greenschist and upper amphibolites facies, respectively. However, the modeling indicates these rocks were exposed to higher-pressure conditions, reaching the transition to eclogite facies. The restricted bulk compositions of these true pelites allow the mineral associations to persist through conditions of higher pressure, as pointed in some theoretical studies.

Increasing metabolic activity of clams and brachiopods over the past 500 million years: A consequence of the changing biological pump?

JONATHAN L. PAYNE[1], NOEL A. HEIM[1], MATTHEW L. KNOPE[1], KATJA MEYER[1] AND CRAIG R. MCCLAIN[2]

[1]Dept. of Geological & Environmental Sciences, Stanford University, Stanford, CA 94304, USA; (jlpayne@stanford.edu)

[2]National Evolutionary Synthesis Center (NESCent), 2024 W. Main St., Suite A200, Box 104403, Durham, NC 27705

Numerous indirect lines of evidence suggest a long-term increase in the metabolic activity of marine animals. However, the timing and magnitude of this increase remain poorly quantified, preventing detailed testing of hypothesized controls. Here we use newly compiled body size data for 6834 genera of brachiopods and bivalves, two of the most abundant and diverse clades of marine animals, to show that mean per taxon, per occurrence, and per capita metabolic rates of primary consumers have increased by approximately two orders of magnitude from the Cambrian to the present day, with most of this increase occurring between Cambrian and Jurassic time (540-140 Mya). Secular trends in the thickness of shellbeds, prevalence of fossils, and intensity of bioturbation indicate that this increase in per capita metabolic activity was not offset by a decrease in the number or total biomass of benthic animals, whether bivalves, brachiopods, or other taxa. Biogeochemical modeling suggests that secular variation in the strength of the biological pump may account for the magnitude and timing of this trend in animal community metabolism.

A forward modelling approach to understanding continental growth

J.L. PAYNE[1], K.M. BAROVICH[1], N.J. PEARSON[2] AND M. HAND[1]

[1]Centre for Tectonics, Resources and eXploration (TRaX), University of Adelaide, S.A., 5005 Australia. (*correspondence: justin.payne@adelaide.edu.au)

[2]ARC Centre of Excellence for Core to Crust Fluid Systems (CCFS), Macquarie University, NSW 2109 Australia.

The rapid expansion of global datasets of U-Pb and Lu-Hf (±O) isotopic data in detrital zircon has provided an avenue to address the questons of the timing and rates of continental growth. Any model suggesting significant growth of the continents in early earth history has dramatic implications for the rate and mechanisms of crustal growth and recycling throughout Earth history. Recent studies using Hf model ages obtained from detrital zircon have suggested 60-65% of the current volume of continental crust existed by the late Archean[1,2].

Studies using Hf model ages for continental growth must deal with the issue of Hf model ages that result from the mixing of melts derived from the mantle and crust and/or multiple crustal sources. Studies commonly assume the consistency of mixing across Earth history will average out any short-term bias or else employ O-isotope data to identify mixed model ages. Each of these approaches has shortcomings that may compromise the robustness of the final continental growth model.

Estimates of the proportion of juvenile crustal addition using the ratio of Hf model ages to model ages plus U-Pb ages in a 100 Myr time slice can be reproduced using synthetic Hf data randomly generated from detrital U-Pb age distributions. The use of O-isotopes to remove mixed Hf model ages also seems to be at odds with studies of granite genesis that suggest a larger proportion of granites contain both mantle and crustal components than interpreted from the use of Hf and O isotope data in detrital zircon datasets.

We propose the use of a forward modelling approach to resolve continental growth. This approach uses a priori geologic information to produce models of continental growth that are testable against the detrital zircon and geological records.

Methane transport and release to the atmosphere in permafrost areas via subterranean groundwater discharge

ADINA PAYTAN[1], ALANNA LECHER[1], NATASHA DIMOVA[1], JOHN KESSLER[2], AND KATE SPARROW[2]

[1]University of California Santa Cruz, Santa Cruz, CA 95064
[2]University of Rochester Rochester, NY 14627

Methane release to the atmosphere in permafrost regions of the Arctic is exacerbated by global warming. This may result in a positive feedback effect, as methane is a powerful greenhouse gas. Accordingly, it is important to gain a good understanding of the processes that contribute methane to the atmosphere, particularly in this region. Large quantities of methane are stored in the Arctic in natural gas deposits, permafrost, and as submarine clathrates. Releases from these sources arising from warming have been reported, however, there are still considerable gaps in our understanding of the methane cycle at present and particularly how predicted climate changes will impact the methane cycle.

Subterranean groundwater discharge (SGD) has been recognized as an important conduit for transport of nutrients, metals, methane and other pollutants from land to receiving water bodies throughout the world, and could be a potential important, yet not quantified, source of methane in the Arctic. SGD can be quantified using geochemical tracers such as Ra and Rn and when combined with methane measurements can elucidate the role SGD has in transporting methane form groundwater to surface water bodies such as Arctic lakes and the coastal ocean, from which this methane will be released to the atmosphere.

We have used Ra and Rn along with analytical calculations and methane concentration and isotope analyses in order to determine the contribution of SGD to the methane budget in areas of different hydrological and permafrost conditions in Alaska. Our results indicate that SGD is a major conduit for methane release contributing significant amounts of methane to surface waters particularly in areas where permafrost is abundant and impacted by seasonal temperature changes.

Bioessential metal sorption at ferrihydrite-bacteria interfaces

CAROLINE L. PEACOCK[1] AND ELLEN M. MOON[2]

[1]School of Earth and Environment, University of Leeds, Leeds, UK. (C.L.Peacock@leeds.ac.uk)
[2]ANSTO Minerals, Australian Nuclear Science and Technology Organisation, Locked Bag 2001, Kirrawee D.C., NSW 2234, Australia. (ellenm@ansto.gov.au)

The association of organic matter with mineral surfaces can exert a profound effect on the behaviour of both the mineral and organic phases. It is becoming apparent that a direct relationship exists between minerals and organics whereby organic matter acts to significantly modify mineral surface physiochemistry and may help preserve mineral reactivity during diagenesis, while minerals similarly help preserve organic carbon leading to burial and long-term carbon storage [e.g., 1]. This relationship is particularly apparent for organics associated with iron (hydr)oxides like ferrihydrite. In these composites the unique surface physiochemistry also produces a complex sorbent with metal sorption properties very distinct from pure iron (hydr)oxides [e.g., 2]. Despite the wide occurrence of iron (hydr)oxide – organic composites, and the major control on metal cycling exerted by the pure end-member components, metal sorption at the composite-water interface is poorly understood.

Here we present the results of on-going research to determine the molecular-level sorption behaviour of bioessential metals with ferrihydrite-bacteria composites. We will show directly for the first time that Cu binds to each of the composite fractions, via the same molecular mechanisms as to the end-member components; namely, a bidentate edge-sharing complex on the ferrihydrite fraction and a monodentate complex to carboxyl functional groups on the bacterial fraction [3]. The presence of the carboxyl groups significantly modifies Cu sorption behaviour on the composites compared to pure ferrihydrite [3,4]. We find that for composites composed predominantly of ferrihydrite this modified behaviour can be modelled in a thermodynamic surface complexation framework by adopting a linear additivity approach, where sorption on the composites is the sum of the pure end-member Cu sorptivities [4]. However, composites composed mainly of bacteria behave in a non-additive manner, which we can explain as a result of their unique surface charge [4]. Modelling and thus predicting metal sorption on these composites is a new challenge.

Understanding electron transfer at Fe-bearing mineral surfaces to optimize contaminant remediation

C.I. PEARCE[1]*, J, LIU[1], B.C. KABIUS[1] A. ARENHOLZ[2] AND K.M. ROSSO[1]

[1]Pacific Northwest National Laboratory, Richland WA, USA (correspondence: *carolyn.pearce@pnnl.gov)
[2]Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA

In order to use natural or engineered materials for contaminant sequestration, it is necessary to fully characterize the material in terms of its structure and reactivity. Even within a nanoparticle, elemental distribution can vary from the interior to the surface, thus surface senstive techniques must be employed to probe mechanisms of interaction between the mineral phase and chemical/biological components present in the subsurface environment.

Here, we present the use of model materials, as well as field samples, in combination with high-resolution spectroscopic and microscopic capabilities, to interrogate interfacial reactivity of Fe-bearing minerals with redox-active contaminants and electron-transfer proteins. A novel and well-characterized set of $Fe_{3-x}Ti_xO_4$ titanomagnetite nanoparticles was selected as the model mineral system. Replacement of Fe(III) by Ti(IV) in the lattice yield a naturally "tunable" solid-state Fe(II)/Fe(III) ratio, which in principle controls the thermodynamic reduction potential of the mineral phase. Also, the high specific surface area of the nanoparticles greatly improves experimental sensitivity to contaminant/protein interaction and accompanying changes to the solid surface. Nanoparticle properties such as size, morphology, crystallinity, element and valance distribution are characterized by STEM-EELS and micro-XRD. X-ray magnetic circular dichroism (XMCD) is used to distinguish between Fe oxidation states and crystallographic sites at the reactive surface with a probing depth of ~4.5 nm (~5 unit cells).

The mechanism and rate of heterogeneous electron transfer from $Fe_{3-x}Ti_xO_4$ nanoparticles, microparticles, and natural materials, isolated from Hanford nuclear reservation sediments, to Tc(VII) is investigated. Electron transfer at microbe-nanomaterial interfaces is characterized by examining the oxidation of $Fe_{3-x}Ti_xO_4$ nanoparticles by the bacterial electron transfer enzyme MtoA, a decaheme *c*-type cytochrome.

Cr isotope fractionation in reducing continental margin sediments

Sedimentary records of redox sensitive metals are commonly used to assess the availability of dissolved oxygen in seawater. However the interpretation of such records is complicated by the fact that metal concentrations can also be influenced by factors such as the detrital flux and primary productivity. Redox sensitive isotopic variations may therefore provide a more robust means of assessing seawater oxygenation. The chromium (Cr) isotope system has considerable promise in this regard as the reduction of soluble Cr(VI) to insoluble Cr(III) has been shown to be associated with resovable isotopic fractionation [1]. Determining when and how Cr isotopes are fractionated in marine sediments will improve our understanding of the mechanisms that control Cr removal from seawater, and will provide a framework for interpreting redox-related variations in the δ^{53}Cr composition of seawater [2].

In order to evaluate the sensitivity of the Cr isotope system to variations in sedimentary conditions we present δ^{53}Cr data from continental margin sediments deposited under a range of redox settings. Oxic samples come from MANOP site H in the eastern Pacific Ocean, where a down core profile is used to assess the behaviour of δ^{53}Cr through the Mn reduction zone. Suboxic samples are analysed from sites along the Californian margin, while anoxic samples come from surface sediments deposited off the coast of Mexico. Previous characterisation of sediment properties at these localities enables variations in δ^{53}Cr to be compared to the behaviour of other redox sensitive metals such as molybdenum (Mo) and uranium (U) [e.g. 3, 4], and helps validate the utility of the Cr isotope system as a tracer of dissolved oxygen in seawater.

SO_2 and O_2 co-injection with potential carbon storage target sandstone from a fresh-water aquifer.

J.K. PEARCE[1,2]*, G. DAWSON[1,2], S. FARQUHAR[2] AND S. GOLDING[1,2]

[1]Cooperative Research Center for Greenhouse Gas Technologies, Canberra, Australia.
[2]School of Earth Sciences, University of Queensland, Australia. Correspondence*:(j.pearce2@uq.edu.au,) (susan.farquhar@uqconnect.edu.au,) (G.Dawson@uq.edu.au, s.golding1@uq.edu.au).

CO_2 and associated co-contaminant gases such as SO_2, NO_X, and O_2 are present in gas streams from coal fired power stations.[1] The cost of carbon capture and storage (CCS) may be reduced if CO_2 can be stored safely together with the co-contaminants.[2] Reservoir and sealing cap-rock samples from a potential carbon geosequestration site in the Surat Basin, Queensland, Australia, have been subjected to laboratory-scale experiments at simulated in situ CO_2 storage conditions. Water-rock-supercritical CO_2 reactions with co-injected SO_2 gas were performed and compared with pure CO_2 reactions on sister rock samples. Reactions with co-injection of SO_2 indicate hightened divalent cation release from carbonates and silicates (5 – 20 times the reactivity with pure CO_2) (Fig.1.) suggesting potential for enhanced long term mineral trapping of CO_2. Extensive surface corrosion of carbonates and silicates was also observed with the co-injection of SO_2 and a resulting pH of 2-3.

New experiments including the co-contaminant O_2 are expected to significantly stimulate redox reactions and will also be presented.

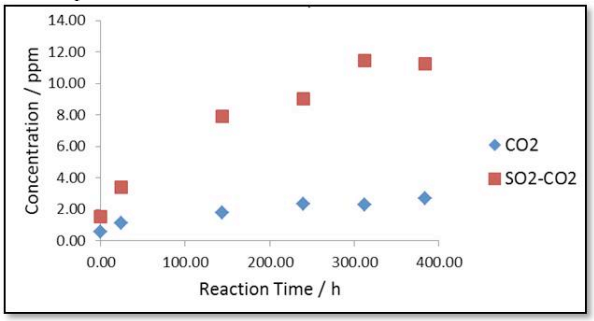

Fig.1: Enhanced evolution of dissolved iron in solution from reservoir rock with SO_2 co-injection (red squares) vs. pure CO_2 storage in situ conditions (blue dimonds).

Microstructural Constraints on Porosity Evolution During Carbonate Replacement Reactions

MARK A. PEARCE[1]*, NICHOLAS E. TIMMS[2], ROBERT M. HOUGH[1] AND JAMES S. CLEVERLEY[1]

[1]CSIRO Earth Science and Resource Engineering, Australian Resources Research Centre, 26 Dick Perry Avenue, Kensington, WA 6151, Australia

Volume change during formation and modification of carbonate minerals can lead to significant changes in rock porosity and permeability. In gold mineralising systems these reactions have the potential to enhance wall rock permeability leading to dissemination of gold away from the main fracture-derived fluid pathways. We present quantitative electron backscatter diffraction data combined with spatially referenced major and trace-element chemistry to investigate how porosity evolves during reactions that produce and modify carbonate minerals. Data are presented showing the chemically driven recrystallisation of large (several mm across) calcite grains to produce aggregates of iron-rich carbonate and dolomite. Recystallisation of calcite by siderite occurs by nucleation of new grains that are in low energy crystallographic orientations with respect to the host, preferentially along pre-existing twin interfaces. Dolomite replaces calcite by nucleation on Fe-rich calcite domains in the host grains. Iron in the recrystallised carbonates is sourced from the breakdown large biotite and ilmenite grains (which now form fine grained polycrystalline aggregates as a result of carbonate metasomatism). Gold grains are found at the reaction interface between biotite (reactant) and muscovite (product). Further experimental data will allow kinetics of these reactions to be established, facilitating integration of these reactions with large-scale mineralisation models.

The hole story about laser ablation ICP-MS

N.J. PEARSON[1], W. J. POWELL[1], K.J. GRANT[1], J.L. PAYNE[2], R.C. MURPHY[1], E. BELOUSOVA[1], W.L. GRIFFIN[1], SUZANNE AND Y. O'REILLY[1]

[1]CCFS/GEMOC, Macquarie University, Sydney, Australia
[2]TRAX, University of Adelaide, Adelaide, Australia
(*correspondence: norman.pearson@mq.edu.au)

Down-hole laser-induced fractionation is one of the largest contributions to the uncertainty budget of LA-ICP-MS measurements of trace elements and isotope ratios. Efforts to improve the accuracy of analyses and to reduce the size of the uncertainty associated with laser-induced fractionation have been divided between developments in laser hardware and data reduction software. Advances in cell design have improved the quantitative transport of material from the ablation site to the ICP and contributed to increased sensitivity and reduced fractionation. Procedures involving rastering the laser or short acquisition times are also commonly adopted to minimize downhole fractionation, but these compromise spatial resolution and depth information. Linear [1], [2] and exponential [3] down-hole models are used in many data reduction software packages and reflect the basic fractionation response for a wide range of laser specifications and operating conditions. In the majority of models the fundamental assumption made is that matrix-matched standards and samples ablate similarly with consistent time-depth relationships [1]. However, further software advances are limited by our current understanding of the fundamental processes of ablation. Here we present the results of a study of the ablation characteristics of zircon using various combinations of laser wavelength, pulse-width, spot size and fluence, in conjunction with laser cell design (New Wave, HelEx) and gas composition and flow. The results are used to identify the optimum set of hardware parameters and operating conditions to maximise spatial resolution, and minimize ablation rate and U-Pb fractionation. A comparison will also be presented between the effects of mass response (instrument mass bias) of a quadrupole (Agilent 7700) and magnetic sector ICP-MS (Nu Attom) on time-dependent fractionation.

Hydrogen isotope systematics of leaf wax *n*-alkanes in *Betula, Pinus,* and *Salix*: Spatio-temporal investigation

N. PEDENTCHOUK[1]* AND Y. ELEY[1]

[1]School of Env. Sciences, University of East Anglia, Norwich, UK (*contact: n.pedentchouk@uea.ac.uk)

The use of D/H composition of *n*-alkyl lipids from leaf waxes as a palaeohydrological proxy depends on a thorough understanding of the factors that control D/H fractionation ($\varepsilon_{l/w}$) between these compounds and the source water. The issue becomes particularly important when sedimentary organic compounds are sourced by only a few species with very different $\varepsilon_{l/w}$ values. This project investigates the magnitude and mechanisms that control $\varepsilon_{l/w}$ in several higher plant species that dominate Northern Eurasian forests and thus contribute a significant amount of biomass to soils and sediments in these ecosystems.

First, we measured the δD values of leaf wax *n*-alkanes from *Betula*, *Pinus*, and *Salix* as well as the δD values of tap water in 11 locations from the UK to central Siberia. Second, we measured the δD values of leaf wax *n*-alkanes and leaf water in the same species that were sampled in Norwich, UK throughout the growing season in April, May, July, and September.

The *n*-alkane δD values of the individual genera correlate very strongly with those of tap water along the transect from the UK to central Siberia – the R^2 values calculated for *Betula*, *Pinus*, and *Salix* are 0.95, 0.97, and 0.82, respectively. However, their $\varepsilon_{l/w}$ values are characterized by consistent differences that are inpedendent of the location along the transect: *Betula c*. -85‰, *Pinus c*. -120‰, *Salix c*. -140‰.

Our time-series $\varepsilon_{l/w}$ data calculated from *n*-alkane and leaf water δD values of Norwich trees sampled from April to September show the same pattern among these genera. Even though the magnitudes of the differences among them are not as large as in the transect data, *Betula* $\varepsilon_{l/w}$ values are consistently more positive than those of *Pinus* (by *c*. 5 to 20‰) and *Salix* (by *c*. 20 to 30‰).

Integration of our spatial and temporal δD data provides strong evidence that the processes that lead to the differences in the $\varepsilon_{l/w}$ values are not limited to the physical processes that control source water δD. We hypothesize that D/H fractionation during leaf water photolysis and biosynthesis plays a major role in determining $\varepsilon_{l/w}$ values in these plants. Our results suggest that leaf-wax-based palaeohydrological studies in northern forest ecosystems may require quantitative analysis of the amount of biomass sourced by common plants with very different $\varepsilon_{l/w}$ values.

Volcanic CO_2 flux measurements by Tunable Diode Laser absorption Spectroscopy

M. PEDONE [1]*, A. AIUPPA[1,2], G. GIUDICE[2], F. GRASSA[2], AND G. CHIODINI[3]

[1]DiSTeM, Università di Palemo, via Archirafi, 36, Palermo 90123, Italy (*correspondence: pedone_maria@libero.it)
[2]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Palermo, via Ugo La Malfa, 153, Palermo 90146, Italy
[3]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Vesuviano, via Diocleziano, 328, Napoli 80126, Itlay

In the last decades, the use of near-infrared room-temperature diode lasers for gas sensing has grown significantly. The use of these devices, for instance in combination with optical fibers, is particularly convenient for volcanic monitoring applications [1,2]. Here, we report on the first results of the application of an open-path infrared tunable laser-based at Campi Flegrei (Southern Italy). Such Diode-laser-based measurements were performed, during two field campaigns (october 2012, and january 2013), in the attempt to obtain novel information on the current degassing unrest of Solfatara and Pisciarelli fumarolic fields.

At each site, we used an ad-hoc designed measurement geometry, using a TDLS (a Gas Finder unit) and several differently positioned retroreflectors (mirrors), to scan the fumaroles' plume from different angles and distances. From post-processing of the data (acquired at 1 hz), we derived tomographic maps of CO_2 concentrations in the plume and, by integration and combination with plume transport speed (from video cameras), we inferred the CO_2 flux directly. The so-calculated fluxes, the first ever obtained at Campi Flegrei, average of ~500 tons/day, and support a significant contribution of fumaroles to the total CO_2 budget. The cumulative (fumarole [this study] +soil [3]) CO_2 output from Campi Flegrei is finally evaluated at 1600 tons/day.

Why was Rodinia underendowed? Comparing the effects of paleogeography versus lithosphere thickness on secular ore deposit preservation

SALLY PEHRSSON*, BRUCE EGLINGTON, DAVID HUSTON, AND DAVID EVANS[1234]

[1]Geological Survey of Canada, Ottawa, Canada; *correspondence:((pehrsson@nrcan.gc.ca)
[2]University of Saskatchewan, Saskatoon, Canada; (bruce.eglington@usask.ca)
[3]Geoscience Australia, Canberra, Australia, (David.Huston@ga.gov.au)
[4]Yale University, Conneticut, US, (dai.evans@yale.edu,)

An empirical observation from the Meso- to Neoproterozoic geologic record is that this period, spanning the assembly and tenure of the supercontinent Rodinia, is one of the least endowed in mineral deposits. This underendowment is puzzlingly at odds with models that suggest peaks in contraction-related deposit formation associated with the supercontinent cycle.

The current model suggests change in lithospheric thickness (more negatively buoyant with time) would result in a lack of preservation of deposits, due to enhanced uplift and erosion. With nearly 30% of VMS and Sedex deposits hosted in high grade terrains irrespective of lithospheric age, Rodinia's high grade belts still are underendowed, hence an alternative explanation must be sought,

New models for the transition from breakup of the Paleoproterozoic supercontinent Nuna to assembly of Rodinia highlight the influence of accretion style and paleogeography in deposit preservation. Rodinia extroverted, hence was dominated by subduction of old oceanic lithosphere and strong advancing accretion. This doomed preservation of its VMS deposits, whch must accrete quickly to be preserved. Rodinia's long-lived, and latitudinally disposed, peripheral orogen setting, with limited back-arc development, meant that open ocean circulation was enhanced, further diminishing potential for VMS and lode gold deposits. Where Nuna evolved from interior to peripheral orogenic settings a similar deposit decline is observed, suggesting that ultimately paleogeography and style of accretion play a significant role in mineral deposit preservation. Hypothetically running geologic history forward in time suggests that the future supercontinent Amasia is destined to be another Rodinia.

Fe, Al and Ti variations in marine sediment: implications in provenance and paleoclimatic analyses

A. PEKETI AND A. MAZUMDAR

National Institute of oceanography, Dona Paula, Goa-India 403004, (adipeketi@gmail.com)

Krishna-Godavari basin (K-G basin) is a pericratonic rift basin, formed during 130-134 Ma ago (lower cretaceous) as a consequence of rifting and subsequent drifting of India from the contiguous Antarctica–Australia land mass [1]. Krishna and Godavari are the major rivers that bring the sediment load to the K-G basin. 80% of the catchment area of Krishna river is occupied by Archean and younger crystalline rocks and the remaining 20% comprises of Tertiary Deccan traps (basaltic) and recent sediments [2]. The drainage basin of Godavari river includes Deccan traps (48%), Archean Granites (39%), Precambrian and Gondwana sedimentary rocks (11%) and recent alluvial cover (2%) [3]. Temporal variations in the Fe_T/Al ratio of a sediment core (MD161/8) from K-G basin indicate the relative contributions of terrestrial load from Deccan basalts and granitic rocks [4]. Good correlation (r^2=0.673/0.74) between Al/Ti and Fe/Ti suggest a common source and geochemical pathways for Fe_T and Al transportation and accumulation in the sediments [5]. Further studies (Sr-Nd isotope studies) are ongoing to quantify the relative contributions of Deccan basalts and Granitic rocks.

Variations in the Fe_{HR}/Fe_T (highly reactive iron/total iron) ratios normalized with respect to the source indicates the weathring/monsoon intensity. Fe_{HR}/Fe_T ratios are closely related to the runoff as high runoff results in increased content of poorly crystalline iron hydroxides/oxides in the suspended load which constitutes the Fe_{HR} content of the suspended particulates [6].

[4]Weizmann Institute of Science, Israel

Sulfur isotope fractionation during microbial sulfate reduction is controlled by the energy metabolism of sulfate reducing microorganisms. While this metabolism responds to variability in the local environment, it is ultimately dependent on the underlying genotype. Since genotype and environment have both changed throughout Earth's history, the geological record of biogenic S isotopes reflects the influence of environmental and evolutionary change. However, the basic interplay between microbial evolution and S isotope fractionation has not been examined.

We investigated the evolutionary response of S isotope fractionation in *Desulfovibrio vulgaris* Hildenborough (DvH) and *Desulfomicrobium baculatum* (Dbac) through experimental evolution. Twelve replicate lines of DvH and three replicate lines of Dbac were serially transferred in batch cultures of defined media at 33ºC. After 1000 generations, the descendant DvH strains were markedly more fit, with relative growth rates increasing by ≈20%. Fitness improvements were even more pronounced for descendant Dbac strains, with 300% enhancement in growth rates after only 200 generations. In both DvH and Dbac lines, the descendant strains have a clear selective advantage over their ancestors, and have undergone evolutionary adaptation to the constant environmental conditions of the experiment.

The ancestral cultures of DvH and Dbac produced sulfide depleted in $^{34}S/^{32}S$ relative to the sulfate of -6.8±1.0‰ and -15.4±0.7‰ respectively. When the assay was repeated on the evolved lines, Dbac reproducibly showed a lower $^{34}S/^{32}S$ fractionation of -12.3±0.4‰ whereas DvH displayed the same fractionation as its ancestor. These observations suggest that evolutionary trajectory of S isotope fractionation correlates with the magnitude of evolutionary adaptation to a specific environment. As these evolutionary changes in the isotopic phenotype mimic, in a broad sense, known physiological responses of dissimilatory sulfate reducing bacteria, it may be possible to disentangle the metabolic and environmental histories imprinted in the S isotope record..

Sorption of Cobalt and Nickel by Biogenic Birnessite

JASQUELIN PEÑA[1]*, ANNA A. SIMANOVA[1], JOHN R. BARGAR[3], AND GARRISON SPOSITO[2]

(*correspondence: jasquelin.pena@unil.ch)
[1]University of Lausanne, Switzerland, jasquelin.pena@unil.ch, (anna.simanova@unil.ch)
[2] Lawrence Berkeley National Laboratory, Berkeley, USA (gsposito@berkeley.edu)
[3]Stanford Synchrotron Radiation Lightsource, Menlo Park, USA,(bargar@slac.stanford.edu)

Birnessite minerals (layer-type MnO_2) produced by bacteria and fungi participate in important biogeochemical processes, particularly trace metal scavenging. Biogenic birnessite, which is enmeshed in a matrix of bacterial cells and extracellular polymeric substances (biomass), has nanoparticulate dimensions and significant structural disorder created by Mn(IV) vacancies. Trace metals tend to adsorb at vacancy sites or become incorporated into the MnO_2 sheet. Thus, the additional sorption sites presented to the solution by the biomass and the mineral particle edges may have a lower affinity for metals than the vacancy sites. In this study we use extended X-ray absorption fine structure (EXAFS) spectroscopy to investigate the mechanisms of Co and Ni sorption in slurries containing Co, Ni and Co + Ni at pH 6 to determine whether metal ions partition to non-vacancy binding sites in the presence of a competing metal. We expect that Co binds strongly to vacancy sites, out-competing Ni, and thus forcing Ni to bind to particle edges or biomass.

In Co-only and Co + Ni samples, we observed similar sorption mechanisms: significant incorporation of Co into the MnO_2 sheet as Co(III) and adsorption at vacancy sites as Co(II). In addition, the fraction of adsorbed Co(II) increased with surface loading. Time-resolved Co K-edge EXAFS spectra acquired from a biomass-free MnO_2 suspension (δ-MnO_2) suggest that adsorbed Co(II) precedes Co(III) incorporation. In contrast to Co sorption, Ni sorption in the Co+Ni samples differed significantly from the Ni-only samples [1]. In the presence of Co, Ni sorption at vacancy sites was markedly reduced, with Ni partitioning to the biomass and birnessite particle edges. Our results indicate that Co uptake into biogenic MnO_2 effectively reduces the proportion of vacancy sites available for Ni sorption, whereas Co uptake is not impacted by Ni sorption. This research is relevant to polluted environments where the attenuation and bioavailability of competing metals may be determined by their affinity to the available sorption sites.

The study on the solubility of the vanadium system focused on Panzhihua, China

Y. PENG[1,2], Y. ZENG[1,2]*, J. J. LI[1], S. FENG[1,2] AND X. D. YU[1]

[1]College of Materials and Chemistry & Chemical Engineering, Chengdu University of Technology, Chengdu, 610059, P. R. China;
[2]Mineral Resources Chemistry Key Laboratory of Sichuan Higher Education Institutions, Chengdu, 610059, P. R. China
(* correspondence: zengyster@gmail.com)

In recent years, the interest of the relationship between microelement and human health increased. Vanadium absence may have negative effects, and it also can be toxic if exposure occurs at high enough levels. It has strong transfer ability in environment. This ability related to the solubility of vanadium in soil solution.

Panzhihua, Sichuan is an important production base of vanadium and titanium magnetite. The vanadium storage is 64% of the total vanadium in China. The vanadium mining and smelting accelerated the vanadium diffusion in soil and water. It causes special environmental problems of vanadium in Panzhihua. Different surface soil in the region, the average mass fraction of vanadium is over 100×10^{-6},[1] far exceeding the background values of Chinese soil vanadium 86×10^{-6}.[2] The amount of vanadium in the soil surrounding smelter is 16.5 times of contrast values. The amount of vanadium in the plant samples is 6.6 times of contrast values.[3]

The solubility of vanadium in soil solution is effected by coexisting ions in soil , such as potassium, sodium, phosphorus and so on. In order to investigate the relationship of solubility between vanadium and the other co-existing ion in soil, the phase equilibria of the quinary system $NaVO_3$ + KVO_3 + NaH_2PO_4 + KH_2PO_4 + $(NH_2)_2CO$ + H_2O and its five quaternary sub-systems were studied at 298 K with isothermal dissoluble method. According to the experimental results, the crystallization form of metavanadate is polyoxovanadate in the weakly acid system. The dissolution and migration of vanadium in aqueous solution has negative correlation with $H_2PO_4^-$ and $(NH_2)_2CO$. The exisiting of K^+ has little effect on the solubility of vanadium. This suggest that in similar soil environment, the solubility of vanadium was restrained by the increase of $H_2PO_4^-$ and $(NH_2)_2CO$, which can affect the transfer ability of vanadium.

Mineralogy and boron geochemistry of mud volcanoes from Northern Apennines (Italy)

MADDALENA PENNISI[1]*, STEFANO BATTAGLIA[1] AND GIOVANNI MARTINELLI[2]

[1]*Istituto di Geoscienze e Georisorse, CNR, Via Moruzzi 1, 56124, Pisa, Italy (m.pennisi@igg.cnr.it)
[2]ARPA Emilia Romagna, Via Amendola 2, 42100, Reggio Emilia, Italy

Mud volcanoes and associated waters of the Emilia-Romagna Apennines were sampled at Rivalta, Montegibbio, Regnano, Nirano, San Clemente and Bergullo localities and analysed for mineralogy and geochemistry. Mud consists of sandy and clayey silt, composed by quartz, calcite, dolomite, feldspar and phylosilicates. The separated clay fraction (< 2 μm, about 20%) is represented by illite - smectite (I-S, 29 to 53%) and illite (I, 30 to 49%), with subordinate chlorite, smectite and kaolinite. Boron concentration varies in the range 100 - 400 μg/g in mud samples, and 5 – 80 μg/ml in waters. The mineralogical assemblage of the clay fraction is investigated together with the $\delta^{11}B$ signature of mud (5.3 to 13.2‰) and waters (17.8 to 43.1‰). These preliminary results allow to investigate: a) the variation of the $\delta^{11}B$ signature in mud samples as compared to the inverse correlation observed between I-S *vs* I; b) the relationship between the boron content and the mud – water isotopic fractionation.
Coupling mineralogical and geochemical data, this research was aimed to investigate the roots of the studied mud volcanoes within the Apennine sedimentary pile.

Energy Metabolism in Sulfate Reducing Bacteria

INÊS A. C. PEREIRA[1]*, ANA RAQUEL RAMOS[1] AND SOFIA S. VENCESLAU[1]

[1]Instituto de Tecnologia Quimica e Biologica, Universidade Nova de Lisboa, Oeiras, Portugal
(*correspondence: ipereira@itqb.unl.pt)

The metabolic pathway involved in dissimilatory sulfate reduction has long been known to involve the activation of sulfate by reaction with ATP to form adenosine-5´-phosphosulfate (APS) performed by the ATP sulfurylase, the reduction of APS to sulfite by the APS reductase (AprBA), and the reduction of sulfite to sulfide by the dissimilatory sulfite reductase (DsrAB). However, how this pathway is associated to energy conservation in sulfate reducing organisms (SRO) has not been clearly established. Our team has characterized several new membrane respiratory complexes from SRO, including the QmoABC and DsrMKJOP complexes involved in the electron transfer pathways to AprBA and DsrAB, respectively [1]. These two complexes are specific to sulfur-metabolizing organisms (sulfate/sulfite/organosulfonate reducers and sulfur oxidizers), and both have subunits that are closely related to subunits of the heterodisulfide reductases from methanogens. I will present recent results on the role of the QmoABC and DsrMKJOP complexes in sulfate reduction, and discuss possible mechanisms of energy conservation associated with both APS and sulfite reduction by the AprBA/QmoABC and DsrAB/DsrC/DsrMKJOP proteins, including an electron confurcation hypothesis involving menaquinone [2].

Coral skeleton records isotope ratios, minor and trace element fluctuations as a response to environmental conditions while it grows in shallow tropical oceans. C- and O-isotope ratios from corals are extensively used as proxies to identify environmental factors in tropical shallow water. The Rocas Atoll is an isolated oceanic reef located in the western part of the South Atlantic and offers a great opportunity to investigate global and local phenomena. Being a pristine reef, as this atoll does not undergo terrestrial outputs, most chemical information from the Rocas Atoll corals portrays ocean-atmosphere interaction. Two colonies of Porites *sp.* (PC2 and PT2) were collected in tidal pools in this atoll. The colonies were cut in slabs and X-radiographied. Sclerochronology was done in scanned X-ray negative images using the software CoralXDS. C- and O-isotope analyses were done along the growth axis of each colony. Both *Porite* colonies display anomalous negative $\delta^{18}O$ (up to -1‰ over the mean value) and slightly positive $\delta^{13}C$ (up to +0.4‰, PC2 and +1‰, PT2 above the respective mean values). Sclerochronology indicated the anomalous values as coincident with the ENSO event of 2009/2010 that led to a coral bleaching event worldwide [1]. Also, a signal of endolithic algae bloom is imprinted in PC2 where anomalous values of $\delta^{18}O$ ocurrs. This is highly related to loss of zooxanthellae (coral bleaching) caused by stress events [2], in this case, probably a thermal stress, since $\delta^{18}O$ depletion points out to an increase of sea-surface temperature. The observed anomalous behavior of carbon and oxygen isotopes in this study makes the Rocas Atoll a promising place for monitoring major climate oscillation in the Tropical South Atlantic Ocean.

Impact of organic acids and siderophores on dissolution of basaltic glasses in ultrapure water at 25°C and pH 6.3

ANNE PEREZ.[1], STÉPHANIE ROSSANO[1], NICOLAS TRCERA[2], DAVID HUGUENOT[1], ERIC VAN HULLEBUSCH[1], AURÉLIE VERNEY-CARON[3] AND LOLA SARRASIN[1]

Although microorganisms seem to play an important role in the alteration processes of basaltic glasses in solution, the elementary mechanisms leading to silicate phases alteration remain unclear as well as the respective role of organic acids, siderophores, water chemistry. In order to link the observed degradations to microbial activities or to the bulk solution properties, abiotic and biotic alteration experiments of synthetic basaltic glasses have been performed. Monolitic and powdered samples were placed in 40mL flasks of buffered solution (pH=6.3) containing additionnaly oxalic acid (0.01M), pyoverdine (Pvd), or micoorganisms (the heterotrophic bacterial strain *Pseudomonas aeruginosa* was chosen) during various alteration times ranging from a few hours to 25 days. Elements release from the glass into the solution was measured by Inductive Coupled Plasma Optic Emission Spectroscopy analysis and their distribution was studied regarding the structure of the alteration layer with Scanning Electron Microscopy coupled to an Energy Dispersive X-Ray Detector. Oxalic acid and Pvd are both able to form water-soluble or -insoluble metallo-organic complexes. Organic acids and siderophores (two bioproducts from bacteria) have been shown to dissolve framework ions of severals minerals 10 to 1000 times more readily than water does. Measuring their impact on dissolution in abiotic conditions without any secondary interactions between glass and bacteria allowed to quantify more precisely and for each bioproduct separatly this improvement in terms of dissolution rates and to define how their presence can impact on dissolution mecanisms already established for ultrapure water. Finally, experiments involving bacteria allowed to complete those results in more complex systems and to identify the distinctive surface pattern of bioalteration.

Constraining the mineral and elemental composition of dust aerosol

C. PÉREZ,[1] R. MILLER[1], J.P. PERLWITZ AND S. RODRÍGUEZ

[1]NASA Goddard Institute For Space Studies, New York, USA, (carlos.perezga@nasa.gov)

[2]Izaña Atmospheric Research Centre, Spain

The climate effect of soil dust aerosols depends upon the particle mineral composition. Dust radiative forcing is related to the presence of iron oxides like hematite. Structural iron within clays makes an additional contribution to marine productivity and carbon uptake. Here, we discuss how to constrain the regional distribution of various iron-bearing minerals using measurements of mineral and elemental composition along with information about soil weathering.

We present a prognostic model of aerosol mineral content, based upon previous work relating the soil fraction of each mineral to the soil type. The model is embedded with the NASA GISS Earth System Model and predicts the regional distribution of illite, kaolinite, smectite, calcite, quartz, feldspar, iron (hydr)oxide, and gypsum. Evaluation of the predicted mineral content is challenging because this quantity is infrequently measured. Elemental composition is more commonly availiable but does uniquely constrain the mineral distribution, partly because the modeled minerals are only a subset of those contributing to observed elemental composition. We use mineral content and elemental composition within the same measured samples to derive a likely chemical composition for each modeled mineral. This can be applied to the model for comparison to the observed elemental composition.

An additional challenge is predicting the size distribution of each mineral at the time of emission. Previous work prescribes the mineral fraction in each of the soil clay and silt size categories. One challenge is that the clay and silt amount is biased by disturbance and disaggregation of larger particles during size characterization of soils. This leads to predictions of excessive structual iron within the clay size at the expense of aggregates in the silt size. We describe how sparse measurements of the mineral size distribution can be used to constrain the emitted size distribution.

The iron-bearing minerals are related to soil weathering that can be related to various measured quantities such as the Parker index. Using published soil measurements, we evaluate the representation of soil weathering in the model, which provides an independent constraint upon the iron-bearing minerals within the soil that are transported by the model.

Oxidation of Cu(I) in Seawater at Low Oxygen Concentrations

NORMA PÉREZ-ALMEIDA, MELCHOR GONZÁLEZ-DÁVILA, J. MAGDALENA SANTANA-CASIANO, ARIDANE G. GONZÁLEZ AND MIGUEL SUÁREZ DE TANGIL

Departamento de Química, Universidad de Las Palmas de Gran Canaria, Campus Universitario Tafira S/N, 35017, Las Palmas, Spain. Email: (mperez@dqui.ulpgc.es)

The oxidation of nanomolar copper(I) at low oxygen (6μM) concentrations was studied as a function of pH (6.7–8.2), ionic strength (0.1–0.76 M), total inorganic carbon concentration (0.65–6.69 mM), and the added concentration of hydrogen peroxide, H_2O_2 (100-500 nM) over the initial 150 nM H2O2 concentration in the coastal seawater. The competitive effect between H_2O_2 and O_2 at low O_2 concentrations has been described. Both the oxidation of Cu(I) by oxygen and by H_2O_2 had a reaction order of one. The reduction of Cu(II) back to Cu(I) in the studied seawater by H_2O_2 and other reactive oxygen intermediates took place at both high and low O_2 concentrations. The effect of the pH on oxidation was more important at low oxygen concentrations, where $\delta \log k / \delta pH$ was 0.85, related to the presence of H_2O_2 in the initial seawater and its role in the redox chemistry of Cu species, than at oxygen saturation, where the value was 0.6. A kinetic model that considered the Cu speciation, major ion interactions, and the rate constants for the oxidation and reduction of Cu(I) and Cu(II) species, respectively, was applied. When the oxygen concentration was lower than 22 μM and under the presence of 150 nM H_2O_2, the model showed that the oxidation of Cu(I) was controlled by its reaction with H_2O_2. The effect of the pH on the oxidation rate of Cu(I) was explained by its influence on the oxidation of Cu(I) with O2 and H_2O_2, making the model valid for any low oxygen environment.

The role of groundwater in the formation of the giant nitrate deposits of Atacama: Iodine-129 and stable chromium isotopic evidence

A. PEREZ FODICH[1]*,[2], F. ALVAREZ[1], G.T. SNYDER[3], R. SCHOENBERG[4] AND M. REICH[1,2]

[1]Dept. of Geology, University of Chile, Santiago, Chile(*correspondence: aliperezfodich@gmail.com)
[2]Andean Geothermal Center of Excellence (CEGA), University of Chile, Santiago, Chile
[3]Dept. of Earth Science, Rice University, Houston, TX, USA
[4]Dept. of Geoscience, University of Tuebingen, Germany

The nitrate deposits of the hyperarid Atacama Desert are a complex mineral association of nitrates, chlorides, sulfates, perchlorates, iodates and chromates. Recent studies have focused mainly on the nitrate, sulfate and perchlorate components and despite the fact that the atmospheric influence is indeed recognized, the formation of these extensive deposits still remains highly controversial.

Here we focus on the so far poorly studied iodine and chromium components of nitrates, and we present the first iodine-129 (^{129}I) and stable chromium isotopic ($\delta^{53/53Cr}$) data for these deposits. Stable iodine in the nitrates is high (10's of ppm to >2000 ppm), exceeding the iodine content of the average continental crust by 3 to 4 orders of magnitude. Futhermore chromium is enriched in the nitrate deposits in its oxidized state Cr(VI), forming chromate minerals, a rare phase of chromium under natural and surficial conditions. Iodine isotopic ratios of nitrate samples are generally low ($_{129}I/I$ ~200-600) and similar to deep marine sediment reservoirs and shales. Stable chromium isotopes of nitrates have positive and highly fractionated values ($\delta^{53/52}Cr$ ~ +1 to +3‰), showing that the chromium signal is highly distinct compared to most chromium terrestrial reservoirs.

The isotopic signatures of iodine and chromium in the nitrates is consistent with a groundwater source rather than an atmospheric one. Therefore, and considering that: (i) low iodine-129 ratios are indicative of deep sedimentary sources and (ii) chromium data reveal significant redox-cycling, most probably related to groundwater transport, we suggest a genetic model where iodine, chromium and eventually other chemical components (e.g. part ot the nitrate and sulfate) were sourced from Jurassic marine shales found upstream in the Precordillera. The formation of nitrate deposits would then be the result of a unique combination of multiple sourcing, groundwater transport processes, and wet and dry (atmospheric) deposition under conditions of increasing desiccation.

Isotopic fractionation of Cu in biofilms from a historic mining site

NATHALIE PÉREZ RODRÍGUEZ[1]*, WOLFRAM ADLASSNING[2], ILIA RODUSHKIN[3], LENA ALAKANGAS[1], AND BJÖRN ÖHLANDER[1]

[1]Division of Geosciences and Environmental Engineering, Luleå University of Technology, Sweden. (nathalie.perez@ltu.se)
[2]Core Facility Cell Imaging and Ultrastructure Research, University of Vienna. Austria.
[3]ALS Laboratory Group, ALS Scandinavia. Luleå, Sweden.

The environmental development of historical mine sites offers a good opportunity to study the metal cycle processes within the system. One of those sites is the spoil heap area of Schwarzwand in Salzburg, Austria. In this location a constant bluish precipitation -composed of Cynaobacteria and secondary copper minerals- in the creeks is present. In this study, the Cu concentration and isotope composition ($\delta^{65}Cu$) in selected samples from biofilm, stream water and heap rocks from Schwarzwand was measured.

Results show a variability towards the heavier Cu isotope from rocks, to water to biofilm samples. An interesting observation is the fact that regardless the Cu concentration in the biofilm that ranges from 100 ppb to 5%, its isotopic signature remains constant, with values from 0.3435‰ to 0.6984‰. Contrary to the expected beaviour of bacterias to be a sink for the lighter Cu isotope [1], the biofilm has a heavier Cu isotope signature compared to the rock and stream water from the site. This biofilm comprises several species of *Phormidium* (Cyanobacteria) embedded in a matrix of organic polymers and detritus. This result implies that in a bulk result the processes that occur in the matrix such as mineral precipitation and adsorption can count in a larger extent to the total Cu isotope in the biofilm system. In addition, the presence of plants such as copper mosses (*Pohlia* spp.) in the biofilm can also isotopically frationate the Cu available to the biofilm, as it has been seen before in plant systems [2].

The results shown can be of importance in the potencial use of such metal-tolerant biofilms for remediation purposes by pointing out the main processes that can cause a fractionation of metals such as Cu and Fe.

Hg isotope fractionation among atmospheric mercury species above a coastal suburban environment (Pensacola, Florida, USA)

VINCENT PERROT[1], VIRGINIA ELLER[2], WILIAM, M. LANDING[3] AND VINCENT SALTERS[4]

[1]National High Magnetic Field Laboratory, Florida State University, Tallahassee, Florida,(perrot@magnet.fsu.edu)
[2]NHMFL, FSU, Tallahassee, Florida,(eller@magnet.fsu.edu)
[3]Department of Earth, Ocean and Atmospheric Science, FSU, Tallahassee, Florida, (wlanding@fsu.edu)
[4]NHMFL and Dept. EOAS, FSU, Tallhassee, Florida, (salters@magnet.fsu.edu)

Mercury is a pervasive global pollutant that bioaccumulates in aquatic food webs after being methylated in the anoxic zones of aquatic systems. Atmospheric deposition of Hg from local, regional and global is the main contributor to Hg in ecosystems. The fate of Hg in the atmosphere is controlled by multiple processes. We measured the Hg isotopic composition of gaseous elemental Hg (GEM, gold coated quartz sand traps), reactive gaseous Hg (RGM, KCl soaked quartz fiber filters, QFF) and particulate aerosol Hg ($Hg_{(p)}$, QFF) in the atmosphere above the coast near Pensacola, Florida, during summer 2012. 4 rain samples were also collected. Both mass-dependent (MDF) and mass-independent (MIF) signatures of GEM were significantly different than those of Hg(II) species. GEM, more than 99% of the total Hg at this site, displayed positive δ^{202}Hg (0.7 to 1.2‰,) whereas both RGM and Hg(p) had negative δ^{202}Hg (-2.4 to -0.1‰). On the other hand, GEM (n=14) had slightly negative Δ^{199}Hg and Δ^{200}Hg average values -0.26±0.09‰ and -0.07±0.03‰, respectively, whereas Hg(p) (n=17) has slightly positive values (0.33±0.13‰ and 0.10±0.04‰, respectively). RGM displays no significant MIF (Δ^{199}Hg=0.02±0.14‰ and Δ^{200}Hg=-0.02±0.10‰). We suggest, in agreement with previous studies, that both oxidation and reduction processes are responsible for the patterns in the isotopic composition of RGM and Hg(p). Preferential scavenging of RGM and Hg(p) (rather than GEM) in wet and dry deposition result in significant variability of the isotopic composition deposited in coastal environments due to seasonal and sporadic changes in air mass trajectories and atmospheric physico-chemistry.

Molecular properties of anion-mineral surface complexes probed with infrared desorption and temperature-excursion experiments

PER PERSSON[1,2]

[1]Centre for Environmental and Climate Research, Lund University, Sweden
[2]Department of Chemistry, Umeå University, Sweden (correspondence: per.persson@cec.lu.se)

Surface complexation theory provides a framework to conceptually describe molecular-level interactions at water-mineral interfaces [1]. Central to this theory is the formation of local molecular entities (surface complexes) with well-defined structures and compositions. Typically, under a given experimental condition several surface complexes co-exist and a challenge in this research is to determine the molecular properties of the individual species. We need this information to make connections between the properties of these species and their influence on, for instance, surface catalytic, dissolution, and redox processes. Previously, mixtures of surface complexes have been disentangled via pH and ionic strength dependence experiments, thereby exploiting differences in the stability of different protonation states and surface bonding interactions. Here we will introduce infrared desorption and temperature-excursion experiments and their potential to differentiate between and characterize anionic surface complexes. For a series of carboxylic acids we will show that differences in desorption rates separate protonated and deprotonated surface complexes. We will also show that the number of bonds between the carboxyls and the surface is the decisive factor determining desorption rates, and not so much the character of the bond i.e. whether these are inner sphere or hydrogen bonded structures. Infrared temperature-excursion experiments distinguish surface complexes based on their fundamental thermodynamic properties. We will show how this approach helps to shed light on the controversy surrounding surface complexes of sulfate.

The space and time complexity of chaotic mixing of silicate melts: implications for igneous petrology

PERUGINI D.[1], DE CAMPOS C.P.[2], ERTEL-INGRISCH W.[2] AND DINGWELL D.B.[2]

[1]Department of Earth Sciences, University of Perugia, Italy (diegop@unipg.it)
[2]Department of Earth and Environmental Sciences, Ludwig-Maximilian-University, Germany

We present new experimental results on the study of the space and time modulation of compositional fields during chaotic mixing between mafic and felsic silicate melts. The experimental strategy was planned using numerical simulations performed using the experimental geometry. These mixing experiments were performed using a recently developed experimental apparatus, which is capable of mixing high-viscosity silicate melts at high temperatures and under precisely controlled conditions of fluid-dynamics and strain. The compositional variability produced by the mixing process was investigated both along linear analytical transects and on high-resolution 2D X-ray maps, covering the mixing patterns.

Our results indicate that chaotic flow fields represent very powerful dynamics to blend silicate melts, even under laminar fluid dynamic conditions (Reynolds number ca. 10^{-7}) and for dissimilar melts with high viscosity ratios (on the order of 10^3). The repetition of stretching and folding processes between the two melts induced a strong increase of contact interfaces thus favoring efficient chemical exchanges. As a result the initial mafic composition is no longer detectable in the mixing system after ca. 2 h (i.e. the duration of the experiment). A further important result is the observation of highly non-linear patterns in inter-elemental plots produced by the onset of diffusive fractionation processes. This is contrary to common thinking that magma mixing should always produce linear trends between pairs of chemical elements.

A new measure, the "concentration variance", is proposed to quantify chemical element mobility during the mixing process. This measure is statistically robust and can be quantitatively used to measure chemical element mobility independently of the geometry in which the compositional variation (i.e. transects, areas, etc.) is embedded or the local strain history of the mingling.

Our results highlight concentration variance as a robust probe of the as yet poorly-understood processes involved in the common petrological process of magma mixing.

Concentration variance decay during magma mixing: a volcanic chronometer to measure magma ascent velocity during explosive eruptions

PERUGINI D.[1], DE CAMPOS C.P.[2] AND DINGWELL D.B.[2]

[1]Department of Earth Sciences, University of Perugia, Italy (diegop@unipg.it)
[2]Department of Earth and Environmental Sciences, Ludwig-Maximilian-University, Germany

The ability of chemical elements to diffuse in silicate melts controls the rates of crystal growth and dissolution kinetics, the rate of homogenization of compositional gradients generated by fractional crystallization and assimilation of country rocks as well as one of the most intriguing processes of all, magma mixing. In the context of mixing the time dependence of mass transfer processes constitutes a powerful tool to define geochemical clocks to estimate timescales of magma dynamics and eruption.

Here we aim to understand the timescale of chemical element mobility during mixing to define a chronometer to dechiper the ascent velocity of magmas during explosive volcanic eruptions. The mixing process was induced experimentally using a high-temperature centrifuge apparatus under controlled thermal and rheological conditions.

Using this novel laboratory-based time-series experiments, we show that the Concentration Variance Decay (CVD, an inevitable consequence of magma mixing) is exponential with time and represents a powerful geochronometer to measure the time from mixing to eruption/quenching.

The mingling-to-eruption time of some explosive volcanic eruptions from Campi Flegrei (Italy) yield durations on the order of tens of minutes. These imply very rapid ascent velocities of 5-8 meters per second.

Application of the CVD geochronometer to the eruptive products may provide unprecedented information about trasport of magmas in active volcanoes and could be decisive for the preparation of volcanic hazard mitigation during volcanic unrest.

Electrical conductivity of partially molten CI-chondritic mantle at high pressures

GIACOMO PESCE[1], GEETH MANTHILAKE[2] AND DENIS ANDRAULT[3]

([1]g.pesce@opgc.univ-bpclermont.fr
[2]g.manthilake@opgc.univ-bpclermont.fr
[3]d.andrault@opgc.univ-bpclermont.fr)

In a primitive Earth scenario, large scale impacts are believed to be responsible of the formation of magma oceans. Such catastrophic events have produced a temperature increase above the mantle liquidus up to a few hundred kilometers depth or more. At present day, the Earth's mantle may also undergo small degree of partial melting at greater depths, but this time the temperature should be just above the solidus. Such partial melting is expected to produce major chemical segregation between the different Earth's reservoirs, which could affect the physical properties of the mantle.

Electrical conductivity is highly sensitive to the presence of melt, and it is one of useful tool to detect melting and its distribution within the mantle. Electrical conductivity of partially molten materials can be accurately determined at high pressures and temperatures using multi anvil apparatus. Our experimental goals are two folds. First, we aim at tracking the onset of melting *in situ* by using electrical conductivity. This will help not only to synthezise samples with well controlled degree of partial melting, but also to refine the sequence of crystallisation of a chondritic mantle for mantle depth up to ~700 km. Second, we aim at determining the effect of partial melting on electrical conductivity in a wide range of mantle pressures. It will therefore provide new clues to localize regions were mantle undergoes melting.

Our preliminary results on chondritic material at shallow mantle conditions (5 GPa) show that, at increasing temperature, electrical conductivity values increase considerably as soon as we reach the solidus temperature, indicating the onset of melting. Cross sections of the recovered samples were investigated using scanning electron microscope and electron microprobe. We aim at determining the solid-liquid phase relations at temperatures intermediate between solidus and liquidus and reconstruct the sequence of phase crystallization.

Water content of the oceanic lithosphere at Hawaii from FTIR analysis of peridotite xenoliths

ANNE H. PESLIER[1,2] AND MICHAEL BIZIMIS[3]

[1]Jacobs Technology, JETS, Houston, TX 77058, USA; (anne.h.peslier@nasa.gov)
[2]NASA Johnson Space Center, Houston, TX 77058, USA
[3]Earth and Ocean Sciences, University of South Carolina, Columbia, SC 29208, USA; mbizimis@geol.sc.edu

Although water in the mantle is mostly present as trace H dissolved in minerals, it has a large influence on its melting and rheological properties. The water content of the continental mantle lithophere is starting to be well constrained thanks to the abundance of mantle xenoliths [1,2], but that of the oceanic mantle lithosphere is mainly inferred from MORB glass data. Using Fourier transform infrared (FTIR) spectrometry, we determined the water content of olivine (Ol), clinopyroxene (Cpx) and orthopyroxene (Opx) in spinel peridotite xenoliths from Salt Lake Crater, Oahu, Hawaii, which are thought to represent fragments of the Pacific oceanic lithosphere that was refertilized by alkalic Hawaiian melts [3,4]. Only Ol exhibits H diffusion profiles, evidence of limited H loss during xenolith transport to the surface. Water concentrations (Ol: 9-28 ppm H_2O, Cpx: 246-566 ppm H_2O, Opx: 116-224 ppm H_2O) are within the range of those from continental settings [1,2] but are three times higher than those from Gakkel ridge abyssal peridotites [6]. The Opx H_2O contents are similar to those of abyssal peridotites from Atlantic ridge Leg 153 but ten times higher than those from Leg 209 [5].

The calculated bulk peridotite water contents (50 to 110 ppm H_2O) are in agreement with MORB mantle source water estimates [7] and lower than estimates for the source of Hawaiian rejuvenated volcanism (~525 ppm H_2O [8]). The water content of Cpx and most Opx correlates negatively with spinel Cr#, and positively with pyroxene Al and HREE contents. This is qualitatively consistent with the partitioning of H into the melt during partial melting, but the water contents are too high for the degree of melting these peridotites experienced. Melts in equilibrium with xenolith minerals have H_2O/Ce ratios similar to those of OIB [9].

Tourmaline breakdown in high-grade metamorphic rocks from the Alamo Complex (Central Iberian Zone, Spain): Implications for evolution of boron during crustal anatexis

PESQUERA A.[1], TORRES-RUIZ J.[2], GIL-CRESPO P.P.[1] AND RODA-ROBLES E[1].

[1]Departamento de Mineralogía-Petrología, Universidad del País Vasco, PO Box 644, E-48080 Bilbao, Spain
[2]Departamento de Mineralogía-Petrología, Universidad de Granada, Campus Fuentenueva, E-18002 Granada, Spain

The Alamo Complex comprises a set of structural-metamorphic domes alternating with low-grade metasedimetary rocks of Upper Proterozoic to Lower Cambrian age in the northern part of the Schist-Greywacke Complex (Central Iberian Zone). Tourmaline is a widespread mineral within the domes, which occurs in clastic metasedimentary rocks, tourmalinites, gneisses, migmatites, leucogranites and pegmatites. Tourmaline composition from metamorphic rocks, with Mg/(Mg+Fe) = 0.35-0.73 and X/(X+Na) = 0.10-0.56 (X = X-site vacancy), as well as the bulk-rock B contents (generally < 100 ppm) do not show systematic variations with increasing metamorphic grade. Large tourmaline crystals occur in the transition from biotite-cordierite-sillimanite-plagioclase gneisses to migmatites. Generally tourmaline is scarce or absent in stromatic migmatites. It appears as subhedral crystals in leucosome layers associated with quartz, plagioclase and biotite. Textural evidence for breakdown of tourmaline is provided by the occurrence of crystals in melanosome domains displaying corroded edges and deep embayments. Boron liberated by destabilization of tourmaline would incorporate into associated melts and fluids and play a significant role in controlling the behaviour of boron during anatexis. Tourmaline-bearing leucogranite sheets and dikes can be found within the migmatite zone, suggesting a genetic relationship between leucogranites and migmatites. The high B contents of the leucogranites (up to 1.2% B_2O_3), in conjunction with the low B contents of the migmatites, suggest that anatexis was an open system process with significant circulation of B-rich fluids. These may have important implications on the melt generation and rheology of the rocks. The activity of B-rich fluids during metamorphism, anatexis and segregation of granitic melts would account for the multistage B-metasomatism that occurred in the Alamo complex during the Variscan orogen.

Geochemical and multiple sulfur isotope study on tap and river water quality in the Beijing urban area

MARC PETERS[1]*, QINGJUN GUO[1]*, HARALD STRAUSS[2], AND GUANGXU ZHU[1]

[1]Center for Environmental Remediation, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing 100101, China (*correspondence: mpeters@igsnrr.ac.cn, guoqj@igsnrr.ac.cn)
[2]Institut für Geologie und Paläontologie, Westfälische Wilhelms-Universität Münster, Corrensstrasse 24, 48149 Münster, Germany

Deterioration of tap and surface water quality in urban areas has become a major environmental concern worldwide. This study presents the first results of a pilot study on tap and river water in Beijing, China, using multiple sulfur isotopes ($\delta^{34}S_{SO4}$, $\Delta^{33}S_{SO4}$) in addition to a large number of physico-chemical and chemical parameters. The concentrations of most inorganic compounds (e.g. SO_4^{2-}, NO_3^-, As, heavy metals) analyzed for 59 tap water samples comply with the drinking water guideline limits as suggested by the WHO. In addition, the majority of 65 river water samples meet the national standards for surface water. However, NO_3^- shows concentrations between 50 and 97mg/L in 15.4% of the river water samples exceeding the maximum standard value of 44 mg/L. SO_4^{2-} concentrations are all below the guideline value of 250 mg/L for both tap and river water, although clearly higher compared to rivers in South China due to a drier climate with less precipitation coupled with urban pollution in the Beijing area. Similarly, $\delta^{34}S$ ranges from +6.4 to +15.4‰ for the vast majority of the tap and river water sulfates suggest urban sewage and chemical detergents as well as atmospheric deposition as the main sulfate sources in Beijing waters. $\Delta^{33}S$ values from -0.061 to -0.006‰ for tap water and between -0.061 and -0.017‰ for river water sulfate show no indication for microbial sulfur metabolism (e.g. sulfate reducers, sulfur disproportionators). In summary, the analyzed dissolved inorganic compounds in Beijing tap and river water do not cause a relevant decline in water quality. Forthcoming isotope data for NO_3^- ($\delta^{15}N$ and $\delta^{18}O$) and SO_4^{2-} ($\delta^{18}O$) will further strengthen the conclusions.

[3]Institut für Geologische Wissenschaften FU Berlin, Germany
[4]Dep of Lithospheric Research, Universität Wien, Austria

Alpha decay of ^{184}Os to ^{180}W has been theoretically predicted, but was previously not observed in particle counting experiments [1]. Sufficiently precise measurements to detect ^{184}Os-decay in natural materials have long been impossible due to the low abundance of ^{180}W (~0.12%). However, recent advances in ICP mass spectrometry have permitted measurements at precisions better than one part in 10,000, by which non-terrestrial abundances of ^{180}W in some iron meteorites could be resolved [2]. Here, we investigate whether these ^{180}W-anomalies can be explained by α-decay of ^{184}Os, by using combined ^{180}W and Os-W concentration measurements. Osmium and W concentrations were determined by isotope dilution in 11 iron meteorites and in one H5 ordinary chondrite (Pultusk). Tungsten isotope compositions were analysed on splits of the same samples by the Neptune multi-collector ICPMS at Cologne-Bonn (for details of the analytical procedure, see [3]). The abundances of ^{180}W in our samples correlate significantly with ^{184}Os/^{184}W ratios (MSWD = 1.3) with a slope of m = 0.000295 ± 0.000060. We propose that this correlation represents a combined isochron for iron meteorites and ordinary chondrites (age: ~4.565 Ga). The slope of this isochron corresponds to a decay constant value for $\lambda^{184}\mathrm{Os}(\alpha)$ of $6.46 \pm 1.34 \times 10^{-14}$ a^{-1}. The calculated half-life is $1.12 \pm 0.23 \times 10^{13}$ years. This value is in good agreement with theoretical predictions (e.g., [4,5]), and is only slightly lower than the minimum estimate from particle counting.

Importantly, the now confirmed ^{184}Os-^{180}W decay system may constitute a viable new chronometer and tracer for geological processes that fractionate Os from W, such as core formation and silicate differentiation. This is illustrated by a measured ^{180}W-deficit in terrestrial basalts relative to chondrites by 1.16 ± 0.69 parts in 10,000, consistent with core formation ~4.5 Ga ago.

Deglacial change in terrestrial carbon storage estimated by benthic δ^{13}C

C.D. PETERSON[1]* AND L.E. LISIECKI[1]

[1]Department of Earth Science, University of California, Santa Barbara, CA, 93106-9630, USA (*correspondence: carlye@umail.ucsb.edu, lisiecki@geol.ucsb.edu)

Terrestrial carbon storage is dramatically decreased during glacial periods due to cold temperatures, increased aridity, and the presence of large ice sheets on land. Most of the carbon released by the terrestrial biosphere is stored in the glacial ocean, where the isotopic signature of terrestrial carbon (δ^{13}C terrestrial carbon = -25‰) is observed as a 0.32-0.7‰ depletion in benthic foraminiferal δ^{13}C. The wide range in estimated δ^{13}C change is due to different subsets of benthic δ^{13}C data and different methods of weighting the mean δ^{13}C by volume. We estimate the glacial-interglacial δ^{13}C change of marine DIC using benthic *Cibicides* spp. δ^{13}C records from 486 core sites (seven to twelve times as many as previous studies). We divide the ocean into eight regions to generate linear regressions of regional δ^{13}C versus depth (0.5-5 km) for the late Holocene (0-6 ka) and Last Glacial Maximum (18-21 ka) and estimate a mean δ^{13}C decrease of 0.39 +/-0.05‰ (2σ). Assuming an isotope change of 0.04‰ in the surface ocean (0-0.5 km), we estimate a whole ocean δ^{13}C change of 0.33‰, equivalent to a terrestrial biosphere decrease of ~500 Pg C. If we account for uncertainty of +/-0.05‰ in our deep ocean estimate and a range of 0.34‰ for possible surface changes, we estimate a terrestrial biosphere decrease of 360-600 Pg C. Our estimate is smaller than a vegetation reconstruction estimate of 750-1050 Pg C [1] and within the uncertainty range of a recent dynamic global vegetation model estimate of 550-694 Pg C [2]. Additionally, our estimate falls in the middle of previous whole ocean δ^{13}C estimates of 0.32‰ [3] and 0.46‰ [4].

Volatile Budget of the Galapagos Plume

M. PETERSON[1]*, A. SAAL[1], E. HAURI[2], M. KURZ[3], R. WERNER[4], F. HAUFF[4], D. GEIST[5] AND K, HARPP[5]

[1]Brown University, Providence, RI, 02912, USA (*correspondence: mary_peterson@brown.edu)

[3]WHOI, Woods Hole, MA, 02543, USA
[4]GEOMAR, Kiel, 24148, Germany
[5]University of Idaho, Moscow, ID, 83844, USA

The study of volatiles (H_2O, CO_2, F, S, and Cl) is important because volatiles influence melting and crystallization, as well as the rheology of the mantle. New volatile data obtained from 89 submarine glass chips collected from the Galapagos show variations between regional mantle sources forming the Galapagos Archipelago.

The concentration of volatiles can be affected by degassing, sulfide saturation, and assimilation of hydrothermally altered material. We use ratios between volatile and refractory elements that have similar incompatibilities to account for melting and crystal fracitonation. Degassing has affected the concentration of CO_2 of the samples, but has had a minor impact on the concentration of H_2O, F, Cl and S. Our samples are sulfide undersaturated. Assimilation of hydrothermally altered material is assessed using Cl/K ratios and the magnitude of the Sr anomaly (Sr/Sr*>1), which can indicate plagiocalse assimilation. Samples depleted in trace elements (TE) have Cl/K ratios greater than the 0.01 expected for a depleted source. They also show a positive correlation between Sr/Sr* and volatile/refractory ratios, indicating assimilation has affected all of the volatile concentrations of these depleted samples. Intermediate to enriched TE samples have been less affected by contamination.

Within our sample suite there are 3 end-member compositions; a high $^3He/^4He$ group (>20*Ra), a TE-enriched group similar to Pinta Is., and a TE-depleted group. The S/Dy ratios for the sample suite cluster around a mean value of 220±41. Between the high $^3He/^4He$ group and the TE-enriched group, H_2O/Ce ranges from 160±33 to 146±28 and the F/Nd varies from 19±1 to 25±2 respectively. The H_2O/Ce ratios of TE-depleted samples are significantly contaminated, but the F/Nd ratio is 16±2. The high $^3He/^4He$ and TE-enriched samples are significantly degassed but the TE-depleted have CO_2/Nb ratios up to 400, slightly higher than expected for undegassed MORB. Uncontaminated Cl/K ratios are defined as the lowest ratios at a given TE enrichment (Nb/La). Our uncontaminated values are consistent with those previously reported for MORB and OIB.

U-Pb-Hf – isotopes of zircon from the eastern part of the Sveconorwegian Orogen, SW Sweden: Implications for the growth of Fennoscandia

ANDREAS PETERSSON[1], ANDERS SCHERSTÉN[1], JENNY ANDERSSON[2] AND CHARLOTTE MÖLLER[1]

[1]Department of Geology, Lund University, Sölvegatan 12, SE-223 62 Lund, Sweden. (andreas.petersson@geol.lu.se; anders.schersten@geol.lu.se; charlotte.moller@geol.lu.se)
[2]Geological Survey of Sweden, Box 670, SE-751 28 Uppsala, Sweden.(jenny.andersson@sgu.se)

Models for the growth of Fennoscandia, including the crust in the eastern part of the Sveconorwegian orogen, have largely been based on U-Pb data and do not discriminate between juvenile and reworked crust. These growth models also stand in contrast with current estimated reworking rates of the Palaeoproterozoic. The present comprehension of the growth of southwestern Fennoscandia involve ~330 million years of semi-continuous, subduction-related magmatism. We present new combined U-Pb and Hf isotopic data, from the Eastern Segment and the Idefjorden terrane of the Sveconorwegian Province, and suggest a revised model of crustal growth. Most of the crystalline basement in this part of the shield formed by mixing of a 2.1 to 1.9 Ga juvenile component and Archaean crust. Our combined U-Pb-Hf data reveal that Archaean reworking decreased between 1.9 and 1.7 Ga and a mixed Svecofennian crustal reservoir was generated. Succeeding magmatism between 1.7 and 1.4 Ga involved reworking of this reservoir with little or no crust generation. An influx of juvenile magma is recorded at *c*. 1.2 Ga by granite to quartz-syenite magmatism with mildly depleted ($\varepsilon Hf_{(1.18\ Ga)}$ of *c*. 3) signatures. The amount of recycled crust in the 1.9-1.7 Ga arc system as recorded by the U-Pb-Hf system is thus in contrast to previously proposed models for the growth of the southwestern part of the Fennoscandian Shield. Our data agree with the proposed long-term subduction along the western margin of Fennoscandia, but suggest substantial reworking of existing crust and minor amounts crustal growth after 1.9 Ga.

Mercury speciation in a historic Hg-mining and smelting area, Apuseni Mts., Romania

L. PETRESCU*[1], D. JIANU[1] AND C. MILU[1]

[1]Bucharest University, Faculty of Geology and Geophysics, Bucharest, Romania (*lucpet@geo.edu.ro)

Few published data exist on mercury content in mine waste dumps from Romania, although mercury contamination in soil is a problem found at many production (active and inactive) sites. The Izvorul Ampoiului abandoned mercury mine is connected with the Neogene vulcanite from the Apuseni Mts. Mercury generally appears in the form of cinnabar (HgS), though native Hg is also occasionally found. Hg mining has been active from the 16th century till 1968. During this period, Izvorul Ampoiului deposit constituting the first productive mine in Romania. An Hg ore smelter located close to the mine had been in operation from 1925 since 1968. The waste material from the mine and the roasting site was dumped in close vicinity of the mine. There is no exact information available on the total production, but in 1967 the plant were processed 18000 tons of ore with a content of 0.468% Hg and were extracted 8434 kg of Hg. A total of 32 minesoils was sampled from the top 15 cm. Concentration of total Hg was determined using an AMA-254 (LECO). In addition from the total Hg determinations, waste samples were also submitted to a sequential extraction procedure (i.e. Kingston method) to remove mobile Hg (leaching with 2%HCl+10%ethanol solution), semimobile Hg (leaching with 33% HNO_3 solution) and nonmobile Hg (leaching with 1:6:7 $HCl:HNO_3:H_2O$ solution). The XRD analysis revealed that the sampled waste material consisted mainly of kaolinite, muscovite, calcite, quartz, halloysite and goethite. Presence of clay minerals and Fe-oxyhidroxides suggested relatively favourable conditions for Hg adsorption to the mineral surfaces. Hg associated with mineral surfaces may undergo methylation processes, and thus, may represent a potential long-term environmental risk. Mercury concentrations in the mine waste samples were highly variable. Total Hg concentrations vary from 3.7 to 27.85 ppm with a mean of 14.03 ppm. These concentrations exceeded the guideline value of 1.0 ppm established by the Romanian Legislation. The sequential extraction shows that the semimobile fraction yielded the highest concentration of Hg, being about 50–57% of total mercury. Contents in the non-mobile fraction were about 30%. Although mobile Hg fraction represents only ~10% of total Hg, this fraction contains the most available Hg, including methylmercury content, not to be overlooked. Subspeciation by solid phase extraction showed that the mobile organic Hg concentration is less significant (approximately 4%). Mobile organic mercury subfraction corresponds, according to the reference method, to the most toxic and bioavailable fraction. These data could not be confirmed with others since there are no existing data about organic mercury content in this area. Further investigations will be carried out in order to elucidate the factors affecting mercury mobility in surrounding soils.

Intrusion mechanisms of mafic plutons in the middle crust: Insights from the Permian Sondalo gabbroic complex (Central Alps)

B. PETRI[1]*, M. MATEEVA[1], G. MOHN[2], G. MANATSCHAL[1], K. SCHULMANN[13] AND E. SKRZYPEK[4]

[1]EOST,Université de Strasbourg, France (*Correspondance : bpetri@unistra.fr)

[3]Center for Lithospheric Research, Czech Geological Survey, Praha, Czech Republic

[4]Uniwersytet Wrocławski, Wrocław, Poland

Across Europe, Late-Carboniferous – Permian bimodal magmatism is one of the last manifestation of the Variscan orogenic cycle. Whereas acid magmatic bodies are mostly restricted to upper and middle crustal levels, mafic intrusions are emplaced through the entire continental crust. The reason for such shallow intrusion levels for basic magmas still remains enigmatic, as buoyancy shall not be the main driving force. In order to understand the emplacement of mafic magmas in rather uncommon levels (< 20km), we characterized the structure of the intrusion of the Sondalo gabbroic complex, exposed in the Austroalpine Campo unit (N-Italy).

Macroscopic foliations, anisotropy of magnetic susceptibility (AMS) data and lithological mapping allow to subdivide the pluton into three concentric areas. From the core composed of Ol-Gabbro to the dioritic rim, the mean magnetic susceptibility (Km) decreases from $1.43*10^{-3}$ S.I. to $8.42*10^{-4}$ S.I., and the mean anisotropy (P) from 1.073 to 1.044. These data reveal the existence of a vertical magnetic and magmatic foliation associated with a vertical magnetic lineation in the centre of the pluton composed of gabbro and Ol-bearing gabbro. The foliation is parallel to both the large granulite-facies metapelitic septa and the surrounding host-rock foliation. In contrary, the more dioritic external facies develops a moderately dipping magnetic fabric roughly parallel to the margins of the pluton.

Our data and field observations suggest that magma ascent was probably facilitated by the mechanical anisotropy provided by the steep fabric in the metapelitic host-rock. The assimilation of H2O-rich melts derived from the surrounding metapelites also made the magma buoyant enough to reach shallower crustal levels.

Using CO_2 flux to constraint a 3D physical model of the Campi Flegrei caldera geothermal system

Z.PETRILLO[1]*, G.CHIODINI[1], A.MANGIACAPRA[1], S.CALIRO[1]; P. CAPUANO[2], G. RUSSO[3], C. CARDELLINI[4] AND R. AVINO[1]

[1]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Vesuviano, Via Diocleziano 328, Napoli, Italy (*correspondence: zaccaria.petrillo@ov.ingv.it)
[2]Università degli Studi di Salerno, Dipartimento di Fisica, Salerno, Italy
[3]Università degli Studi di Napoli Federico II, Dipartimento di Scienze Fisiche, Napoli, Italy
[4]Università di Perugia, Dipartimento di Scienze della Terra, Italy

Fluids release at depth has a primary role in generating volcanic unrest periods at Campi Flegrei (CF). According to [1] 5000 ton/day of a CO_2 - H_2O gas mixture is released in the Solfatara area (~1.4 km^2). Heat flux associated to this degassing process was estimated to be ~100MW, representing the most important term in the energetic balance of the whole caldera. We have developed a 3D physical model of the CF geothermal system which accounts for the caldera rocks physical properties, bathymetry and water table topography. The new model, developed by using the TOUGH2 code simulator, was constrained by density values obtained by tomographic inversion of gravity data collected both onshore and offshore the caldera. Empirical relations between density and porosity and between porosity and permeability, derived by published data on samples cored in deep wells or collected in outcrops, allowed us to characterize the main rocks physical parameters controlling the dynamic of the CF geothermal system. We have investigated the effects of the injection at depth, in axis with Solfatara crater, of a hot gaseous mixture rich in CO_2 (5800 ton/day), according with the estimated mass flux released in the area through diffuse degassing. We show that the effects of the water table topography together with the bathymetry and the heterogeneous distribution of the rocks physical properties, lead to important differences in the hydrothermal circulation of fluids at CF. These constraints allow the activation of convective cells with different behaviour, which produce variable pattern of temperature inside the hydrothermal system. As a consequence, the predominant effect is again represented by a central plume below the Solfatara crater, but with a non-axisymmetric structure and a wider extension. Additionally, high temperature zones are present near the coastline and the in the middle part of the submerged area of the caldera with a SE-NW alignment.

Composition-dependent anisotropic interdiffusion tensor obtained from cation exchange between alkali feldspar and NaCl-KCl salt melt

E. PETRISHCHEVA, R. ABART AND A.-K. SCHAEFFER

University of Vienna, Department of Lithospheric Research, Vienna, Austria (elena.petrishcheva@univie.ac.at)

While homogeneous diffusion is fully described by a scalar diffusivity, diffusion in anisotropic crystals requires a tensor describing transport in each direction and correlations between different directions. Reconstruction of the scalar diffusion coefficient is an important inverse problem, which is addressed using backward integration of the concentration profile from a known solution of the diffusion equation. Moreover, by adjusting an experimental setup, even a composition-dependent diffusion coefficient can be reconstructed from the self-similar solution of the nonlinear diffusion equation.

We demonstrate that this method can be naturally generalized for an anisotropic system. The generalization is then applied to quantify the full composition-dependent anisotropic diffusion tensor for Na-K interdiffusion in alkali feldspar. Composition profiles obtained from cation exchange at 850°C and 1 bar between oriented cylinders and plates of sanidine with $X_{Or} = 0.84$ and a KCl salt melt show a plateau of compositions in equilibrium with the salt melt at the crystal surfaces separated from the unaffected interior regions of the crystals by a transition zone that is sharp in the *b*-direction and comparatively shallow in all directions lying in the *a*-*c* plane. Given that a 40 fold molar excess of alkali cations in the salt mixture relative to the feldspar was applied, the composition of the salt remained essentially constant during cation exchange. The presence of an inflection point in the composition profiles can thus only be explained by a composition dependent Na-K interdiffusion coefficient.

For 850°C we show that the Na-K interdiffusion coefficient is by a factor of about 10 larger in the *a*-*c* plane than in *b*-direction. There is only a weak composition dependence in the range $0.86 < X_{Or} < 0.95$. Only at $X_{Or} > 0.95$ the interdiffusion coefficient increases by about a factor of 10. These results were thoroughly tested by obtaining numerical solutions of the nonlinear diffusion equation with the reconstructed diffusion tensor and the initial conditions describing the experimental setup. Thereafter the numerical results were compared with the actually observed concentration profiles. Good agreement was found.

Mixing, mingling and enclave crumbling in the post-Minoan dacitic magmas of Santorini volcano, Greece

PETRONE CHIARA MARIA*[1], FRANCALANCI LORELLA[2], AND VOUGIOKALAKIS GEORGIOS E.[3]

[1]The Natural History Museum, Dept. Earth Sciences, Cromwell Road, SW7 5BD London, UK, (*correspondence: C.Petrone@nhm.ac.uk)
[2]Dipt. Scienze Terra, Universita' degli Studi di Firenze, Italy
[3]I.G.M.E., 3rd Entrance Olympic Village, Athens, Greece

The post-caldera islets of Palea- and Nea-Kameni formed as a result of nine eruptive events from A.D. 46-47 to 1950 in the center of the Santorini Minoan caldera. The erupted products are represented by dacitic lava flows and domes hosting basaltic to andesitic mafic enclaves. Dacitic rocks have low porphyritic index that increases with time, whereas their degree of evolution decreases pointing to the composition of the mafic enclaves. Enstatite contents of pyroxene and anorthite contents of plagioclase decrease from mafic enclaves to host lavas. Sr isotopes systematically increase with time and toward the less evolved composition of lavas and mafic enclaves, whereas Nd isotopes decrease. Whole rocks and mineral separates of mafic enclaves from the younger events are more Sr-radiogenic than their host lavas, the opposite occurs in the A.D. 46-47 lavas and enclaves.

Mixing and mingling processes between dacitic and mafic magmas, along with crumbling of the mafic enclaves in the host lavas are responsible for the observed textural and geochemical characteristics of the dacitic host lavas. The variations of Sr-Nd isotopes with time in the enclave magmas seem to indicate assimilation of limestone from the basement by the most mafic magmas; this process is associated to new mafic magma inputs and femic phase crystallization. A shallow layered reservoir with dacitic magmas overlaying lower mafic magmas is supported by our data. Crystal fractionation and cumulitic processes affect the lower part of the plumbing system allowing further layering of the mafic magmas, generating the variable and complex textures shown by the mafic enclaves. Different portions of the layered reservoir were frequently and variably sampled during time, as testified by variable types, compositions and distributions of mafic enclaves in the different eruptions. All this allows us to suggest periodic arrivals of mafic magmas in the post-Minoan plumbing system of Santorini, also implying for a still active magmatic system whose behaviour needs to be fully evaluated, also in the light of the 2011-2012 unrest.

A novel 2D LA-ICP-MS data analysis and visualization solution

JOSEPH A. PETRUS[1]* AND BALZ S. KAMBER[2]

[1]Laurentian University, Department of Earth Sciences, Sudbury, Ontario, Canada (*correspondence: jpetrus@laurentian.ca)
[2]Trinity College Dublin, Department of Geology, Dublin, Ireland, (kamberbs@tcd.ie)

Microscale mapping of geochemical data, both isotopic and trace elemental in nature, by LA-ICP-MS has become tremendously popular in recent years [1]. Typically, such maps are produced by continuously analyzing the elements of interest while rastering a laser over an area and periodically monitoring gas blanks and standards. In order to properly interpret the resulting data, sophisticated processing, visualization and analyses are usually required. Although software packages exist to help with the aforementioned tasks [2,3,4], they tend to emphasize data processing and visualization, but quantitative analysis remains difficult.

Here we report the capabilities of a new LA-ICP-MS mapping tool that focuses on visualization and analysis by leveraging Iolite's [2] extensive data processing capabilities. It is written in Python and makes use of the matplotlib plotting library to produce publication quality figures. The key features include map-wide multi-phase internal standard corrections, extracting traverses, integrating arbitrarily shaped two-dimensional regions, and inspecting regions on the map *via* standard diagrams (*e.g.*, concordia or REE). Furthermore, the package can be integrated with Iolite to provide a convenient workflow.

Examples of zoned igneous phenocrysts from historic lava flows, zoned Precambrian pyrite of a sulfur reducing baceria origin, reaction textures in spinel peridotite, and complex zircon will be provided to demonstrate the functionality and strengths of this new mapping tool.

The influence of functional groups on organic aerosol hygroscopicity

M. D. PETTERS[1], S. R. SUDA[1], G. YEH[2], A. MATSUNAGA[2], C. STROLLO[2], P. J. ZIEMMANN[2] AND S .M. KREIDENWEIS[3]

[1]Department of Marine Earth and Atmospheric Sciences, North Carolina State University, Campus Box 8208, Raleigh, NC

[2]Air Pollution Research Center, University of California, Riverside, CA 92521-0001, USA.

[3]Department of Atmospheric Science, Colorado State University, Fort Collins, CO 80523-1371, USA.

Organic aerosols in the atmosphere are composed of a wide variety of species, reflecting the multitude of sources and growth processes of these particles. Especially challenging is predicting how these particles may act as cloud condensation nuclei (CCN). Köhler theory relates the particle's dry diameter to its critical supersaturation. A hygroscopicity parameter, kappa, parameterizes this relationship in terms of the particle's chemical composition. Previous studies have characterized kappa values for a range of organic model compounds. Here we extend these studies by designing new model systems that allow systematic investigation of the influence of the number and location of particular functional groups on the organic aerosols' kappa value. Organic compounds were synthesized via gas-phase and liquid-phase reactions. Aerosol products from gas-phase reactions were collected on filters, extracted using ethyl acetate, and fractionated by reversed-phase high-performance liquid chromatography using gradient elution with acetonitrile and water. The eluate was atomized, the solvent was removed by evaporation, and the residual aerosol particles were analyzed as a function of retention time using high-resolution scanning flow CCN analysis. Individual organic compounds eluting from the synthesized mixture were identified using thermal desorption particle beam mass spectrometry. These experiments yielded changes in kappa that can be attributed to the addition of one or more hydroxyl, nitrate, carboxyl, aldehyde, hydroperoxide, and methylene functional groups while otherwise maintaining the structure of the organic molecule. Our results show that the addition of hydroxyl and carboxyl groups can significantly increase a particle's kappa value, while the addition of hydroperoxide, nitrate, and methylene groups does not. We anticipate that our results contribute to a mechanistic understanding of chemical aging and will help to guide input and parameterization choices in models that rely on simplified treatments such as the atomic oxygen-to-carbon ratio to predict the evolution of organic aerosol hygroscopicity.

LA-ICP-MS: a success story of in-situ element & isotope ratio analysis

T. PETTKE

University of Bern, Institute of Geological Sciences, CH-3012 Bern, Switzerland (pettke@geo.unibe.ch)

LA-ICP-MS has become the method of choice for in-situ trace element analysis, recently expanding into applications traditionally dominated by other analytical techniques. In its beginning ~30 years ago [1], fundamental problems arising from poorly controlled LA of material to element ionization from dry particles orders of magnitude larger than dried liquid aerosol to sensitive and representative transient signal recording dominated research initiatives (Longerich and co-workers [2]). High-UV LA combined with MS detection has since become the preferred instrumental combination [3].

And where are we today? Studies on technical parameters have greatly improved our understanding of fundamental processes occurring at various sites in the instrumentation. Hand in hand goes prominent progress achieved in "fitting LA-ICP-MS for purpose", by developing new or significantly refining analyical protocols. However, praised seminal instrumental developments have not resulted in quantum leaps; hence, neither LA-ICP-MS analytical protocols nor instrumentations have changed radically in the past decade.

This contribution outlines the interplay between fundamental instrumental parameters for successful LA-ICP-MS measurement of element concentration and isotope ratio data and addresses components critical to analytical accuracy, including calibration materials [4]. Emphasis will be put on the quantification of the bulk composition of phase mixtures (e.g., fluid inclusions [5,6]) for which LA-ICP-MS is the undisputed analytical instrument of choice. Precise and accurate isotope ratio and radiometric age determinations are now feasible from ever decreasing sample amounts, emphasizing the relevance of analytical sensitivity.

Common perception is that instrumental possibilities (e.g., sensitivities, resolution in space and time, signal detection, element and isotope ratio fractionation) dictate the progress in LA-ICP-MS applications. However, no modern equipment can compensate for lack of sound instrumental and geoscientific understanding of how to employ LA-ICP-MS for solving analytical problems.

Carbon cycling in the rhizosphere is a nexus of biophysical interactions between plant roots, microorganisms, and the soil organo-mineral matrix. Plant roots provide 30-40% of soil organic C inputs, accelerate the rate of organic matter mineralization by ~10X, and support an active microhabitat for microbial transformation of soil C. Our research on how roots influence decomposition of soil organic matter in both simplified and complex microcosms uses geochemical characterization, molecular microbiology, isotope tracing, metabolomics and novel imaging approaches ('ChipSIP' and 'STXM-SIMS') to trace the fate of isotopically labelled root exudates and plant tissues. Our work in synthetic rhizospheres suggests root exudates drive O_2 limitation, alter metal chemisty and mineralogy, and influence the availability of SOM. Using a combination of X-ray spectromicroscopy and NanoSIMS, we have imaged the deconstruction of $^{13}C/^{15}N$-labeled ligno-cellulose in model plant cells in situ, and mapped associations of plant cell-derived decomposition products with specific soil minerals. In the more complex rhizospheres surrounding roots of the annual grass *Avena fatua*, the microbial community undergoes a compositional succession as the plant grows, senesces, and dies. We have developed an isotope array that allows us to follow root C into bacterial, fungal, and microfaunal communities. The presence of root detritus significantly alters the soil microbial community over short time spans, leading to a higher proportion of eukaryotic microbes and Bacteroidetes. Finally, we have characterized the molecular cocktail of compounds exuded by *Avena* roots, and showed that increased belowground C allocation and root biomass driven by elevated CO_2 correspond to a greater amount of root-derived ^{13}C in the 'heavy' soil fraction, commonly assumed to reflect longer term stabilization.

CO_2 mineralization in percolated olivine-rich rocks: Control of olivine crystallographic orientation and fluid flux

S. PEUBLE[1,*], M. ANDREANI[2], M. GODARD[1], B. VAN DE MOORTELE[2] AND P. GOUZE[1]

[1]Géosciences, CNRS-Université Montpellier 2, France *(peuble@gm.univ-montp2.fr)
[2]Laboratoire de Géologie de Lyon, France

In situ carbonation of ultramafic rocks is potentially an effective means for mitigating atmospheric CO_2 concentrations. CO_2 mineralization reactions in sub-surface conditions are controlled by the coupling of flow and transport processes and of chemical reactions occurring at the mineral-fluid interfaces. To better understand the roles of the structure of rocks and of fluid fluxes on the reactivity of ultramafic systems, we performed a reactive percolation experiment using a sintered olivine core (ø 6.35 mm × L 13 mm) in which CO_2-rich fluid was injected at P-T conditions similar to that expected for *in situ* storage. The sample was then characterized by EBSD and FIB-TEM.

EBSD analyses indicate a weak crystal preferred orientation (CPO) of the olivine (ol) aggregate resulting from sintering, with $[010]_{ol}$ parallel to the axis of cylinder. We observe the development of a dense network of microcracks parallel to $(100)_{ol}$. Symmetrical etch pits indicating olivine dissolution are observed on $(010)_{ol}$ surfaces. Two reaction products were identified: dolomite (dol) and magnesite (mgn). EBSD analyses revealed a statistical relationship between the olivine fabric and the direction of carbonate (carb) growth, marked by $(10\text{-}14)_{carb}$: $(10\text{-}14)_{mgn}$ is parallel to $(001)_{ol}$ and $(10\text{-}14)_{dol}$ is parallel to $(100)_{ol}$. FIB-TEM analyses indicate however that carbonate growth is non-topotactic.

At all scales, $[10\text{-}14]_{carb}$ is systematically oriented parallel to the main direction of fluid flow. In our sample, sintering induced the localization of $(001)_{ol}$ and $(100)_{ol}$ and the development of microcracks parallel to the cylinder axis, which is also parallel to the main direction of fluid fluxes. As a consequence, fluid fluxes and chemical transport were promoted and the olivine-fluid surface area was larger in that direction compared to that perpendicular to fluid fluxes. In turn, these conditions facilitated the development of local concentration gradients and the growth of carbonates at the olivine surface, where local fluid velocity tends toward zero, thus explaining that $(10\text{-}14)_{carb}$ is statistically parallel to $(001)_{ol}$ and $(100)_{ol}$.

Our results suggest that carbonate growth is controlled by the hydrodynamic conditions rather than by the olivine CPO during *in situ* carbonation of ultramafic rocks.

Crustal evolution determines seawater Sr and Nd isotope records

BERNHARD PEUCKER-EHRENBRINK[1]

[1]Woods Hole Oceanographic Institution, Woods Hole, MS 25, MA 02543, USA, (behrenbrink@whoi.edu)

Radiogenic isotope ratios record time-integrated parent-daughter ratios, and are thus sensitive to the chemical composition and time. The oceans recieve the integrated runoff from the continental surface and preserve these signals in marine sedimentary records. Radiogenic isotope records of seawater and marine sediments have been reconstructed over the past five decades for many of the radiogenic isotope systems. For some systems (Sr) excellent records do exist that integrate seawater signals for the entire ocean, whereas global records of radiogenic isotopes with short marine residence times are much more difficult to establish (Nd, Pb).

Here, I attempt to link long-term (Phanerozoic) records of marine radiogenic isotope systems to records of the evolution of the continental surface that interacts with the hydrologic cycle. For the present we can show that the dissolved and particulate loads from the continents integrate different portions of the continental surface (Peucker-Ehrenbrink *et al* , 2010). For instance, the areas generating dissolved loads are characterized by significantly older bedrock (~400 Myr) than those generating particulate loads (~320 Myr), with both being younger than the mean bedrock age of the non-glaciated, exorheic portion of the continental surface (~450 Myr). This age bias reflects the disproportionate role active margins and high-standing ocean island play in exporting sediment to the oceans.

Using present-day systematics as a guide, I argue that the first-order trough-like shape of the Phanerozoic marine Sr isotope record reflects the rejuvenation of the continental surface involved in exporting Sr to the ocean from the early Phanerozoic to the mid Jurassic that is followed by an "aging" that continues into the Quaternary. This long-term evolution of the continental surface is mirrored by a similar, though much less well-constrained, record of rejuvenation affecting areas involved in exporting Nd to the oceans. As Nd export to the ocean is overwhelmingly tied to export of the detrital load to the ocean, the first-order co-evolution of both records is suggestive of underlying trends in the evolution of the continental surface that connects the terrestrial hydrologic cycle with the oceans.

Fertile magmatism in a changing compression and extension regime on the Central Balkan Peninsula

I. PEYCTHEVA[1,2], ST. GEORGIEV[1], V. GROZDEV[1], P. MARCHEV[1] AND A. VON QUADT[2]

[1]Geological institute, BAS, Sofia, peytcheva@erdw.ethz.ch
[2]IGP, ETH-Zurich,(quadt@erdw.ethz.ch)

The Balkan Peninsula is one of Europe's mineralized regions with world-class ore deposits. Numerous Cu-(Au-Mo) porphyry and Au-(Cu) epithermal deposits are formed during the oblique Late Cretaceous northward subduction of the Tethys beneath the European continent and the Palaeogene postcollisional extension. Integrated U-Pb zircon, Sr-Nd-Hf isotope and geochemical analyses on Palaeogene rocks in W Bulgaria, SE Serbia and eastern FYR Macedonia aim to constrain the temporal and tectono-magmatic evolution of the region that favour significant ore-formation.

After the cease of the subduction at ~70 Ma and the accretion of the Morava-Rhodope/Getic units the region is marked by a collision/compression and break of magmatism till ~60 Ma when rift-like alkaline basalts in eastern Serbia formed. Their trace-element and isotope signature define a depleted source, similar to the European Asthenospheric Reservoir (Cvetkovic at al., 2004). It is followed by Na calk-alkaline rhyolites at ~45 Ma, displaying typical adakitic signature. Sr-Nd whole rock and Hf-zircon isotope data define a mantle dominated source ($^{87}Sr/^{86}Sr_{(i)}$ 0.7047-0.7051; εNd between -0.2 and +2.4; εHf-zircons of +4 to +10). Eocene adakite-like magmatic rocks can be traced further to S-SE in the Rhodopes and to Turkey, and are likely related to subduction-enriched lithospheric mantle but asthenospheric OIB-like mantle source could be an alternative option.

The Cenozoic magmatism in W-SW Bulgaria and E Macedonia changed to normal crustal-dominated granitic composition (33-30 Ma, $^{87}Sr/^{86}Sr_{(i)}$ 0.709-0.716; εNd -6 and -10; εHf-zircons -2 to -8), but was more mantle influenced in Surdulitsa (SE Serbia) at 34 Ma. The magmatism migrated further to SW and show magmatic ages at 29-24 Ma in Kratovo-Zletovo and the Buchim-Borov dol. Less radiogenic strontium ratios 0.7060 and slightly negative εNd -2.6 to -3.1 define an increase of mantle input from a subduction-enriched mantle litosphere.

Tectonic reconstructions suggest a repeated change of compression/collision and extension episodes that were plausible for the generation of fertile magmatism. The latter reveal signature of subduction-enriched mantle source but magma composition was additionally crustal modified and controlled by the crustal composition and thickness.

Biological Diversity and Potential in Geothermal Systems

BRENT PEYTON[1] AND HOPE LEE[2]

[1]Director, Thermal Biology Institute, Montana State University, Bozeman, MT 59717 USA (bpeyton@coe.montana.edu)
[2]Pacific Northwest National Laboratory, Richland WA 99352 USA (hope.lee@pnnl.gov)

Geothermal environments are very small in size and distribution on Earth, however, they play strategic role in the pursuit of novel microbial activity for industrial and energy related processes. Hot springs are natural ecosystems where microorganisms have adapted to high temperatures and unique geochemical environments, over centuries, making them ideal to study for understanding extreme ecosystems. Thermal features are also “target” environments for isolating novel and robust microorganisms for biotechnology and energy applications.

Thermal environments have been a source of beneficial microorganisms, including the discovery of unique microorganisms and thermostable enzymes (e.g., Taq polymerase), for the degradation of biomass, and the production of lipases, and for algal biofuels. This presentation will include a brief overview of Yellowstone thermal areas, and results of interdisciplinary geochemical and microbial investigations in the Heart Lake Geyser Basin focused on characterization of unique microbial communities, microbes for enzyme discovery, and for algal biofuels applications.

Correlated chemical and temporal evolution of Cenozoic magmatism in SE-Germany (Heldburg region)

J.A. PFÄNDER*[1], A. KLÜGEL[2], S. JUNG[3] AND J. ROHRMÜLLER[4]

[1]TU Bergakademie Freiberg, Germany. [2]Universität Bremen, Germany. [3]Universität Hamburg, Germany. [4]Bayerisches Landesamt für Umwelt, Hof, Germany. (*correspondence: pfaender@tu-freiberg.de)

Detailed petrogenetic models on the causes and sources of Cenozoic magmatism in Central Europe have been developed based on a large number of trace element and isotope data. Due to only sparsely available geochronological data, however, the timescales of the underlying processes (e.g. mantle convection and regional "plume" activity) often remain unclear.

Here, we present new high-resolution $^{40}Ar/^{39}Ar$ ages along with major and trace element data from a series of basanites and melilitites from SE-Germany (Heldburger Gangschar) in order to constrain the temporal and chemical evolution of magmatism in this region. This, in turn, provides information on the temporal evolution and dynamics of the underlying melting processes.

The ages indicate two magmatic events, an older one between ~40 and ~25 Ma, and a younger one from ~17.6 to ~13.1 Ma. The older group comprises mostly melilitites, the younger group are basanites. Although incompatible trace-element patterns (REE and multi-element diagrams) of both groups are similar and indicate enriched mantle sources, specific geochemical tracers indicate different processes involved during magma genesis. For example, the older melilitites differ from the younger basanites by having higher and more variable Nb/Ta (17.7 - 20.7 vs. 18.3 - 19.4), higher Sm/Yb, Ho/Lu and CaO, and more pronounced negative Rb and K anomalies in primitive mantle-normalized trace element diagrams. This indicates a stronger influence of residual amphibole on magma genesis during the earlier stage of magmatism, possibly in the lithospheric part of the mantle, and is consistent with the higher variability in Nb/Ta in the older rocks. La/Yb is high in the melilitites (47 - 63) and unrelated to their ages, but is inversely correlated with age in the basanites (26 to 47). This indicates (i) low degrees of partial melting during the first magmatic event, and (ii) higher but gradually decreasing degrees of partial melting over time and/or a different mantle source during the second stage of magmatism. The second event can be interpreted as a waning pulse of ascending mantle beneath the Heldburg region, active until magmatism ended at about 13 Ma.

[2]Section for Microbiology, Department of Biological Sciences, Aarhus University, 8000 Aarhus C, Denmark

Centimetre long bacterial filaments belonging to the Desulfobulbaceae family mediate electric coupling of oxygen reduction and sulfide oxidation in spatially separated regions of marine sediments [1,2]. Their cell numbers are equal throughout the few millimetres of oxic and the underlying 2-3 cm of anoxic sediment. Thus, only about 10% of the cells are responsible for the reduction of oxygen for the entire filament, using the electrons produced by sulfide oxidation of all connected cells below. As a consequence, a much higher electron turnover per cell must be assumed for those cells with access to oxygen.

In this study, we evaluated whether the higher metabolic rate in the oxic zone coincides with increased energy conservation. Our experimental approaches involved comparison of carbon and ammonia incorporation rates in different filament sections by using stable isotope labelling and nanoSIMS. Moreover, we estimated the vertical distribution of current production by microprofiling electric fields and conductivities in artificial sediment systems.

Our preliminary data suggests that the highest metabolic activity is indeed exhibited by cells in the oxic zone, where excess energy seems to be conserved in storage components rather than used for cell growth. Futhermore, we found that current production, and thus sulphide oxidation, takes place throughout the top 2-3 cm of the anoxic sediment zone, which includes a zone where no free sulphide is detectable.

High-precision tantalum isotope measurements by MC-ICPMS

M. PFEIFER[1,2,*], C. MÜNKER[1,2] AND S.T.M. PETERS[1,2]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, Germany (*correspondence: m.pfeifer@uni-koeln.de)
[2]Steinmann-Institut für Geologie, Mineralogie und Paläontologie, Rheinische-Friedrich-Wilhelms-Universität Bonn, Germany

Tantalum-180(m) is the rarest observationally stable nuclide in the solar system and has a relative abundance of 0.01201 ± 8% [1]. Furthermore, ^{180m}Ta is the only nuclide that is stable in an excited state, whereas in ground state it undergoes decay to ^{180}Hf and ^{180}W with a half-life of 8.1h. Therefore, the nucleosynthetic origin of solar system ^{180m}Ta and the relative contributions from s-process branching at ^{179}Hf and from neutrino process in core-collapse supernovae are uncertain [2]. Isotope analyses on natural materials may provide a clue to the source of this nuclide. However, the extremely low ^{180m}Ta/^{181}Ta ratio challenges sufficiently precise measurements. Here we present a high precision method as well as first data on extraterrestrial material.

Tantalum from two basalts (La Palma, Canary Islands) and one L6 chondrite (Wagon Mound) was separated by anion exchange chromatography modified after [3,4]. Measurements were conducted with a Neptune MC-ICPMS using $10^{12}\Omega$ amplifiers on masses 180 (Ta, Hf, W) and ^{178}Hf for monitoring the large isobaric interference by ^{180}Hf (rel. ab. 30.64%). ^{183}W was monitored for correction of the minor ^{180}W interference (rel. ab. 0.12%). ^{181}Ta was tuned to 40-45V to achieve optimum precision. Instrumental mass bias was corrected for externally by doped Yb, using different ratios between masses 171 to 176 and the exponential law. This protocol enables more precise measurements than using doped Re [4], and the external reproducibility (2σ) was typically better than ±7 ε-units for ca. 80ng of sample

We found that our anion exchange chromatography procedure can efficiently separate interfering Hf and W from Ta. Measured solutions had both Hf/Ta and W/Ta of less than 0.00002, sufficiently low to measure ^{180m}Ta/^{181}Ta ratios accurately. First results for the L6 chondrite and the La Palma basalts are indistinguishable from the terrestrial isotopic value defined by the Alfa Aesar™ standard solution.

Uranium partitioning and isotope composition in shales of the Middle Devonian Marcellus Formation

THAI T. PHAN[1,*], ROSEMARY C. CAPO[12], BRIAN W. STEWART[12], SHIKHA SHARMA[13] AND JAIME TORO[3]

[1]National Energy Technology Laboratory - Regional University Alliance, 626 Cochrans Mill Rd., Pittsburgh, PA 15236, USA

[2]Department of Geology and Planetary Science, University of Pittsburgh, PA, 15260, USA (*correspondence: thaiphan@pitt.edu)

[3]Department of Geology and Geography, West Virginia University, Morgantown, WV, 26506, USA

Natural gas extraction from the Middle Devonian Marcellus Shale has raised interest in investigating the distribution and behaviour of NORM (naturally occurring radioactive material) associated with both produced water and drill cuttings from this unit. The Marcellus is a variably calcareous shale with intercalated limestone. Based on core extracted in Greene County, southwestern Pennsylvania, uranium (U) concentrations in Marcellus Formation samples range from 3 to 47 ppm. Sequential extraction experiments indicate that 30 to 95% of the U is held in the silicate fraction. Although there is a positive correlation of whole rock U concentration with TOC as observed by others, U associated with the oxidizable (organic) fraction contributes less than 25% (and usually <10%) of the total. Up to 64% of the U was found in the 1.0 N acetic acid leachate, which has implications for uranium release into the environment from relatively soluble carbonate minerals in drilling waste. The source of NORM in Marcellus produced water is primarily radium [1], the daughter product of U and Th. The low U concentrations measured in produced water samples from three Marcellus Shale gas wells (0.1 to 0.5 μg/L) may result from U reduction and precipitation as UO_2 or U_3O_8, consistent with relatively high Mn^{2+}(1-8 g/L) and Fe^{2+}(20-120 g/L) concentrations.

$^{238}U/^{235}U$ ratios of Marcellus shale obtained by MC-ICPMS using the double spike method fell in a narrow range of 137.80 to 137.85, similar to other black shales. $^{238}U/^{235}U$ ratios in the carbonate fraction of calcareous shale units were in the range of marine carbonate; however carbonate cements extracted from black shale units were isotopically heavier by an average of 0.7 ‰. $^{238}U/^{235}U$ ratios in the organic matter and silicate fractions generally overlap and are lower than coexisting carbonate cement by about 0.3 ‰.

Isotopic and mineralogical evidence for atmospheric oxygenation in 2.76 Ga old paleosols

P. PHILIPPOT[1]*, Y. TEITLER[1], M. GERARD[2], P. CARTIGNY[1], E. MULLER[1], N. ASSAYAG[1], G. LEHIR[1] AND F. FLUTEAU[1]

[1]Institut de Physique du Globe, Sorbonne Paris Cité, Univ Paris Diderot, CNRS, Paris, France (philippot@ipgp.fr)

[2]Institut de Minéralogie et de Physique de la Matière Condensée, Univ Paris Jussieu, IRD, 75252 Paris, France

Recent chemical and isotopic data from Archean marine sediments indicates that alteration of continental surfaces have contributed a substantial fraction of the flux of redox-sensitive elements (S, Cr, Mo) to the ocean several hundreds of millions of years prior to the Great Oxidation Event (GOE ; between 2.45 and 2.32 Ga). However, controversies regarding the factors controlling these deliveries (increase of atmospheric oxygen, acid rock drainage, microbial activity on land) have highlighted the problems of identifying a reliable proxy of continental surface alteration during the Archean. Unlike marine proxies, which are indirect climatic records, paleosols, which form at the atmosphere-lithosphere interface, can provide direct constraints on the weathering processes at the time of formation. Here we present new sulfur isotope and mineralogical data from the reference 2.76 Ga old Mount Roe Basalt paleosols at Whim Creek (Western Australia). The data are from new lithofacies that were not documented in previous studies. These lithofacies contain a Fe^{3+}-montmorillonite, calcite and sulfate mineralogical assemblage and display enrichments in Cr and Mo compared to the original basalt. Sulfur isotope analysis of microscopic sulfate inclusions preserved in Fe^{3+}-montmorillonite and calcite yielded $\delta^{34}S$, $\Delta^{33}S$ and $\Delta^{36}S$ values that are different from the field of mass independent (MIF) Archaean sulfates. $\Delta^{33}S$ values overlap the field of post-Archaean, mass dependent (MDF) terrestrial materials. In a $\Delta^{33}S$-$\Delta^{36}S$ diagram, sulfates plot away from the MIF slope ~-1 defined by Archaean samples and overlap the MDF slope of ~ -7 defined by post-2.32-Ga old sulfides. The large range of $\delta^{34}S$ (up to 20‰) between different samples indicates that S-isotope heterogeneities are preserved on a small scale. Such heterogeneities are best explained by repeated cycles of microbial sulfate reduction producing sulfides followed by the re-oxidation of sulfides into sulfates during oxidative weathering and/or microbial oxidation of microbially-derived ^{34}S-depleted sulfides. These results suggest that the concentrations of free oxygen in the Late Archaean climate system has increased, at least transiently, to levels similar to the GOE.

New generation multi-collector mass spectrometers require new $^{40}Ar/^{39}Ar$ standards

D. PHILLIPS[1]* AND E. MATCHAN[1]

[1]School of Earth Sciences, The Univerity of Melbourne, Parkville, VIC, 3010, Australia (*correspondence: dphillip@unimelb.edu.au)

The accuracy of $^{40}Ar/^{39}Ar$ ages is dependent on the availability of mineral standards of known age. Popular standards include Fish Canyon Tuff sanidine (FTCs) [1], Alder Creek Rhyolite sanidine (ACRs) [2] and Mt Dromedary biotite (GA1550) [3]. Despite common usage, the ages of these standards is contentious, with published values varying by >2% [4, 5]; well beyond the ±0.1% goal of EARTHTIME.

In this study, we report ultra-high precision, $^{40}Ar/^{39}Ar$ analyses of FCTs, ACRs and GA1550 biotite aliquots, using a multi-collector ARGUSVI mass spectrometer. Step-heating results resolve distinct (~1%) age gradients for all samples, attributed to argon loss and/or extraneous argon contamination. This discordance complicates efforts to assign accurate ages to these standards, with different heating protocols also likely to cause inter-laboratory bias.

These data suggest that these minerals are non-ideal as high precision $^{40}Ar/^{39}Ar$ standards. In broader terms, the results mandate a re-evaluation of high precision $^{40}Ar/^{39}Ar$ ages referenced to these standards, including the astronomically calibrated ages for FCTs [6], and $^{40}Ar/^{39}Ar$ ages used to define new decay constants [4].

Lack of isotopic exchange between organics and clays in Semarkona chondrite: submicrometer scale heterogeneity of the D/H ratio.

PIANI, L.*[1,2], ROBERT, F.[1] AND REMUSAT, L.[1]

[1]LMCM, UMR CNRS 7202, MNHN, Paris, France.
[2]CRPG, UMR 7358, CNRS-Université de Lorraine, France.
*(correspondence: piani@crpg.cnrs-nancy.fr)

Organics and clays are the main hydrogen bearing phases in non-equilibrated chondrites. These primitive solid reservoirs recorded the signatures of the early solar system. While organics are formed prior to accretion of the parent body, clays are thought to have formed during its aqueous alteration. As a consequence, clays may contain the H isotopic signature of the hydrothermal fluids and may provide the composition of the ice accreted on the parent body. Both phases can exhibit highly heterogeneous D/H ratios depending on the chondrite [1–4]. However, their intimate mixing within the chondrite matrix [5] makes it difficult to investigate possible interactions between clays (water) and organics, because local isotopic measurements are not possible with current analytical techniques.

An analytical protocol was developed using the nanoscale secondary ion mass spectrometer NanoSIMS 50. D^-/H^- and OD^-/OH^- ratios were deconvoluted to allow localized semi-quantitative information on the isotopic composition of organics and clays to be obtained [6]. Using this protocol, measurements were carried out on Au-pressed matrix pieces of the Semarkona unequilibrated ordinary chondrite.

No isotopic equilibrium was observed between organics and clays. Relatively isotopically homogeneous organic matter ($\delta D \sim 2000‰$) is mixed with extremely heterogeneous clays (with δD from 0 to more than 10,000‰), attesting to a lack of global isotopic exchange between organics and water. Moreover, micrometer-size areas of exceptionnally D-rich inorganic material were identified and these are surrounded by D-poor material (mostly clays and/or organics). The origin of the most D-rich inorganic material remains puzzling, however, the observations demonstrate the limited extent (few μm) of aqueous alteration on the Semarkona parent body and suggest that the parent body accreted ice from several regions of the solar system.

Site-specific carbon isotope neasurement of organics by gas source mass spectrometry

ALISON PIASECKI[1], JOHN EILER[1], ALEX SESSIONS[1], JOELMA P. LOPES[2], JULIANA A. LEMINI[2] AND LUIZ C. S. FREITAS[2]

[1]Caltech Pasadena, CA, USA (piasecki@gps.caltech.edu)
[2]Petrobras, Brazil

Most isotopic measurements constrain the bulk compositions of molecules or minerals, averaging over non-equivalent sites. Site-specific isotope measurements potentially could add new constraints regarding the sources and reaction histories of molecules. For example, previous studies demonstrate that biosynthetic reactions, such as decarboxylation of pyruvate, lead to even/odd ordering and more complex pattens of ^{13}C enrichment within fatty and amino acids, with differneces of up to 30‰ between adjacent C positions. Such variations are potentially preserved in the products of thermal degredation of biomolecules (e..g, propane). And isotopic structures of these products may also reflect the mechanisms and conditions of the 'cracking' reactions by which they are produced from larger biomolecules at elevated temperatures, and/or measure their later consumtion by thermal or bio-degredation.

We have developed a new mass spectrometric tecnique for measuring the difference in ^{13}C enrichment between the terminal central C position in propane. Our measurement based on comparison of the $\delta^{13}C$ values of one- and two-carbon fragment ions, each of which is analyzed using a new high resolution mass spectrometer, the MAT 253 Ultra. We appiled this technique to a sample suite of wet (i.e., ethane and propane-rich) natural gases. Conventional interpretations of $\delta^{13}C$ values of these components of these gases suggest they are a single suite that varies only in its level of thermal maturity. However, we find these samples can be divided into two populations that differ by 5 ‰ in the $\delta^{13}C$ of their central carbon position. Within each of these populations, the $\delta^{13}C$ of the terminal carbon position can vary by up to 7 ‰. Several interpretations of these data are possible; a simple hypothesis we suggest is that the central carbon position samples the $\delta^{13}C$ of the source rocks (which are known to be a mix of lacustrine and marine rocks in this suite), whereas variations in $\delta^{13}C$ of the terminal carbon within any set of samples from a given source increases with increasing thermal maturity. We are now exploring this and other hypotheses through experiments, modeling, and measurements of other suites. More generally, this work suggests a path toward site-specific measurements of a variety of organic molecules.

Evaluating the fossilization potential of Fe(II)-oxidizing bacteria

AUDE PICARD[1], MARTIN OBST[1] AND ANDREAS KAPPLER[1]

[1]Center for Applied Geoscience, Eberhard Karls University Tübingen, Tübingen, Germany (aude.picard@uni-tuebingen.de ; martin.obst@uni-tuebingen.de ; andreas.kappler@uni-tuebingen.de)

The hunt for microfossils in the rock record has been pursued for several decades to reconstruct the individual steps in life evolution as well as the appearance of microbial metabolisms [1]. Given the small cell size and the limited morphological diversity in the microbial world, the biogenicity of microbial-like structures has always been questioned. Fossilization experiments have shown that microorganisms can be well preserved in silica [2]. However the presence of Fe^{3+} appears essential during the fossilization process in silica [3, 4]. In this study, we investigate the fossilization potential of Fe(II)-oxidizing bacteria after exposition to pressure (P) and temperature (T) conditions simulating diagenetic processes during sediment burial and rock formation. Within this project we seek to propose a "biosignature" for microbial Fe metabolism to be compared to the rock record. *Gallionella*-like microorganisms produce twisted stalks – structures made of a polysaccharide bone and coated with Fe(III) oxyhydroxides – as a result of growth and Fe(II) oxidation [5]. A Fe(II)-oxidizing microbial mat containing twisted stalks was collected at the Segen Gottes mine (SW Germany) and incubated at various P/T conditions in a hydrothermal autoclave. Twisted stalks were preserved at the highest P/T conditions tested (1 week at 250°C/140 MPa) and after the longest incubation (4 months at 170°C/120 MPa). Fe(III) minerals evolved from ferrihydrite to hematite with increasing P/T conditions. Polysaccharidic and peptidic components were altered at the highest P/T conditions tested. However organic carbon was relatively well preserved. It seems that Fe(III) oxyhydroxides covering the organic carbon are acting as a protectant to maintain the morphology and organic components of the twisted stalks and might be able to preserve these structures over geological times.

Effect of Hafnium on Glass Structure and Dissolution

EM PIERCE[1*], SN KERISIT[2], F ANGELI[3], T CHARPENTIER[3], JP ICENHOWER[4], J HOPF[1]

[1]Oak Ridge National Laboratory, (pierceem@ornl.gov) [2]Pacific Northwest National Laboratory [3]Commissariat a l'Energyie Atomique [4]Lawrence Berkley National Laboratory

Reactions that occur at the solid-water interface control the composition of the worlds fresh water, soil development and nutrient distribution, the cycling of elements in the Earth's Critical Zone, and to predict the impact from the disposal of vitrified nuclear waste [1]. Recently, multi-scale or hybrid models, which capitalize on advancements in the understanding of solid-water interfacial reactions, have been used to better describe the macroscopic interactions occuring in the systems [2]. However, knowledge gaps in the fundamental understanding of solid-water reactions impede the ability to accurately describe microscopic processes (e.g., sorption, surface layer formation, etc.) that represent the underlying phenomena controlling macroscopic reaction kinetics.

An important step in improving our ability to accurately forecast radionuclide release from vitrified waste is to establish a link between the glass atomic-level structure and macroscopic dissolution behavior. This study extends the previous work by Pierce et al. [3], by evaluating the effect the high-valence cation hafnium has on the structure and chemical durability of alkali aluminoborosilicate glass.

Results from flow-through experiments show a ~100× decrease in the dissolution rate with increasing Hf content from 0 to 20 mol% HfO_2. The results also reveal a divergence in the magnitude between the average steady state rates measured in dilute and near-saturated conditions. Monte Carlo simulations indicate that the divergence in glass dissolution behavior results from the formation of a low coordination Si sites when Si from the saturated solution adsorbs to Hf on the glass surface. The residence time of the low coordination Si site is longer at the glass surface and increases the density of anchor sites from which altered layers with higher Si densities can form than in the absence of Hf. These results illustrate the importance of understanding solid-water/solid-fluid interactions by linking macroscopic reaction kinetics to nanometer scale interfacial processes.

Back to the future: high-sensitivity noble gas mass spectrometers with modern electronics.

J. PIERONEK[1]*, W. HAMES[2], T. BECKER[3], P. RENNE[3], M. BILLOR[2] AND A. ILLIES[4]

[1]JVP Systems, 3525 Del Mar Heights Rd., San Diego, CA, 92130, USA (*correspondence: jvp@jvpsystems.com); [2]Geology, Auburn University, Auburn, AL 36849, USA; [3]Berkeley Geochronology Center, Berkeley, CA 94709, USA; [4]Chemistry, Auburn University, Auburn, AL 36849, USA.

Spectrometers designed 30 years ago, operated in a single-collector mode, remain capable of routinely measuring argon isotopic ratios that may vary over five orders of magnitude, with precisions better than 0.2% for gas species in quantities of ~ 10^{-16} mol. Aging electronics are the Achilles heel of these systems. A focus of our activities is to develop a new generation of novel electronic device upgrades for the control of typical noble gas mass spectrometers (e.g., the MAP-215 and similar instruments). Over the past 30 years, most analog circuits have been redesigned to use MOS (Metal Oxide Semiconductor) technologies that consume less power, are smaller, and allow more circuitry to improve the performance of a given device. Such devices can incorporate circuitry to protect against external or internal transients. For example, a newly designed emission regulator is able to sustain leakage (as caused by the slow deposition of filament metal on the insulating components of the source) between the source, half-plates, filament and repeller without damage. Considering electromagnet and filament control, stability to within 1 to 2 parts per million can be achieved. The use of 24-bit analog to digital converters coupled with more powerful, responsive power supplies will result in significantly reduced electromagnet settling time. The thermal stability of these devices is enhanced by using state of the art, low power, enclosed circuitry with convective cooling. Multiple sensor inputs are incorporated to allow monitoring and logging of environmental conditions such as temperatures and humidity. All critical voltages and currents are controlled, and monitored over an Ethernet interface. This control eliminates noise from potentiometers and other moving electromechanical components, and permits full logging of parameters useful in automatic tuning algorithms. This level of control also will permit expedient changes and tuning of source parameters for analysis of different isotope groups (He, Ar, etc.). It is possible to completely control all of these electronics remotely through a standard web browser. Test data generated in this effort are presented in this forum for analytical standards and geologic samples of varying age and context.

Anomalous CO_2 contents in a shallow aquifer of the Mt.Amiata geothermal area, Italy

L.PIEROTTI[1]*, G.CORTECCI[1], G.FACCA[2] AND F.GHERARDI[1]

[1] CNR-Istituto di Geoscienze e Georisorse, Pisa, Italy (*correspondence: l.pierotti@igg.cnr.it)
[2] Instruments Care, Pisa, Italy

In the framework of a project funded by Seismic Service of the Tuscany Region [1], the Bagnore thermal spring (Mt.Amiata geothermal area) has been selected as a suitable site to identify possible hydrogeochemical anomalies related to seismic activity. Since 2004, the Bagnore spring (T_{WATER} = 21.5°C) has been monitored in continuous (more than 8×10^5 data available today) with an automatic station equipped for the measurement of temperature, pH, EC, Eh, and the dissolved content of CO_2 and CH_4. During the period 2004-2012, 68 discrete sampling campaigns for the determination of selected chemical-physical parameters in situ (T, pH, EC, alkalinity), and chemical parameters in the laboratory (Na, K, Ca, Mg, Cl, SO_4, NO_3, B), have also been performed. From all these data, it emerges that the low salinity (240 mg/l) waters of the Bagnore spring belong to the Ca-SO_4 chemical type, and are characterized by a background P_{CO2} value of about 0.04 bar. Significant H_2S and H_3BO_3 anomalies have been also detected, suggesting that the shallow aquifer feeding the Bagnore spring effectively absorbs gases diffusing from below. Isotopic analyses on TDIC ($\delta^{13}C$ = -7.8 and -11.6‰) and dissolved SO_4 ($\delta^{34}S$ = -6.9‰) point to exclude the hypothesis of a prevalently magmatic origin for the gases interacting with waters in the shallow volcanic aquifer. TDIC is thus interpreted as the result of the mixing between CO_2 of metamorphic origin and soil-derived CO_2. Low, basically radiogenic $^3He/^4He$ ratios in gas vents of the area [2], further support this hypothesis. The $\delta^{34}S$-SO_4 signature possibly indicates that H_2S absorbed in the shallow aquifer derives from thermochemical reduction of Triassic anhydrite ($\delta^{34}S$ = 15.5‰) in the geothermal reservoir, at an estimated temperature of about 300°C.

During the last three years, two anomalous, progressive increases in P_{CO2} (up to 0.07 bar) and SO_4 concentration (up to +10%), correlated with a measurable decrease in pH (up to -0.3 pH units, down to 5.6) and HCO_3 concentrations, have been observed over several months. These trends ended just a few days before two seismic events of magnitude 2.5 and 2.7.

Origin of the chemical and U-Sr isotopic variations of soil solutions, stream and source waters at a small catchment scale (the Strengbach case; France)

[1]PIERRET M.C.,[1] STILLE P., [1-2]PRUNIER J. AND [1A]CHABAUX F.

[1]Laboratoire d'Hydrologie et de Géochimie de Strasbourg, EOST, Université de Strasbourg et CNRS, 1 rue Blessig 67084 Strasbourg, France
[2]Université Paul Sabatier, CNRS et IRD, Observatoire Midi-Pyrénées, 14, avenue Edouard Belin, 31400 Toulouse, France

This is the first comprehensive study dealing with major and trace element data as well as $^{87}Sr/^{86}Sr$ isotope ratios and ($^{234}U/^{238}U$) activity ratios (AR) determined on the totality of springs and brooks of the Strengbach catchment. It shows that the small and more or less monolithic catchment drains different sources and streamlets with very different isotopic and geochemical signatures. Different parameters control the diversity of source characteristics. Of importance are especially the hydrothermal overprint of the granitic bedrock, which was stronger on the granite from the northern than from the southern slope, and the different meteoric alteration processes of the bedrock causing the formation of 0.5 to 9 meter thick saprolite and above the formation of an up to 1m thick soil system. The chemical compositions of the source waters in the Strengbach catchment are only to a small extent the result of alteration of primary bedrock minerals and rather reflect dissolution/precipitation processes of secondary mineral phases like clay minerals.

The ($^{234}U/^{238}U$) AR however, are decoupled from the $^{87}Sr/^{86}Sr$ isotope system and reflect to some extent the level of altitude of the source. In addition, the important thickness of the saprolite allows to explain the low ($^{234}U/^{238}U$) AR <1, which are uncommon for surface waters. Preferential flow paths along constant fractures in the bedrocks might explain the over time homogeneous U AR of the different spring waters.

At the soil scale, the geochemical signatures of soil solutions result mainly from biological impact (recycling, degradation and exudation), weathering of secondary phases and atmospheric inputs.

This study further highlights the fact that processes controlling the chemical and isotopic water signatures are different at the soil and catchment scales.

Characterisation of cronstedtite synthesized by iron clay interaction in a cooling procedure

I.PIGNATELLI*[1], E. MUGNAIOLI[2], J. HYBLER[3], R. MOSSER-RUCK[1] AND M. CATHELINEAU[1]

[1]GeoRessources UMR-CRNS 7359, Université de Lorraine, Faculté des Sciences et Technologies, Campus Aiguillettes, BP 70239, 54506 Vandoeuvre-lès-Nancy, France (* correspondence : isabella.pignatelli@univ-lorraine.fr).

[2]Institut für Physikalische Chemie, Johannes Gutenberg-Universität Mainz, Welderweg 11, 55128 Mainz, Germany.

[3]Institute of Physics, Academy of Science of Czech Republic, Cukrovarnicka 10, 16253 Prague 6, Czech Republic.

The cooling of steel containers in radioactive waste storage has been simulated by an original step by step experiment from 90°C to 40°C. Among newly formed clay minerals observed in run products, cronstedtite has been undoubtedly identified by different analytical techniques (XRD, TEM and SEM). This is the first time that cronstedtite is so abundant and well-crystallized in an iron-clay interaction experiment. The formation of cronstedtite is favoured by the release of Fe and Si in solution after the dissolution of quartz, T-O-T phyllosilicates and iron metal. Cronstedtites are characterised by various morphologies: pyramidal (truncated or not) crystals have been observed from 90°C to 60°C experiments, whereas conic crystals with a rounded or hexagonal cross-section occur only in 90° and 80°C experiments. The mean formulae of pyramidal and conic crystal are very similar:

$(Fe^{2+}_{2.17}Fe^{3+}_{0.80}Mg_{0.03})(Si_{1.20}Al_{0.07}Fe^{3+}_{0.73})O_5(OH)_4$

Pyramidal crystals are, thus, more frequent and show different polytypic sequences as well as various degree of disorder. Polytypes $2M_1$, $1M$ and $3T$ have been identified thanks to TEM investigations. The two monoclinic polytypes are very rare in nature, at the contrary of $3T$ polytype (Hybler *et al* 2008). Thanks to the cooling procedure, the stability range of cronstedtite with respect to the temperature is determined. Between 90°C to 60°C cronstedtite appears to be stable and 50°C corresponds to the lower limit of cronstedtite stability as confirmed by crystal alteration. The occurrence of cronstedtite seems to be favored both by temperature range (90°-60°C) and by the progressive temperature decrease, as shown by the comparison of our results with those of previous studies carried out on the same starting claystone but with slightly different experimental conditions (duration time, liquid/rock or iron/clay ratios).

Evidence for global metasomatic enrichment in oceanic lithosphere

S. PILET[1], N. ABE[2], L. ROCHAT[3], D. BUCHS[4] AND P.O. BAUMGARTNER[5]

[1]University of Lausanne, CH, Sebastien.Pilet@unil.ch
[2]Jamstec, Yokosuka, JP, abenatsu@jamstec.go.jp
[3]University of Lausanne, CH, Laeticia.Rochat@unil.ch
[4]Cardiff University, UK, BuchsD@cf.ac.uk
[5]University of Lausanne, CH, Peter.Baumgartner@unil.ch

Oceanic lithosphere is generally interpreted as mantle residue after MORBs extraction. However, some models [1, 2] suggest that this lithosphere could be re-enriched by metasomatic processes in the periphery of ridges. Xenoliths from OIBs could not be used to confirm or invalidate this hypothesis because the metasomatism observed in these xenoliths is likely to be related to the hot spot activity itself. Direct evidence for refertilization of oceanic lithosphere at a global scale is thus missing. Here we used Petit-spot lavas and their enclosing xenocrysts to suggest that oceanic lithosphere is likely to be metasomatized before its recycling in subduction zones.

Petit-spot lavas are interpreted as the surface expression of low degree melts extracted from the base of the lithosphere by plate flexure or crack propagation [3]. Petit-spot lavas accreted in the north of Costa Rica [4] show the presence of cpx xenocrysts similar to cpx observed in metasomatic veins wordwide. The composition of these cpx xenocrysts suggests crystallization at high pressure (15-25 km) in a differentiated liquid percolating across the lithosphere. Similar liquids are identified in Petit-spot lavas sampled on the Pacific plate in front of Japan [5]. These rocks do not contain high-pressure cpx xenocrysts, but contain low-Mg# cpx interpreted as cpx crystallized at low pressure in a liquid similar in composition to that from which cpx xenocrysts observed in Costa Rica petit-spot lavas crystallized. These different observations suggest that the lithosphere is re-enriched by metasomatic process before its subduction. Plate flexure allows low degree melts present at the base of the lithosphere to percolate and differentiate across the oceanic lithosphere, producing a refertilisation of this lithosphere, and in some cases the emission of Petit-spot lavas at the surface. Modelling of the effect of this metasomatic enrichment on the composition of the lithosphere suggests that portions of recycled oceanic lithosphere could correspond to an enriched mantle component rather then depleted mantle.

Study of surfaces of Al_2SiO_5 minerals by Lateral Force Microscopy

CARLOS PIMENTEL[12], CARLOS M. PINA[12] AND ENRICO GNECCO[3]

[1]Departamento de Cristalografía y Mineralogía, Universidad Complutense de Madrid, Spain, (cpimentelguerra@geo.ucm.es , cmpina@geo.ucm.es)
[2]Instituto de Geociencias UCM-CSIC (IGEO)
[3]IMDEA Nanociencia, Madrid, Spain. (enrico.gnecco@imdea.org.)

Kyanite, sillimanite and andalusite (Al_2SiO_5) are polymorphic minerals which traditionally have been used as geobarometers and geothermometers. However, P-T determinations using Al_2SiO_5 minerals are problematic. Transformations between Al_2SiO_5 polymorphs involve breaking strong Si–O and Al–O bonds. This, combined with the small free energy differences between polymorphs, makes difficult to determine the P-T fields of these minerals, which usually persist as metastable phases [1].

The aim of this work is to study the nanotribological properties of kyanite, sillimanite and andalusite surfaces and their relationship with different Si–O and Al–O bonds schemes. We measured friction on Al_2SiO_5 cleavage surfaces immersed in water using a lateral force microscope (LFM) at RT. Lateral deflection signals along different crystallographic directions were measured and converted into frictional forces after an adequate calibration [2]. While frictions measured at the microscale on different Al_2SiO_5 surfaces were compared, 10×10 nm^2 frictional maps provided detailed structural information (see Figure). The methodology and preliminary results presented here represent a new approach to the study of the Al_2SiO_5 polymorphs.

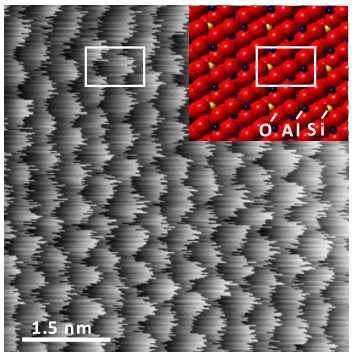

Figure: LFM image of kyanite (100) face showing the surface lattice. The inset shows the kyanite surface structure.

Nanotribology of mineral surfaces in aqueous environments

CARLOS M. PINA[12], CARLOS PIMENTEL[12] AND ENRICO GNECCO[3]

[1]Departamento de Cristalografía y Mineralogía, Universidad Complutense de Madrid, Spain, cmpina@geo.ucm.es; (cpimentelguerra@geo.ucm.es.)
[2]Instituto de Geociencias UCM-CSIC (IGEO)
[3]IMDEA Nanociencia, Madrid, Spain. (enrico.gnecco@imdea.org.)

Investigations on the structure of mineral surfaces are fundamental to gain a better understanding of their reactivity. The latest developments in surface sensitive techniques and, in particular, in atomic force microscopy (AFM), have provided interesting information on the terminations of mineral faces at the nanoscale. Despite this, nanotribology studies of mineral surfaces are still scarce. Recent works have, however, demonstrated that friction measurements performed with lateral force microscopy (LFM) can be used to obtain detailed crystallochemical and crystallophysical information on mineral surfaces [1-3].

Here we present friction measurements conducted on carbonate, sulphate and silicate mineral surfaces using LFM operating in water. Measured friction forces at the nanoscale are typically in the range of 10 nN and they were found to vary with the crystallographic direction. In all cases, crystal lattices could be resolved and the surface unit cells were measured. On the surfaces studied no reconstruction nor relaxation phenomena were observed.

Our LFM measurements were extended to study epitaxial overgrowths on mineral surfaces [4]. Frictional maps allowed us to resolve substrate and overgrowth surface lattices and to determine epitaxial relationships. Furthermore, by increasing the vertical force of the LFM, we removed overgrown islands attached on the substrates. Depending on the mismatch between overgrowth and substrate lattices, different shear strengths for overgrowth detachment in the range of 5 to 150 MPa were calculated.

The results that we present here demonstrate that LFM in liquid is a very suitable technique to study mechanical properties of mineral surfaces and epitaxial phenomena at a molecular scale.

Equilibrium isotope fractionation factors in liquids from path integral molecular dynamics simulations

C. PINILLA*[1], M. BLANCHARD[1], G. FERLAT[1], E. BALAN[1], R. VUILLEUMIER[2] AND F. MAURI[1]

[1]IMPMC, Université Pierre et Marie Curie, CNRS, IRD, 4 Place Jussieu, 75252, Paris Cedex 05, France
[2]Ecole Normale Supérieure, Département de Chimie, UMR CNRS-ENS-UPMC nº 8640, 24 Rue Lhomond, F-75231 Paris Cedex 05, France

The equilibrium fractionation factor between two phases is of importance for the understanding of many planetary and environmental processes. Although thermodynamic equilibrium can be achieved between minerals at high-temperature, many processes in Earth and environmental sciences involve reactions between liquids or aqueous solutions and solids [1]. In crystals, the fractionation factor α is theoretically modelled using a statistical thermodynamic approach to calculate the equilibrium constants of isotope exchange reactions from the vibrational energy levels of the phases [2]. These calculations are mostly based on empirical or ab-initio description of the systems to extract the harmonic vibrational information. In the case of a periodic systems such as liquid phases and solutions, further approximations are however required and could include the use of finite-size molecular clusters or the use of relaxed configurations taken from molecular dynamics (MD) runs.

In this work we present a systematic study of the calculation of the D/H and $^{18}O/^{16}O$ equilibrium fractionation factor in water for the liquid/vapour and ice/vapour phases using several levels of accuracy within the simulations. Namely, we use MD in combination with an empirical potential model for water. The exact fractionation factor for this potential is obtained from thermodynamic integration using Path Integral MD calculations. Compared with standard MD, this method makes it possible to take into account quantum effects in the thermodynamic modelling of liquids. We compare these results with those of the modelling strategies usually used, which involve the mapping of the quantum system on its harmonic counterpart. Accordingly, we discuss the implications of these approaches for the calculation of fractionation factors in liquid systems.

[4]ELETTRA Syncrotron Light Laboratory, Triest, Italy

We have carried out detailed petrographic, petrophysical (EBSD), geochemical and fluid inclusion study (e.g. Raman, FTIR coupled synchrotron radiation, FIB) on spinel lherzolite xenoliths from Barombi Mbo (BM) and Nyos Lake coupled with study of the H2O content of their nominally anhydrous minerals (NAMs). Results indicate that the BM protogranular xenoliths provide a characteristics of a juvenile subcontinental lithospheric mantle suffered low degree partial melting and record deformation regime governed by combination of simple and pure shear. The NAMs in BM xenoliths show moderate bulk water content (100-130 ppm). Their fluid inclusions consist of high-density CO2-H2O(-H2S) system, which also contain phlogopite as a step-daughter mineral. The porphyroclastic Nyos xenoliths preserve a transpressional deformation regime and metasomatism indicated by the presence of pargasite. Nyos xenoliths have low bulk NAMs H2O content (10-60 ppm) and their fluid inclusions also contain high-density CO_2-H_2O(-H_2S) fluids with phlogopite and pargasite step-daughter minerals.

[2]AORI, The University of Tokyo, Kashiwanoha, Chiba 277-8564 Japan
[3]Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI 48109-1005, USA

Fifty-six groundwater samples were collected for noble gases analysis from Ordovician fractured aquifers and Quaternary granular aquifers at the Bécancour Basin. This is one of several basins collecting waters from the Appalachian Mts and discharging into the St. Lawrence River, between Montreal and Quebec, eastern Canada. Multiple goals were at the origin of this extensive survey. The main goals of this study were to identify groundwater flow paths and to estimate groundwater residence times. In particular, helium was coupled to alcanes (CH_4, C_2H_6, C_3H_8) to identify gas seepage potentially originating in the deeper Utica shales, a local target for shale gas exploration.

Helium isotopic data show the occurrence of three components: atmospheric, i.e., an air saturated water (ASW) origin, tritiogenic and terrigenic. Tritiogenic helium is found both in Quaternary granular and Ordovician fractured aquifers. In the eastern border of the basin, a helium isotopic gradient with depth is observed, from values close to atmospheric $^3He/^4He$ (R) ratio of 1Ra at the surface up to 4.5Ra at 60 m depth. Preliminary minimum ^3H-^3He ages range from modern to 32 yrs. Waters show radiogenic ^4He concentrations from 10^{-7} to 10^{-5} ccSTP/g, i.e., up to three orders of magnitude higher than ASW. Interestingly, some of these samples contain tritium suggesting that these are young waters enriched by extraformational ^4He (^4He excess). In these two areas, concentration gradients with depth are apparent, suggesting vertical migration of He from deeper horizons. Using an advective-diffusive model, ^4He fluxes were estimated and range from 3.2×10^{-10} to 1.2×10^{-9} mol m^2 yr^{-1}, flux values that are smaller than the average crustal flux of 1.7×10^{-6} mol m^2 yr^{-1} but closer to a pure flux from *in situ* production of 2×10^{-9} mol m^2 yr^{-1}.

Mineralogy and distribution of Indium and Selenium metals within zinc-rich ore types of the Neves Corvo deposit, Portugal

The Neves Corvo deposit is located in the Portuguese segment of the Iberian Pyrite Belt (IPB). The deposit is hosted by an upper Devonian to lower Carboniferous Volcanic-Siliceous Complex and embraces six orebodies: Graça, Corvo, Neves, Zambujal, Lombador and Semblana.

The Neves Corvo deposit has important contents of a wide range of high-tech elements, which can be profitable commodities such as the case of Indium (In) and selenium (Se). Indium average grades deposit ranges in between 30 to 215 ppm. Graça, Lombador and Zambujal orebodies have the higher average grades on indium, respectively 215, 152 and 150 ppm. These higher indium grades were observed within zinc-rich ores (MZ) at the Graça and Lombador oredodies and in the copper-zinc-rich ores (MCZ) of the Zambujal orebody. Indium is present as minor element in the structure of major minerals such as chalcopyrite, sphalerite, stannite group minerals and fahlores. Selenium average grades vary in between 10 and 3220 ppm. Lombador and Zambujal orebodies have the highest selenium average concentration, showing 2560 and 3220 ppm, respectively. At the Zambujal orebody the high selenium grades occur in the lead-zinc-rich ores (MZP), while in the Lombador orebody the highest selenium grades were detected at the copper-zinc rich ores (MCZ). Selenium occurs both as Se-minerals and as minor element in the structure of major sulfide minerals. Selenium mineralogy is represented by selenium-bearing galena containing up to 30% of clausthalite (PbSe) end member and junoite ($Pb_3Cu_2Bi_8[S,Se]_{16}$), which is described here for the first time either at the Neves Corvo deposit, or the Iberian Pyrite Belt. Selenium also occurs as minor element in fahlores group minerals and sphalerite.

Constraining the Nd isotopic composition of Antarctic Bottom Water formed in the Weddell Sea

ALEXANDER M. PIOTROWSKI [1], CLAUS-DIETER HILLENBRAND[2], CLAIRE S. ALLEN [2], EUGENE DOMACK [3], AND ANDREAS MACKENSEN [4]

[4]Alfred Wegener Institute, Bremerhaven, Germany

The Southern Ocean is a key region linking ocean circulation and global climate. Antarctic Bottom Water (AABW) ventilates much of the world's deep ocean as it propagates, together with Circumpolar Deep Water, via the Antarctic Circumpolar Current (ACC) from the Atlantic sector of the Southern Ocean into the Indian and Pacific sectors, and spreads northwards into deep basins. Proxy data from sediment cores suggest that during Late Quaternary glacial periods, increased volumes of AABW filled the deep ocean, perhaps enlarging the carbon reservoir of the world ocean and lowering atmospheric carbon dioxide. Much of the evidence for glacial circulation of deep and bottom water masses is based on stable carbon isotope ($\delta^{13}C$) records from benthic foraminifera. This proxy, however, can be interpreted as either indicating changes in water mass sources, biological productivity or air-sea gas exchange. This is especially problematic in the glacial Southern Ocean where all three of these controls are likely to have been dramatically different than today. Thus Nd isotopes have been utilized as a deep water source tracer to reconstruct the balance of North Atlantic Deep Water (NADW) and AABW in the global deep ocean. Here we constrain the Nd isotopic composition of AABW formed in the Weddell Sea, allowing us to more accurately determine past changes in the mixing ratio of NADW and AABW at other coresites. The Nd isotopic composition of reductive sediment leaches, foraminifera, and Holocene Fe-Mn coatings on dropstones were analysed from cores located along the flowpath of the clockwise flowing Weddell Sea gyre. These allow us not only to constrain potential temporal variability in the Nd isotopic composition of newly-formed AABW, but also to show how it acquires this Nd isotopic composition as it flows northwards along the Antarctic Peninsula.

Organomineralization drives early chimney edification at the hyperalkaline hydrothermal field of the Prony Bay (New Caledonia)

PISAPIA C.[1]*, GERARD E.[1], GERARD M.[2], MENEZ B.[1] AND THE HYDROPRONY TEAM

[1]IPGP, 75238 Paris Cedex 05, France (*correspondence: pisapia@ipgp.fr, emgerard@ipgp.fr, menez@ipgp.fr)
[2]IMPMC, 75005 Paris, France (martine.gerard@impmc.upmc.fr)

The serpentinization process of ultra-mafic rocks by hydrothermal fluids at ultra-slow spreading ridges is recognized as a potential energy source for the development of (sub)surface lithoautorophic microbial ecosystems. The hydrogen generated by the hydration of Fe^{2+}-bearing silicates can reduce CO_2 coming either from mantle degassing or seawater forming methane and other light hydrocarbons similarly to methanogenesis. In the 2000's the discovery of the Lost City Hydrothermal Field (LCHF) hosted on ultramafic susbstratum near the Mid-Atlantic ridge changed our vision of how and where life can have emerged on Earth and on other planets [1]. It highlighted the importance of serpentinization for the abiotic production of prebiotic molecules and for the sustaining of deep microbial life.

The Prony Bay Hydrothermal Field, discovered in New Caledonia, presents strong mineralogical, geochemical and microbiological similarities with the Lost City Field. The low-temperature (40°C) hyperalkaline springs (pH 11) rich in hydrogen and methane discharge at shallow depth (0-50mbsl) forming carbonated chimneys that host peculiar microflora.

We used a combined geomicrobiological approach (SEM, XRD, Q-ICP-MS, CLSM and FISH) to track microbial cells within the mineralized edifice and to evaluate their impact on the carbonation and (bio)mineralization processes. Similarly to the LCHF [2] the mineralogy is here dominated by brucite and aragonite being replaced by calcite when ageing signing seawater incursions. Filamentous bacteria belonging to the Firmicutes phylum were found to initiate the mineral nucleation through organomineralization processes in active discharging conduits. Mineralized filaments appear ubiquitous in the early stages of the chimney formation, then being consolidated as the mineralization proceeds. It leads to peculiar morphologies whose diagenesis need to be further investigated to be then searched for in the rock record as biosignatures of primitive serpentinization-based ecosystems.

Evidence for crustal contribution to recent compositional changes at Mt. Etna volcano

BRADLEY PITCHER[1]*, WENDY A. BOHRSON[2] AND MARCO VICCARO[3]

[1]Oregon State University, Corvallis, OR, USA (*correspondence: pitcherb@onid.orst.edu)
[2]Central Washington University, Ellensburg, WA, USA (bohrson@geology.cwu.edu)
[3]Universita di Catania, Catania, Italy (m.viccaro@unict.it)

Numerous studies have shown that lavas erupted in the last 4 decades at Mt. Etna are characterized by abrupt geochemical changes. Recent (post-1971) lavas are enriched in some alkali elements, have higher $^{87}Sr/^{86}Sr$, and have lower plagioclase to clinopyroxene modal abundance ratios than historic eruptions (i.e. 1329-1971). *In situ* plagioclase compositional and isotopic data provide crucial insights into possible causes for these changes. Core to rim electron microprobe transects were performed on 133 plagioclase crystals from 11 different samples with eruption dates between 1329 and 2005. Plagioclase An (mol%) ranges from 32 to 92, and cores of recent plagioclase tend to exhibit higher An than historic cores. Core and rim $^{87}Sr/^{86}Sr$ for 87 of these crystals, collected by LA-ICP-MS, augment TIMS whole-rock and groundmass data. Plagioclase $^{87}Sr/^{86}Sr$ range from 0.7030 to 0.7036, and with the exception of 7 analyses, are less radiogenic than whole rock $^{87}Sr/^{86}Sr$ (0.7033 and 0.7036), which, in turn, are less radiogenic than groundmass values (0.7035-0.7037). While a majority of crystals from all samples exhibit core to rim increases in $^{87}Sr/^{86}Sr$, recent rims have higher $^{87}Sr/^{86}Sr$ and larger Sr isotope gaps between rim and whole rock compared to their historic counterparts. In addition, recent plagioclase exhibits more potassic rims for a given An % than the rims of historic crystals, despite having similar core values; this indicates that potassium enrichment must occur during the timeframe of plagioclase crystallization. We propose that an increase in H_2O content of recent parental magmas suppressed plagioclase crystallization to shallower depths, yielding lower plagioclase to clinopyroxene modal abundance ratios and higher An cores. This delayed crystallization enhanced production of latent heat at shallow depths, causing a higher degree of contamination by sedimentary country rock. The Sr isotope disequilibria among plagioclase, whole-rock and groundmass, along with the K enrichment documented in recent rims, strongly suggest that late-stage crustal assimilation, together with other differentiation processes and features inherited from the source, contributed to generate the final signature of recent magmas at Mt. Etna.

Impact of Saharan dust and polluted aerosol on the microbial food web of the Eastern Mediterranean – a mesocosm approach

The impact of Saharan dust and polluted aerosol on the microbial food web of the oligotrophic Cretan Sea was studied during a mesocosm experiment that took place at the mesocosm facility of HCMR in Crete (http://mesoaqua.eu/cretacosmos), in May 2012, in the framework of the projects ATMOMED-MESOAQUA and ADAMANT-THALIS. “Pure” Saharan dust (1.6 mg/l) and mixed aerosols (1 mg/l), collected in Crete and elsewhere, were each added to 3 mesocosms of 3 m^3, while 3 more mesocosms were used as control (no addition). Preliminary results of primary production and phytoplankton biomass (mainly *Synechococcus*) indicate a net response of the autotrophic community to both Saharan dust and mixed aerosol additions between days 1 and 4. The response of the heterotrophic bacterial community to both treatments was also clear but was faster than the one of the phytoplankton and lasted only from day 0 to day 2. The above-mentioned biological parameters were related to the temporal distributions of numerous chemical species, such as inorganic and organic nutrients, total proteins, total mono- and poly-saccharides and their molecular composition profiles, in order to highlight the production and degradation dynamics of organic matter.

Fluid geochemistry and Natural Gas Hazard (CO_2, Rn) in the urban area of Rome (central Italy)

L. PIZZINO AND A. SCIARRA

Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy (*correspondence: luca.pizzino@ingv.it)

The city of Rome is located in the Roman Comagmatic Province, where large sectors experience a huge degassing both from soils and aquifers [1, 2]; gas composition is dominated by CO_2, that can act as a carrier for other minor components such as N_2, CH_4, H_2S and Rn. Gases are produced at depth (throughout mantle degassing and/or decarbonation processes) and upraise towards surface through fault and fracture systems, thus characterising well defined enhanced permeability belts. Gases exhaled from soils and aquifers can enter houses, potentially reaching harmful indoor levels [3]. Indeed, some gases (CO_2, H_2S) can have a short-term toxicity, while others (i.e. radon) can cause lung cancer at prolonged exposures. As a consequence, an evaluation of the level of Natural Gas Hazard (NGH) to which these areas are exposed, is required. By now, detailed information on CO_2 and Rn distribution in ground waters was assessed for the volcanic complexes around Rome [1, 4], allowing to discriminate areas where deep fluid upraise and where analysis of indoor-gas levels has to be carried out, in order to lessen their impact on human health. Such an investigation is still lacking for the urban sector of the Italian capital, where about 2500000 people habitually live.

A detailed geochemical study in ground waters started in 2011 and is currently going on in the roman area; 128 water wells and 16 springs were investigated for their chemical and isotopic composition. The preliminary investigation allowed us to recognise and mark off areas in which deep fluids upraise, generally characterised by the presence of hypothermal and CO_2-rich waters. In particular, the role of deep CO_2 as a sound marker of deep tectonic structures in this sector of central Italy, is emphasised. Waters rich in deep CO_2 are located in the southern and in the north-eastern sectors of Rome, that can be considered as potential NGH-prone areas; hypothermal waters have been found in the south-western part of Rome. Radon-rich waters roughly mimic the CO_2 distribution and circulate mainly in the southern sectors of Rome. So far, no H_2S-rich groundwater has been found.

Petro-geochemical evidence for vapour transport in andesite shear fractures

M.PLAIL[1]*, M.EDMONDS[2], J.BARCLAY[1], M.C.S. HUMPHREYS[3]AND R.A.HERD[1]

[1]School of Environmental Sciences, University of East Anglia, UK (*correspondence: m.plail@uea.ac.uk)
[2]Department of Earth Sciences, University of Cambridge, UK
[3]Department of Earth Sciences, University of Oxford, UK

The andesitic Soufrière Hills Volcano (SHV), active since 1995, emits large fluxes of volcanic gases (dominantly H_2O, CO_2, SO_2, HCl). The gas is largely decoupled from the flux of magma to the surface, indicating efficient magma-vapour segregation. Effective open-system degassing at dome forming eruptions may control eruption style. However, evidence for vapour transport through magma is not often preserved in the erupted rocks. We present the first petro-geochemical evidence for metal-bearing vapour transport in shear zones in SHV andesite and a model for their formation.

Andesite blocks in deposits from SHV contained narrow shear zones (2 m x 2-10 cm), with alternating low porosity, fine-grained (~30-70 μm) and higher porosity, coarser-grained (~100-350 μm) bands. The higher porosity (7-19% vol) bands consist of broken and comminuted crystals compositionally identical to mineral compoisitions in the SHV andesite. However, the low porosity (~1%) bands have elevated zones of oxides (<8% vol) and cordierite. Bulk ICP-MS analyses indicate that metal concentrations (Cu, Ni, Pb, Au, Ag and Zn) are greatly enhanced relative to the surrounding andesite. For example, Cu and Au concentrations are >10 times higher than in the andesite host. Cu is present as Cu-Fe sulphide inclusions in Ti-magnetites and plagioclase phenocrysts. We also demonstrate that trends in metal enrichment in the shear zones match well with published experimental metal vapour/melt partition coefficients.

The enhanced metal and volatile concentrations in the shear zones indicate that these zones acted as permeable pathways for metal-bearing gas in the shallow volcanic system. The shear fractures formed in response to brittle failure at high magma strain rates and viscosity, along which metal-bearing vapour or fluid was transported. The gas pathway survived until frictional heating at the slip surface created a partial melt upon which volatiles and metals were resorbed, thus preserving the geochemical signature of the magmatic gases. The subsequent recrystallization of the peraluminous partial melt on cooling resulted in the highly unusual presence of volcanic cordierite.

Earth surface redox constraints from the ancient Cr cycle

NOAH J. PLANAVSKY[1], CHRISTOPHER T. REINHARD[1], XIANGLI WANG[2], WOODWARD W. FISCHER[1], THOMAS M. JOHNSON[2] AND TIMOTHY W. LYONS[3]

[1] California Institute of Technology (planavsky@gmail.com)
[2]University of Illinois, Urbana Champaign
[3]University of California, Riverside

Stable Cr isotope ratios of sedimentary rocks provide a historical record of large kinetic isotope fractionations associated with redox reactions at the Earth's surface. Cr in most igneous phases exists as Cr(III), which remains stable/immobile during terrestrial weathering under reducing conditions. Furthermore, both theoretical and experimental studies indicate that Cr will undergo limited fractionation during non-redox-dependent transformations. In marked contrast to non-redox processes, the oxidation and reduction of Cr induce large isotope fractionations. Therefore, Cr isotopes are ideally suited to track redox processes.

To date, iron formations have been the most utilized Cr isotope archive. Iron formations, as chemical precipitates, have the potential to trap an aqueous Cr isotope signature, rather than carrying a predominantly detrital Cr load. Further, iron oxides sorb significant amounts of Cr. And therefore iron oxide-rich rocks have a much higher potential than other chemical precipitates (e.g., cherts and carbonates) to have Cr isotope signatures that are rock buffered during burial alteration.

Based on previous work and our new results, the Archean iron formation Cr isotope record is generally characterized by near-crustal δ^{53}Cr values suggesting a lack of significant Cr redox cycling. In stark contrast, Neoproterozoic iron formations and Phanerozoic ironstones exhibit large and variable Cr isotope fractionations—a clear signal of substantial Cr redox cycling. Rather surprisingly, we found four mid-Proterozoic ironstones with limited Cr isotope variability despite having significant authigenic Cr enrichments. *In situ* Cr abundance work confirms that Cr in the examined samples is present in depositional phases (e.g., iron ooids) rather than in detrital Cr-rich phases (e.g., chromite). Our new results fill in a previously exisiting billion-year gap in sedimentary Cr isotope data and suggest that, in the Neoproterozoic, there was a permanent switch to a more oxidative Cr cycle. These results suggest limited Cr isotope fractionations due to low (relative to standard models) environmental oxygen concentrations for intervals of the mid-Proterozoic.

Modelling scavenged ocean tracers: Rare earth element transport and fractionation

YVES PLANCHEREL[1], XINYUAN ZHENG[1], PETER SCOTT[1], SAMAR KHATIWALA[2]AND GIDEON M. HENDERSON[1]

[1]University of Oxford, Earth Sciences Department, Oxford, OX1 3AN, (yvesp@earth.ox.ac.uk)
[2]Lamont-Doherty Earth Observatory, Columbia University, New York, USA

Insoluble metals such as rare-earth elements (REEs), Al, and Th have not been so widely studied as nutrients or dissolved gases as tracers of ocean process, but are seeing increasing interest driven by extensive new datasets and by a desire to undertand the cycling of micronutrients metals (e.g. Fe, Cu) which are critical for biology and have a component of insoluble behaivour. Insoluble tracers have spatial oceanographic gradients dominantly controlled by their propensity to attach to particles (scavenging). In the ocean, REEs are interesting because, when normalized to their source composition (i.e. continental inputs), they show a systematic and relatively smooth (except Ce) progression from the light to the heavy REEs. The shape of this REE-pattern, which is the macro-scale representation of the lanthanide contraction, varies spatially in the ocean as a function of source proximity, water-mass mixing, water mass age and particle concentration. Because source types are similar for most REE (mostly rivers and dust), and REEs do not influence the particle field, the slight differences amongst the source-normalized dissolved REE concentrations in the ocean interior reflects the balance between physical transport and scavenging. Light REE (LREE) scavenge more readily than heavy REE (HREE) so HREE are more sensitive to transport than LREE.

In this study we exploit the LREE-to-HREE progression and explore the value of a new tracer (REE*) defined by the incremental differences between REEs in the pattern. We first present the large scale distribution and mean gradients of REE from the analysis of a global REE data set assembled from published historical values and new GEOTRACES measurements. Secondly, we discuss results from a set of sensitivity modeling experiment, based on the transport matrix formalism, designed to better understand controls on the distribution of REE in the ocean, the potential value of REE* as a water mass tracer, and the use of REEs to understand scavenged elements more generally.

Did thioarsenates start off the early arsenic cycle?

BRITTA PLANER-FRIEDRICH[1]

[1]Bayreuth University, Environmental Geochemistry Group, Universitätsstrasse 30, 95440 Bayreuth, Germany, (b.planer-friedrich@uni-bayreuth.de)

Arsenic is known as a poison, but there is a diversity of microorganisms that can conserve energy from oxidation or reduction processes in the As cycle. Two inorganic species are commonly thought to exist: Arsenite and Arsenate. Chemolithotrophic arsenite oxidation requires strong oxidants, such as nitrate or oxygen as electron acceptors. That means arsenate production could have only taken place after the onset of oxygenic photosynthesis about 2.5 billion years before present. Dissimilatory arsenate reduction with organic carbon or sulfide as electron donors completes the As cycle.

However, it has been suggested that arsenite could be oxidized in the absence of oxygen, by anoxygenic photosynthesis (1) which is known for Sulfide or Fe^{2+}, but was unsuspected for As. It would enable a full As cycle already 3-3.5 billion years ago. Evidence for anoxygenic As photosynthesis came from two hot springs in Mono Lake, a saline lake in California, USA. The hot springs contain 100-130 μM As, supposedly all arsenite, 5000 μM Sulfide and are dominated by *Oscillatoria*-like cyanobacteria and an *Ectothiorhodospira* strain. Incubations of slurried biofilms showed arsenite oxidation in the light with CO_2 fixation (1).

We re-analyzed As speciation in these hot springs by our IC-ICP-MS method (2) and discovered that arsenite actually is only a minor species (<3%). Instead, thioarsenates ($AsS_nO_{4-n}^{3-}$) dominate (78-95%). The observed anoxygenic production of arsenate (from thioarsenates, instead of arsenite!) could thus be a novel microbial metabolism. An alternative explanation is that there is no anoxygenic arsenic photosynthesis, but arsenite oxidation occurs as an abiotic follow-up to sulfide oxidation. Laboratory experiments show that monothioarsenate forms from arsenite and S^0, an initial product of anoxygenic sulfide photosynthesis. Upon depletion of the S^0 reservoir, monothioarsenate is desulfidized and forms arsenate. Thioarsenates might thus have been key reactive intermediate As species to help kick off a full As cycle before the advent of free oygen by abiotically freeriding the microbially catalzyed S cycle.

Short Timescales of Magma Ascent Recorded in Melt Inclusion Diffusion Profiles

TERRY PLANK[1], ALEXANDER S. LLOYD[1], PHILIPP RUPRECHT[1], ERIK HAURI[2] AND YOUXUE ZHANG[3]

[1]Lamont-Doherty Earth Observatory, Palisades, NY, USA, (tplank@ldeo.columbia.edu)(, alloyd@ldeo.columbia.edu)
[2]Department of Terrestrial Magnetism, Carnegie, Washington, DC, USA, (ehauri@ciw.edu)
[3]Dept of Earth & Environmental Sci., Univ of Michigan, Ann Arbor, MI, USA,(youxue@umich.edu)

The rate of magma ascent is a primary proposed control on the eruptive vigor of volatile-rich magmas. Yet, very few quantitative estimates exist, in part because few geochronometers work at such short timescales (minutes to days). Here we present results of two different diffusion clocks, both of which record the minutes prior to and during eruption. The first involves diffusion of volatile species along melt embayments, as the partially-enclosed melt strives to equilibrate with surrounding degassing melt during magma ascent. NanoSIMS analysis (~5 micron spots) provides profiles of H_2O, CO_2 S, Cl and F along 100-300 micron tubes hosted in olivine from the 1974, sub-Plinian eruption of Volcan de Fuego in Guatemala. Fully-enclosed melt inclusions from the same samples constrain the initial volatile contents, and the decompression-degassing path followed by the melt exterior to the embayments. Despite very different diffusivities and solubilities, H_2O, CO_2 and S profiles all yield a consistent ascent rate in three different ash and lapilli samples: 13-16 m/s. Such rapid ascent, 8-9 km in 9-10 minutes, may contribute to the explosivity of this eruption.

Fully-enclosed melt inclusions from the same samples preserve major element profiles (MgO, CaO, Al_2O_3) that derive from olivine-growth on the inclusion rim and diffusion within the inclusion. We fit profiles using a coupled diffusion-growth model, where olivine growth is limited by both the rate of undercooling and the supply of MgO to the interface. While multiple cooling histories are possible, a constant cooling rate of 0.3-0.5K/s fits diffusion profiles across the ~ 50 micron diameter inclusions, with growth of ~ 0.4 microns of olivine in ~ 10 minutes. The similar timescales (~ 10 min) for both chronometers point to rapid decompression and cooling in the run-up to this explosive eruption. Extension of these melt inclusion clocks to other volcanic systems should provide new data on ascent, degassing and cooling rates, and their relationships to eruptive magnitudes.

On the hunt for a Gondwanan suture zone in South India

DIANA PLAVSA[1]*, ALAN S. COLLINS[1], JOHN F. FODEN[1] CHRIS CLARK[2] AND M. SANTOSH[3]

[1]Centre for Tectonics, Resources and Exploration (TRaX), University of Adelaide, Australia
[2]The Institute for Geoscience Research (TIGeR), Curtin University of Technology, Australia.
[3]School of Earth Sciences and Resources, China University of Geosciences Beijing, China

The Southern Granulite Terrane (SGT) of India is located at the apex of the Indian subcontinent and is a Proterozoic mobile belt that was involved in the amalgamation of the Gondwana supercontinent. The tectonic evolution and geochemical characterization of individual crustal domains within the SGT is rendered difficult due to the intensity of metamorphism (ultra-high-temperature conditions) associated with the ca. 550–500 Ma collision between Neoproterozoic India and the African continents.

Here, we use Sm–Nd isotopes, U–Pb zircon geochronology and whole-rock geochemistry of the basement rocks combined with the Lu–Hf and U–Pb isotopic systems in detrital zircons from the overlying Neoproterozoic sequences to define Indian versus African affinities of the rock packages. The results are used to place constrains on the spatial distribution of individual crustal domains during the Proterozoic. Our results show that the metasedimentary rock packages north of the proposed suture zone (Palghat Cauvery Shear Zone) have Palaeoproterozoic maximum depositional ages and detrital signatures typical of Indian basement rocks, while those to the south have Neoproterozoic maximum depostional ages and probable African sources.

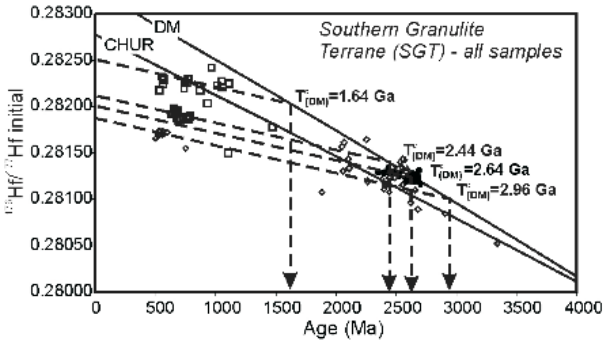

Figure 1: Initial $^{176}Hf/^{177}Hf$ vs. Age (Ma) evolution plot of detrital zircons from arcoss the SGT.

Self-organizing reactive porosity waves allow large-scale fluid escape from subducting oceanic lithosphere

OLIVER PLÜMPER[1], TIMM JOHN[2], YURI Y. PODLADCHIKOV[3] AND MARCO SCAMBELLURI[4]

[1]Department of Earth Sciences, Utrecht University, The Netherlands (o.plumper@uu.nl)
[2]Institut für Mineralogie, Univeristy of Münster, Germany
[3]Institute of Earth Sciences, Univeristy of Lausanne, Switzerland
[4]Dipartimento per lo Studio del Territorio e delle sue Risorse, Univeristà di Genova, Italy

At subduction zones seawater-altered oceanic lithosphere is returned to the Earth's mantle, where increasing temperatures and pressures results in the progressive destabilization of the hydrous minerals to release large amounts of aqueous fluids. This cycling of volatiles is one of the most distinctive features of subduction zones and has fundamental consequences for Earth's geodynamics and chemical cycles. Fluids released from the subducting slab trigger sub-arc mantle melting leading to explosive volcanism and induce petrophysical changes during dehydration that are thought to be the principal source of intermediate-depth intra-slab earthquakes. In all these cases large-scale transport systems need to form where fluids can escape from the subducting slab to either migrate up-dip along the plate interface or into the overlying mantle wedge. However, permeability is minimal at the depths and confining pressures relevant to subduction settings, thus insufficient to allow for pervasive fluid flow with high enough fluxes to efficiently drain the subducting oceanic plate. Evidence of the volatile cycle indicates that a fluid extraction mechanism is required that can keep pace with the slab descent velocity of cm/year to avoid the fluid being lost to the mantle. The tendency of fluid flow to occur channelized in space and time, illustrated in nearly all high-pressure terrains as vein networks, points to a potential mechanism. Channelized fluid flow would enable efficient fluid release rates with high local fluid fluxes over long distances. However, how a dehydrating system with an initially low, pervasive fluid production develops into channelized fluid extraction network is largely unknown. By using an interdisciplinary approach of field observations, reaction microstructures and numerical modeling we investigate the most prominent devolatilization reaction for the deep volatile cycle, the breakdown of serpentine phases within the subducting oceanic mantle. Based on our findings we formulate a fully consistent mechanistic model of metamorphic fluid escape during mineral dehydration.

Formation conditions of sapphirine-bearing assemblages from some complexes of Siberia

K.K.PODLESSKII

Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry (IGEM), Russian Academy of Sciences, Staromonetny per. 35, 119017 Moscow, Russia (kkp@igem.ru)

Samples of granulites containing sapphirine-bearing assemblages from the Sutam, Chogar and Sharyzhalgay complexes, Siberia have been investigated with the microprobe, and their formation conditions have been estimated both with conventional thermobarometry and, where possible, with thermometry based on Ti contents of quartz [1]. With the estimates based on different methods showing good agreement, anomalously low temperature of 700±50°C has been obtained for the sapphirine + quartz bearing assemblages from the Sharyzhalgay complex (figure below), while metamorphic conditions estimated for the samples from other complexes correspond to conventional high-temperature ranges. Textural relations in the studied samples show that in many cases sapphirine formed due to retrograde reactions after spinel, aluminous orthopyroxene or sillimanite.

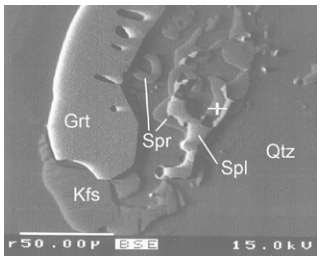

Figure 1, BSE image of Grt+Spr+Spl+Qtz assemblage in sample B-125 from the Sharyzhalgay complex.

Comparison of calculated stability fields of sapphirine-bearing assemblages with the estimates of temperature and pressure based on the mineral compositions indicate relatively low water activity in the course of metamorphism. However, lack of reliable experimental data on changes in composition of sapphirine with temperature and pressure inevitably requires considerable ambiguity in modeling reactions involving this mineral [2].

Fe K-edge XANES of synthetic and natural silicate glasses: composition and fO_2 dependent structural properties

BT POE[1], C ROMANO[2], G CIBIN[3], DB DINGWELL[4], K-U HESS[4] AND M POTUZAK[5]

[1]Dipartimento INGEO, Universtà G. D'Annunzio, Chieti Italy (poe@ingv.it)
[2]Dipartimento di Scienze, Università degli Studi Roma Tre, Roma Italy (claudia.romano@uniroma3.it)
[3]Diamond Light Source Ltd., Oxfordshire UK (giannantonio.cibin@diamond.ac.uk)
[4]Department for Earth and Environmental Sciences, Ludwig-Maximilians University, Munich Germany (dingwell@lmu.de, hess@lmu.de)
[5]Corning Inc., New York, USA (potuzakm@corning.com)

The pre-edge region of the Fe K-edge x-ray absorption spectrum is well known to be sensitive to both local structural order (coordination number, polyhedral type) and valence state of iron. We have examined several Fe-bearing silicate glasses, both synthetic and remelted natural samples with wide-ranging chemical compositional characteristics, quenched from superliquidus temperatures and oxygen fugacities ranging from air to ca. 10^{-8}. Their Fe K-edge spectra were acquired on the GILDA beamline (BM08) at ESRF using a Si (311) monochromator. The pre-edge region of the spectra of all glasses were background subtracted and then normalized before being fit to the sum of two Lorenzian-shaped peaks. The energies of these two peaks remained nearly independent of glass composition and fO_2 whereas intensities and linewidths varied. For individual series of samples having the same chemical composition and varying oxygen fugacity, we observe a smoothly varying centroid position as a function of log fO_2, consistent with changes in Fe^{3+}/Fe^{2+} observed in many previous studies of this type, and verified for several samples using wet chemical analyses. Differences in the behavior of the centroid vs log fO_2, however, from one series to another can be traced to compositional parameters such as degree of polymerization of the melt (e.g. NBO/T). We also observe systematic variations in total integrated intensities as a function of both fO_2 and chemical composition, allowing us to predict the degree to which Fe gradually transforms from a network former to a network modifier as oxygen activity decreases. The subtle differences applied to the structural role of a single chemical component in a multicomponent natural silicate melt could result in important differences in its physical properties and dynamic behavior.

Expanding hypoxia challenging marine life: Metazoan adaptations and limitations revisited

HANS-O. PÖRTNER[1]

[1]Integrative Ecophysiology, Alfred-Wegener-Institute, Am Handelshafen 12, 27570 Bremerhaven, (correspondence: Hans.Poertner@awi.de)

Expanding hypoxia in the world's oceans has led to renewed interest in the adaptation of organisms to life in hypoxic waters and to quantifying their sensitivity. The paper will discuss concepts and present understanding of hypoxia effects in the context of other marine drivers, predominantly temperature, and CO_2, which may combine with further anthropogenic stressors such as pollutants. In animals the concept of oxygen and capacity dependent thermal tolerance (OCLTT) has been proposed as a suitable integrator of various effects, from molecular to ecosystem level of biological organisation. Recent studies confirm applicability of the concept to climate related phenomena in the field. It has successfully explained effects of climate-induced temperature changes on species abundance and biogeographical ranges and appears applicable to climate related shifts in species distribution, temperature related phenology and predominance based on differential temperature dependent performance ranges which are sensitive to hypoxia. Focusing on various degrees of hypoxia, the paper will discuss the living conditions in hypoxic zones and which life forms those conditions can or do not support. Furthermore, it will be investigated how interactions of hypoxia with temperature and CO_2 may have played a key role in metazoan evolution during climate oscillations in earth history.

Li and Ca isotope evidence for continental weathering as a driver of End-Ordovician glaciation

PHILIP POGGE VON STRANDMANN[1], ANDRE DESROCHERS[2] AND TONU MEIDLA[3]

[1]Department of Earth Sciences, University of Oxford, UK, (philipvs@earth.ox.ac.uk)
[2]Department of Earth Sciences, Univsity of Ottowa, Canada
[3]Institute of Geology, University of Tartu, Estonia

The end-Ordovician Hirnantian interval (~445Ma) represents one of the largest mass extinctions in Earth history, and coincides with low temperatures, a major glaciation, and a significant drop in sealevel. However, this time period is also characterised by relatively high pCO_2 levels, and therefore the processes that triggered the glaciation, and its consequences for marine chemistry and life, are not well understood. Proposed causes include an increase in marine productivity and burial of organic carbon (causing a positive C isotope excursion), leading to drawdown of CO_2 [1], but also oscillations in silicate weathering (as a major sink of atmospheric CO_2), potentially due to continental movement and later ice-sheet coverage [2].

Lithium isotopes are a relatively novel tracer of continental weathering. Li is almost entirely situated in silicates, rather than carbonates, and its isotopic fractionation in rivers is demonstrably due to the intensity of silicate weathering. In addition, Li isotope fractionation remains constant in marine carbonates, regardless of changes in temperature or type of skeletal calcite. Calcium isotopes yield information on the balance of continental weathering vs. carbonate precipitation in the oceans, and hence the combination of Li and Ca isotopes can be used to examine CO_2 removal and sequestration processes.

We have determined Li and Ca isotope ratios through multiple marine carbonate sections from Anticosti Island in Canada and Inju in Estonia. The sections show an increase in δ^7Li, reaching its peak slightly earlier than the peak in the C isotope excursion caused by the glaciation. This suggests that silicate weathering intensities decreased, while silicate weathering fluxes increased, in the run-up to the glaciation. We further investigate this with a series of dynamic models, using changes in ocean chemistry (Li, Ca, Sr and Os isotopes) to constrain the evolution of continental and marine processes through this period of extreme climate change.

Variability of biogeochemical characteristics of bottom sediments near the B.Goloustnoe seep (Lake Baikal)

T. POGODAEVA[1]*, O. PAVLOVA[1], G. KALMYCHKOV[2], O.SHUBENKOVA[1] AND T. ZEMSKAYA[1]

[1]Limnological Institute SB RAS, Ulan-Batorskaya St., Irkutsk 664033, Russia (*correspondence: tatyana@lin.irk.ru)
[2]Vinogradov Institute of Geochemistry SB RAS, 1 Favorsky St., Irkutsk 664033, Russia

In order to assess the short-term activity, we studied the area near the methane seep B.Goloustnoe within two winter expeditions, during the ice period, and three summer expeditions. Bottom sediments in the area are saturated in methane (99.3vol.%) of mixed (biogenic + thermogenic) genesis [1]. Methane concentrations in the studied sediments reached 70 mL/L of sediments. Bottom sediments indicated fresher calcium bicarbonate waters, with salinity of up to 100 mg/L, than the water in Lake Baikal. At the same time, bicarbonate ion concentration in the surface layer was less than 1.2 mM. We have determined a temporal variability in chemical composition of pore waters and methane concentrations. Additionally, we have identified the variability in the distribution and number of hydrocarbon oxidizing aerobic and anaerobic microorganisms (HCOM). Trends in concentration profiles of bicarbonate ions consistently changed the directions, from horizontal to left and right inclined. In the surface sediment layer, sulfate ions occurred (being absent), accumulated (up to 0.15 mM), and disappeared again. The profiles of methane curves showed decrease in methane concentration in the near-surface layers of the sediments indicating its consumption. Using pmoA-gene specific primers was obtaned in surface sediments representatives of types I, II, X methanotrophs. Size of the consumption zone was inversely proportional to the methane concentration in the core. At moderate concentrations of methane in sediments, thickness of the consumption zone in the methane seep B.Goloustnoe reached 1.2 m.

These factors suggest the situation variability at this site: change, termination, and renewal of gas flows; and gas discharge is accompanied by the discharge of low-salinity waters. Underlying gas hydrates may be the source of these waters. Intensity of gas-containing fluids changes chemical environment causing fluctuations in the development of aerobic and anaerobic microorganisms.

Tracing industrial atmospheric emissions using radiogenic isotopes

A. POIRIER[1], J. GOGOT[1] AND A. BOULLEMANT[2]

[1]Geotop-UQAM, CP8888, Succ. Centre-ville, Montréal, QC, H3C 3P8, Canada
[2]RioTintoAlcan, 1188 rue Sherbrooke Ouest, Montréal, QC, H3A 3G2, Canada

Large industrial complexes are generators of large economic boost in the area where they establish themselves. But a big industry, such as an aluminium smelting complex inevitably has some environmental impact on its immediate surroundings.

Our study aims at monitoring one aspect of such impact, namely the dispersion of particulate matter in the atmosphere, and their eventual fallout on the regional level. Two radiogenic isotope systems were used in order to do so: osmium (Os) and lead (Pb). These metals were found to be present as traces in the carbon anodes, one of the main raw materials to be used in such Al-smelting industrial process. These anodes are consumed during the electrolytic process and produce CO_2 when reducing Al_2O_3 to liquid metallic Al. Large gas emissions so formed entrain some particulate matter at the stacks, despite the use of high efficiency gas and dust scrubbers.

From our results of osmium content and lead isotopic composition, the main conclusion of our study is that some of the dust generated by this type of industry does escape to the atmosphere, but seems to be falling back very close to its source (e.g. nearby the emitting chimneys) and in this specific case stays nearly completely within the boundaries of the industrial complex.

*corresponding author: Franck.Poitrasson@get.obs-mip.fr

Pioneering studies revealed that for some river waters, large δ^{57}Fe fractionations are observed between the suspended and dissolved load, and isotopic variations were also recognized on the suspended matter along the hydrological cycle. On land, soil studies in various locations have shown that δ^{57}Fe signatures depend mostly on the weathering regime. It thus seems that Fe isotopes could become an interesting new tracer of the local interactions between soils, rivers and the biosphere.

We therefore conducted Fe isotope surveys through multidisciplinary field missions on rivers from the Amazon Basin. It was confirmed that acidic, organic-rich black waters show strong Fe isotope fractionation between particulate and dissolved loads. Furthermore, this isotopic fractionation varies along the hydrological cycle, like previously uncovered in boreal waters suspended matter. In contrast, unfiltered waters show very little variation with time.

It was also found that Fe isotopes remain a conservative tracer even in the case of massive iron loss during the mixing of chemically contrasted waters such as the Negro and Solimões tributaries of the Amazon River. Given that >95% of the Fe from the Amazon River is carried as detrital materials, our results lead to the conclusion that the Fe isotope signature delivered to the Atlantic Ocean is undistinguishable from the continental crust value, in contrast to previous inferences.

The results indicate that Fe isotopes in rivers represent a promising indicator of the interaction between organic matter and iron in rivers, and ultimately the nature of their source in soils. As such, they may become an interesting tracer of changes occurring on the continents in response to both weathering context and human activities.

Probing gold and sulfur geological fluids at extreme conditions by in-situ spectroscopy

Although aqueous fluids account for a tiny fraction of our planet, they play a key role in chemical elements transfer on Earth. These fluids dissolve and precipitate minerals, form economic ore deposits, and control geochemical cycles of metals and volatiles. Knowledge of the chemical status of dissolved elements - their speciation, and the solubility of minerals is the key to quantifying the geological impact of such fluids operating at 'extreme' conditions of high pressure and temperature in Earth's interiors. Because these milieus are not accessible to direct observations, their study requires in-situ spectroscopic approaches.

In this contribution, we report on our recent findings on the behavior of sulfur and gold in hydrothermal-magmatic fluids, revealed by in-situ Raman and X-ray absorption spectroscopy coupled with thermodynamic and molecular modeling. Results challenge the long-standing paradigm that sulfate (HSO_4^-, SO_4^{2-}) and sulfide (H_2S, HS^-) are the two major forms of sulfur in terrestrial fluids [1]; they demonstrate that in the liquid and supercritical fluid phase in addition to these two common sulfur redox states, the trisulfur ion, S_3^-, forms in significant amounts above ~300°C and over a range of depth (to ~100 km) [2]. The S_3^- ion binds gold in hydrothermal fluids, forming stable [HS-$Au^{(I)}$-S_3] complexes largely enhancing the metal solubility; thus, S_3^- is likely to be an important carrier of sulfur and associated metals (Au, Pt, Cu, Mo) for magmatic-hydrothermal deposits in subduction zones [3]. The formation of S_3^- requires a revision of metal speciation models in S-rich aqueous and carbonic fluids [3, 4, 5] and, potentially, silicate melts, operating in the Earth's crust and upper mantle.

Carbonatites out of a subducted altered oceanic crust? Experimental evidences for epidote-dolomite eclogite melting at 3.8–4.2 GPa

S. POLI

Dept. of Earth Sciences, University of Milan, 20133 Milan, Italy (stefano.poli@unimi.it)

Current knowledge on the solidus temperature for carbonate-bearing rocks suggests that carbonatitic magmas should not at the slab-mantle interface, unless thermal relaxation is promoted by a variety of possible tectonic scenarios. For a mildly warm subduction path, COH-bearing altered MOR basaltic eclogites are expected to loose all H_2O component at epidote breakdown, located at approx. 2.8-3.0 GPa. Above this pressure limit, the solidus of a carbonated basaltic eclogite has a minimum temperature of approx. 1000 °C at 4.0-4.5 GPa. However, the oceanic crust includes a range of gabbroic rocks, altered on rifts and transforms, with An-rich plagioclase abundances from 50% to 80% in volume. It has been shown that epidote disappearance with pressure depend on the normative anorthite content of the bulk composition considered, we therefore expect that altered gabbros might display a much wider pressure range where epidote affects solidus relationships.

New experimental data from 3.8 to 4.2 GPa, 750°C to 1000 °C are intended to unravel the effect of variable bulk and volatile compositions in model eclogites, enriched in the normative anorthite component (An37 and An45). Experiments are performed in a piston cylinder and multianvil machines apparatus.

At 3.8 GPa, 800 °C, fluid saturated conditions, garnet, omphacite and kyanite coexist with epidote, dolomite and magnesite. At 900 °C, fluid-rich conditions, garnet and Na-poor clinopyroxene coexist with a silicate fluid/melt of granitoid composition, a carbonatitic melt and a Na-carbonate. Close to fluid-saturation, 4.2 GPa, 900 °C, garnet and Na-rich clinopyroxene coexist with a carbonatitic melt and dolomite. The carbonatitic melt is richer in Ca compared to dolomite, consistently with phase relationships in the model system $MgCO_3$-$FeCO_3$-$CaCO_3$. The H_2O-component deriving from a fluid-absent melting of epidote, enlarged in its pressure stability in An-rich gabbros, promotes melting of carbonates.

The possibility of extracting carbonatitic melts from a variety of gabbroic rocks in a subducting slab, at depths in the order of 120-130 km, offers new scenarios on the metasomatic processes in the lithospheric wedge of subduction zones and a new mechanism for recycling carbon.

Impact of climate change on soil microorganisms and carbon cycling in an arable ecosystem

CHRISTIAN POLL, SVEN MARHAN AND ELLEN KANDELER[1]

[1]Institute of Soil Science and Land Evaluation, Soil Biology Section, University of Hohenheim, Emil-Wolff-Str. 27, D-70593 Stuttgart

Carbon cycling in terrestrial ecosystems provides a feedback mechanism to climate change by releasing or sequestering additional atmospheric CO_2. However, the role of soil microorganisms as key players in this feedback mechanism is still unclear. The Hohenheim Climate Change (HoCC) experiment was established in summer 2008 to manipulate soil temperature and precipitation on an arable field. Soil temperature is increased by 2.5°C in 4 cm and is combined in a factorial design with the following precipitation manipulation treatments: a) ambient, b) precipitation amount decreased by 25% during summer and increased by 25% during winter, c) drought periods increased by 50% during summer, d) combination of b and c. The experimental plots were planted with spring wheat (*Triticum aestivum*, 2009), spring barley (*Hordeum vulgare*, 2010), oilseed rape (*Brassica napus*, 2011) and winter wheat (*Triticum aestivum*, 2012). Soil samples (0-5 cm, 5-15 cm and 15-30 cm depth) were taken at four occasions in 2009 and 2010 and at three and two occasions in 2011 and 2012, respectively. Data of aboveground biomass, soil organic carbon, soil microbial biomass, ergosterol content, hydrolytic enzyme activities and CO_2 fluxes (weekly measurements) will be presented. Results from 2009 and 2010 indicate that changes in soil temperature and precipitation differently affected aboveground biomass and that these effects depended on the crop. Effects of elevated soil temperature on microbial biomass and CO_2 fluxes were related to moisture conditions during the different seasons of the year in 2009 but not in 2010 [1]. First evaluation of ergosterol contents and enzyme activities from 2009 to 2012 indicate that soil warming increases fungal biomass and microbial activity depending on the time of sampling. Overall, the presentation will give insight into the complex interactions between climate change, soil moisture and soil microorganisms as key players of carbon cycling in the investigated arable ecosystem.

Fe β-factors for sulfides from NRIXS synchrotron experiments

V.B. POLYAKOV[1]*, E.G.OSADCHII[1], D.A.CHAREEV[1], A.I.CHUMAKOV I.A.SERGEEV[3]

[1]Institute of Experimental Mineralogy, RAS, Chernogolovka, 142432, Russia (*corespondence: polyakov@iem.ac.ru)
[2]European Synchrotron Radiation Facility (ESRF), BP 220, F-38043 Grenoble, France
[3]Forschungszentrum Juelich GmbH.

We obtained equilibrium Fe isotope fractionation factors (β-factors) for troilite pyrrhotites, sphalerite, pyrite, and chalcopyrite nuclear inelastic x-ray resonant scattering (NIXRS) experiments perfomed in ESRF (Fig. 1).

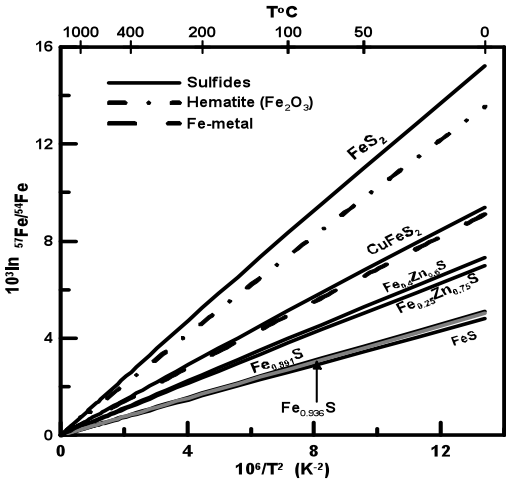

Figure 1: NIRXS-derived β-factors of sulfides.

The β-factor for troilte from our experiment coinsides with that obtained in [1] from NRIXS data [2]. β-factors for pyrrhotites and sphalerite are quantified first time. The Fe β-factor for pyrite agrees excellently with DFT calculations [3] and deviates significantly from the Mössbauer-derived β-factor [4]. The β-factor for chalcopyrite agrees with those calculated in [5] based on data in [6]. Our experiments with chalcopyrite, performed at different temperatures, revealed that anharmonicity may effect on the NRXIS spectrum and lead to overestimating the NIRXS-derived β-factor.

Thermochronological estimates of uplift and cooling rates of the Bodonchin metamorphic wedge

O.P. POLYANSKY*AND V.P. SUKHORUKOV

V.S.Sobolev Institute of Gology and Mineralogy, SB RAS. Pr. Ac. Koptyug 3, Novosibirsk, 630090, Russia (*correspondence: pol@igm.nsc.ru)

Reconstructing the tectonic history of the structures of the Irtysh-Bulgan lineament (SW Mongolia) is of interest for solving the problem of continental crust formation. Based on the new thermochronological and geothermobarometric data, we analyze the metamorphic conditions and tectonic evolution of the Bodonchin zonal complex in the Mongolian Altay [1]. A crustal fragment exposed on the southern slope of the Mongolian Altay consists of isocline-folded rocks, over 20 km thick, and shows a continuous metamorphic zoning from greenschist facies to migmatites. Using THERMOCALC P-T estimates we calculated the thermal state of the crust beneath Mongolian Altay during terrane collision and reconstructed the paleogeotherm at the peak of syncollisional metamorphism. The thermal state of the crust was characterized by high radiogenic heat production (1.66 μW/m3) and elevated heat flow (45 mW/m2). The estimated P-T conditions in two zones (staurolite-kyanite schists and migmatites) of the Bodonchin complex correspond to the paleogeotherms with average temperature gradients of $\partial T/\partial z$ = 25.5 and 27.2ºC/km. The data from isotope dating of zircon and other metamorphic minerals (Bt, Ms, Amp) were used to construct a thermochronological model for the retrogressive stage of polymetamorphic evolution. The uplift rates of metamorphic rocks as a result of thrusting within the Bulgan Fault zone were estimated at 315–1010 m/Myr.

Magma dynamics at Etna before the 122BC Plinian eruption: Constraints from plagioclase zoning profiles

MASSIMO POMPILIO[1]* AND PAOLA DEL CARLO[1]

[1]Istituto Nazionale di Geofisica e Vulcanologia, Sez. di Pisa, Italy (*correspondence: pompilio@pi.ingv.it)

The 122 BC Plinian eruption of Etna is one of the best studied highly-explosive basaltic eruption since detailed stratigraphic, textural, and compositional data, including pre-eruptive volatile content, are available. Former studies [1] proposed an eruption model in which an abrupt decompression event triggered a sudden bubble nucleation allowing the magma to develop rapidly into a microvesicular foam or alternatively the attainment of some critical threshold in rheology of foam-like magma was invoked and the occurrence of special external forces was excluded [2]. The above mechanisms, both feasible, still don't consider adequately the state and the evolution of the magmatic plumbing system before the eruption. To fill this gap we measured zoning profiles in plagioclases of different size (from large megacrysts to microphenocrysts) belonging to the Plinian deposit and plagioclase phenocrysts erupted during the Strombolian activity that preceded the paroxysmal phase. To detail the whole temporal evolution of the system we assumed that megacrysts found in Plinian products have recorded the whole pre-eruptive history, while phenocrysts and microphenocrysts account only for the final phases. Similarly, we considered the zoning of plagioclases of the Strombolian activity as representative of the state of the magmatic system before the climatic phases. Plagioclase zoning has been interpreted by comparison with synthetic profiles obtained from the thermodynamic modelling of different magmatic processes that involved single/multistage and open/closed-system paths [3]. Results indicate that the magmatic system underwent a complex evolution that entails: i) existence of at least two distinct magmatic environments; ii) progressive migration of magmas between these two environments iii) progressive overfilling and destabilization of the shallow plumbing system before the Plinian phase. This picture emphasizes the active role of the magma transfer in determining the eruptive style and allows to identify what is the combination of factors that can favour the development of such a large explosive event.

Leucoxene Photoactivity in the Water – Mineral System

A. PONARYADOV[1]*, O. KOTOVA[1] AND YU. RYABKOV[2]

[1]Institute of Geology Komi SC UB RAS, Syktyvkar (*correspondence: alex401@rambler.ru)

[2]Institute of Chemistry Komi SC UB RAS, Syktyvkar

The photocatalytic activity of leucoxene in the water – mineral system was studied. Leucoxene was extracted from samles of titaniferous sandstones taken from quarry of Pizhemskoe deposit (Russia) (malorucheiskaya suit, Devonian). Mineral composition is presented by quarts, leucoxenized ilmenite, zircon, tourmaline, amphibole. Samples KAH-1, KAH-1-2 and KAH-1-3 were studied (Table 1).

Grain-size analysis was carried out and the TiO_2 content was measured for each grain-size fraction. Fractions with the highest TiO_2 content are shown in Table 1.

Sample	Fraction, mm	TiO_2 content, wt.%
KAH-1	-0.315+0.25	10.60
KAH-1-2	-0.25+0.2	12.25
KAH-1-3	-0.05	14.91

Table 1: TiO_2 content in studied samples.

Photocatalytic activity of the samples was studied using test reaction of degradation of 2, 4, 6-trichlorphenol (TCP) in water.

According to the obtained results photocatalytic activity of leucoxene samples is in direct relation with TiO_2 content and specific surface area.

The project was done under the financial support of projects 12-5-6-016-ARKTIKA and 12-M-35-2055.

Inter- and intra-specific variability of trace metals in shells of *Mytilus* sp., *Serripes* sp., and *Arctica* sp.

A. PONNURANGAM[1,2]*, A. KOSCHINSKY[1], M. BAU[1], T. BREY[2] AND J. BIJMA[2]

[1]School of Engineering and Science, Jacobs University, Bremen, Germany (*correspondence: a.ponnurangam@jacobs-university.de)

[2]Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

Bivalve shells contain within their structure a record of their past growth in the sea due to the sequential deposition of layers of mineralised material, laid down according to the organism's growth rate. For this reason, the importance of bivalve shells as proxy archives for changes in environmental conditions like ocean acidification, is increasingly recognized. However, data for trace metal concentrations in bivalve shells are quite scarce and underrepresented.

The incorporation of trace metals, including rare earth elements and yttrium (REY), as well as uranium in shells of *Mytilus* sp., *Serripes* sp. and *Arctica* sp. was investigated through bulk trace metal analysis. The chemistry of these trace metals in terms of speciation and complexation, makes them particularly useful in acting as geochemical proxies of oceanic change. We looked at the availability and variability of trace metals in shells from different locations and at the extent to which these shells reflect the ambient seawater trace metal content.

Differences in element concentrations were found within and between species. Clear-cut differences in concentrations of REY were observed between the different species of bivalves. Shells of the same species from different sampling locations were found to be enriched differently. Some shells exhibited more seawater-like signatures while others reflected signature patterns of particulate matter. Furthermore, major trace elements like uranium, also varied within species obtained from different locations. *Serripes* sp. from Svalbard were found to contain higher concentrations of uranium than those from Alaska.

Our findings demonstrate the extent of within-species spatial biomineral variability and provide hints as to how shells may or may not reflect characteristics of ambient seawater. If the incorporation of trace metals in biominerals is indeed sensitive to environmental condition, these elements may add to proxy based reconstruction of environment history.

Whether graphites is able to reflect an economical aspect of metalliferous strata

V.A.PONOMARCHUK[1,2]*, T. N. MOROZ[1], A.N. PYRYAEV[1], A.V. PONOMARCHUK[1] AND D.V. SEMENOVA[1]

[2] Novosibirsk State Universitet (*correspondence: ponomar@igm.nsc.ru)

A carbon situated in numerous of Au-, Pt-, Pd-ore and other metals deposits. Carbon-metal correlation is wide discussed and contrary points of view are exist: active (metalorganic+transport) and passive (reducing environment) role of carbon. In order to understand correlation described above comparative study have ben performed. It include morphological (scanning microscopy), microelemental (synchrotron radiation –X-Ray fluorescence), isotopic composition investigations and carbon ordering degree analysis (Raman spectroscopy) of Malomyr, Suhoy Log (Russia) and Suzdal (Kazakhstan) black shale deposits. Moreover, graphites in Pt–Low_Sulfide Ores of Verhnetalnahsk intrusion have ben studied [1,2].

The main propeties of the black shale deposit graphites are moderate generation temperature (200-400°C), low degree of carbon ordering (I_{D1}/I_G – from 0.6 to 1.2) and wide range of carbon isotopic composition (generally from -18 to -28 $‰_0$). Graphites in Pt–Low_Sulfide Ores of Verhnetalnahsk intrusion characterized by nanostructured topology (Fig.), high generation temperature (450 - 750°C), high Pt content (less than 50 ppm), high degree of carbon ordering (I_{D1}/I_G – from 0.02 to 0.2) and short range of carbon isotopic composition (fron -13.5 to -15 $‰_0$). Preliminary conclusion: only nanostructured graphite is able to reflect economical characteristics of metalliferous strata.

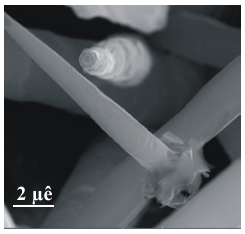

Figure. Scan-image of nanostructured graphite: "T"-joint nano- and microtubes.

Isotopes of elemental carbon in the Chelyabinsk meteorite

V.A. PONOMARCHUK[1,2]*, N.M. PODGORNYKH[1], A.N. PYRYAEV[1] AND A.V. PONOMARCHUK[1]

[1]Institute of Geology and Mineralogy, 630090 Novosibirsk, Russia;
[2] Novosibirsk State Universitet
(*correspondence: ponomar@igm.nsc.ru)

Isotope composition of elementaly carbon in Chelyabinsk meteorite fragments (date of iron-fall – 15 February 2013) was studied. A fragments covered by dark fusion crust with thickness about 1 mm had amorphous or sometime roundish shape with size about 0.7-1.5 cm. Outer crust and traces of silicate material melting were removed mechanically. Mineralogical composition of fragments under investigation was reported by [1,2]. The meteorite previously classified as LL5 chondrite (S4, W0) [GEOKHI RAS].

Analytical procedure includes advance warming-up (1000°C) of samples in helium continuous flow during two hours. Then the samples were combusted in oxygen (950°C) during 40 minutes. Carbon isotope composition were determined using Thermo Finnigan 253 mass spectrometer and GasBanch with specially-constructed line [3]. Table exhibit obtained data.

Table. Carbon content and isotopic composition of elemental carbon in Chelyabinsk meteorite. Variation of given isotopic composition values not exceed ~1,5 $‰_0$ within at least two measurements.

Sample	Weight mg	Content C, ppm	Carbon-13 (PDB)
2.36	29.2	340	-24,5
2.55	7.51	1270	-23.6
3.14	7.15	6710	-22.7
2.73	8.91	2120	-16.8
4.03	10,8	3700	-17,9

Thus carbon content and $\delta^{13}C$ values remains in usual order for CO-type meteorites [4].

The results of preliminary study of magnetic fabric in the Panj-Kuh granitoid, SE Damghan - Iran

M. POORALIZADEH MOGHADAM*[1], M. SHEIBI[2] AND H.GHASEMI[3]

[1]MSc. student of Petrology, Department of Geology, Shahrood University of Technology, Shahrood, Iran
(*correspondence: Mahdokht.p.petro@shahroodut.ac.ir)
[2,3]Faculty Member, Department of Geology, Shahrood University of Technology, Shahrood, Iran
(sheibi@shahroodut.ac.ir and h_ghasemi@shahroodut.ac.ir)

Panj-Kuh pluton (15 km^2) is located in the most northern part of Central Iran structural zone, SE Damghan. The pluton intruded in Eocene volcanic - sedimentary rocks and compositionally ranges from monzonite to syenite. It is I-type granite, calc-alkaline and metaluminouin in nature and it's associated Fe oxide deposit created by sodic-calcic and potassic alteration [1].

Magnetic fabric on the Panj-Kuh granitoid carried out by (MFK1-FA) Kappbridge susceptometer (AGICO, Brno) operating at low field (4×10^{-4}T; 920 Hz) at Geomagnetic Lab of Shahrood University of Technology. According to the determined measurements (41 stations and 262 fragments), mean values of the magnetic susceptibility (Km) for syenite and monzonite are 37880 and 22713 μSI, respectively. The rocks due to the relatively high average magnetic susceptibility (Km>400 μSI) belongs to ferromagnetic granites and the magnetite is the main iron bearing mineral carrying magnetic susceptibility. Where the Na-Ca alteration - characterized by the partial or full absence of magnetite and biotite and appearance of albite and scapolite – is intensified, magnetic susceptibility magnitude is decreased. The main identified microstructural types in the studied pluton is magmatic. The percentage of anisotropy (P%) values vary from 1 to 1.2 and show positive correlation with degree of deformation. Shape parameter of magnetic ellipsoid (T) values varies from 0.93 to -0.48 and most of magnetic ellipsoids are oblate.

Estimates of REE distribution in the hydrothermal ore forming fluid of the Iul'tin and Svetloe deposits

J.A.POPOVA[1], A.YU.BYCHKOV[1,2], S.S.MATVEEVA[1] AND T.M. SUSHCHEVSKAYA[2]

[1]Moscow StateUniversity, Moscow, Russia julka_p@rambler.ru
[2]Vernadsky Institute of Geochemistry RAS, Moscow, Russia

Two Sn-W deposits, Svetloe and Iul'tin (Chukotka Penninsula, Russia) take place within the Iul'tin ore district. Both deposits belong to the cassiterite-quartz formation, are confined to an intersection of deep-seated faults, have spatial and genetical relation to the Upper Cretaceous graniti magmatism and show similar sequences and composition of mineral assemblages.

REE content in single grains of fluorite, wolframite and scheelite was measured by ICP-MS at the Element-2 instrument. REE concentrations in the hydrothermal fluid were obtained based on the distribution coefficients of mineral/fluid [1].

REE content in Svetloe and Iul'tin wolframites allows to suggest that for the wolframites the fluid was magmatic one. This magmatic fluid was enriched by Sm, Gd, Tb, Dy and was characterized by Eu minimum. Regularities of REE spectra changes indicate the presence of two generations of fluorite in the deposits. For the first fluorite generation the fluid is magmatic one, its composition corresponds to the wolframite magmatic fluid. For the second fluorite generation the fluid is exogenous, the Eu minimum is absent or indistinct, these fluorites are enriched in light REE.

The content of the REE were determined in fluid inclusions using aqueous extracts from quartz. This method showes lower REE concentrations that calculated ones based on mineral composition, but the regularities of REE spectra changes also correspond to the presence of two fluids sourses (exogenic and magmatic).

The evolution of fluid was calculated based on thermodynamical model of ore deposition for Iul'tin deposit. Modeling demonstrated that the REE content changes due to both mixing of two different fluids and minerals (wolframite and fluorite) deposition.

This study was supported by RFBR 13-05-00954.

Primary and secondary biogenic aerosols

ULRICH PÖSCHL

Max Planck Institute for Chemistry, Multiphase Chemistry Department, Mainz, Germany;(u.poschl@mpic.de)

Biogenic aerosols comprise primary biological particles (PBAP) such as bacteria, spores and pollen emitted from the Earth surface as well as secondary organic matter (SOA) formed by reaction and condensation of gaseous precursors in the atmosphere. PBAP are essential for the spread of organisms in the biosphere, and numerous studies have suggested that PBAP and SOA can be important for atmospheric processes, including the formation of clouds and precipitation.

The sources and diversity, atmospheric abundance and transport, physicochemical properties and transformation of biogenic aerosols, including their activity as cloud condensation and ice nuclei (CCN, IN), however, are not yet well characterized. Thus, their actual influence on the evolution, present state and future development of the Earth system, the hydrological cycle and other biogeochemical cycles is not yet well constrained. General perspectives and recent advances shall be outlined and discussed.

Silicon diffusion in liquid iron: Kinetic implications for metal-silicate equilibration

ESTHER S. POSNER*, DANIEL J. FROST AND DAVID C. RUBIE

Bayerisches Geoinstitut, Universität Bayreuth, Germany (*correspondence: esther.posner@uni-bayreuth.de)

Silicon is a likely light element in the Earth's core on the basis of Si depletion in the mantle relative to primitive chondrite compositions. Previous studies reveal Si solubility in liquid iron to increase at elevated pressures, which implies that Si would partition from the basal region of a magma ocean into metallic cores of impacting bodies during accretion. The core-mantle boundaries (CMBs) of differentiated bodies are characterized by chemical disequilibrium implying ongoing transport of primary elements, such as Si, between a liquid outer core and the base of silicate mantle. We are conducting a series of high *P-T* experiments to constrain the diffusivity of Si in liquid iron in order to understand the kinetics of chemical transport and equilibration during core formation and processes occurring at CMBs.

Experimental diffusion couples comprised of highly polished cylindrical disks of 99.97% Fe and metallic Fe_6Si were contained in an MgO capsule and annealed within the *P-T* range 2023–2523 K and 7–25 GPa in a multi-anvil apparatus. To minimize the occurrence of diffusion prior to reaching the target temperature, a rapid heating rate of 20°C/sec was used to ramp the temperature to the required value. Experimental durations were very short (< 30 sec) and terminated by quenching at ~500°C/sec by switching off the electrical power. Recovered capsules were cut and polished parallel to the axis of the cylindrical sample and measured using EMPA 10 μm-step line scans. The data were fit to the error-function solution to the diffusion equation in accord with "zero-time" initial condition profiles.

Preliminary results indicate that silicon diffuses in liquid iron at least one order of magnitude slower that Fe self-diffusion [1], which could influence the viscosity of the outer core if silicon is present.

The bacterial C-isotope archive: modern anoxygenic phototrophs elucidate past processes in S and Fe-rich systems

N.R. POSTH[1], L.A. BRISTOW[1], K.S. HABICHT[1], R.P. COX AND D.E. CANFIELD[1]

[1]Nordic Center for Earth Evolution (NordCEE), Institute for Biology, University of Southern Denmark, Campusvej 55, 5230 Odense M, Denmark (*correspondence: nicolep@biology.sdu.dk)

Anoxygenic phototrophic bacteria oxidizing sulfide, thiosulfate, elemental sulfur or Fe(II) are considered to be among the earliest organisms on Earth. As sulfur and iron were abundant on early earth, Fe and S oxidation states and isotopic signatures in the rock record are routinely utilized as markers for the rise of oxygen. In another approach, studies of modern S and Fe-oxidizing anoxygenic phototrophs afford us the opportunity to investigate how these organisms may have influenced the geochemical evolution of our planet.

Sulfide-rich, meromictic, Lake Cadagno (Switzerland) is an ideal location to study purple and green sulfur anoxygenic phototrophic bacteria as analogues of ancient systems (*eg., Tonolla et al , 2003; Canfield et al , 2010)*. The stable chemocline allows for the development and maintenance of a geochemical gradient and S-cycling microbial community.

We present work carried out on the C-isotopic signatures imparted by S-metabolizing anoxygenic phototrophic bacteria both in pure culture and in the lake waters to understand how C-fixation pathways, water column cycling, sedimentation and diagenesis can influence the isotope record. Combining $^{13}C/^{12}C$ analysis of field and pure culture POM and DIC, FISH-SIMS and eco-physiological studies, we aim to elucidate the C-isotope signature of the microbial carbon lifecycle. Part of our focus is to clarify whether the isotopic biosignature is a combination of all bacterial community members or dominated by a single member. Future work will compare this S-rich system to Fe-rich analogues.

The uranium mineralization of Pen Ar Ran (Armorican Massif), France: An atypical "vein type" deposit

POUJOL, M.[1]*, BALLOUARD, C.[1], BOULVAIS, P.[1], CUNEY, M.[2], CATHELINEAU M.[2] AND GAPAIS, D.[1]

[1]UMR CNRS 6118, Géosciences Rennes, OSUR, Université Rennes 1, 35042 Rennes Cedex, France. (*Correspondence: marc.poujol@univ-rennes1.fr)
[2]UMR CNRS 7566 G2R, Université de Lorraine, 54506 Vandoeuvre-lès-Nancy, France

Twenty percent of the uranium produced in France was extracted in the Armorican Massif, in three different locations (Pontivy, Guérande et Mortagne) which belong to the "High Heat Production Belt", a 100 km wide NW-SE zone characterized by elevated contents in radioactive elements present in most of the geological formations [1], including 320 to 315 Ma old peraluminous granites [2].

In the Guérande uranium district, the Pen Ar Ran deposit is located in a deformed zone, at the contact between porphyroids and quartzitic black schists. This deformed zone corresponds to an E-W shear zone that affected both the metamorphic formations (porphyroids and black schists) and the intrusive Guérande leucogranite, during its emplacement. Mineralization is under the form of massive veins carrying pechblende and sulphide that are spatially associated with the leucogranite. However, this uranium deposit is different from the other “vein type” known in France because of the unusual nature of its uranium oxides (between pechblende and uraninite). Furthermore, the fluids responsible for this mineralization are hotter (350-400°C) than elsewhere.

The question of the source of the uranium is also complex. The uranium content of the metamorphic formations is rather low (around 3 ppm) but it is also low in the leucogranite (max. 9 ppm). It is however possible that the uranium was leached out of the granite by surface derived oxidizing fluids while the granite was still at depth [3]. Therefore, the leucogranite could represent the source of the uranium. In order to test this hypothetis, we performed a comprehensive petrological, geochemical, and geochronological study of the Guérande granite and compared these data to the available data from the porphyroid and the uranium mineralization.

Controls on redox-nutrient cycling in the Cretaceous greenhouse ocean: Insights from S isotope systematics

SIMON W. POULTON[1], SUSANN HENKEL[2], CHRISTIAN MÄRZ[3], HANNAH URQUHART[3], SASCHA FLÖGEL[4], SABINE KASTEN[5], JAAP S. SINNINGHE DAMSTÉ[6] AND THOMAS WAGNER[3]

[4]IFM-GEOMAR, Kiel, Germany
[5]Alfred Wegener Inst., Bremerhaven, Germany
[6]NIOZ, NL-1790 AB Den Burg, The Netherlands

Oceanic anoxic events (OAEs) were a frequent occurrence in the Cretaceous greenhouse ocean. Based on a variety of paleoredox indicators, euxinic water column conditions are commonly invoked for these OAEs. However, in a high resolution study of OAE3 deep sea sediments [1], revised paleoredox indicators suggest that euxinic conditions fluctuated with anoxic ferruginous conditions on orbital timescales. Building upon this, we here present new data for a continental shelf setting at Tarfaya, Morocco, that spans a period prior to, and during, the onset of OAE2. We again find strong evidence for orbital transitions from euxinic to ferruginous conditions. The presence of this distinct cyclicity during OAE2 and OAE3 in shallow and deep water settings, coupled with its occurrence on the anoxic shelf prior to the global onset of anoxia, suggests that these fluctuations were a fundamental feature of anoxia in the Cretaceous ocean.

The observed redox cyclicity has major implications for the cycling of phosphorus, and hence the maintenance and longevity of OAEs. However, despite this significance, controls on the observed redox cyclicity are essentially unknown. Here, we utilize S isotope measurements (pyrite S and carbonate-associated S) from the deep sea and shelf settings to model oceanic sulphate concentrations across the redox transitions. Perhaps surprisingly, we find no evidence to suggest that ferruginous conditions arose due to extensive drawdown of seawater sulphate (as pyrite-S and organic-S) under euxinic conditions. Instead, S isotope systematics in the deep sea imply increased sulphate concentrations during ferruginous intervals. Based on these observations and other major element data, we infer that the redox cyclicity instead relates to orbitally-paced fluctuations in continental hydrology and weathering, linking the redox state of the global ocean to climate-driven processes on land.

Introducing a comprehensive data reduction algorithm for high-precision U-Th geochronology with isotope dilution MC-ICP-MS

ALI POURMAND[1]*, FRANÇOIS L.H.TISSOT[2], MONICA ARIENZO[1], DAVID MCGEE[3] AND ARASH SHARIFI[1]

[1]*Neptune Isotope Lab., University of Miami - RSMAS, Miami, FL, USA, apourmand@rsmas.miami.edu

[2]Origins Lab., Department of Geophysical Sciences, University of Chicago, Chicago, IL 60637, USA

[3]Department of Earth, Atmospheric and Planetary Sciences, MIT, Cambridge, MA 02139

Multi collector inductively coupled plasma mass spectrometry (MC-ICP-MS) is being increasingly utilized for U-Th geochronology of carbonate deposits with comparable precision to thermal ionization mass spectrometry (TIMS) [1, 2]. While attention has been paid to propagation of uncertainties for U-Th-Pb analysis by TIMS and the isochron technique [3,4], a comprehensive data processing scheme is lacking for MC-ICP-MS. To address this need, we have developed an algorithm in Mathematica application to allow for step-by-step monitoring of the data reduction process. The program is flexible and affords the user easy control over input variables. Adjustments for background and spike isotope contributions, abundance sensitivity and instrumental mass bias are implemented through the code, followed by age calculation and propagation of uncertainties with Monte Carlo simulation. A rigorous standard bracketing procedure was adopted using Uranium (CRM-112A) and Th (IRMM-035) standard solutions, doped with IRMM-3636a $^{233}U/^{236}U$ "double-spike", to account for deviations of isotope ratios from certificate values and improve accuracy. Following a single U/TEVA extraction chromatography step to separate U from Th, ten replicate ages from a speleothem in Cathedral Cave (CC), Utah showed excellent agreement (R^2 = 0.999) with results previously measured at the University of Minnesota by single collection ICP-MS [5]. The external reproducibility of our analytical technique was evaluated by analyzing six aliquots of an in-house standard, prepared by homogenizing a piece of the CC speleothem, which returned a mean age of 21468±120 y (2SD). A limited amount of the standard powder is available upon request for interlaboratory calibration. We have successfully dated 36 samples from caves in the Bahamas, the Dominican Republic and Iran.

Carbon mineralization in artificial wetlands

I. M. POWER[1]*, J. MCCUTCHEON[2], A. L. HARRISON[1], G.M. DIPPLE[1] AND G. SOUTHAM[3]

[1]The University of British Columbia, Vancouver, BC V6T 1Z4, Canada (*correspondence: ipower@eos.ubc.ca; aharriso@eos.ubc.ca, gdipple@eos.ubc.ca)

[2]The University of Western Ontario, London, ON N6A 5B7, Canada (jmccutc3@uwo.ca)

[3]The University of Queensland, St Lucia, Brisbane QLD 4072, Australia (g.southam@uq.edu.au)

Carbon mineralization is a promising strategy for mitigating global climate change. We have extensively studied the microbiology, geochemistry, and mineralogy of alkaline wetlands found in hydromagnesite [$Mg_5(CO_3)_4(OH)_2{\cdot}4H_2O$] playas as a biogeochemical analogue for carbon mineralization [1]. These wetlands are fed by Mg-HCO_3 groundwaters and are unique habitats for carbonate precipitating microbes, including cyanobacteria and algae. Growth of these phototrophs within pond systems has also been proposed for producing biofuel [2]. Carbonate precipitation and biomass production could be facilitated using specially designed artificial wetlands that receive waters rich in dissolved cations (e.g., Mg^{2+} and Ca^{2+}). This offers a low energy strategy for sequestering carbon dioxide (CO_2) within carbonate minerals and biomass. Utilization of phototrophs is advantageous in that many species are halophilic and can be grown on non-arable land such as mine sites [3]. As a potential application, we consider mine tailings facilities that produce Mg-rich leachate waters. In microcosm experiments, a phototrophic consortium was able to induce carbonate precipitation from leachate waters, yet precipitation was limited by the availability of CO_2. A larger-scale (10 m long) flow-through wetland fed by Mg-HCO_3 waters demonstrated that a carbon sequestration rate of 120 t CO_2/ha per year could be achieved. Geochemical modeling using mine site water budgets also indicates that up to 17% of a mine's annual greenhouse gas emissions could be sequestered [4]. Coupling of carbonate precipitation and biomass production in artificial wetlands may represent an economically efficient alternative to other technologies currently under development for CO_2 sequestration.

Anomalous abundances of He and mobile metals in surface media over the deeply buried Millennium U deposit, Athabasca Basin, Canada

MICHAEL J. POWER[1]*, KEIKO HATTORI[1], DANIELE L. PINTI[2] AND ERIC G. POTTER[3]

[1]Department of Earth Sciences, University of Ottawa, Ottawa, Canada (correspondence: mpowe102@uottawa.ca)
[2] GEOTOP, Université du Québec à Montréal, Montréal, Canada
[3] Geological Survey of Canada, Ottawa, Canada

We examined soil and noble gas geochemistry over the Millennium uranium deposit, Athabasca Basin, SK, Canada. It has indicated resources of 68.2 million lbs U_3O_8 at ~750 m depth, along a major fault in granites & metamorphosed pelites of Archean to Paleoproterozoic age below the Athabasca sandstones.

110 soil samples along two transects 503 and 333 m long over the deposit yielded anomalous values in U (≤0.6 ppm), Pb (≤35 ppm) and Cu (≤15 ppm) in aqua regia digestion of humus, when compared to the $\mu \pm 2\sigma_x$ for metal values. Anomalous values were also detected for U (≤102 ppb) Pb (≤2100 ppb), and Cu (≤220 ppb) in B-horizon soils leached by ammonium acetate compared to the $\mu \pm 2\sigma_x$ of metal values. Most anomalies were directly above the ore zones and surface traces of major faults, including the ore-hosting Marker fault. Gas samples were collected in monitoring wells and drill holes by submerging diffusion samplers at 10 to 42 m below the surface for 3 days. The ^{4}He, ^{22}Ne, ^{36}Ar, ^{40}Ar, ^{84}Kr and ^{132}Xe were measured by quadrupole mass spectrometry at GEOTOP. Analytical uncertainties range from 1.5 to 4.6% of the measured amount. Measured ^{4}He concentrations in water ranges from 6.89 x 10^{-8} to 4.23 x 10^{-5} ccSTP/g. The lower amount is identical to that expected by equilibration with the atmosphere (Air Satured Water value or ASW). The higher amount is clearly related to radiogenic ^{4}He produced by the U ore and released in the water. Indeed, three samples yielded anomalous $^{4}He/^{36}Ar$ ratios, 715, 239 and 108 times the ASW value, clearly indicating the addition of radiogenic ^{4}He. Ratios of $^{4}He/^{22}Ne$ (790, 340 and 130 times ASW value), $^{4}He/^{84}Kr$ (690, 240 and 110 times ASW), and $^{4}He/^{132}Xe$ (580, 210 and 95 ASW) were also observed, confirming the results.

Broad geochemical anomalies in soil and gas at the property show that fault-controlled redistribution of elements and gases possibly exists over the deposit. Our results suggest upward migration of metals and He to surface through these geological features – detectable by geochemical exploration methods for U using two different surface media.

Isotope geochemistry of Wayang Windu geothermal field, Indonesia

R. PRASETIO*[1], B. WIEGAND[1], M. SAUTER[1] AND D. MALIK[2]

[1]GZG, Universität Göttingen, Goldschmidt Str. 3, 37075 Göttingen, Germany (* rasi_prasetio@yahoo.com)
[2]Star Energy, Ltd. Jl. Letjen S. Parman Kav. 62-63, 11410 Jakarta, Indonesia

Wayang Windu geothermal field is located in West Java, Indonesia, associated with Quaternary active volcanoes. The geothermal system is transitional between liquid and vapor dominated systems [1]. Naturally occurring isotopes, i.e. δD, $\delta^{18}O$ and $^{87}Sr/^{86}Sr$ were combined with gas compositions and chemical data of the fluids to characterize fluid-rock interaction and properties of the reservoir. Several samples were collected from thermal manifestations and deep wells.

Most of the thermal manifestations and deep well fluids are bicarbonate type and have neutral pH values, except for steam heated waters, which are acid sulphate type waters. Deep brine fluids are of mature chloride type. Gas-mineral (i.e. pyrite and iron oxides [2]) equilibria indicate that reservoir temperatures vary between 230-300°C. δD and $\delta^{18}O$ compositions suggested that although fluids from thermal manifestations and deep fluids are of meteoric origin, deep fluids may have recharged from a lower elevation than fluids of the thermal manifestations. Furthermore, deep fluids show a strong oxygen shift, indicating water-rock interaction, while $\alpha D_{l\text{-}v}$ and $\alpha^{18}O_{l\text{-}v}$ model calculations indicate steam separation (boiling) at ~200°C. $^{87}Sr/^{86}Sr$ ratio vary between 0.7046-0.7058 and are similar to $^{87}Sr/^{86}Sr$ ratio of Sunda arc calc-alkaline volcanic rocks [3].

Geochemical constrains and tectonic significance of Late Cretaceous mafic dykes from the Bhavani shear zone, South India

P.PRATHEESH* AND V. PRASANNAKUMAR

Department of Geology, University of Kerala, Trivandrum 695 581, India (*Correspondence: pratheeshponline@gmail.com)

South Indian Granulite Terrain (SIGT), a composite crustal unit, comprises multiply deformed litho-blocks dissected by crustal-scale shear zones with the history of multiple phases of reactivation. The Palaghat-Cauvery Shear System (PCSS), the prominent among these, is an Archaean crustal boundary with repeated reactivation and is believed to have an integral role in the modeling and reconstruction of Gondwana supercontinent. This terrain bears significant evidences of extensive magmatic activity in the form of dyke swarms, puncturing the granulites as well as the shear zone rocks. Mafic dyke swarms of varying composition and age are common in all the lithological units of the Palaghat-Cauvery Shear System (PCSS). The present study is an attempt to discuss the characteristic geochemical signatures and the tectonic background of the probably late Cretaceous mafic dykes which have important relations to the timing and tectonics of amalgamation of the Gondwana supercontinent. The mafic dykes, occurring at different parts of the Bhavani Shear Zone (BSZ), a constituent of the PCSS, are relatively fresh and have distinguishing structural relations and geochemistry. Geometrical analysis of joint patterns in these dykes suggest both predefined and self generated path for emplacement, the strain localised domains in the shear zone exerting a spatial control.

Geochemical studies indicate sub-alkaline tholeiitic basalt nature for these dykes with both high-Mg and high-Fe tholeiitic characters. Incompatible elements modeling suggests a depleted mantle source for these dykes and the average REE distribution in these dykes indicate considerable fractionation and possible crustal contamination as well as probable elemental mobility. Tectonic discriminations imply MORB characteristics as well as oceanic island affinity. Correlation of geochemical characteristics with other coeval units in the similar tectonic environments suggests an affinity to Marion Hotspot. In general comparison, these basalts are similar to the 45^0 E Indian Ocean ridge basalts and the basaltic rocks of eastern Madagascar volcanic province. The characteristic features of these dykes are discussed in terms of late Cretaceous Indian ocean tectonics and Gondwana reassembly.

Computational Study of Rutile and Quartz Interfaces with Aqueous Solutions

M. PŘEDOTA[1], O. KROUTIL[1,2], Z. CHVAL[2] AND S. PAŘEZ[3]

[1]Faculty of Science, University of South Bohemia, České Budějovice, Czech Republic (predota@prf.jcu.cz)
[2]Faculty of Health and Social Studies, University of South Bohemia, České Budějovice, Czech Republic
[3]Institute of Chemical Process Fundamentals, Academy of Sciences of the Czech Republic, Prague, Czech Republic

In the past, we have obtained numerous simulation and experimental results of the TiO_2/aqueous solution interface including structure of adsorbed water and ions [1], hydrogen bonding and profiles of distance-dependent viscosity and diffusivity [2]. Here we will present our results on prediction of zeta potential (ζ) from molecular dynamics simulations and determination of dielectric properties of the interface. Our results show that the molecular nature of water and specific interactions of ions with the surface are key phenomena giving rise to the observed behavior.

In contrast to our works on TiO_2 and SnO_2 interfaces, our modelling of quartz (101) interface has been initiated only recently [3]. We have developed a model of negatively charged quartz, necessary for modeling of quartz surfaces above its point of zero charge ($pH_{pzc} \approx 2$-4.5), by a modification of the ClayFF force field [4], keeping the simple form of interaction potentials and introducing modified *ab initio* derived charges for a limited number of surface atom species. We present results of interactions of quartz (101) surface with aqueous solutions of NaCl and small organic molecules representing basic building blocks of larger biomolecules and functional groups of organic matter. As model molecules, benzoic acid, phenol, and salicylic acid were chosen. We studied interactions of molecules with surface for a set of surface charge densities 0.00, -0.03, -0.06 and -0.12 C/m^2, approximately corresponding to pH values 4.5, 7.5, 9.5 and 11.

Os-isotopes constraints on the dynamics of orogenic mantle: the case of central Balkans

D. PRELEVIĆ[1] G. BRÜGMANN[1], M. BARTH[1], M. BOŽOVIĆ[1], V. CVETKOVIĆ[2] AND S F. FOLEY[1]

[1]Geocycles Research Centre, University of Mainz, Becherweg 21, 55099 Mainz, Germany

[2]Faculty of Mining and Geology, University of Belgrade, Djušina 7, 11000 Belgrade, Serbia

The origin and evolution of Phanerozoic SCLM during orogenesis is a puzzling issue because of its multi-episodic and time-integrated melting and enrichment history. This is especially so in the Alpine-Himalayan accretionary orogen, which formed at a diffuse and long lived convergent boundary between Eurasia and Gondwanaland. The accretion of thin continental slivers and numerous oceanic island arcs resulted in a complex collage of continental blocks intercalated with ophiolitic terrains. The net effect of this accretion is mingling of severely mismatched geological and geochemical compositions.

We aim to monitor lithospheric mantle development under the Balkan part of the Alpine-Himalayan belt. In our holistic approach we combine Os isotopic and HSE as well as whole rock and mineral compositions of a number of mantle xenoliths in Palaeocene alkaline basalts, Mesozoic ophiolites and Oligocene-Miocene lamproitic lavas sourced within the lithospheric mantle.

Both ophiolitic peridotites and lithospheric mantle of the Balkan sector of the Alpine-Himalayan belt demonstrate similarly high extents of the previous melt extraction. Further resemblance is seen in the Os isotopic variation observed in ophiolites and in the Serbian lithospheric mantle, implying fluid-induced enrichment of a depleted Proterozoic/Archaean precursor, whereby the enriched component had suprachondritic Os isotopic composition. The ultimate source of this component is attributed to the subducting oceanic slab. We tentatively propose a two-stage scenario connecting lithospheric mantle with ophiolites and lamproites in a geologically reasonable fashion: i) the first stage took place in a suprasubduction oceanic environment, and it is responsible for the fluid-related enrichment of depleted mantle; ii) the second-stage connects the lithospheric mantle and lamproites during the partial melting that generated lamproitic melts. This is in accordance with the recent model[1] proposing that the part of the lithospheric mantle under the Balkans has seen oceanic lithosphere development.

Effect of surface heterogenity and interfacial water on surface potential

T. PREOČANIN[1], D. NAMJESNIK[1], M. SAPUNAR[1], J. LÜTZENKIRCHEN[2] AND N. KALLAY[3]

[1]Faculty of Science, University of Zagreb, Horvatovac 102a, Zagreb, Croatia, tajana@chem.pmf.hr

[2]Institut für Nukleare Entsorgung , Karlsruher Institut für Technologie (KIT), Hermann-von-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen, Germany

At the metal oxide crystal plane, exposed to the electrolyte aqueous solution, one or more amphotehric surface groups could be present. Different surface groups could be regulary distributed according to crystal structure, but also on two or more distinct surface patches.

The stability of surface groups depends on their thermodynamic and kinetic properties. If more than one kind of surface group is present at the crystal plane the surface potential, as well as the other surface properties, would depend on surface concentrations of each surface sites, their thermodynamic equilibrium constants, and potential interactions between them. It is exptected that the most stable surface species predominates at the surface and determines the overal surface properties. Different surface areas at the same crystal plane are in direct electrical contact through the bulk of the crystal, and consequently they are affected by same surface potential if the solid is conductive. The resulting surface potential is influenced by equilibrium at all surface patches, and will be somewhere between two extreme values characterized individulal surface areas.

The effect of two different surface sites and surface transformations of hematite 001 surface [1] were measured by means of single crystal electrode [2]. The results are interpreted by surface complexation model using the general model of electrical interfacial layer.

The measured Ψ_0(pH) function is nonlinear with a broad zero-potential region around the point of zero potential. Electrokinetic measurements of the same crystal planes give the clear isoelectric points and higher values of the zeta potential with respect to surface potentials. This unexpected behavior could be explained by considering pH dependent charging of the interfacial water layer affecting electrokinetic behaviour but not the surface potential [3].

New Frontiers in Natural and Chemical Tracers monitoring for Reservoir management

HUGUES PREUD'HOMME[1]

[1]LCABIE – UMR5254 – IPREM, 2 avenue Angot 64053 PAU cedex 9, FRANCE

Tracing test campaign in oil or gas reservoir is one of the most powerfull techniques to obtain experimental data for a better description and understanding of the reservoir, interwell connectivity, multilevel/allocation approach or to design a future Enhanced Oil Recovery. It's also a usefull tool to modelize the water flow in simulation models of porous media/rocks, laboratory core test or just to estimate the residual oil saturation. After decades of used of radionucleides, this time is over, new frontiers in analytical sciences are benefit to direct multi-monitoring of ultra-trace element (natural tracers) or ultra trace of chemical/geothermal such as halogenated or fluorescent tracers. Simple (no sample preparation), sensitive (ppt or ng.L^{-1} level), rapid (less than 6') and robust (direct analysis even in brine or high salinity reservoir water (150g.L^{-1}).

We will discussed here of the analytical development story and we highlight with figures of merit obtained along reservoir monitoring. We will finished with a few perspectives offered by the techniques such as well integrity and geological storage monitoring.

Simulation of magma ascent prior to the high risk caldera forming eruptions of Campi Flegrei

O. PREUSS[1] AND M. NOWAK[1]

[1]University of Tuebingen, Department of Geosciences, Wilhelmstr. 56, 72074 Tuebingen, Germany

The dynamic magmatic processes prior to the 39 ka Campanian Ignimbrite (CI) eruptions at Campi Flegrei (CF), occurring during magma ascent, cannot be observed directly in nature. Therefore, experimental simulations of CI magma ascent are necessary and will give detailed insight to the mechanisms of CF super eruptions.

A pressure decrease during magma ascent accompanied with fluid oversaturation in the melt initiates bubble nucleation, growth, coalescence and segregation, and possible partial crystallization, which lead to a substantial density decrease and a change in viscosity. These processes may act as driving forces for increased ascent rates and may lead to catastrophic eruption styles.

Discrepancies of previous studies demonstrate that the *P-T-t* conditions and volatile contents (H_2O, CO_2, Cl) of the primitive melt prior to the eruption, generating the CF volcanic products are not well constrained. This study is focused on the conduction of continuous decompression experiments [1] using a trachytic CI composition [2] to gain insight into the dynamic degassing processes. First isothermal decompression experiments, above the liquidus at 1050 °C, are performed using a starting pressure of 200 MPa and H_2O content of 5 wt% and a continuous decompression to 75 and 50 MPa with different decompression rates. Additionally, two different types of sample material (glass cylinders / glass powder) are used.

Changes in decompression rate and type of starting material lead to significantly different degassing behavior of the melt. Fast decompression rates lead to massive volatile oversaturation, thus bubble nucleation is the predominant mechanism. In contrast, bubble growth is the prefered mechanism at slow decompression rates to reequilibrate the system. In ongoing experiments, additional volatiles (CO_2, Cl) will be added to simulate conditions closer to the CF volcanic system. To investigate heterogeneous bubble nucleation caused by decompression induced crystallization processes, experiments will be performed at lower temperatures below the liquidus.

Crystallization temperatures of carbonate phases at Kennecott, Alaska based on clumped isotope thermometry

JASON B. PRICE* AND JOHN M. EILER

Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA 91125, USA
*jprice@caltech.edu

We measured growth temperatures of eight carbonate phases from the Bonanza Cu-(Ag) mine, Kennecott, Alaska, using the clumped isotope paleothermometer. A comparison of these data with independent geologic constraints, including phase equilibria of hydrothermal silicates and sulfides, suggests measured temperatures reflect carbonate growth conditions (Fig. 1). This method provides a means to document the low-temperature histories of ore bodies and to clarify ambiguous paragenetic positions of unmineralized carbonate phases. Clumped isotope measurements are accompanied by $\delta^{18}O$ measurements, which together with measured temperatures, are used to calculate $\delta^{18}O_{water}$ values for the mineralizing fluids; this helps to constrain the fluid source(s) and genetic model for the Kennecott deposits.

Calcite phases that predate Cu deposition grew at low temperatures (43-71°C); carbonate phases associated with copper deposition are much warmer (89-157°C); postmineral calcite phases are again cool (38-59°C). Limestone wallrock adjacent to the orebodies displays the largest temperature range of any subset (79-164°C) and may reflect burial diagenesis, metamorphism, and/or metasomatism. Premineral baroque dolomite, including zebra dolomite, grew at 102-142°C. Calcite veins containing Cu-sulfides grew at 89-157°C. Synmineral dedolomitization formed in the range 98-109°C. Only one calcite sample crystallized within the stability field of djurleite (<93°C), a volumetrically important component of the ore. Calculated compositions for $\delta^{18}O_{water}$ support a fluid mixing model to form the Cu deposits, whereby a 0‰ fluid carrying sulfide mixed with a metamorphogenic, Cu-bearing fluid of 5-8‰ derived from the Nikolai Greenstone.

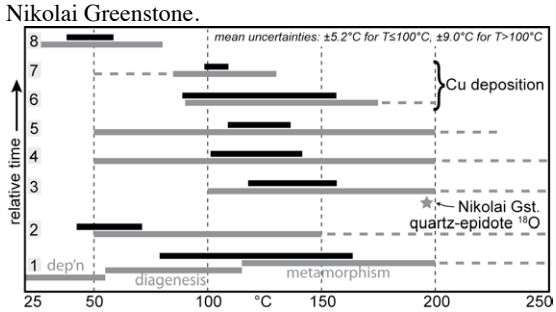

Fig. 1: Independently constrained temperature ranges (grey) and measured temperature ranges from clumped isotope paleothermometry (black) for carbonate phases at Kennecott, Alaska. 1) limestone wallrock, 2) premineral cal. 3) cal. in epidote-quartz veins in Nikolai Greenstone, 4) hydrothermal baroque dol., 5) cal. infilling dol. breccia, 6) Cu-bearing cal. veins, 7) dedolomite selvages, 8) postmineral cal.

Microbial diversity in an arsenic-rich shallow-sea hydrothermal system undergoing phase separation

ROY E. PRICE[1,*], RYAN LESNIEWSKI[2], AND JAN P. AMEND[1,2]

[1]Dept. of Earth Sciences, University of Southern California, Los Angeles, USA
[2]Dept. of Biological Sciences, University of Southern California, Los Angeles, USA
*Corresponding author: royprice@usc.edu

Phase separation is a ubiquitous subseafloor process in hydrothermal vent systems, yet investigations of how this process affects microbial ecology are rare. We evaluated prokaryotic diversity in arsenic-rich shallow-sea vents off Milos Island (Greece) by comparative analysis of 16S rRNA clone sequences from two vent sites with similar pH and temperature but marked differences in salinity. Clone sequences were also obtained for arsenic functional genes (AFGs) involved in arsenite oxidation (*aioA*-like). Bacteria in the surface sediments (0 to 1.5 cm) at the high salinity site consisted of mainly *Epsilonproteobacteria* (*Arcobacter sp.*), which transitioned to almost exclusively Firmicutes (*Bacillus sp.*) at ~10 cm depth. On the other hand, the low salinity site consisted of Bacteroidetes (Flavobacteria) in the surface and predominantly *Epsilonproteobacteria* (*Arcobacter sp.*) at ~10 cm depth. Archaea in the high salinity surface sediments were dominated by the orders Archaeoglobales and Thermococcales, transitioning to Thermoproteales and Desulfurococcales (*Staphylothermus sp.*) in the deeper sediments. In contrast, the low salinity site was dominated by Thermoplasmatales in the surface and Thermoproteales at depth. The abundance of free and dissolved gases, and other redox couples, were similar at the two sites, suggesting that salinity and/or arsenic concentrations may select for microbial communities that can tolerate these parameters. Many of the archaeal 16S rRNA sequences contained inserts, possibly introns, including members of the Euryarchaeota, something not reported previously. Clones containing *aioA*-like genes affiliated with either *Alpha-* or *Betaproteobacteria*, although most were only distantly related to published representatives. Most clones (93 out of 105) originated from the deeper layer of the low salinity, higher arsenic site, which is also the only sample with overlap in AFG and 16S rRNA gene data, suggesting arsenotrophy as an important metabolism.

CO_2-olivine interaction in porous media - an experimental study

J. PŘIKRYL[1], A. STEFÁNSSON[1] AND B. SIGFÚSSON[2]

[1]Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavík, Iceland (jap5@hi.is)
[2]Reykjavík Energy, Baejarhalsi 1, 110 Reykajvik, Iceland

Increased anthropogenic CO_2 emissions have caused an imbalance in the CO_2 cycle and resulted in climate change. One potential way to reduce CO_2 is to convert it to carbonate minerals. Mafic and ultramafic rocks provide good candidates for such carbonate sequestration due to high availability of divalent cations like Mg^{2+}, Ca^{2+} and Fe^{2+}. Such permanent CO_2 storage in basalts has recently received considerable attention.

In order to study the mineralization reactions upon continues injection of aqueous CO_2 solutions into porous media containing Mg-Fe rich rocks, reaction transport experiments and simulations were conducted. The system studied involved reacting olivine (93 % forsterite) with aqueous solutions contain CO_2 and NaCl at acid to alkaline pH values. The experiments were conducted using a 1-D flow-through reactor at 70°C. Using the solution chemistry, the reaction progress, carbonate mineralization rate and porosity changes were studied as a function of time. The experimental results were supported by 1-D reactive transport simulations conducted with the aid of the PHREEQC program. According to the experimental results and the reactive transport simulations olivine progressively dissolves forming secondary minerals and solutes that are partially transported out of the column (system). The exact reaction path was found to depend on solution composition and pH and reaction progress (time). The mass movement of the system at a particular steady state as well as porosity changes may be divided into three stages. Stage I is characterized by initial olivine leaching, stage II is characterized by mineralization formation and decrease in porosity and stage III is characterized by remobilization of the previously formed secondary minerals and eventual increase in porosity. The results of this study have important implications on the continuous CO_2 injection and potential carbonate sequestration into porous rocks.

Redox state during core formation on planetesimals

E. A. PRINGLE[1]*, P. S. SAVAGE[1], J. BADRO[2], J.-A. BARRAT[3] AND F. MOYNIER[1]

[1]Washington Univ., St. Louis, MO 63130, USA (*correspondence: eapringle@wustl.edu, savage@levee.wustl.edu, moynier@levee.wustl.edu)
[2]IPGP, Paris, France (badro@ipgp.fr)
[3]Université de Brest, I.U.E.M., Plouzané, France (barrat@univ-brest.fr)

Formation of the terrestrial planets likely involved accretion of planetesimals large enough to have previously differentiated metallic cores. However, the physicochemical conditions prevailing during planetesimal differentation remain poorly understood. The asteroid 4-Vesta is the smallest extant planetary body known to have differentiated a metallic core. HED (Howardite, Eucrite, Diogenite) meteorites, which are thought to sample 4-Vesta, provide us with an opportunity to study core formation in planetary embryos.

Partitioning of elements between the core and mantle of a planet fractionates their isotopes according to formation conditions. One such element, silicon, shows large isotopic fractionation between metal and silicate, and its partitioning into a metallic core is only possible under very distinctive conditions of pressure, oxygen fugacity and temperature. Therefore, the silicon isotope system is a powerful tracer with which to study core formation in planetary bodies.

Here we show through high-precision measurement of Si stable isotopes that HED meteorites are significantly enriched in the heavier isotopes compared to chondrites ($\Delta^{30}Si = 0.1 \pm 0.06$ ‰). This is consistent with the core of 4-Vesta containing at least 1 wt.% of Si, which in turn suggests that 4-Vesta's differentiation occurred under more reducing conditions ($\Delta IW \sim -4$) than those previously suggested from analysis of the distribution of moderately siderophile elements in HEDs.

Is oxygen-17 of atmospheric nitrate a tracer of industrial pollution?

B. PROEMSE[1], B. MAYER[1], M. FENN[2] AND C. ROSS[2]

[1]University of Calgary, 2500 University Drive NW, Calgary, Alberta, Canada, T2N 1N4.
[2]USDA Forest Service, Pacific Southwest Research Station, 4955 Canyon Crest Drive, CA 92507, USA
*Correspondence: bcpromse@ucalgary.ca

The oxygen isotopic composition of atmospheric nitrate ($\Delta^{17}O$-NO_3, $\delta^{18}O$-NO_3) provides useful information about the oxidation pathways of nitrogen compounds in the atmosphere resulting in the formation of nitrate. Oxygen-17 contents (expressed as $\Delta^{17}O=\delta^{17}O-0.52*\delta^{18}O$) may be anomaleously enriched in atmospheric nitrate as a result of the interaction with ozone (O_3), whereas other oxidants (OH, HO_2, NO_3) contribute insignificant amounts of $\Delta^{17}O$. We postulate that in addition to the ability of $\Delta^{17}O$ as a proxy of oxidation pathways in the atmosphere, $\Delta^{17}O$ may also constitute a potential tracer for industrially derived atmospheric nitrate in close proximity of some anthropogenic emission sources.

The Athabasca Oil Sands Region (AOSR) in northeastern Alberta, Canada, holds one of the World's largest heavy oil reserves. The processing and upgrading of oil sands has raised concerns about potential environmental impacts of industrial nitrogen (N) emissions on neighbouring aquatic and terrestrial ecoystems. Stable isotope techniques may help to assess such impact in the case where industrial emissions are isotopically distinct from background values. Atmospheric nitrate in bulk deposition and throughfall was collected using ion exchange resins over ~6 months time periods from summer 2007 to summer 2011. Nitrate deposition rates, nitrogen and the triple oxygen isotopic compositions ($\delta^{15}N$, $\delta^{18}O$, and $\Delta^{17}O$) of atmospheric nitrate in bulk deposition and throughfall were determined. Nitrate emitted in $PM_{2.5}$ (particles with a diameter <2.5 μm) from one of the major emission stacks was also analyzed for $\delta^{15}N$, $\delta^{18}O$, and $\Delta^{17}O$ and was not anomalously enriched in oxygen-17 ($\Delta^{17}O$-NO_3 ≈ 0‰), providing a potential tracer of industrially derived nitrate [1]. $\delta^{18}O$ and $\Delta^{17}O$ values of atmospheric nitrate deposition showed distinct trends towards lower values with increasing nitrate deposition rates in all sampling periods. This relationship between the oxygen isotopic composition and atmospheric nitrate deposition rates allowed for the estimation of industrial contributions to atmospheric nitrate deposition in the AOSR [2].

[1] Proemse, Mayer, Chow & Watson (2012), Atm. Env. 60, 555-563. [2] Proemse & Mayer (2012), in: K. Percy (Ed) Developments in Environmental Science, 11, 243-266.

Gas-solutions interaction in hydrothermal ore forming processes

V.YU. PROKOFIEV[1], S.L.SELECTOR[2] AND N.N. AKINFIEV[1]

[1]IGEM RAS, per. Staromonetny 35, Moscow, 119017 Russia, vpr@igem.ru
[2]IPCHE RAS Leninsky pr., 31-4, 119071, Moscow, Russia, sofs@list.ru

The heterogenic fluid participates in the ore forming process at many hydrothermal deposits. The origin of such a fluid is usually explained by the phase separation of a homogeneous gas-saturated water-salt fluid. An alternative model of ore-forming process in which a heterogeneous fluid occurs by mixing a water-salt solution and the gas fluid is discussed in this report.

A thermodynamic modeling of the adiabatic process of interaction of water-salt fluid (1M NaCl) with gaseous CO_2 at 350o C, 1 kb was carried out. According to this model the process of increasing of carbon dioxide amount in the system accompanied by the gas phase appearance at CO_2 concentration of about 3m. The gas volume increases with the addition of CO_2 to the system up to 8 m. Meanwhile the water proceeds into the gas phase, the salt concentrations and ionic strength of the solution increase. Synchronously gold solubility decreases by about 20%.

Thermodynamic modeling characterizes only one aspect of the process of aqueous fluid with the gas mixing, but this process is much more complex.

The process of gas passing through the liquid increases the interphase, which leads to a number of inter-fluids border effects. Such process is called "barbotage", it is easy-to-realize technically and it is used in series of technological processes.

Barbotage is broadly used in technologies for heating and mixing of aggressive liquids, as well as for solutions scavenging. Barbotage generates the gas emulsions and leads to formation of large interfacial area at liquid - gas interphase boundary. It promotes the intensifications of heat- and mass-exchange processes and deeper gas-liquid chemical interaction. Spontaneous formation of scores of small bubbles can cause a cavitation. Barbotage facilitates also the flotation process.

The signs of the barbotage participation in some natural hydrothermal ore-forming systems are demonstrated in the report. The gas-liquid interaction must be considered upon the study of hidrothermal ore deposits.

This work was carried out within the framework of the Russian Foundation for Basic Research (projects 12-05-01083-a).

The Ediacaran-Cambrian transition witnessed a major restructuring of the planetary biota, however the accompanying changes in major biogeochemical cycles, inlcuding that of O2, are less well constrained. We developed a novel approach of determining nitrate content in carbonates as a proxy for the availability of dissolved O2 and applied it to investigate changes in O2 and nitrogen cycles through this important transition in Earth history. Nitrogen (N) may be present in the environment in six different oxidation states, from N3- in ammonium to N5+ in nitrate, with the oxidation state dictated by the ambient environmental redox state: under anoxic conditions, fixed inorganic N is likely to be stable in form of ammonium, while in the presence of dissolved O2, the main form is nitrate. Therefore, the abundance of nitrate should reflect availibility of dissolved O2, but geologic records of oceanic nitrate have not been previously explored.

We surveyed the concentrations of CAN in carbonates from the ~2.3 Ga year old Duitschland Formation (South Africa), the ~1.4 Ga year old Belt Supergroup (Montana, USA), a series of deep and shallow water limestones spanning ~ 800 to 540 Ma years from Death Valley (California, USA) and north-western Mexico, as well as a set of early to late Phanerozoic carbonates. We found a distinct step function increase in the levels of measured CAN between 600 and 540 Ma. We argue that a sharp nitrate increase, recorded in these carbonates may reflect a rapid increase in atmospheric O2 through this time period, which would have led to rapid transformation of fixed N to oxidized forms (from ammonium to nitrate). In the Duitschland Formation, which has been suggested to contain a geochemical record of the first transient O2 "whiffs" in Earth history, we found evidence for a transient presence of CAN between 2.2 and 2.4 Ga. However, a significant degree of dolomitization of many samples calls for further investigation of CAN dynamics with respect to this common diagenetic process.

Impact of basalt weathering and plant recycling on Mg transport from the soil to the river under permafrost environment: A stable Mg isotope study in Central Siberia.

PROKUSHKIN A.S.[1], MAVROMATIS V.[2], POKROVSKY O.S.[2] AND VIERS J.[2]

[1]V.N. Sukachev Institute of Forest, SB RAS, Akademgorodok, Krasnoyarsk, Russia, prokushkin@ksc.krasn.ru (*)
[2]GET, CNRS, UMR 5563, Toulouse, France, mavromat@get.obs-mip.fr, oleg@get.obs-mip.fr, viers@get.obs-mip.fr

To unravel the different sources of Mg generated by basalt weathering in Central Siberia under permafrost conditions and larch deciduous forest, we measured the Mg isotopic composition of large rivers (Nizhnaya Tunguska and Kochechum, tributary of Enisey) and a small stream, snow, surface flow, interstitial soil solutions, plant biomass, litter and soils. During winter baseflow, the dissolved Mg isotope composition of large rivers is significantly lighter compared to the source basaltic rocks and atmospheric deposition, suggesting a deep undergournd source such as sedimentary carbonate rocks. During spring flood and in the summer-fall season, δ^{26}Mg increases by 0.3-0.2 ‰ and approaches the Mg isotope comosition of ground vegetation (dwarf shrubs, mosses) and soil organic horizon. Overall riverine waters are 0.6-1.0 ‰ lighter than the unaltered bedrock and deep minerals soil horizon.

Despite low variability of Mg isotopic composition between *Larix gmelinii* organs (i.e. stem wood, roots, needles etc.), there is a 0.2-0.3 ‰ enrichment in δ^{26}Mg of larch needles in the course of growing season, from June to September. It likely demonstrates plant uptake of isotopically heavier Mg along with the progressive thawing of mineral soil (deepen soil active layer). Taken together, Mg isotope approach indicates the important contribution of vegetation (larch needles, mosses and dwarf shrubs) in riverine Mg isotope signature and help to reveal the contribution of isotopically light carbonates or sedimentary rocks in large rivers of Central Siberian Plateau.

Interaction of organic matter with different minerals in an artificial soil incubation experiment

GEERTJE JOHANNA PRONK[1,2], KATJA HEISTER[1] AND INGRID-KÖGEL-KNABNER[1,2]

[1]Lehrstuhl für Bodenkunde, Technische Universität München, 85350 Freising-Weihenstephan, Germany
[2]Institute for Advance Study, Technische Universität München, Lichtenbergstrasse 2a, 85748 Garching, Germany

The interaction between minerals, organic matter (OM) and microbes leads to the formation of complex biogeochemical interfaces in soil. It is challenging to characterize these interactions in natural soils, where environmental conditions are highly variable. Therefore, we performed an incubation experiment with so-called 'artificial soils' composed of mixtures of clean model materials, where the development of organic matter (OM) was followed in a simplified system. The artificial soils were composed of 8 different mixtures of quartz, illite, montmorillonite, ferrihydrite, boehmite and charcoal, manure as OM source, and a microbial inoculant extracted from a natural arable soil. They were incubated up to 18 months. Development of OM during incubation was determined from CO_2 respiration, C and N content, and particle size and density fractionation. The OM composition was determined by e.g. solid-state ^{13}C nuclear magnetic resonance (NMR) spectroscopy and acid hydrolysis.

The artificial soil mixtures developed quickly into aggregated materials, and nitrogen-rich, proteinaceous material, originating from microbial debris, acumulated in the <20 μm size fraction. Furthermore, density fractionation showed an increasing association of OM with minerals. There was no effect of mineral composition on the respiration rate. However, the presence of a clay mineral led to a higher content of non-hydrolysable N, indicating that interactions took place between N-containing OM and clay mineral surfaces. Contrary to expectations, the presence of ferrhydrite had no effect on OM. We conclude that OM preferentially interacted with the clay minerals in this system.

Overall, the artificial soil incubation experiment provided a system, where the turnover of the original manure substrate could be studied in a simplified system. Due to the well-defined composition of the artificial soils, this experiment gives us new insight into the dynamics of interactions between specific minerals and charcoal, OM and a microbial community during the turnover of organic matter in a soil-like system.

Carbon isotope analysis in conglomerates of the Cambro-Ordovician Cow Head Group, western Newfoundland as a proxy for the origin of carbonate cements

SARA B. PRUSS[1], DAVID A. FIKE[2] AND KATIE A. CASTAGNO[3]

[1]Department of Geosciences, Smith College, Northampton, MA USA, spruss@smith.edu
[2]Department of Earth and Planetary Sciences, Washington University, St. Louis, MO USA 63130, dfike@levee.wustl.edu
[3]Department of Marine Affairs, University of Rhode Island, Kingston, RI USA 02881, katie@castagno.com

The radiation of complex skeletal organisms in the Upper Cambrian to Middle Ordovician interval is preserved in the Cow Head Group at Cow Head, western Newfoundland, in approximately 255 m of deep-water slope deposits. Conglomerate beds are a ubiquitous feature of the Cow Head Group and span Upper Cambrian through Middle Ordovician stratigraphy. To determine the source of carbonate cements and the relationship between clast and matrix in individual samples, conglomeratic samples were microdrilled in several places for carbon isotope analysis. Generally, clasts showed the most consistent isotopic variability within a single sample, but individual matrix values could vary by as much as 3.5. The large variability of carbon isotope values in individual samples, particularly in the matrix, suggests some role for local organic matter remineralization, perhaps in the presence of low oxygen which may enhance precipitation, and that these samples may not be recording DIC. Additionally, the low variability in some beds and the overlapping values of both clast and matrix carbonate indicates that clasts were occasionally sourced locally and that these values might best be approximating DIC. This study, along with complementary trace element analyses, provide important constraints on the possible sources of carbon in cements for allodapic conglomerate deposits that straddle this Cambro-Ordovician interval.

Oxygen fugacity vs. mineralogical control on transition metal (Fe, Cr, V) stable isotope compositions of Mariana forearc peridotites

J. PRYTULAK[1]*, P. BONNAND[23] AND I.J. PARKINSON[24]

[1]Department of Earth Science and Engineering, Imperial College London, UK. (*j.prytulak@imperial.ac.uk)
[2]Depart. Environ., Earth Ecosys., The Open University, UK
[3]Department of Earth Sciences, Oxford University, UK. pierre.bonnand@earth.ox.ac.uk
[4]School of Earth Sciences, Unversity of Bristol, UK. Ian.Parkinson@bristol.ac.uk

Controversy surrounds the oxygen fugacity (fO_2) of subduction zones. Emerging redox-sensitive stable isotope systems may provide an independent assessment if their isotopic fractionation can be linked to fO_2. However, other factors such as mineral coordination number can also influence stable isotope fractionation. Here we present the first investigation of combined Fe, Cr and V stable isotope compositions. We investigate peridotites from two forearc seamounts drilled on ODP Leg 125. The studied peridotites have been characterised for major and trace elements, modal mineralogy and fO_2 (ranging from FMQ -0.7 to +1.8) [1]. We find no correlation between Fe, Cr, or V isotopes and fO_2. Iron isotope compositions are generally heavier than the terrestrial mantle [e.g., 2], but show significant scatter. Chromium and V isotopes are positively correlated with V isotopes displaced to heavier values than comparably depleted peridotites [3]. Chromium isotope compositions are within the range published for mantle xenoliths [4]. However, Cr isotopes correlate with modal clinopyroxene in forearc harzburgites. These results suggest that Cr and V isotopes may be more robust to secondary processes than Fe isotopes and that mineralogy may have a greater influence on Cr and V stable isotope fractionation than oxygen fugacity.

Radiogenic heat potential of the Sardinian Variscan crust

A. PUCCINI[1]*, G. XHIXHA[2,3], S. CUCCURU[1], G. OGGIANO[1], M. KAÇELI XHIXHA[1], F. MANTOVANI[2], C. ROSSI ALVAREZ[4] AND L. CASINI[1]

[1]University of Sassari, Department of Science of Nature and Environmental Resources, Via Piandanna, 4 - 07100 Sassari, Italy (*correspondence: apuccini@uniss.it)
[2]University of Ferrara, Physics Department, Via Saragat, 1 - 44100 Ferrara, Italy. Istituto Nazionale di Fisica Nucleare (INFN), Ferrara Section, Via Saragat, 1 - 44100 Ferrara, Italy
[3]Agricultural University of Tirana, Faculty of Forestry Science, Kodër Kamëz - 1029 Tirana, Albania
[4]Istituto Nazionale di Fisica Nucleare (INFN), Padova Section, Via Marzolo, 8 - 35131 Padova, Italy

The ^{40}K, $^{238,235}U$ and ^{232}Th composition of the Variscan crust is derived from *in-situ* radiological characterization using a portable gamma-ray spectrometer [1]. Details about the analytical procedure and statistical processing of spectrometric data is given in [2]. A total of 400 measurements were performed in Sardinia, because of excellent exposure and detailed geologic information on the architecture of the Corsica-Sardinia Batholith and its country rocks [3].

The results of gamma-ray spectrometry measurements indicate that most granitoids have potential heat production rate between 0.49 and 6.92 μW m^{-3}. Both migmatites and low-grade metasediments are characterized by lower values in the range 1.3 – 3.1 μW m^{-3}. The U-Th-K abundances in the Sardinian Variscan crust are 1283^{+340}_{-463} Bq kg^{-1}, 47^{+18}_{-29} Bq kg^{-1} and 67^{+21}_{-31} Bq kg^{-1} respectively for ^{40}K, ^{238}U and ^{232}Th. These values are slightly higher than those typical for the upper continental crust [4]. However, the average heat production rate of the Variscan crust of northern Sardinia is about half of that inferred in the Bohemian Massif [5]. Therefore, we argue that selective enrichment of heat-producing elements in the crust cannot account for early Permian HT metamorphism in this part of the Variscan chain.

Isotopic and Elemental Evidence of Magma Ocean Processes Recorded in Early Archean Komatiites

IGOR S. PUCHTEL[1], RICHARD J. WALKER[1], MATHIEU TOUBOUL[1] AND JANNE BLICHERT-TOFT[2]

[1]Dept. of Geology, Univ. of Maryland, College Park, MD 20742, USA (correspondence: ipuchtel@umd.edu)
[2]Ecole Normale Supérieure de Lyon, 69007 Lyon, France

Isotopic and elemental data for well-characterized Archean komatiite systems from around the globe provide critical new insights into early-Earth processes. Combined new ^{142,143}Nd, ^{182}W, ^{176}Hf, and ^{186,187}Os isotopic data for early Archean komatiite systems are consistent with formation, followed by long-term isolation, of deep-seated mantle domains with fractionated time-integrated Sm/Nd, Hf/W, Lu/Hf, and Pt/Os ratios at ca. 4400 Ma. These domains were likely generated as a result of crystallization of a primordial magma ocean, with Mg-perovskite, Ca-perovskite, and Fe-Pt alloy acting as the fractionating phases [1]. The inferred mantle domains were largely mixed away by 2.7 Ga on the scale of mantle reservoirs sampled by late Archean komatiite lavas emplaced worldwide, as evidenced by uniform time-integrated Sm/Nd, Lu/Hf, Re/Os, and Pt/Os ratios in late Archean komatiite systems. The total HSE abundances present in the sources of early Archean komatiite systems, corrected for the inferred Pt fractionation during crystallization of the terrestrial magma ocean, are 70-75% of those in estimates of the modern PM, and are within the range of the total HSE abundances present in the sources of late Archean komatiite systems, indicating little change in HSE abundances in the Archean mantle between 3.5 and 2.7 Ga.

Higher Pt abundances in late Archean komatiites compared to their early Archean counterparts have been taken as evidence for sluggish, downward mixing of late accreted material into the mantle [2]. Our ^{142,143}Nd, ^{182}W, ^{176}Hf, and ^{186,187}Os isotopic and HSE abundance data for early Archean komatiite systems are inconsistent with such a scenario; instead, our data require that late accretion of HSE to Earth was largely complete by the time the terrestrial magma ocean had crystallized. Rather than downward mixing of an HSE-rich late veneer, the Pt concentration variations observed in Archean komatiites [2] may reflect sluggish mixing of diverse post-magma ocean domains characterized by variably fractionated HSE abundances.

Chemical reactions of hydrogen in depleted gas reservoirs – a major research topic of the H_2STORE project

D. PUDLO[1], S. HENKEL[1], R. GAUPP[1] AND THE H_2STORE TEAM[2]

[1]Friedrich-Schiller-University Jena, Institute of Geosciences, Burgweg 11, D-07749 Jena, Germany (*corresdondence: dieter.pudlo@uni-jena.de)
[2]German Research Centre for Geosciences, Potsdam (GFZ) & Clausthal University of Technology & Centre National de la Recherche Scientifique, Université de Lorraine

The collaborative project H_2STORE (= Hydrogen to Store) investigates the feasibilty of hydrogen underground storage in porous sandstones. Thereby a special emphasis is given to depleted gas reservoirs and gas storage sites, which commonly are comprised of reservoir sandstone layers and sealing mudstone cap rocks.

The most fundamental study on interaction of hydrogen with reservoir sandstones was given by Foh *et al* [1]. However there, only specific single mineral behaviour with hydrogen were regarded not taking into account the chance of complex interactions with further reservoir compounds. The complexity of potential reactions of hydrogen within depleted gas reservoirs arises from (a) reactions of hydrogen with the total mineral assemblage and thereby generated most variable reaction components, which might react quite different, than assumed monomineralic systems, (b) reactions with (commonly) high saline formation water, present in the pore space of the reservoir sandstones, (c) reactions with the residual remnants (e.g. crude oil, bitumen) of the HC-sites, and (d) reactions with microbiological organisms (e.g. bacteria) present at depths.

Thus, reactions in depleted gas/oil reservoirs and hydrogen are highly complex and asks for detailed investigations.

In the H_2STORE project several kinds of laboratory experiments at reservoir conditions and numerical simulation approaches are planned to investigate reactions given above. The relevance of these regards for hydrogen underground storage in porous media is that by these mineralogical, geo-, hydro-, and biochemical interactions the reservoir quality (e.g. porosity, permeability) can be strongly affected and an impact on the recharge rate for injected hydrogen and on the potential of green methane ("power-to-gas") production is most reasonable.

Carbonate biomineralization under aerobic and anaerobic conditions by a novel deep subsurface bacterial isolate

FERNANDO PUENTE-SÁNCHEZ[1], MÓNICA SÁNCHEZ-ROMÁN[1], NURIA RODRIGUEZ[12], DAVID FERNÁNDEZ-REMOLAR[1], VÍCTOR PARRO[1] AND RICARDO AMILS[12]

[1]Centro de Astrobiología (INTA-CSIC), 28850 Madrid, Spain. E-mail: puentesf@cab.inta-csic.es
[2]Centro de Biología Molecular Severo Ochoa (CSIC-UAM), 28049 Madrid, Spain.

The Iberian Pyritic Belt (IPB), one of the largest massive sulphide deposits on the world, is considered to be a Martian analogue.

A recent study [1] has shown the occurrence of micro-scale iron bearing carbonate minerals in sediments from the acidic Tinto River (IPB, Huelva, Spain) as well as in its subsurface. Even though microbial agents responsible for iron and carbonate precipitation in the river sediments are being identified, the specifics on subsurface biomineralization in Martian analogue environments are still poorly understood.

In order to further elucidate this and other open questions, the Iberian Pyritic Belt Subsurface Life (IPBSL) project is currently in progress. In that context, two boreholes (BH11 and BH10) of 339m and 613m depth were drilled into the IPB subsurface.

In this study we report the ability of the novel actinobacteria isolate NR2A-C7, obtained from a 297m deep sample from the IPBSL BH11, to mediate the precipitation of iron and carbonate under aerobic and anaerobic conditions. The minerals formed included crystalline iron phosphates and iron-calcium carbonates with similar composition to minerals identified in core samples from the same borehole.

Calcium carbonate precipitation by CO_2 uptake in alkaline solutions

B. PURGSTALLER[1], A. NIEDERMAYR[2] AND M. DIETZEL[1]

[1]Graz University of Technology, Institute of Applied Geosciences, Graz, Austria (purgstaller@student.TUGraz.at)
[2]Ruhr University Bochum, Institute of Geology, Mineralogy and Geophysics, Bochum, Germany

The uptake of CO_2 in Ca^{2+} ion bearing alkaline solutions causing subsequent precipitation of $CaCO_3$ is valid for many natural and man-made environments, e.g. formation of travertine and scaling [1, 2]. However, significant gaps of knowledge exist in respect to combined CO_2 uptake and $CaCO_3$ precipitation kinetics.

In the present study CO_2 uptake and $CaCO_3$ precipitation mechanisms and rates were experimentally studied by diffusion of CO_2 through a polyethylene membrane (0.2 mm) from an inner to an outer solution containing 10 mM of $CaCl_2$ (25°C). The pH was kept constant during two analogous sets of experiments at 8.3, 9.0, 10.0 11.0 or 11.5 by titration using 500 mM NaOH solution.

By exceeding a supersaturation threshold $CaCO_3$ is formed in the outer solution. (Micro)Raman and XRD pattern as well as SEM images clearly reveal the formation of calcite and vaterite at all pH values, whereas at pH ≥ 10.0 aragonite additionally occurs. NaOH titration curves and $[Ca^{2+}]$ reflect CO_2 uptake rates (∝ ACAR: aqueous CO_3^{2-} accumulation rate [3]) and precipitation rates of $CaCO_3$ (R). At elevated pH of the outer solution the ACAR is significantly higher and less time for nucleation of $CaCO_3$, t_{fc}, is required compared to lower pH conditions (e.g. pH 8.3 and 10.0 result in ACAR = 10 and 122 μM h^{-1} l^{-1} and t_{fc} = 7.8 and 1.6 h, respectively). At the given total experimental time of 20 h the amount of precipitated $CaCO_3$ was similar for all 10 experiments. This can be explained by the significantly higher R values subsequent to nucleation at low versus high pH (e.g. pH 8.3 and 10.0 with R = 645 and 178 μM h^{-1} l^{-1}, respectively) which correlates with a general decrease of $[>CaHCO_3^0]$ at the $CaCO_3$ surface [4]. Finally, the R values decrease to a nearly constant value of 93 ±10 μmol h^{-1} l^{-1} in all experiments.

In-situ pH and carbon dioxide solubility in NaCl fluids

G. PURSER*, C.A. ROCHELLE AND L. JONES[1]

[1]British Geological Survey, Environmental Science Centre, Keyworth, Nottingham, NG12 5GG, UK.

pH measurements give crucial insight to processes taking place during CO_2-water-rock reactions both in the laboratory and the field. The pH will govern the chemical species present and subsequent chemical reactions. Accurate determination of pH is important in the laboratory for a detailed understanding of the state of experiments and to test/validate predictive computer simulations. Degassing of samples on depressurisation changes solution pH, hindering accurate assessment of in-situ pH. We have used a commercially available high-pressure pH probe, coupled with high pressure fluid preservation methods to determine CO_2 solubility and pH at elevated temperatures and pressures relevant to geological storage conditions. Measurements were made at a range of salinities from deionised water to 2M NaCl, over temperatures of 40°C to 80°C, and pressures of 50 bar to 200 bar. Results show pH to decrease with increasing salinity, increasing pressure and decreasing temperature. For a subset of the conditions we have also measured pH associated with impurities of SO_2 and NO_2. Our experiments were constrained by the working pressure limits of the commercially available pH probes used, and we are developing different techniques to potentially extend the measuring capabilities up to 500bar.

^{81}Kr concentrations in deep fracture waters of the Withwatersrand Basin, South Africa

[7]Star Diamond, Beatrix & Masimong mines, South Africa

^{81}Kr has been proposed since many years an ideal tracer for dating subsurface fluids on timescales up to 2 million years. However, only recently the method became practicable for real case investigations due to significant analytical improvements [1]. In this study radioactive noble gas isotopes (^{81}Kr, ^{85}Kr and ^{39}Ar) were applied for the characterisation of fracture waters in the deep gold mines of the Witwatersrand Basin, South Africa [2]. Those waters catalyzed interest because of deep microbial communities that persists to depths of over 3 km [3]. The key objective of the present study is to further constrain the origin of the fluids, to determine the timing of deep subsurface life and to test the ^{81}Kr method in all kinds of environments. In contrast to expectations [4] we discovered that underground production of ^{81}Kr is a significant process in the rocks of the Withwatersrand and Ventersdorp Supergroups. All measured ^{81}Kr activities from fracture water were significantly higher than in atmospheric equilibrium. This is most likely related to elevated U/Th concentrations in the rock strata. Radiometric decay dating is complicated in such cases

High pressure garnet-bearing ultramafites and basites from the Main Uralian Fault: Comprehension of the Uralian mantle composition

E.V. PUSHKAREV

Institute of Geology and Geochemistry Ural Division of RAS, Pochtovy str. 7, Yekaterinburg, 620075, Russia (pushkarev@igg.uran.ru)

Three types of high pressure (HP) garnet-bearing rocks associated with the lherzolite massifs have bean distinguished in the Main Uralian Fault (MUF) zone (Southern Urals, Russia): 1) olivine-spinel-pyrope websterite (Mg# = 0.91-0.83), 2) garnet clinopyroxenites (Mg# = 0.85-0.72), 3) amphibole-pyroxene-ilmenite-garnet basites (Mg# = 0.91-0.65-0.45). The comparison with HP rocks from the orogenic lherzolite complexes gives some similarities only for garnet pyroxenites. But the most Uralian HP rocks have CaO/Al2O3 >1. It is much higher than those in primary mantle and in rocks from ophiolites (CaO/Al2O3 = 0.8–0.9). It indicates these rocks could not be the source or protolith of the Uralian HP rocks. It is supposed, that mantle source must be enriched in clinopyroxene and probably had a wehrlite composition. Perhaps, the most magnesium-rich high-pressure ultramafites in the MUF are relicts of such Paleozoic metasomatized mantle. Some of the garnet-bearing rocks could be the melts crystallized at the deep level close to the boundary between garnet and spinel facies. The study is supported by RFBR grants 13-05-00597, 13-05-96031, and scientific programs 2-C-5-1004 and 12-5-008-NDR

Coupled dissolution and precipitation at mineral – fluid interfaces

ANDREW PUTNIS[1], CHRISTINE VETA PUTNIS[1] AND ENCARNACIÓN RUIZ-AGUDO[2]

[1]Institut für Mineralogie, University of Münster, Germany. putnis@uni-muenster.de; putnisc@uni-muenster.de

[2]Department of Mineralogy and Petrology, University of Granada, Spain. encaruiz@ugr.es

When a mineral reacts with an aqueous solution with which it is out of equilibrium the first step of any reaction sequence is the dissolution of the mineral surface. The dissolution of even a few monolayers of the parent surface may result in a fluid boundary layer that is supersaturated with respect to a more stable solid phase. Nucleation of this product phase on the parent surface will depend on nucleation kinetics and will be enhanced if there is a degree of epitaxy (i.e. structure matching) between the two solids. The nucleation of the product on the surface of the dissolving parent enhances the dissolution rate of the parent that in turn increases the growth rate of the product. Such an autocatalytic reaction leads to a feedback mechanism between dissolution and precipitation such that their rates become equal.

Continuation of the transformation (replacement) reaction depends on keeping open fluid transport pathways to the reaction interface between the parent and product solids. In other words porosity must be generated in the product phase. The generation of porosity depends on two factors: the relative molar volumes of the two solid phases, and even more importantly, the relative solubilities of the two phases in the fluid i.e. their relative stabilities under the relevant physico-chemical conditions.

These simple ideas, encompassed in the term “interface-coupled dissolution-precipitation” have very wide application to mineral-fluid reactions in the earth as well as in industrial processes. Central to the whole concept is the importance of the mineral-fluid interface. The fluid at this interface can become supersaturated while the “bulk fluid” away from the interface plays no direct role in the reaction except as a fluid reservoir, i.e. it can remain undersaturated with respect to the reaction products.

Examples of mineral-fluid reactions will be given, starting from direct in situ observations by Atomic Force Microscopy and their relevance to mechanisms of incongruent dissolution and “leaching”, to hydrothermal experiments of mineral replacement mechanisms and their relevance to mineral-fluid interaction in rocks.

An example of CO_2 sequestration: Direct nano-scale observations of brucite [Mg(OH)2] dissolution

CHRISTINE V. PUTNIS[1], JÖRN-ERIK HÖVELMANN[2], ENCARNI RUIZ-AGUDO[3] AND HÅKON AUSTRHEIM[4]

[1]Institut für Mineralogie, University of Münster, Corrensstrasse 24, 48149 Münster, Germany
[2]Fachbereich Geowissenschaften, Universität Bremen, Postfach 330440, 28334 Bremen, Germany
[3]Department of Mineralogy and Petrology, University of Granada, Fuentenueva s/n 18071 Granada, Spain
[4]Department of Geosciences, University of Oslo, PO box 1047 Blindern, 0316 Oslo, Norway

The dissolution and carbonation of brucite on (001) cleavage surfaces was investigated in a series of *in situ* and *ex situ* Atomic Force Microscopy (AFM) experiments at varying pH (2- 12), temperature (23-40°C), aqueous $NaHCO_3$ concentration (10-5-1 M), and PCO_2 (0-1 atm).

Dissolution rates increased with decreasing pH and increasing $NaHCO_3$ concentration.

Simultaneously with dissolution of brucite, the growth of a Mg-carbonate phase (probably dypingite) was directly observed. In $NaHCO_3$ solutions (pH 7.2 - 9.3), precipitation of Mg-carbonates was limited. Enhanced precipitation was, however, observed in acidified $NaHCO_3$ solutions (pH 5, DIC $\approx$ 25.5 mM) and in solutions that were equilibrated under a CO_2 atmosphere (pH 4, DIC $\approx$ 25.2 mM). Nucleation predominantly occurred in areas of high dissolution, such as deep step edges, suggesting that the carbonation reaction is locally diffusion-transport controlled within a fluid-mineral boundary layer and is the result of interface-coupled dissolution-precipitation. More extensive particle growth was also observed after *ex situ* experiments lasting for several hours. This AFM study contributes to an improved understanding of the mechanism of aqueous brucite carbonation at low temperature and PCO_2 conditions and has implications for carbonation reactions in general.

Different styles of metasomatism in lithospheric mantle beneath Central Europe

JACEK PUZIEWICZ[1], MAGDALENA MATUSIAK-MAŁEK[1], THEODOROS NTAFLOS[2] AND MICHEL GRÉGOIRE[3]

[1]University of Wroclaw, Poland, jacek.puziewicz@ing.uni.wroc.pl
[2]University of Vienna, Austria
[3]University Tolouse III, France

The lithospheric mantle beneath Central Europe (SE Germany, SW Poland, W Czechia) was sampled by many eruption of alkaline lavas forming the Central European Volcanic Province. The volcanic activity was concentrated in the Eger (Ohře) Rift in the western part of Czechia and its surroundings. The investigated mantle xenoliths show that this lithospheric mantle is mostly harzburgitic and widely affected by cryptic metasomatism.

The study of Księginki xenolith suites (mantle peridotites and pyroxenites) shows that the lithospheric mantle beneath the Eger Rift was – at least in places – extensively chemically rejuvenated and thermally homogenised by alkaline lavas on their way to the surface. The xenoliths representing the mantle located outside the rift evidence significant variability. The "Fe-metasomatism", leading to slight decrease of Mg/(Mg+Fe) ratios in olivine, ortho- and clinopyroxene is common in lithospheric mantle located outside the Rift. This metasomatism is usually melt-induced and probably related to Cenozoic alkaline magmas moving pervasively through the harzburgites. The metasomatic events caused by CO_2-bearing silicate melt or by different agents were also deciphered in the region. A metasomatic high-Mg and very low Al clinopyroxene occurring in strongly depleted harzburgites was recently discovered in some localities. Its REE patterns as well as major element composition suggest that it might have originated from fluids generated in a supra-subduction (Alpine orogeny related?) setting. This demonstrates that the Central European lithospheric mantle recorded not only young metasomatic events related to Cenozoic rifting and alkaline melts.

Carbon isotopes and microelements distribution in fractions of brown coals

A.N. PYRYAEV*, V.A. PONOMARCHUK AND D.V. SEMENOVA

Institute of Geology and Mineralogy, 630090, ac. Koptuga st. 3., Novosibirsk (*correspondence: pyrayev@gmail.com)

Pyrolysis of coals [1, 2 etc] and element emission in a coal combustion process [3 etc] has been extensively investigated in many studies. Unfortunately, isotopic and microelement composition of extracted coal fractions and relationship of this parameters was not investigated carefully.

Pyrolysis (500°C) of three brown coals (1, 2 and 3) of varying R_{vt}^0 (0.77, 0.49 and 0.41 %, respectively) have been carried out in close isothermal vacuum (5 millibar) system. Two/tree fractions of pyrolized coals were collected: A - transparent high-volatile distillate; B - viscous oligomeric (probably) distillate; C - ash that remains after pyrolysis of coal. Yield of the distillates (25-70 wt. %) depends on coal type. Carbon isotope composition were determined using Thermo Finnigan 253 mass spectrometer and GasBanch. Difference in isotopic composition of fractions of one coal reaches 5.4 ‰.

Pyrolysis of coals lead to partial transfer of microelements from a coals to a distillates. Microelemental composition (25 elements) of initial coals and they fractions were determined using SR-XRD-analysis. Microelement content in distillates decreases from 1100 ppm (Ca) to 0.4 ppm (Y). Such microelements as V, Nb, Th and U was not transferred at all. Some microelements were transfered to a distillates almost totally (Pb, As, Zn).

The major conclusions: 1 - vacuum pyrolysis of brown coals lead to decompostion of coals in distillates and ash that differs in carbon isotopic compositions; 2 - distillates contains some microelements and may be considered as transfer agents of microelements in coals. This point is able to explain formation of polymetallic ores in the neighborhood of coal basin; 4 - it may be suggested occurene of correlation between isotopic and microelemental composition of coal fractions.

Polymetamorphic complexes of the Urals as indicators of formation of the Ural part of the East European Craton

A. M. PYSTIN

Institute of Geology KSC UB RAS, Syktyvkar, Russia,Syktyvkar State University pystin@geo.komisc.ru

Archean and Paleoproterozoic formations are known in the section of the Ural Lower Precambrian. They are high-temperature and complicatedly dislocated polymetamorphic complexes. There are enough strong reasons to interpret these complexes as tectonically displaced fragments of the crystalline basement, adjacent to the west of the platform.

The lowest age of metamorphic processes in granulite complexes (gneiss-granulite and granulite-metabasite) is limited by 2.8-2.7 Ga. Dynamic regimes of this metamorphic phase varied from moderate (gneiss-granulite complexes) to relatively high (above 10 kbar, granulite-metabasite complexes). Considering the various material composition of granulites of different pressure, we can assume that they were formed in Wilson's cycle.

Gneiss-migmatite complexes were formed under sequential manifestations of the granulite metamorphism which was replaced by the amphibolite facies metamorphism of moderate pressures and accompanying granitization. The lowest age limit of this metamorphic stage is ca. 2.1 Ga. The time of the amphibolite facies metamorphism in the gneiss-migmatite complexes is estimated as 1.95-1.75 Ma.

Eclogite-gneiss and eclogite-schist complexes, obviously, also belong to the Lower Proterozoic. Eclogite formation could take place synchronously with the granulite metamorphism, ca. 2.1 Ga in the lowest age.

Thus, it is reasonable to assume that in the Early Proterozoic metamorphic processes occurred under sharply different dynamic conditions, typical of subduction-collision systems.

The evolution of ultra-high-temperature and high-pressure metamorphic processes in the Ural polymetamorphic complexes generally correlates with the metamorphic development of the Early Precambrian complexes, adjacent to the west of the platform area. Thus, accretion-collision complexes formed 2.88 to 2.58 Ga in the Fennoscandian Shield (Fennoscandia) were revealed. The granulite and eclogite metamorphism correlates in time with uniting of Volga-Ural region and Sarmatia (ca. 2.1 Ga), and more recent amphibolite facies metamorphism and associated granitization - with merging of these two megablocks and Fennoscandia (1.8-1.7 Ga).

Zircon as an indikator of metamorphic conditions

YU. I. PYSTINA

Institute of Geology KSC UB RAS, Syktyvkar, Russia,Syktyvkar State University yuliya_pystina@mail.ru

For many years, studying the material composition of the Uralian polymetamorphic complexes with intent to reconstruct metamorphism and to determine the conditions of rock formation, we have been typing zircons [1,2]

We conducted a comparative study of irregularly-shaped zircons (the third morphotype) from two polymetamorphic complexes: the Parikvasshor and Selyankin in the Polar and Southern Urals, accordingly.

In the Parikvasshor complex zircon is represented by colorless or pale grains. Its content in zircon fraction is 55-65%.Optical heterogeneity of zircons is confirmed by microprobe studies. The central part of crystals is enriched in Hf and Fe, and the edge in Th and U; Th/U and Zr/Hf increase from the crystal center to its edge (0.3 to 0.8 and 57.5 to 105.4, respectively). ZrO_2/HfO_2 also increases from the center to the edge.

Irregularly-shaped zircons form plagiogneisses of the Selyankin complex are pale. Crystal sizes are 0.1-0.25 mm, the surface is smooth and shiny. The central part of crystals is enriched in U and Fe, and the edge in Th and Hf; Zr/Hf increases from the crystal center to its edge (102.5 to 337.5). Th/U and ZrO_2/HfO_2, on the contrary, decrease from the center to the edge (from 5.06 to 0.44 and from 1384.6 to 692.5) correspondingly.

The Selyankin complex is composed of rocks that consistently undergone metamorphism of the granulite and amphibolite facies. Irregularly-shaped zircons indicate the decrease of crystallization temperature to lower stages of the amphibolite facies. The regressive character of the process is confirmed by the decrease of ZrO_2/HfO_2 from the center to the periphery of crystals. As it is known, such a decrease points out to crystallization of the mineral at the fall of temperature and pressure [3]. Rocks of the Parikvasshor complex were subjected to progressive metamorphism of low to medium levels of the amphibolite facies. This is reflected in the geochemical composition of zircon of the third morphotype. ZrO_2/HfO_2 in them increases from the center to the periphery of the

Environmental degradation and health risks in Pearl River Delta, China

J. QI

South China Normal University, Guangzhou 510631, PR China (jungzh@163.com)

With the rapid process of industrialization and urbanization, cities have multiplied and expanded rapidly over the past 2 decades. Cities are sources of creativity, technology, and engines for economic growth. However, they are also sources of health hazards from the changed society, degraded environment and regional climate change.

The Pearl River Delta, including 9 cities (Guangzhou, Shenzhen, Foshan, Zhuhai, Dongguan, Zhongshan, Huizhou, Jiangmen, Zhaoqing), covers an area of 24437 km^2 and a large population of 42.8 millions. The unprecedented environmental degradation in the region, accompanied by complex interaction between urbanization and global environmental change, which places human health at risk on a large spatial and temporal scale. A range of urban health hazards and associated health risks in the Pearl River Delta result from a variety of factors including heat islands, air pollution, water crisis, soil pollution, infectious diseases, and urban consumerism; in addition, some hazardous health conditions are associated with inequality in living and working conditions. For sustainable development on environment and human health in the Pearl River Delta, it is urgent to understand the possibilities of health problems resulting from environmental changes related with urbanization. The author suggest 3 main areas for policy action and research direction: (1) the need to get full-scale information related to environmental monitoring data and health data, (2) the need to discuss the relationship among economic development, natural resources, environmental pollution and human health, (3) the need to provide new methodological approaches and techniques to implement interventions for sustainable development in the Pearl River Delta.

$^{40}Ar/^{39}Ar$ geochronology of phengite from blueschist facies rock of the Myanmar and its implication

MIN QI[1], ZEMING ZHANG[1], HUA XIANG[1], ZENGQIU ZHONG[2] AND HUANING QIU[3]

[1]Institute of Geology, Chinese Academy of Geological Sciences, No. 26 Baiwangzhuang Road, Beijing 100037, China, minqiqi@gmail.com

[2]China university of Geosciences, No. 388 Lumo Road, Wuhan, 430074, China

[3]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, No. 511 TianHe Area, Guangzhou, 510640, China

High-pressure (HP) low-temperature (LT) metamorphic rocks (blueschist and eclogite) in orogenic belts provide valuable information related to subduction processes of oceanic lithosphere. The blueschist together with garnet amphibolite, marble, quartzite are the associated rocks of the Myanmar jadeitite occurred in ultramafic rocks of the east ophiolite belt along the eastern margin of the Indian plate. The blueschist is composed mainly of glaucophane, phengite, albite, quartz, epidote with minor of actinolite and sphene. Among them glaucophane occurs as large grains whereas actinolite is fine hair-like in the matrix. The amphiboles in blueschist show variable compositions. Phengites in blueschists are characterized by a high Si content of 3.35–3.37 pfu, Mg content of ca. 0.27 pfu, Fe content of ca. 0.17pfu. The 40Ar/39Ar dating performed on phengite from the blueschist obtained an age of 147.0 ± 1.5 Ma, representing the metamorphic event during the subduction of oceanic crust. This age is older than 40Ar/39Ar ages of 123.9 ± 3.4 Ma of jadeite and 134.8 ± 1.4 Ma of sodic amphibole from the Myanmar jadeitite, and also older than the 100-80 Ma ages of high-pressure metamorphism of the blueschist derived from the subduction of the Neo-Tethys in the Western Himalayan orogen. To our knowledge, the 147 Ma age is probably the earliest time for the initial subduction of the Neo-Tethys beneath the Eurasian continent.

Cr isotopic evidence of enzymatic reduction of Cr(VI) catalyzed by a sulfate-reducing bacterium

LIPING QIN[1,2], RUYANG HAN[2], ROMY CHAKRABORTY[2], JOHN N. CHRISTENSEN[2] AND HARRY R. BELLER[2]

[1]Key Laboratory of Crust-Mantle Materials and Environments, University of Science and Technology of China, Hefei, 230026, China (lpqin@ustc.edu.cn)

[2]Lawrence Berkeley National Laboratory, 1 Cyclotron Rd., Berkeley, CA 94720, USA

Several studies have suggested that Cr isotopic signature could be used for distingushing between different Cr(VI) reduction pathways [1,2]. We previously showed distinct Cr isotopic fractionation behavior under aerobic versus denitrifying conditions with a single bacterial species, *Pseudomonas stutzeri* strain RCH2, even though the Cr(VI) reduction rates were comparable under those two conditions [3].

To further evaluate Cr fractionation mechanisms associated with enzymatic Cr reduction, in the current study, we used the sulfate-reducing bacterium *Desulfovibrio vulgaris* strain RCH1 isolated from DOE's Hanford 100H site. We found significant Cr(VI) reduction with lactate as the electron donor either in the presence or absence of sulfate; thus, the Cr isotopic signature was examined with and without sulfate. Under both conditions, Cr isotopic fractionation followed the same Rayleigh fractionation with an α value of 0.99806. This value is significantly smaller than the abiotic fractionation factors observed previously and is also smaller than the values from experiments with *Shewanella oneidensis* MR-1 using much lower electron donor concentrations [2], but is very similar to values from experiments with higher electron donor concentrations with either *P. stutzeri* RCH2 under aerobic conditions [3] or *S. oneidensis* MR-1 [1]. Since abiotic reduction of Cr(VI) by sulfide and Fe(II) could also have been involved in these experiments, abiotic reduction experiments with these reagents were conducted. The α values in these experiments were very different from 0.99806, implying that enzymatic reduction was dominant under the conditions tested with strain RCH1.

Petrology and geochemistry of the Mesozoic potassic and sodic volcanic rocks in the Yishu deep fault zone, Shandong Province, eastern China: Petrogenesis and inferences on the evolution of the mantle sources

JIAN-SHENG QIU*, LIANG LIU AND YOU-LIAN LI

State Key Lab for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (*correspondence: jsqiu@nju.edu.cn)

Late Mesozoic potassic volcanic rocks are widespread along the Yishu deep fault zone and its both sides, but some sodic volcanic rocks are also developed in several parts of this region, especially in the interior of the fault. These rocks provide important constraints on the nature and evolution of the Late Mesozoic lithospheric mantle beneath the region. LA–ICP–MS zircon U–Pb dating yields ages of 124.0~118.7 Ma for the potassic rocks, and of 106.4~96.5 Ma for the sodic ones. Both the potassic and the sodic volcanic rocks show similar trace element features of LILE and LREE enrichment and HFSE depletion. However, the sodic volcanic rocks have lower REE (especially LREE) contents, lower Rb/Sr and La/Nb ratios, and display somewhat Pb depletions in the spidergram profiles. All the rocks have enriched Sr and Nd isotopic compositions, but the sodic volcanic rocks have slightly lower I_{Sr} ratios and higher $\varepsilon_{Nd}(t)$ values with respect to the spatially coexisted potassic volcanic rocks, e. g., the I_{Sr} and $\varepsilon_{Nd}(t)$ values of the coexisted sodic and potassic rocks in Tangtou basin are 0.7097~0.7100, -10.0~-11.8 and 0.7100~0.7106, -15.5~-17.0, respectively. Zircon $\varepsilon_{Hf}(t)$ values of the sodic rocks are also higher than that of the potassic rocks (specially -4.2~-16.6 for the sodic rocks and -13.2~-24.3 for the potassic rocks). The elemental and isotopic systematics indicates that the potassic volcanic rocks were generated by melting of enriched lithospheric mantle which was most likely induced by hybridism of foundering lower crust of the North China Craton at mantle depths, but the magma source of the sodic volcanic rocks contain some proportions of depleted asthenosphere mantle components. Based on a synthesis of the geology and geochemistry, it is suggested that the continued extension thinned the lithosphere and induced the upwelling of asthenospheric melts which mixed with previously enriched lithospheric mantle. Decompression partial melting of the mixed mantle source produced the sodic volcanic rocks.

Experimental study of the reaction kinetics between CO_2-bearing solution and olivine

LIN QIU[1]*, ZHENGRONG WANG[1], SHUANG ZHANG[1], SHUN-ICHIRO KARATO[1], JAY J. AGUE[1], MICHAEL ORISTAGLIO[1], EDWARD BOLTON[1] AND DAVID BERCOVICI[1]

[1]Department of Geology and Geophysics, Yale University, New Haven, CT, USA
(*correspondence: lin.qiu@yale.edu)

Olivine, as one of the main constituents in mafic/ultramafic rocks, has been suggested as a promising candidate for trapping anthropogenic CO_2 permanently as carbonates because of its high dissolution and carbonation rates. In this study, we employed an experimental approach to quantitatively evaluate the carbonation reaction kinetics as CO_2-rich solution interacts with olivine (Fo_{90}).

Gem-quality olivine grains and olivine powders (<30μm or 50μm) reacted with CO_2-containing solutions (e.g., 0.25 to 3M $NaHCO_3$ solutions, fluid/rock mass ratio 5 to 10) in gold capsules placed in a hydrothermal autoclave over durations of 1-14 days at 200 ºC and 150 bar. The carbonation fraction (CF, the percentage of carbonated olivine over original olivine) was determined by comparing the concentration of dissolved-inorganic-carbon (DIC) in the solution before and after carbonation reactions.

Our results show that the CF could increase by ~20 times using fine olivine powders (<30μm) relative to the larger grains (~0.18 g/each), and the CF has a positive linear correlation with the concentration of $NaHCO_3$. The maximum CF in our study reaches ~45%, obtained using <30μm olivine powders and 3M $NaHCO_3$ solutions within one day of the reaction. Further increase of experimental time, however, will not improve the CF, but result in the precipitation of secondary minerals (including talc), and sometimes the decomposition of the carbonates (i.e., magnesite). However, this scenario could be prevented by using less amount of solutions ($fluid/rock_{mass}$ = 1); in which case, the carbonation reaction is much faster as SiO_2 precipitates as amorphous Si-layer without the formation of secondary minerals. The amorphous Si layers still have voids and channels for the fluid/rock interactions. These observations help constrain the kinetics of the olivine carbonation reactions.

Triplite in Baxiannao W deposit, southern Jiangxi, and its geological significance

QIU LIWEN[1] AND LI GUANGLAI[2]

[1]State Key Laboratory for Mineral Deposits Research, Nanjing University, Nanjing 210093, China
[2]College of Earth Science, East China University of Technology, Fuzhou 344000, China

A pink mineral was newly found in the Baxiannao tungsten deposit, southern Jiangxi province, China. Analytical results from Laser Raman spectra shows that its Raman shift (425.34, 454.64, 601.12, 981.97, 1040.50, 1073.1 cm^{-1}) is in good concordance with that of sample Triplite R050186 from the rruff data base (432.08, 453.29, 611.42, 981.69, 1043.40, 1072.33 cm^{-1}). The d values of high peak of powder XRD analysis are 1.639, 1.759, 2.032, 2.110, 2.221, 2.517, 2.602, 2.690, 2.735, 2.864, 3.038, 3.278, 3.442, 3.660, 4.299, 5.668, respectively, which well fit the standard 25-1080 triplite. Chemical composition from electron-microprobe analysis is MnO 50.19%~50.96%, FeO* 7.74% ~7.78%, MgO 2.75%~2.89%, CaO 1.75%~2.12%, P_2O_5 30.95%~31.51%, F 7.21%~7.94%, and H_2O 0.45%~1.02%, and hence the calculated chemical formula is $(Mn, Fe, Mg, Ca)_2PO_4(F, OH)$. All these data prove that the mineral is triplite, the manganese end-member of triplite-zwieselite series. It occurs in the wolframite-bearing quartz vein and associated with quartz and fluorite, which indicates that the ore-forming fluid was rich in phosphor and fluorine. The triplite contains a lot of fluid inclusions of two phases. Almost all the fluid inclusions are aqueous-rich and many of them are larger than 150um. Raman spectra show that the liquid phase is water while the gas phase contains not only H_2O, but also CH_4 and CO_2. The discovery of triplite together with quartz and fluorite in the tungsten deposit suggests that the related granite is most likely attributed to the fluorine-rich category.

Geology and geochemistry of the Fenghuangshan skarn Cu deposit at Tongling area, Anhui Province, East China

HONGYING QU [1]*, RONGFU PEI[1], HONGCAI FEI [2], JINWEN LI [1], YONGLEI WANG [1] AND HAOLIN WANG [1]

[1]MLR Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing 100037, China (*correspondence: hongyingqu@126.com)

ACTA Geological Sinica (English Edition), Beijing, 100037, China

The Fenghuangshan skarn Cu deposit at Tongling area, Anhui Province, is a component of the Middle-Lower Yangtze River metallogenic belt. The Xinwuli quartz monzodiorite and granodiorite related to mineralization at Fenghuangshan are intermediate-acidic intrusive rocks derived from alkline basalt of upper mantle and contaminated by crust materials during magma evolution. We carried out key study for this deposit. Geochemical features, ore-forming fluids and chronology have been studied to understand ore-forming mechanism. Carbon, hydrogen and oxygen isotopes indicate that ore-forming fluids in the deposit mainly are derived from the magma with input of minor amount of meteoric water at the late stage of the mineralization. Sulfur and lead isotopic analysis indicate that ore-forming materials are from the mantle source. Re-Os isotopic dating of molybdenite from the Fenghuangshan Cu deposit yielded an isochronal age of 141.1±1.4 Ma with the model ages ranging from 139.1±2.4 to 142.0±2.2 Ma, which is consistent to zircon SHRIMP U-Pb ages of the related quartz monzodiorite and granodiorite. Dating analysis yielded ages of 136.0±2.0 to 143.0±2.4 Ma for the quartz monzodiorite (a weighted average of 139.4±1.2 Ma) and ages from 136.7±2.0 to 145.3±2.4 Ma for granodiorite (a weighted average of 141.0±1.1 Ma). These studies discuss that the relationship between mineralization and intrusion, helping to understand other skarn Cu deposits which have similar ore-forming settings.

Classification of gemstone tourmalines from Central Brazil by chemistry nomenclature

H.A. QUEIROZ [1] AND N.F.BOTELHO[2]

[12]University of Brasilia,Brazil ([1]hudsonq@gmail.com, [2]nilsonfb@unb.br)

Several handpicking mines were important gemstone sources, mainly tourmalines, during the 1970's and 80's in Tocantins State, Central Brazil.

The studied tourmalines exhibit a wide range of colours, black, dark and light blue, dark and light green, pink, purple and colourless, sometimes exhibiting zonation. Classification of tourmalines based on colour, for instance rubellite, indicolite, verdelite, was substituted by chemical nomenclature accordingly Henry *et al*. [1], based on crystal microprobe analysis and the cation distribution.

In colored crystals there are solid-solutions between four species, schorl, elbaite, liddicoatite and rossmanite. Dark-blue and dark-green crystals are examples of schorl-elbaite series; light green, pink and colourless are either elbaite-rossmanite or elbaite-liddicoatite series. Apparently, the calcic tourmaline liddicoatite occurs more frequently in pegmatites hosted in Ca-rich rocks, in a similar way of those from Anjanabonoina, Madagascar [2].

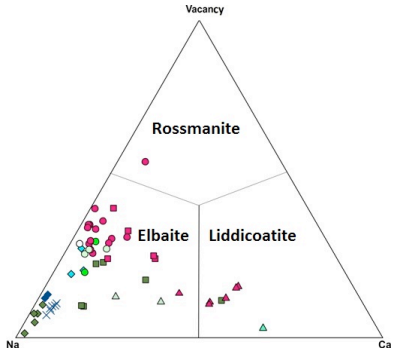

Figure 1: Colored tourmaline species by X site ccupancy. The color of each data point is indicative of the color of tourmaline.

Levels and geochemistry of urban and rural atmospheric particulate matter in Spain

X. QUEROL, A.ALASTUEY, T. MORENO AND M. VIANA

Institute of Environmental Assessment and Water Research, IDAEA, CSIC, Barcelona, Spain

A review of PM10, PM2.5 and PM1 geochemistry data collected in1999-2011 from 40 air quality monitoring data, each with 1 to 10 years of data coverage, is presented with the aim of describing major features of urban, industrial and rural source contribution, as well as describing the major concentration trends and their causes.

Ambient air PM levels have markedly decreased in the last decade by around 35%. Although EC limit values are exceeded only in a few hotspots, urban PM levels still exceed by far the WHO guidelines. Causes accounting for these trends are discussed according geochemical data.

Spatial gradients are very clear across Spain, especially levels of sulphate, nitrate, ammonia and mineral matter. Different emission patterns and climate features may account for these gradients. The incidence of African dust outbreaks on PM levels is also briefly described. Levels of carbonaceous aerosols are mostly influenced by vehicle exhaust emissions. Ranges of concentrations of levels of around 30 trace elements in the 40 sites are presented and discussed. The influence of major industrial hotspots is evidenced, but also the impact of vehicle wear emission in ambient levels of a number of relevant metals is evidenced. Results point to the very high impact of vehicle exhaust and road dust emissions on levels and composition of PM in urban areas. Biomass burning emissions may have local impact but not much at urban scale in the largest urban agglomerations in Spain. Finally, the relevance of specific industrial hotspots is also shown.

Multi-Wavelength Raman survey of IOM from primitive meteorites

E. QUIRICO[1]*, F-R ORTHOUS-DAUNAY[1], P. BECK[1], L. BONAL[1], R. BRUNETTO[2], E. DARTOIS[2], T. PINO[2], G. MONTAGNAC[3], JN ROUZAUD[4], C. ENGRAND[5] AND J. DUPRAT[5]

[5]CSNSM IN2P3/Université Paris Sud Orsay France

We report a survey of the structure of Insoluble Organic Matter (IOM) of a series of 27 CR, CM, CI and ungrouped C2 carbonaceous chondrites by means of Infrared and Multi-Wavelength Raman micro-spectroscopy (244, 514 and 785 nm laser excitations). The IOM in some of these chondrites displays Raman and Infrared signatures that point to the past action of short duration thermal metamorphism, presumably triggered by impacts (e.g. PCA 91008, QUE 93005, Tagish Lake). Interestingly, IOM from other chondrites also display Raman characteristics consistent with a thermal processing. In this regard, IOM and Soluble Organic Matter (SOM) could be considered as two byproducts of organic precursors decomposed by thermo-degradation. The place where this process occurred, within parent body or protosolar disk prior accretion, cannot be firmly identified given the lack of precise knowledge on the nature of the organic precursors and of the time-temperature history of the parent asteroid. Our data also confirm that IOM is structurally more homogeneous in chondrites than in stratospheric IDPs and Antarctic Micrometeorites (AMMs). This suggests IOM contained in these particles was formed under more varying conditions. However, other mechanisms as ions irradiation or atmospheric heating/oxidation cannot be fully excluded for accounting for these variations.

Los Morros olivine basalts from the Domeyko Cordillera in the Antofagasta region, northern Chile

O.M. RABBIA[1]*, C. JARA[2], L.B. HERNÁNDEZ[1] AND E. ARAGÓN[3]

[1]Instituto GEA, Universidad de Concepción, P.O. Box 160c, Concepción, Chile (*correspondence: rabbia@udec.cl)

[2]Cía. Minera Barrick Ltda. Barrio Industrial Alto Peñuelas Sitio 58, Coquimbo, Chile (cjara@barrick.com)

[3]Centro de Investigaciones Geológicas (UNLP-CONICET), La Plata, Argentina (earagon@cig.museo.unlp.edu.ar)

In the eastern flank of the Domeyko Cordillera at 23º45' S two types of olivine basalts crop out as lava flows covering the Permian crystalline basement and as sills in Jurassic limestones. The basalts lay on an uplifted crustal block within the transpressional Domeyko fault system (DFS).

One type is an olivine-phyric alkali basalt, with Mg# 62-67, Ni 120-190 ppm and Cr 205-338 ppm. The Ta/Hf (>0.4); La/Nb (<2) and Ba/Nb (12-31) ratios suggest an intraplatelike affinity (OIB-type mantle source).

The other, is an olivine-clinopyroxene-phyric transitional basalt (in TAS diagram), with high Ba/Nb (90-100) and Th/Nb (>0.2) ratios indicating an arc affinity. A primitive character is suggested by: Mg# 70-74; Cr 870-1100 ppm, Ni 220-300 ppm and olivine phenocryt with core compositions (2300-3200 ppm Ni and Fo_{88-92}) in the range of mantle olivi-nes. Its source is more refractory than that of the alkali basalt.

New $^{40}Ar/^{39}Ar$ step-heating ages ranging from 55.6±1.4 to 56.7±1.0 Ma (this work) place the alkaline magmatism in the Palocene-Eocene transition. These ages are close to, but slightly older than the 52.5±1.8 Ma (K/Ar, [1]) for the spatially associated transitional basalts with arc-affinity.

The nature and close relationship in space and time of these basalt types is consistent with short crustal residence time and deep major-faults in extensional zones. The Los Morros basaltic magmatism may imply that the inverse structures of the DFS associated to these mafic rocks may represent step-inverted normal faults inherited from Paleocene and/or previous extensional episodes, later reactivated by the transpressional Incaic tectonic event, which uplifted the Domeyko Cordillera during the Eocene-Oligocene time.

Metal isotope fractionation during microbial processes in the Critical Zone

K. RABE[1]*, A. SCHIPPERS[2], S. WEYER[1], S. SCHUTH[1] AND M. LAZAROV[1]

[1]Leibniz Universität Hannover, Institut für Mineralogie, Callinstr. 3, 30167 Hannover, Germany (*correspondence: k.rabe@mineralogie.uni-hannover.de)

[2]Bundesanstalt für Geowissenschaften und Rohstoffe, Stilleweg 2, 30655 Hannover, Germany (Axel.Schippers@bgr.de)

Oxidation of sulfide minerals (e.g. pyrite) in sulfidic mine waste leads to the formation of acid mine drainage [1]. Herbert and Schippers (2008) found large Fe isotope fractionations ($\Delta^{56}Fe$: -1.4‰ to -2.4‰) between pore water and Fe(oxy-)hydroxides in mine tailings and concluded that this was the product of microbially catalyzed iron cycling [2].

In this study the potential of Fe and Cu isotope fractionation analysis is investigated to fingerprint microbial oxidation of metal sulfides in mine tailings. We focus on the investigation of the metal isotope fractionation between the sulfides and the metal(oxy-)hydroxides. We tested the selectivity of a sequential extraction method consisting of six extraction steps, to distinguish between sulfates, carbonates, Fe(oxy-)hydroxides, oxides, sulfides and silicates [3, 4]. For this test we used a synthetic test sample with known Fe isotope ratios of the components. The first results show that for Fe isotopes no significant isotope fractination occurs during the extraction.

In the next steps we will adopt this sequential extraction method to natural samples from a porphyry copper mine tailings in Chile [5, 6] and determine the Fe and Cu isotope compositions of the particular fractions. In addition, we will perform laboratory experiments of microbial mineral oxidation and compare the isotope fractionation with that in the mine tailings.

Groundwater Resource Management of Rampurbaghelan Area, Satna District, Madhya Pradesh India

RABINDRA N. TIWARI

Department of Geology, Govt. P.G. Science College Rewa, Madhya Pradesh (email : geogppandey@gmail.com)

The paper deals with management of groundwater resource of Rampurbaghelan area Satna district, Madhya Pradesh. Geologycally, the area is a part of Bhander Group of Vindhyan Supergroup. The limestone and shale are the main aquifers of the area. For the assessment of groundwater resource, groundwater recharge, groundwater development stage, water table trends, water table fluctuation etc. have been studied. The Pre and Post monsoon water tables are falling. The calculated stage of groundwater development suggests that the area falls in semicritical category. However due to decline in water level, quality and quantity of groundwater have been adversely affected. For scientific management, utilization and augmentation of groundwater resource, the following suggestions have been recommended:

Artificial recharge structures like percolation pond, check dam and contour trenches should be preferred at suitable sites with the help of geological and geomorphological data.

The area having moderate slope can be utilise for contour bunding. The soil taken from the trenches may be placed down the hill in the form of bund. The soil erosion and vegetal. cover can be controlled by growing such seeds of grasses and shrubs on the bunds which are suitable to the area.

Recharge augmentation is positive may, while pumpage control is negative way of management. In extreme cases, when pumpage control is to be observed in the area, the best way of monitoring is at the level of Gram Panchayat.

The groundwater management policies and practices should transcend from academic echelon to actual field implementation. All the related departments publics, stake holders and research institution should be jointly initiate the sustainable action plan with short term and long term plan strategy. Besides these, NGO's may play vital role to conserve the groundwater resource of the area.

The awareness programme is honestly and urgently needed.

Proteogenomic insights into completely oxidizing sulphate reducers (*Desulfobacteriaceae*)

RALF RABUS[1]

[1]Institute for Chemistry and Biology of the Marine Environment (ICBM), University Oldenburg, Oldenburg, Germany; rabus@icbm.de

Sulfate-reducing bacteria are pivotal to carbon turnover in marine sediments, as Jørgensen (1982) demonstrated in his seminal work on organic carbon rich shelf sediments. The observed high in situ activities could concurrently be explained best by the key properties of newly discovered sulphate reducers belonging to the family *Desulfobacteriaceae* (Widdel 1988): (i) capacity to completely oxidize organic carbon to CO2, and (ii) broad nutritional versatility spanning from simple fermentation end-products to less well degradable substrates such as aromatic compounds. These early findings and concepts motivated more recent genomic and proteomic investigations to further our molecular understanding of this group´s physiological capacity. The first published genome of a *Desulfobacteriaceae* member was that of *Desulfobacterium autotrophicum* HRM2 (Strittmatter *et al*. 2009), which degrades long-chained fatty acids and is capable of chemolithoautotrophy (with H_2 and CO_2). The 5.6 Mbp genome displayed an unusually high degree of plasticity and contains a large suite of genes for regulation and electron transport. The recently completed genome of *Desulfobacula toluolica* Tol2 (Wöhlbrand *et al*. 2012) in combination with sub-proteomics and metabolite analysis allowed a detailed reconstruction of the catabolic network for aromatic-compound utilization and discovery of new degradative capacities. Taken together first genome-based insights are emerging that causally explain the ecosystems function of *Desulfobacteriaceae*.

Sedimentary and diagenetic features of the Oolithe Blanche formation (Middle Jurassic): New contribution from Ca, Sr, C, O isotopic compositions

SETAREH RAD[1], YASIN MAKLHOUFI[2], CATHERINE GUERROT[1], CHRISTINE FLEHOC[1] AND PIERRE-YVES COLLIN[3]

[1]BRGM, 3, avenue Claude-Guillemin, Orléans, France
[2]UPMC Univ. Paris 06, UMR 7193, ISTeP, Paris, France
[3]Université de Bourgogne, UMR CNRS 5561, Dijon, France

The Oolithe Blanche formation is present in the Paris Basin at more than 1500 m depth in the middle of the basin and on outcrops at the basin edges. This Bathonian formation (Middle Jurassic) is composed of very shallow marine oolithic and bioclastic limestones, located within a shoreface depositional environmental (Casteleyn *et al*., 2010).

Calcium, strontium, carbon and oxygen isotopes have been analysed both in ooids and interparticular cement directly extracted from the limestone in order to study sedimentary and diagenetic environment.

The $^{44}Ca/^{40}Ca$ ratios (expressed as $\delta^{44/40}Ca_{SW}$) were measured by TIMS using a ^{42}Ca-^{48}Ca double-spike. Carbon and oxygen isotopic ratios were measured by IRMS.

Preliminary results show a range of $\delta^{44/40}Ca_{SW}$ from -0.74‰ to -1.09‰ in the cement and from -0.85‰ to -1.05‰ in ooids. Carbon isotopic signature show a range of $\delta^{13}C$vs PDB range from 1.5‰ to 2.7‰ in the cement and from 1.5‰ to 2.4‰ in ooids while $\delta^{18}O$vs SMOW vary from 21.5‰ to 23.9‰ in the cement and from 21.2‰ to 24.9‰ in ooids.

This first multi-isotopic approach on Oolithe Blanche formation seems to be consistent with the diagenetic evolution of Paris Basin. Effects of diagenesis on the isotopic signatures will be discussed.

Role of small urban reservoirs in regulating watershed quality

L.K. RADEMACHER[1]* AND K.L. FAUL[2]

[1]University of the Pacific, Stockton, CA, 95211, USA (*correspondence: lrademacher@pacific.edu)
[2]Mills College, Oakland, CA, 94613, USA (kfaul@mills.edu)

Many coastal creeks in California drain small upstream reservoirs. These reservoirs were originally created to store drinking water, but many are currently maintained for recreation, irrigation, and other purposes. More than 200 of these reservoirs are located within the San Francisco Bay (SFB) area, which is western North America's second largest urban area. As a result, these small individual reservoir/creek systems contribute a significant proportion of pollution to the coastal ocean. Understanding modern and historic biogeochemical cycling in urban watershed/reservoirs systems provides new insight into anthropogenic influences on the function of these systems, how differing management strategies in these systems may mitigate or exacerbate contaminant discharge to the urban-influenced coastal ocean, and how best to manage these systems for improved water quality and beneficial use in the future.

The present study investigates three watershed/reservoir systesms in the east SFB region to better understand biogeochemical cycling in disturbed urban environments. For example, Lion Creek/Lake Aliso is an acid mine drainage impacted system and the Don Castro/San Lorenzo Creek system is influenced by freeways and residental land uses. In comparison, the relatively undeveloped Lake Anza/Wildcat creek is primarily surrounded by parkland. Water quality data (including standard geochemistry, as well as nutrient and trace element concentrations) from reservoir inlets and outlets at each of these systems is collected biweekly. Depth profiles of pH, conductivity, temperature, and dissolved oxygen within each lake are also collected biweekly. In addition, sediment cores from multiple locations in each lake were collected and analyzed for nutrient and trace element concentrations.

Preliminary results indicated urban reservoirs play an important role in biogeochemical cycling in urban watershed and downstream water quality. Lake water column structure varies over the course of a year with reducing conditions prevailing during warm summer months and more oxidizing conditions occuring during more winter months. The oxygenation state of these lakes ultimately plays a significant role in whether metals and nutrients are mobilized or retained. In addition, sediment cores from each of the lakes indicate changes in how these lakes cycle elements has changed through time in response to differing managing strategies.

[4]Diamond Light Source, OX11 0DE Didcot, UK

Cordierites and beryls are isostructural minerals that may diffuse significant amounts of H_2O and CO_2 through their structural channels, running along the *c* axis, [1]. Experimental introduction of CO_2 in cordierite-like structure was studied by several authors [2, 3], who pointed out the extreme difficulty to reach sample saturation and homogenization.

In this work we treated cordierite and beryl volatiles-free

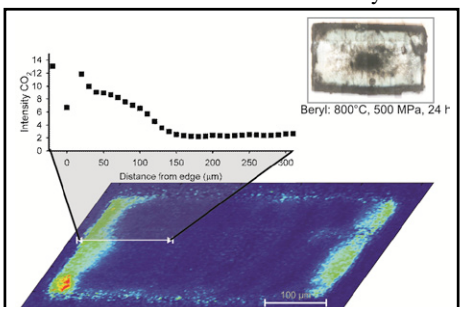

Figure 1 - FPA image and single spot IR transect of a

single-crystals in CO_2-saturated environment at different PTt conditions. The run products were analyzed via micro-FTIR spectroscopy in order to quantify the CO_2 content and its distribution across the sample.

Preliminary results show that pressure plays a major role in diffusing gaseous CO_2 across both cordierite and beryl, whereas the effect of temperature is less pronunced. Detailed FPA (focal-plane-array of detectors) imaging shows that the diffusion occurs along the structural channels starting from the basal pinacoids along the *c*-axis direction. As expected, no diffusion occurs perpendicularly to the *c*-axis. The diffusion path of CO_2 does not exceeds 200 μm even after 10 days. Sample cracks formed during the experimental runs speed up diffusion; measured CO_2 contents along these cracks are even 4 times higher than in the rest of the sample.

Glacial-interglacial changes in ocean carbonate chemistry constrained by boron isotopes, trace elements, and modelling

JAMES W.B. RAE[1], JESS F. ADKINS[1], ALAN FOREMAN[2], CHRISTOPHER CHARLES[2], ANDY RIDGWELL[3], GAVIN L. FOSTER[4], DANIELA N. SCHMIDT[3] AND TIM ELLIOTT[3]

[1]Geological and Planetary Sciences, Caltech, Pasadena, USA jamesrae@caltech.edu
[2]SCRIPPS Institution of Oceanography, UCSD, La Jolla, USA
[3]University of Bristol, Bristol, UK
[4]School of Ocean and Earth Science, National Oceanography Centre, University of Southampton, Southampton, UK

Deep ocean carbon storage and release is commonly invoked to explain glacial-interglacial CO_2 cycles, but records of the carbonate chemistry of the glacial ocean have, until recently, been scarce. Here we present new boron isotope ($\delta^{11}B$) data from detailed depth profiles and time series, that record the pH of the deep ocean at the last glacial maximum (LGM), and how it evolved over the deglaciation. We examine these data using a recently developed tracer fields modelling approach [1]. This has previously been applied to $\delta^{18}O$ data to investigate changes in circulation at the LGM. Here we extend this method to the non-conservative tracers $\delta^{11}B$ and $\delta^{13}C$, allowing us to constrain the roles of circulation, the biological pump of organic carbon and $CaCO_3$, and carbonate compensation, in setting deep ocean carbon storage at the LGM. Finally, we show how deep ocean carbon storage evolved over the deglaciation, with pulses of stratification breakdown in the Southern Ocean and North Pacific causing CO_2 release from the deep ocean to the atmosphere.

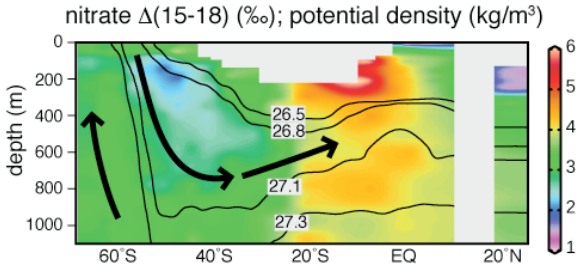
Revealing Pacific Ocean organic matter remineralization and circulation using the dual isotopic composition of nitrate

PATRICK A. RAFTER[1] AND DANIEL M. SIGMAN[1]

[1]Department of Geosciences, Princeton University

Here we show that the difference between the N and O isotopic composition of nitrate, or Δ(15-18), is sensitive to organic matter remineralization and largely reflects known patterns of surface ocean nitrogen cycling. For example, incomplete nitrate consumption in high latitude surface waters and N fixation in the subtropical North Pacific lowers subsurface Δ(15-18), while complete consumption in the lower latitudes elevates subsurface Δ(15-18) (see Figure 1 below). This sensitivity is exploited to estimate the $^{15}N/^{14}N$ of sinking organic matter and to track the modification of nitrate as it passes from the deep Pacific Ocean, through the Southern Ocean surface, and into intermediate-depth waters—a pathway that is necessary for resupplying the low latitude surface ocean with nutrients (Figure 1).

Figure 1: Nitrate Δ(15-18) along ≈150°W in the Pacific Ocean (see colour bar) and potential density (lines). Deep-sea nutrients are brought to the high latitude surface ocean and transported to lower latitudes within the potential density range of 26.5 to 27.1 kg/m^3 (arrows). Changes in nitrate Δ(15-18) along these isopycnals largely result from organic matter remineralization.



Growth medium and carbon source of unusual rounded diamonds from alluvial placers of the North-East of Siberian Platform

A.L. RAGOZIN[1]*, V.S. SHATSKY[1,2], D.A. ZEDGENIZOV[1] AND W.L. GRIFFIN[3]

[1]V.S. Sobolev Institute of Geology and Mineralogy SB RAS, Koptyuga Ave. 3, Novosibirsk 630090, Russia, (*correspondence: ragoz@igm.nsc.ru)

[2]A.P. Vinogradov Institute of Geochemistry SB RAS, Favorsky str. 1a, Irkutsk 664033, Russia

[3]CCFS/GEMOC, Macquarie University, NSW 2109, Australia

About 70% of diamond placer deposits of the Siberian platform are concentrated in the northeastern part. Primary sources of diamonds of these placers have not yet been established. Some diamonds are neither characteristic to the pipes located nearby nor to any of the known kimberlite pipes of Yakutia. A significant part of the diamonds belongs the variety V [1]. These diamonds are characterized by rounded morphology and radial mosaic-block internal structure. The diamonds enriched in isomorphic nitrogen (up to 3500 ppm) and have light carbon isotopic composition ($\delta^{13}C$:-19.6÷-24.1‰). The Coe inclusions suggests eclogite paragenesis also supported by the light carbon isotopic composition. Moreover, diamonds contain numerous microinclusions (<1 μm). Rt, Grt, Ap, Kfs, Dy, Omph and Jd have been identified among microinclusions associated with fluid (or melt) inclusions of composition varied from carbonatitic (enriched in Ca, Mg, Fe, Cl, Ba and Sr) to silicic (enriched in Si, Al, Ti, K). Bulk trace element patterns of microinclusions as determined by LA-ICP-MS are similar to that observed in cuboid diamonds from Siberian Platform. Fluid inclusions have demonstrated that growth environment involved H_2O, CO_2, N_2, CH_4 and heavier hydrocarbons [2]. The compositions of fluid inclusions in one crystal could change from CO_2 to essentially hydrocarbons from center to the periphery.

Thus the obtained data for unusual rounded diamonds (variety V) indicates the possible connection between the formation of diamonds and subduction events. Variations of the growth media composition may be caused by the interaction between the metasomatizing fluids and silicate substrate.

Petrological and Geochemical Evidences for the Origin of the Neyriz Ophiolites, SE Zagros, Iran

MOHAMMAD RAHGOSHAY[1] AND IMAN MONSEF[2]*

[1]Shahid Beheshti University, Earth Sciences Faculty, Tehran, Iran (M-Rahgoshay@sbu.ac.ir)
[2]Industrial and Mining Research Center, ZaminOmran, Shiraz, Iran,
(*Correspondance: Iman_monsef@yahoo.com)

The Late Cretaceous Neyriz ophiolites in south eastern of Zagros are a remnant of Neo-Tethyan oceanic lithosphere with nearly continuous NW-SE-trending belt. The ophiolite consists chiefly of mantle (ultramafic) and crustal (cumulates, volcanic and sub-volcanic rocks) sequences.

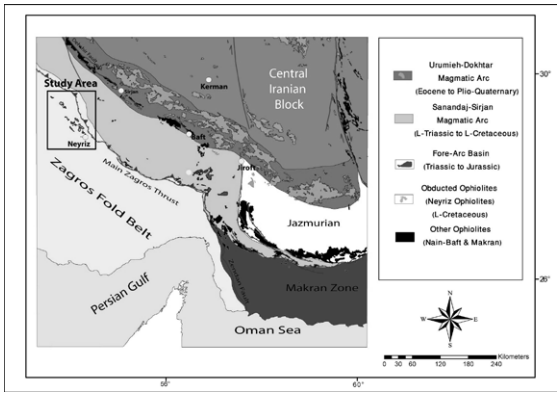

Figure1: Structural sketch map of Iran with Neyriz ophiolites

The mantle sequences consist of harzburgite, dunite, pyroxenite, gabbroic pockets, diabasic dykes and chromitite presented by mantle deformation conditions. Chromitite ore deposits with podiform and lenses structures are located in dunitic envelope of ultramafic host rocks. The chromitites are alpine type with high values of Cr#, Mg# and Fe^{+2}/Fe^{+3} ratio and low values of Al_2O_3 and TiO_2.

The crustal sequences consist of layered gabbros, isotropic gabbros, plagiogranites, sheeted dykes, and pillow lavas. Most of the mafic rocks have flat chondrite-normalized REE patterns and are strongly depleted in incompatible elements (negative Ta-Nb anomalies), similar to depleted tholeiites affinity.

The Neyriz oceanic lithosphere was probably formed within marginal basin system that was later accreted to the northern margin of the Arabian plate.

Tracing the time-resolved magmatic evolution of the Hegau volcanic field (Southern Germany) through apatites

MEINERT RAHN[12] AND ANETTE VON DER HANDT[23]

[1]Swiss Federal Nuclear Safety Inspectorate, Brugg, Switzerland, meinert.rahn@ensi.ch
[2]Albert-Ludwigs-Universität, Freiburg, Germany
[3]University of Minnesota, Department of Earth Sciences, avdhandt@umn.edu

Major outcrops of Tertiary–Quaternary mafic alkaline volcanic rocks form the Central European Volcanic Province (CEVP). The Hegau volcanic field is found at the southern periphery of the CEVP, around 60-70 km to the east of the Upper Rhine graben. Age dating suggests a period of volcanic activity between 15 and 7 Ma [1-3]. Three main lithological units can be distinguished, i.e. from old to young: (1) tuff layers (so-called “Deckentuff”) intercalating with surrounding Miocene sediments, (2) olivine melilitites forming cones, but no lava flows, and (3) isolated phonolite peaks. Carbonatites occur subordinately in the Hegau province, mostly evidenced by calcite-apatite-magnetite aggregates, but suggesting the coexistence of silicate and carbonate melts in the source area.

We investigated apatites from Deckentuffs and phonolites, as their composition is expected to reflect whole rock compositional variation and in particular any changes between silicate and carbonate melt origin [4]. Apatites are often the only fresh remnants of the associated volcanic products; they occur in all lithological units and commonly display a complex internal growth pattern. EPMA and SIMS techniques are applied to decipher the major and trace element compositional evolution. The combination of fission track age dating with chemical composition allows a time-resolved investigation of the evolution of the Hegau volcanic field and its relation to the Kaiserstuhl volcanism.

In addition, apatites with Hegau compositional patterns can be found as thin tuff layers intercalated with sediments as much as 60 km away from the Hegau volcanic field. This suggest a more explosive volcanism which is corroborated by the occurrence of diatreme breccias in the Hegau. Multiple magmatic cycles can be discerned on the basis of apatite composition.

Journal paper isotopic composition as climate proxy

P RAHUL[1] , P GHOSH[1]* AND SNEHA SURESH[2]

[1]Centre for Earth Sciences, Indian Institue of Science, Bangalore (* pghosh@ceas.iisc.ernet.in)
[2]Pondicherry University, Pondicherry

The increasing use of fossil fuels mainly due to burning of coal and petroleum since the beginning of industrial revolution has caused steady rise in CO_2 concentrations in the atmosphere. CO_2 is well mixed in global atmosphere through general circulation. There is a consistent pattern observed between concentration rise and carbon isotopes in atmospheric CO_2. The isotopic signature seen in CO_2 of atmospheric air is transferred to the biosphere through exchange mechanisms. The $\delta^{13}C$ signature of fossil fuel derived CO_2 being lighter than other natural sources and preferential uptake of $^{12}CO_2$ from atmosphere by plants, provide us an opportunity to understand its fluctuations over time through stable isotopic analyses of plant materials [1]. In the present study we investigated the transfer of $\delta^{13}C$ signal from raw plant material to paper in archives of periodicals and magazines. Study by Yakir (2011) [2] shows a depleting trend in $\delta^{13}C$ of paper cellulose through time and linked it to global-scale increases in plant intrinsic water-use efficiency. In our study we have investigated the $\delta^{13}C$ of paper produced from Europe and America capturing atmospheric CO_2 trends mimicking the rise in global temperature for time period of last 100 years. The representative samples of journal papers are retrieved from the library at four to five year resolutions avoiding any ink contamination. We recorded a sudden drop in $\delta^{13}C$ value (-22.9‰ to -24.39‰) in cellulose composition coinciding with the time period from 1920 to 1925. The global temperature anomalies for the same period ranges from -0.25°C to -0.14°C. Detailed examination of $\delta^{13}C$ variability revealed impacts of historically important events on atmospheric CO_2 via cellulose in paper. Analyses performed on archives of a regionally published journal confirms global patterns and along with the capturing signatures of regional industrial revolution. Analyzes of $\delta^{18}O$ in the cellulose further confirm the signature of global climatic events due to its linkage with the hydrological cycle. The study identified a potential new reliable archive which can supplement proxy records at much higher time resolutions.

Crustal structure beneath the Dharwar craton, India

S. S. RAI*, KAJALJYOTI BORAH, S. GUPTA AND K. S. PRAKASAM

National Geophysical Research Institute, Hyderabad-50007 India
(*Correspondence: shyamsrai@gmail.com)

We report significant lateral variability in shear wave velocity and Moho depth in the Archean crust beneath the Dharwar craton, India using earthquake waveform data recorded over 50 broadband seismographs (Figure a). The craton is a continuously exposed Archean continental fragement from north to south, and divided into the west Dharwar craton (WDC) of age 2.7-3.36 Ga, and the east Dharwar craton (EDC) of age, dominantly, 2.5 Ga. The craton progressively transition into the Southern Granulite Terrain (SGT) with age of metamorphism around 2.6 Ga.

The inversion of receiver function data reveals significant variation of Moho depth, viz., 38-54 km in the WDC, 40-46 km in SGT, and 32-38 km in the EDC. The average shear wave velocity of crust beneath the WDC is ~3.85 km/s as compared to ~3.60 km/s in the EDC. We infer highly variable thickness (16-30 km) of mafic cumulate (Vs ≥ 4.0 km/s, Vp ≥ 7.0 km/s) beneath the WDC, in contrast with a thin one (<5 km) beneath the late Archean EDC. The 3.36 Ga greenstone belt in WDC has maximum basal layer thickness of ~30 km. The result suggest the mafic crust and exceptional thickness of crust beneath the WDC (>50 km) as compared to felsic to intermediate composition for the EDC crust with almost flat Moho (~36 km) (Figure b). Considering the surface exposure of 15-20 km crust, based on P-T condition, in the southern segment of WDC, we speculate a Himalaya-like crustal thickness (50-70 km) beneath the mid-Archean crust pointing towards a plate-tectonic like scenario at ~3.0 Ga. In contrast, the EDC is possibly evolved as a consequence of subduction and delamination that led to a felsic crust with a nearly flat Moho.

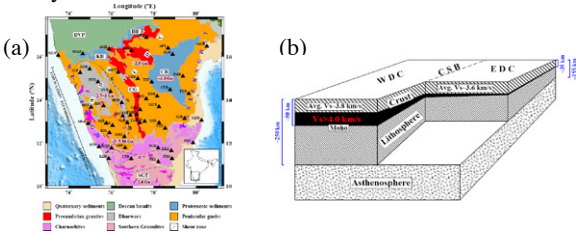

Figure:(a) Tectonic map of Dharwar craton. Seismic stations are shown as black triangles (b) Schematic showing distinct crust-mantle character of the WDC and EDC.

Kinetic parameters of pelagic nitrifying communities: consequences on nitrite dynamics in the Seine River downstream of Paris

M. RAIMONET[1], L. VILMIN[2], N. FLIPO[2], T. CAZIER[1], V. ROCHER[3] AND A. M. LAVERMAN[1]

[1]UMR 7619 Sisyphe, Université Pierre et Marie Curie, 4 place Jussieu, 75252 Paris, France (melanie.raimonet@upmc.fr)
[2]Centre de Géosciences, MINES ParisTech, 77300 Fontainebleau, France
[3]SIAAP-Direction du Développement et de la Prospective, 82 avenue Kléber, 92700 Colombes, France

Elevated nitrite concentrations are observed in the Seine River downstream of Paris and its main waste water treatment plants (WWTP). In order to understand the persistence of nitrite in the Seine, we determined kinetic parameters of pelagic ammonia- and nitrite-oxidizing communities. *In situ* ammonia- and nitrite-oxidation rates were deduced by determination of the kinetic parameters of the two processes combined with modeling. We compared the *in situ* rates and kinetic parameters upstream and downstream of the WWTPs during different seasons. The results showed both spatial and temporal variations of the *in situ* nitrification rates and kinetic parameters (e.g., maximal oxidation rate, half-saturation constant). At each given site and season, the *in situ* ammonia- and nitrite-oxidation rates were however similar, most likely resulting in little changes in water column nitrite concentrations. The results confirm that the elevated nitrite concentrations monitored in the Seine River are due to high nitrite released by the WWTP. In addition, the low nitrification rates and the equilibrium between ammonia- and nitrite-oxidation rates appear to prevent the elimination of nitrite from the system, leading to its persistence over more than 100 kilometers. The spatial and temporal variations of kinetic parameters reflect the dynamic microbial community structure and activity and may have implications on biogeochemical models.

Computer simulations of carbonates in water

PAOLO RAITERI[1]*, RAFFAELLA DEMICHELIS[1] | AND JULIAN D. GALE[1]

[1]Nanochemistry Research Institute and Department of Chemistry, Curtin University, Perth WA 6845, Australia (*correspondence: p.raiteri@curtin.edu.au)

Over the last thirty years a lot of effort has been made to understand the structural, surface and crystal growth properties of carbonates in aqueous environments, both experimentally and computationally. The ever increasing resolution of experimental techniques and power of supercomputer are rapidly closing the gap between what the two approaches can achieve. Arguably calcium carbonate is among the most studied minerals, but while there is a general consensus that its crystalline phases grow via an amorphous precursur, there is still much debate about the existence of pre-nucleation clusters and whether the nucleation follows a classical or non-classical pathway. Moreover, other carbonates are comparatively less studied and less understood.

Here we will present a recent force field developed to reproduce the thermodynamic properties of the alkaline-earth carbonates X-CO_3 (X=Mg, Ca, Sr and Ba). This force field is used to study the different stages of the crystallisation mechanism, from isolated ions in solution to pre-nucleation clusters, nanoparticles and the growth of fully developed crystals. These studies include the calculation of reaction free energies (Figure 1), IR spectra and both structural and dynamical properties, and they demonstrate that carefully developed computational models are capable of quantitatively reproducing experimental observations.

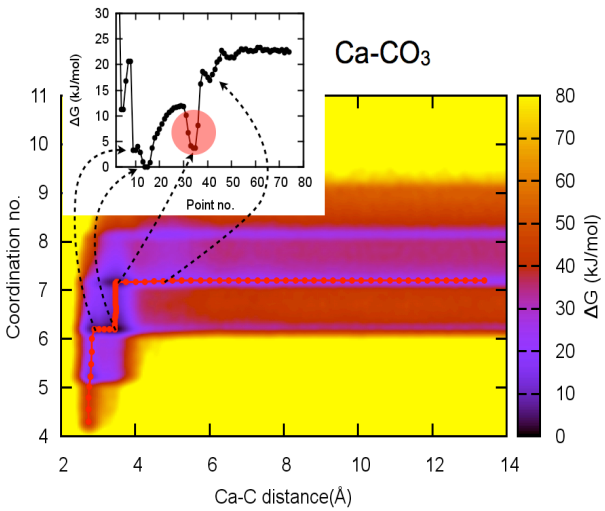

Figure 1 Ca-CO_3 pairing free energy calculated using the metadynamics technique with 2 collective variables.

Presence of > 3.3 Ga old crust and Neoarchean juvenile magmatic accretion in eastern most part of the Dharwar craton: Evidence from Peddavura greenstone belt.

M.RAJAMANICKAM[1] AND S.BALAKRISHNAN[1]*

[1]Department of Earth Sciences, Pondicherry University, Puducherry- 605014 (*correspondence: balakrishnan.srinivasan@gmail.com)

Neoarchean witnessed rapid growth and stabilization of continents.The Dharwar Craton had significant addition of juvenile material and consequent crustal growth during 2.9 to 2.5 Ga ago in greenstone-granite terrains. [1, 2, 3]. Rocks of Peddavura greentone belt in eastern Dharwar craton was studied for Rb-Sr and Sm-Nd systematics to understand crustal growth in the Dharwar Craton.

Peddavura greenstone belt consists of pillowed basalt, basaltic andesites and rhyolites inter-layered with ferrugenous chert. Basalt and basaltic andesites define a Rb-Sr isochron age of 2551±19 Ma (MSWD=1.16), whereas, rhyolites were scattered and do not show any age. Sm-Nd system also does not yield any age for both the rock types.

The Rb-Sr age could represent time of thermal event that was strong enough to completely reset the Rb-Sr isotopic system in the basaltic rocks. The scattering of samples in Sm-Nd evolution diagram could be due to either low-temperature alteration or heterogeneity in their sources. The basalt and basaltic andesites show variation in their ε_{Nd} values, whereas they have similar ε_{Sr}. This implies that magmas representing these rocks might have derived from variably LREE enriched and depleted mantle sources. Rhyolites show larger variation in their ε_{Nd} as well as in ε_{Sr} which are negatively correlated. Parental magmas of rhyolites derived by partial melting of short-lived basaltic rocks were contaminated with older crustal rocks similar to the Gorur-Hasan gneisses. Thus, we infer presence of older crust, > 3.3 Ga, in the eastern most part of the Dharwar Craton.

[3]Sub-Department of Environmental Technology, Wageningen University, 6700 EV Wageningen, The Netherlands

Arsenic contamination of soil and drinking water is a serious problem of worldwide concern [1, 2]. The efficiency of a novel combined strategy relying on enhancing microbial As mobilization with subsequent immobilization on nanosized iron phases for the treatment of mining impacted soil (As >2000 ppm; Lower Silesia, Poland) was evaluated.

Three bioreactors were operated in parallel assessing 1) inherent As reducing capacity of the soil; 2) biostimulation with external electron donor and 3) bioaugmentation with dissimilatory arsenate reducing microorganisms. Mobilization rates of As, Fe, Mn were anlyzed using ICP-MS, whereas aqueous As speciation was analysed by LC-ICP-MS. Potentially formed hazardous As volatiles were trapped in 1% H_2O_2 (Fig.1). Addition of an external electron donor resulted in both lower total and bioavailable As fraction in soils. Different iron phases were evaluted for their As sorption/desorption capacity of different As species following microbial mobilization. Nanosized ferrihydrite prooved to be the most effective and cheap As sorbent evaluated.

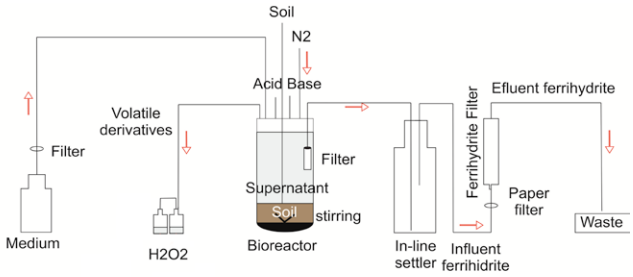

Figure 1: Scheme of bioreactor design.

Elevated pressure of carbon dioxide affects growth of thermophilic *Petrotoga* sp.

JANA RAKOCZY[1]*, CLAUDIA GNIESE[2], AXEL SCHIPPERS[1], MICHAEL SCHLÖMANN[2] AND MARTIN KRÜGER[1]

[1]Bundesanstalt fuer Geowissenschaften und Rohstoffe (BGR), Stilleweg 2, D-30655 Hannover

[2]Institut für Biowissenschaften, TU Bergakademie Freiberg, Leipziger Str. 29, D-09599 Freiberg

Carbon capture and storage (CCS) is considered a promising new technology which reduces carbon dioxide emissions into the atmosphere and thereby decelerates global warming. However, with CCS being a very young technology, there are yet a number of factors that need to be investigated before declaring CCS as being safe. Our research investigates the effect of high carbon dioxide concentrations and pressures on an indigenous microorganism that colonises a potential storage site.

Growth experiments were conducted in liquid culture using the thermophilic thiosulphate-reducing bacterium *Petrotoga sp*., isolated from formation water of the gas reservoir Schneeren (Lower Saxony, Northern German Plain). Growth (OD_{600}) was monitored over 10 days at different carbon dioxide concentrations (50%, 100%, and 150% in the gas phase), and was compared to cultures grown with 20% carbon dioxide. An additional growth experiment was performed over a period of 145 days with repeated subcultivation steps to detect long-term effects of carbon dioxide. Short-term cultivation at 50% and 100% carbon dioxide slightly reduced cell growth. In contrast, long-term cultivation at 150% carbon dioxide reduced cell growth and finally led to cell death. This suggested a more pronounced effect of carbon dioxide at prolonged cultivation and stresses the need for closer consideration of long-term effects.

Experiments with supercritical carbon dioxide at 100 bar completely inhibited both growth of a freshly inoculated culture and a pre-grown culture demonstrating the lethal effect of supercritical carbon dioxide. This effect was not observed in control cultures with 100 bar of hydrostatic pressure.

Evaluating the Role Mafic Crustal Assimilation in the Generation of Western US Continental Basalts

RAMOS, FRANK C., GLADISH, E., SLATER, N. AND PALIEWICZ, C.[1]

[1]New Mexico State University, Las Cruces, NM 88003 USA

Western US continental basalts are generally thought to reflect pristine geochemical and isotopic signatures inherited from heterogeneous mantle sources. Such thoughts rely on a lack of magmatic interactions with crustal sources. Assessments for the role of potential crustal interactions typically focus on modifications expected for Si-rich materials such as increased SiO2 or highly elevated trace elements such as Ba. In contrast, mafic crustal assimilation may impart only limited SiO_2 and trace element variations depending on the exact nature of the mafic crust and the degree to which the mafic materials are melted. Tholeiites and alkalic basalts erupted along and the Colorado Plateau-Rio Grande rift transition zone and within the Rio Grande rift itself retain geochemical and isotopic variations that are similar to those expected to result from mafic crustal assimilation. Results allow for the possibility that asthenospherically derived magmas assimilated variable amounts of mafic crust resulting in a range of isotopic and geochemical characteristics that are similar to those expected for trace element enriched heterogeneous subcontinental lithospheric mantle sources. Whole rock isotope signatures in a few of the younger flows (e.g., Bandera and McCartys flows, Zuni Bandera volcanic field, and the Carrizozo flow, Rio Grande rfit) vary extensively (e.g., 87Sr/86Sr of 0.7028 to 0.7035 for the Bandera flow, 0.7037 to 0.7084 for the McCartys flow, and 0.7044 to 0.7052 for the Carrizozo flow) and are consistent with more complicated petrogenetic histories involving a range of potential mantle and crustal sources. Here, we present phenocryst and melt inclusion major and trace element compositions to identify and track chemical variations retained in whole rocks and melt inclusions and integrate isotopic signatures of these components imposed during crystallization. Additional mineral signatures of plagioclase and xenocrystic materials will be discussed and the petrogenetic histories of selected young alkalic and tholeiitic basaltic from the Rio Grande rift and Zuni-Bandera volcanic field will be assessed to evaluate the potential role of mafic crustal assimilation in the genesis of respective trace element and isotopic signatures of these continental basalts.

Melt-rock reaction in oceanic troctolites (Ligurian ophiolites, Italy) as revealed by trace element chemistry of olivine

E.RAMPONE[1]*, G.BORGHINI[1,2], L.CRISPINI[1], M.GODARD[3], B.ILDEFONSE[3] AND P.FUMAGALLI[2]

[1]DISTAV, University of Genova, I-16132 Genova, Italy (*correspondence: betta@dipteris.unige.it)
[2]University of Milano, I-20133 Milano, Italy
[3]UMR CNRS, Universite Montpellier 2, Montpellier, France

Several recent studies have documented that reactions between melt and crystal mush in primitive gabbroic rocks (via reactive porous flow) has an important control in the formation of the lower oceanic crust and the evolution of MORBs. In this context, an open issue concerns the origin of olivine-rich rocks, whether they formed by fractional crystallization of primitive melts or by open system reactive percolation of pre-existing (possibly mantle-derived) olivine matrix. To address this topic, we performed high-quality in-situ trace element analyses (by LA-ICP-MS) of olivine in the ideal study case of the Erro-Tobbio ophiolite Unit (Ligurian Alps), where mantle peridotites show gradational contacts with an hectometer-scale body of troctolites and plagioclase wehrlites, and both are cut by later decameter-wide lenses and dykes of olivine gabbros. Previous studies [1] inferred that they represent variably differentiated crystallization products from primitive MORB-type melts. Olivines in the three rock types (mantle peridotites, troctolites, ol-gabbros) exhibit distinct geochemical signature and well-defined elemental correlations. As expected, compatible elements (e.g. Ni) show the highest contents in peridotites (2580-2730 ppm), intermediate in troctolites (2050-2230 ppm) and lowest in gabbros (1355-1420 ppm), whereas moderate incompatible elements (e.g. Mn, Zn) show the opposite behaviour. By contrast, highly incompatible elements like Zr, Hf, Ti, HREE are variably enriched in olivines of troctolites and the enrichment in absolute concentrations is coupled to development of significant HFSE/REE fractionation (Zr_N/Nd_N up to 80). Preliminary AFC modeling show that such large Zr_N/Nd_N ratios in olivines are consistent with a process of olivine assimilation and plagioclase crystallization at decreasing melt mass, in agreement with textural observations. In-situ trace element geochemistry of olivine, possibly combined with CPO measurements, thus appears a powerful tool to investigate reactive percolation and the origin of olivine-rich rocks in the lower oceanic crust.

Quantification of the *in situ* heterogeneity of RMs for microanalytical methods

MICHAEL H. RAMSEY[1] AND MICHAEL WIEDENBECK[2]*

[1]University of Sussex, UK; (m.h.ramsey@sussex.ac.uk)
[2]Helmholtz Zentrum Potsdam, Germany (*correspondence: michael.wiedenbeck@gfz-potsdam.de)

A range of laboratory techniques is available for the geochemist wishing to characterize the chemical and/or isotopic compositions of solid materials at the nanogram or smaller sampling mass range. Examples of widely available techniques are based on the electron probe, laser ablation ICP-MS and secondary ion mass spectrometry (SIMS).

When operating at such small test portion masses there are three fundamental requirements that a reference material (RM) should enable: (1) method calibration, which is typically based on one or a few discrete fragments of the RM, (2) evaluation of method repeatability, which is commonly based on multiple analyses on a single RM fragment, and (3) method development and validation. An additional consideration is that most such materials must necessarily be characterized using laboratory methods operating at the milli-gram or larger sampling scale.

In order to meet all of these requirements it is evident that a microanalytical RM must be assessed for heterogeneity *in-situ* at a variety of scales, and that the corresponding heterogeneity component must be considered for each application being undertaken. When calibrating an instrument it is essential to know the likely variation between the mean content of individual sample aliquots (chips or fragments). This information can commonly be obtained from "bulk sample" analyses conducted on mm-sized units, be it via wet chemical, gas source mass spectrometer or other methods. For evaluating the repeatability of a microanalytical method it is necessary that the *in situ* heterogeneity of the material be quantified at the equivalent sampling scale. For method development and validation a detailed knowledge of a RM's major element composition, as well a knowledge of its heterogeneity at the given sampling scale, are both necessary.

Our work focuses on developing experimental and mathematical tools that will quantify *in situ* heterogeneity at the various sampling scales while taking into account the analytical uncertainties intrinsic to the laboratory method being used to characterize such variations. The ultimate goal of our work is to enable SIMS to assess in detail the isotopic characteristics of candidate RMs at sampling masses well below 1 ng and with overall heterogeneity being evaluated at the < 0.1 ‰ level.

Cryo-XPS monitoring of cell wall compositional changes for *Bacillus subtilis* as a function of pH and Zn^{2+} exposure

MADELEINE. RAMSTEDT*, LAURA. LEONE, ANDREY. SHCHUKAREV AND PER. PERSSON

Department of Chemistry, Umeå University, 90187 Umeå, Sweden,
correspondance: madeleine.ramstedt@chem.umu.se

Bacteria such as *Bacillus subtilis* and *Escherichia coli* adjust and alter their gene transcription and protein production depending on the environment they are exposed to. For example, membrane-bound protein complexes are up-regulated at high pH in *B. subtilis* and several enzymes that reduce acidity and transport metals out of the cell are up-regulated at low pH [1]. It has also been reported that building blocks in the cell wall change with varying pH.

X-ray Photoelectron Spectroscopy (XPS) is a surface sensitive analysis method that has been used by several researchers to successfully analyze the chemical composition of bacterial cell walls [e.g. 3,4,5]. In this presentation we will show how we have used cryo-XPS together with a recently developed curve fitting model to predict the chemical composition of the surface of bacterial cells [2]. We have used this to study changes in the surface composition of *B. subtilis* exposed to environments with varying pH and/or Zn^{2+} content. We will also compare the obtained ratios of different substances with ratios obtained using previously published methods based on equation systems [3,4,5].

(*correspondence: marie-eve.randlett@eawag.ch)

The successful drilling operations of the International Continental Scientific Drilling Program (ICDP) PaleoVan project allowed the recovery of 220-m long sediment cores, which represents approximately the last 600 ka. This exceptional climatic archive was investigated for two relevant organic molecular proxies; alkenones and hydrogen stable isotopic composition of n-alkanes C29 (δD of n-C_{29}). The potential of unsaturation patterns in alkenones for reconstructing past temperatures in Lake Van was assessed through investigation of algae types responsible for alkenones biosynthesis using ancient DNA stratigraphy. The diversity of alkenones producers within the core hampered the use of a single calibration curve for reconstructing temperature based on alkenone unsaturation patterns, as found elsewhere [1,2]. On the other hand, the δD of n-C_{29} co-vary with the salinity of the pore water profile in Lake Van. The latter organic proxy therefore seems to be a promising tool for reconstructing changes in the source water salinity due to variable precipitation/evaporation ratio, as previously suggested [3].

$\Delta^{17}O, \delta^{17}O, \delta^{18}O$ variation in precipitated water at Jungfraujoch (3571 m) - relation to meteorological parameters and low altitude stations

S. RANJAN[1] AND M. LEUENBERGER[1]

1Climate and Environmental Physics, Physics Institute and Oeschger Centre for Climate Change Research University of Bern, Bern, Switzerland shyam@climate.unibe.ch (* Presenting Author)

We have analysed precipitated water sample of seven stations from high altitudes Jungfraujoch (3571 m) to low altitudes Basel (292 m). $\Delta^{17}O$, $\delta^{17}O$, $\delta^{18}O$ was analysed for Jungfraujoch (A) from 1983 to 2011 and Grimsel (B), Guttanen (C), Meiringen (D), Locarno (E), Bern (F) and Basel (G) from 2003 to 2005. pH, temperature, relative humidity, air pressure and precipitation data was available through MeteoSwiss. $\Delta^{17}O$, $\delta^{17}O$, $\delta^{18}O$ and pH variations were analysed by using the conventional CO_2-equilibrium method and a pH sonde with a repeatibility of ± .01 pH unit. Positive correlation were found between $\delta^{18}O$ & $\delta^{17}O$, temperature and relative humidity, while poor correlation were found between $\Delta^{17}O$ & $\delta^{18}O$, $\Delta^{17}O$ & $\delta^{17}O$, pH & relative humidity, air pressure and precipitation of all station. Year 2003, one of the hottest period of Europe and at the same period, highest $\Delta^{17}O$ values were observed at station A, C, D, G but not at station B, E & F which require further in-depth research. Interestingly, the decreasing trend of pH was observed at all stations. Except at the station G, highest pH of all stations was greater than 10 pH unit while lowest pH was less than 3 units at station A. Only station A is mostly exposed to the free troposphere and receive signals at a continental scale. Contrary to all others stations, low pH was observed mainly during 1991 to 1993 period at station A, which is originating most probably from multiple large volcanic erruptions (Pinatubo, which was 2nd largest eruption of 20th century). Increasing concentration of atmospheric CO_2 have only a small effect on pH changes in precipitated water compared to the results we have observed. Further explainations will be given in the presentation.

U-Pb Dating of Carbonates and Fluorite: Prospects for Understanding Fluids from Deposition Through Burial

Minerals such as carbonates and fluorite record information about the fluids from which they formed such as the salinity, temperature, degree of rock-water interaction, as well as details of the source(s) of these fluids. The U and Pb concentrations, U oxidation state and molecular speciation and Pb isotope compositions in these minerals may reveal important information about the nature of the fluids and, in favorable cases, can be used to date the time of mineral formation. The application of emerging *in situ* microbeam analytical techniques such as synchrotron XRF, LA-ICP-MS, and SIMS offers the possibility of tracking the mineralogical and geochemical evolution of these minerals from the time of deposition of limestones through burial diagenesis, faulting and vein formation. Dating of the time of deposition provides a framework for understanding the climate history and fossil information encoded in the rock. Key genetic aspects for ore and hydrocarbon deposits could be provided by a more thoroughly dated history of formation. The timing of tectonic events may be constrained by dating vein fillings of associated fault and fracture systems.

Studies have shown great potential for U-Pb and U-series dating of carbonates precipitated from meteoric fluids and for dating of vein calcite, associated with faulting and with ore mineralization. We will review these studies with insights based on synchrotron and laser ablation work, and present new work on the application of U-Pb dating of fluorite and calcite from a variety of settings, and discuss the expanding applications of these methods to geological problems.

The selective sorption of K^+ from water solutions by Ca-zeolites

SERGEY V. RASHCHENKO[12]* AND LIDIA K. KAZANTSEVA[1]

[1]Sobolev Institute of Geology and Mineralogy SB RAS, 3 Koptyug Avenue, 630090 Novosibirsk, Russia (*Correspondence: rashchenko@igm.nsc.ru)
[2]Novosibirsk State University, 2 Pirogov Street, 630090 Novosibirsk, Russia

The geochemistry of potassium during subduction-related processes does not seem to be a solved problem yet. The important role of subducted oceanic lithosphere as a potassium source for alkali-rich subduction magmatism was repeatedly discussed [1]. However, MORB basalts contain less than 0.16% of K_2O [2] and so cannot be considered as important source of this component. To avoid such discrepancy, some authors consider terrigenous sediments to enrich subducting lithosphere in K_2O [3]. We suggest the alternative mechanism of this enrichment consisting in cation exchange between seawater and zeolitized rocks of the ocean floor. To prove the probability of such process we carried out the experimental modeling of interaction between Na^+/K^+ water solutions and Ca-zeolites as common secondary minerals appearing during hydrothermal alteration of basalts.

The water solution with Na^+/K^+ molar ratio close to that of seawater (0.06) was used in our experiments. The obtained results for laumontite and stellerite are given in the Table 1.

%	Laumontite	Stellerite
CaO	7.34 → 5.51	8.03 → 2.27
Na_2O	1.56 → 2.67	0.14 → 4.71
K_2O	0.47 → 1.43	0.05 → 2.46

Table 1: The change in the cation composition of Ca-zeolites due to 30 days of hydrothermal treatment by Na^+/K^+ solution.

As one can see, a significant change in cation composition of Ca-zeolites occurs after interaction with Na^+/K^+ water solution. Moreover, the K^+/Na^+ molar ratio of alkali cations absorbed by laumontite (0.58) and stellerite (0.35) clearly demonstrates the selective sorption of K^+ from solution with low K^+/Na^+ ratio (0.06). Such phenomenon caused by features of zeolites crystalline frameworks probably plays an important role in interaction of zeolitized rocks of ocean floor with seawater and enriches the sedimentary part of oceanic litosphere in potassium.

Integrated geo-microbial and adsorbed soil gas studies with seismic data interpretation for successful evaluation of Hydrocarbon Resource Potential

M. A. RASHEED*., SANTOSH DHUBIA., SYED ZAHEER HASAN., B.KUMAR AND P.H.RAO

Petroleum Research Wing, Gujarat Energy Research and ManagementInstitute, Gandhinagar, Gujarat, India. abdul@germi.res.in

The hydrocarbon microseepage of light hydrocarbon gases (C1 – C4) can be identified using geochemical means, which provides evidence of charge traps and structures. These light hydrocarbon microseepage gases likewise directly influence shallow anaerobic soil and sediment environments, creating a spectrum of microbial activity. The indicator light hydrocarbon oxidizing bacteria are isolated and enumerated using microbial techniques. Therefore, an integrated and complementary microbial microseepage signature can identify gaseous hydrocarbon microseepage, which occurs directly above charged oil and gas reservoirs in on/offshore region. Present day exploration for oil and gas requires a coordinated effort based on the synergy of geophysics, geology, and geochemistry. The proposed study aims at integrated approach interpreting the geochemical and seismic data to understand the mechanism of hydrocarbon seepage and to evaluate the hydrocarbon potential as well. The main objective of the study is to integrate the seismic and the geochemical data. The seismic gives a clear picture of subsurface tectonics, structures, faults, factures and reservoir distribution and extension (Attributes) Integrating the subsurface with the surface geochemical data, helps to know the seepage pattern and type of system. Such a study, will lead to the successful exploration. It will be more useful in the virgin areas, and also during Exploration and Development of the fields.

Algal biofuels: A sustainable pathway to mitigate energy demand

MOHAMMED ABDUL RASHEED*, SYED ZAHEER HASAN AND B.KUMAR

Petroleum Research Wing, Gujarat Energy Research and Management Institute,
Gandhinagar, Gujarat, India.
*(Correspondence: abdul@germi.res.in)

Algal fuels are generating considerable interest around the world. These fuels may represent a sustainable pathway for helping to meet the energy demand. Algae is a preferred biodiesel base because algae grow more rapidly and occupy less space compared to other plants used for biodiesel such as corn, soy, canola and other lipid producing organisms. The algae strain, *Chlorella vulgaris*, contains 30% lipids by mass. Thus, a common goal is to create a manageable and cost effective process for manufacturing biodiesel on a large scale. Microalgae are single-cell, photosynthetic organisms known for their rapid growth and high energy content. Some algal strains are capable of doubling their mass several times per day. In some cases, more than half of that mass consists of lipids or triacylglycerides—the same material found in vegetable oils. These bio-oils can be used to produce such advanced biofuels as biodiesel, green diesel and green oil[1]. Algae consume carbon dioxide as they grow, so they could be used to sequester CO_2 being released from power stations and other industrial plant that would otherwise go into the atmosphere. Meeting the world's fastly growing energy demands will require a multitude of sources. Several private and government agencies are putting efforts to reduce capital and operating costs and make algae fuel production commercially viable. The challenges that need to be addressed are, the exploitation of naturally occurring photosynthetic microalgae, which provides a green and renewable resource of feedstock biomass to meet increasing energy needs and especially the demand for liquid fuels thereby isolation, screening and evaluation of naturally occurring algal strains which exhibit high growth rate and large-scale photo bioreactor design and optimization, to outdoor mass culture and downstream processing. Challenges to be addressed include refinement of the cultivation process, downstream processing of biomass, and development of an economic feasibility model for commercialization of algae-based biofuels and biomaterials.

Oxygen isotopes ($\delta^{18}O$) and Mg/Ca in the *Globigerinoides ruber* (w) are analysed from the Bay of Bengal and Andaman Sea sediments. Mg/Ca, Cd/Ca and B/Ca are also determined in *Cibicidoides wuellerstorfi* and *Uvigerina peregrina* in two cores from the same basins. Furthermore, neodymium isotopic ratios (ε_{Nd}) of seawater in two sediment cores are determined. Our results show that seawater oxygen isotope values were most enriched between 17.8 and 14.6 ka. We also find coincidence between the onset of intermediate water warming at 17.8 ka, and the onset of increase in atmospheric CO_2. In the tropical Indian Ocean, the deep water (>2,200 m) warmed after the surface, in sharp contrast with the warming found in the intermediate water which occurs earlier. Furthermore, an inverse relationship between the intermediate and surface waters is also found during the Bolling-Allerod and Younger Dryas periods in which surface water warmed (cooled) and intermediate water cooled (warmed). We hypothesize that the cause of warming of the northern tropical Indian Ocean intermediate water does not lie within the tropics, rather an increase in Southern Hemisphere spring insolation combined with sea-ice albedo feedbacks, consistent with the hypothesis suggested earlier. The hypothesized mechanism involves an increase in upper circumpolar deep-water circulation into the Indian Ocean.

Nitrate- and nitrite dependent anaerobic oxidation of methane

OLIVIA RASIGRAF[1], BAOLI ZHU[1], DORIEN M. KOOL[2], MIKE S. M. JETTEN[1] AND KATHARINA F. ETTWIG[1]

[1]Department of Microbiology, IWWR, Radboud University Nijmegen, The Netherlands
[2]Royal NIOZ, Department of Marine Organic Biogeochemistry, Texel, The Netherlands

The first described enrichment culture capable of anaerobic oxidation of methane (AOM) coupled to nitrite and nitrate reduction was a consortium of *Methylomirabilis oxyfera* bacteria (80%) and archaea (10-20%) [1], the latter later named AOM-associated archaea (AAA) [2]. However, after prolonged incubation (several months) with elevated nitrite the AAA disappeared from the enrichment culture, and *M. oxyfera* bacteria were shown to oxidize methane without an archaeal partner. Subsequent isotope labeling studies with *M. oxyfera* showed that it can produce oxygen from nitric oxide, which is then used for methane oxidation via a monooxygenase reaction [3]. The isotope fractionation factors for carbon and hydrogen during methane oxidation by *M. oxyfera* were determined, and were in the same range as previously reported for aerobic methanotrophs [4]. Recently we investigated the capacity of *M. oxyfera* bacteria to fix CO_2 via the Calvin-Benson-Bassham cycle and their unusual lipid composition. Furthermore, based on the genomic information and physiological studies, the AAA were shown to possess the capacity for reverse methanogenesis and nitrate reduction. AOM by both *M. oxyfera* and AAA is of great interest for the understanding of and the linkage between the biogeochemical cycles of methane and nitrogen.

Deposition of the precursor sediments of banded iron formations

B. RASMUSSEN[1]*, B. KRAPEZ[1], J.R. MUHLING[1,2] AND D.B. MEIER[3]

[1]Dept of Applied Geology, Curtin University, Kent Street, Bentley, WA 6102, Australia (*correspondence: b.rasmussen@curtin.edu.au)
[2]CMCA, The University of Western Australia, Stirling Highway, Crawley, WA 6009, Australia
[3]School of Earth and Environment, The University of Leeds, Leeds, LS2 9JT, United Kingdom

Banded iron formations (BIFs) are derived from iron-rich chemical sediments whose composition is used to make inferences about the early Precambrian ocean, atmosphere and biosphere. Before geochemical information from BIFs can be reliably interpreted, their origin and post-depositional history must be understood. However, the identity of the original sediments and how those sediments were deposited is contentious due to a long history of post-depositional overprinting and the absence of direct modern analogues. Most depositional models are based on the interpretation that the initial precipitate comprised ferric oxyhydroxides that formed when ferrous iron was oxidized in the water column and settled on the seafloor. The lack of well-defined grain-shapes and current-generated structures has been used to infer a pelagic origin for the primary sediments.

New sedimentological and petrographic studies of well-preserved intersections of BIF in the 2.63-2.45 Ga Hamersley Group, Western Australia, show the presence of abundant silt-sized spherical particles (or microgranules) in mm-thick chert microbands. The microgranules are most common in the least-altered BIF where they define sedimentary laminations, implying a depositional origin. They were deposited in lamina sets comprising a basal microgranule-rich lamina overlain by amorphous mud with dispersed microgranules. Seafloor silicification is interpreted to have preferentially replaced the amorphous clay matrix, implying that the precursor sediment must have comprised two particle sizes: silt and clay. Micrograding is interpreted to record plane laminations resulting from deposition of iron-rich muds entrained in dilute turbidity currents. The presence of micrograded structures in other BIFs, implies that resedimentation of precursor sediments was common.

A model is proposed in which ferruginous oceans with elevated silica favoured the growth of iron-silicate minerals proximal to active ridge systems. The hydrothermal muds accumulated on a sloping seafloor and were resedimented by dilute turbidity currents, and deposited on the basin floor as thin, laterally extensive sheets.

Mantle Source Characteristics and Petrogenesis in the Lunar Crater Volcanic Field

C. RASOAZANAMPARANY[1], E. WIDOM[1]*, J.A. CORTES[2], E.I. SMITH[3], G.A. VALENTINE[2], D. KUENTZ[1] AND R. JOHNSEN[3]

[1]Department of Geology, Miami University, Oxford, USA, widome@muohio.edu (*presenting author)
[2]Department of Geology, State University of New York, Buffalo, USA, gav4@buffalo.edu
[3]Department of Geoscience, University of Nevada, Las Vegas, USA, gene.smith@unlv.edu

The nature of the mantle sources and the role of lithospheric assimilation in producing compositional variations in basaltic monogenetic volcanic fields remains controversial. To address these issues, we have performed major and trace element and Sr, Nd, Pb, Hf and Os isotope measurements on 19 mafic lavas from 4 volcanic centers in the northern Lunar Crater Volcanic Field (LCVF), Nevada. Three eruptive centers (Giggle Springs, <100 Ma; and Hi Desert and Mizpah, ~620-740 Ma) are located within ~500 m of each other; the Marcath volcano (~40 ka), the youngest eruptive center in the field, is located ~6 km SW of these cones. The lavas have essentially constant Nd and Hf isotope ratios, but significant heterogeneity in Sr and Pb isotopes, and superchondritic Os isotope ratios. The older Mizpah and Hi Desert lavas exhibit HIMU-like trace element and Sr-Pb isotope signatures, with Nb-Ta enrichment, Rb, Cs and K depletion, and high $^{206}Pb/^{204}Pb$ but low $^{87}Sr/^{86}Sr$. In contrast, the younger Marcath and Giggle Spring lavas have enriched mantle (EM) type signatures with high Ba, Rb and Cs, and lower $^{206}Pb/^{204}Pb$ and higher $^{87}Sr/^{86}Sr$. Together, the LCVF lavas produce a negative correlation between Sr and Pb isotopes that could be attributed to lower crust assimilation. However, the lack of correlation of isotopes with indices of fractionation, OIB-like Nb/U ratios, and a positive correlation of $^{187}Os/^{188}Os$ with Nb/U argue against an important role for crustal assimilation. Instead, the compositional variations are attributed to heterogeneous mantle sources. Mixing models indicate that incorporation of ~18% of 0.8Ga recycled oceanic crust into a depleted mantle source can explain the trace element and isotopic signatures of the HIMU lavas. Subsequent addition to the HIMU-like source of minor (~1%) hydrous fluid derived from subducted oceanic crust could account for the chemical and isotopic compositions of the EM lavas. Our data indicate that the mantle source region in the LCVF is characterized by chemical and isotopic heterogeneity over a very small spatial scale (<500m), and that the nature of the mantle source and the depth of melt generation has changed systematically with time.

Compositions and zoning of coexisting minerals in alkaline-ultrabasic rocks, phoscorites, and carbonatites from the Kovdor Complex, Kola Peninsula

I. RASS AND E. KOVALCHUK

Institute of Geology of Ore Deposits, Petrography, Mineralogy & Geochemistry, Russ. Acad. Sci., 35 Staromonetny, 119017 Moscow, e-mail: rass@igem.ru

The compositions of coexisting pyroxene, magnetite, perovskite, schorlomite, titanite, and apatite in silicate and carbonate rocks were studied by electron-probe microanalysis (EPMA) techniques. The principally different major- and trace-element compositions and zoning of the above minerals from magmatic and metasomatic rocks reflect their different crystallization circumstances (P, T, fO_2, pCO_2 $aSiO_2$) in the Earth's crust. Magnetite in silicate rocks is noticeably richer in Ti than this mineral in carbonatites and phoscorites. The Ti content decreases from the cores to rims of magnetite crystals in any magmatic rock but shows the opposite tendency in magnetite of metasomatic Ne-Px rocks. A higher proportion of the magnesioferrite component in magnetite from phoscorites compared to that in silicate rocks is likely attributed to higher oxygen fugacity during the crystallization of the former. Apatite in younger derivatives of silicate rocks bears higher Sr concentrations. Its crystals exhibit core-to-rim variations in the contents of F (by up to 3.2 wt.%), REE, and SiO_2. The F content increases in apatite from magmatic rocks and decreases in that mineral from metasomatic ones. The SiO_2 content of apatite in silicate rocks reaches ~1 wt.% and shows a core-to-rim increase, whereas its concentrations in carbonatitic and phoscoritic rocks are noticeably lower. The presence of Si-rich apatite suggests its crystallization at shallower depths, at which CO_2 activity is lower. The occurrence of Ti-rich andradite and titanite in Px-Ne rocks instead of perovskite is due to a higher $aSiO_2$.

Diurnal Chemical Characteristics of $PM_{2.5}$ over a Source Region of Biomass Burning Emissions in the Indo-Gangetic Plain

RASTOGI N[1], SINGH A[2] AND SINGH D[2]

[1]Geosciences Division, Physical Research Laboratory, Ahmedabad, India
[2]Department of Physics, Punjabi University, Patiala, India
nrastogi@prl.res.in

Wintertime haze/fog has been observed every year over the Indo-Gangetic Plain (IGP); however, the understanding on corresponding particulate composition is meager. The diurnal chemical characteristics of $PM_{2.5}$ were investigated during October-2011 to March-2012 at a site (Patiala, 30.2 ^{o}N, 76.3 ^{o}E; 250 m amsl) located in the source region of biomass burning emissions over IGP. The study period covers characteristic emissions from post harvest paddy-residue burning during October-November (P1), from fossil, wood, and bio-fuel burning during December-February (P2), and from variable regional sources during March (P3).

A striking diurnal variability was observed in $PM_{2.5}$ mass, SO_4^{2-}, NO_3^-, NH_4^+, K^+, OC, EC, and WSOC during P1 with ~30 to 300% higher concentrations of species in nighttime samples. The averaged WSOC/OC ratios for daytime and nighttime samples were ~0.65 and 0.47, respectively in all seasons, suggesting the enhanced daytime secondary organic aerosols formation. The NO_3^- was comparable and OC was higher than SO_4^{2-}, indicating their importance as scattering species over IGP. The averaged $(OC + SO_4^{2-} + NO_3^-)/EC$ ratios for the daytime samples were ~12, 15 and 5.5, and for the nighttime samples were ~18, 14, and 6 during P1, P2 and P3, respectively, indicating the dominance of scattering type species in all the seasons with noticeable diurnal difference during P1, and the contribution of absorbing species (EC) increases from P1 to P3. A strong linear correlation ($r^2 = 0.86$) has been observed between all daytime and nighttime OC and K^+, suggesting that the K^+ can be used as a tracer for biomass burning emissions over IGP with the OC/K^+ characteristic ratio of ~16. Water-soluble species were dominant (≥55%) in $PM_{2.5}$ during winter (P2), and could be the major contributor to fog formation over IGP under favourable meteorological conditions. This study has implications in understanding the effects of biomass burning emissions on regional air quality and climate over IGP, and designing appropriate mitigation strategies.

Isotopic evidence for a crustal Pb source in the giant Broken Hill Pb-Zn-Ag deposit, NSW, Australia

MASSIMO RAVEGGI[1]*, DAVID GILES[2], JOHN FODEN[2], SEBASTIEN MEFFRE[3], MIKE RAETZ[1] AND IAN NICHOLLS[1]

[1]School of Geosciences, Monash University, Melbourne, Australia.

John.Foden@adelaide.edu.au
[3]CODES, The University of Tasmania, Hobart, Australia.
smeffre@utas.edu.au

The Paleo to Meso-Proterozoic Willyama Supergroup, together with the Broken Hill Pb-Zn-Ag deposit, hosts a wide variety of unusual rocks with mineralogical compositions comprising various proportions of quartz ± Fe-oxide ± garnet ± accessories (QFeGA), as well as mafic and felsic ortho-gneisses that intruded at ca. 1685 Ma. Major, trace, REE and U/Pb zircon geochronology data suggests that the QFeGA lithologies are syn-sedimentary, hydrothermal meta-sediments with limited detrital input, similar to hydrothermal sediments forming at present day spreading centers. Neodymium isotope data suggests that the hydrothermal fluids responsible for their deposition were in equilibrium with the Willyama Supergroup (meta)sedimentary sequences.

Lead isotope data from the mafic and felsic ortho-gneisses lie within error on the same 1685 Ma $^{207}Pb/^{206}Pb$ reference isochron with an initial Pb isotope composition of Broken Hill orebody (galena). This is inconsistent with independent geochemical evidence showing that the mafic and felsic ortho-gneisses were derived from end-member mantle and crustal sources respectively. It is inferred that Pb isotope data is the result of a period of regional homogenisation due to pervasive crustal hydrothermal flux at the time of emplacement of the mafic and felsic rocks (ca. 1685 Ma). This is coincident with formation of the QFeGA rocks and the Broken Hill deposit. It is interpreted that the Pb (and other metals) scavenged by this hydrothermal system from the Willyama Supergroup (meta)sedimentary sequences, provided the metals for the Broken Hill orebody

[5]University of North Carolina, Chapel Hill, jezinglis@gmail.com

Oscillations of sea level, whether rapid or gradual, influence the degree and style of shorline formation including reef framework construction, destruction, and preservation. Using insight from modern shoreline systems, members of the PLIOMAX project have mapped mid-Pliocene, MIS11, and MIS5e shorelines at numerous localities around the world and modeled the effects of subsequent glacial isostatic adjustment (GIA) on their current position. For both MIS5e and MIS11 we conclude that an ice sheet stability threshold was crossed in the last few kyr of each interglacial resulting in the catastrophic collapse of polar ice sheets with a rise in eustatic sea level to ~9m or more above present. We further show that dynamic topography, supported by convectively maintained stresses generated by viscous flow in the mantle and associated buoyancy variations in the lithosphere, plays a significant role in the post-depositional displacement of Pliocene and even much younger Pleistocene shorelines. We will discuss how we are using predicted global patterns of GIA and dynamic topography to guide field efforts aimed at extracting the eustatic component of sea level change during past warm climates. We also discuss how our field data is helping, in turn, to constrain uncertainties in models of both GIA and the long-term convective evolution of the Earth (uncertainties in mantle viscosity, for instance).

Giving microbial communities a solar supercharge: does the transition to photosynthesis in extreme environments drive taxonomic, biochemical, and metabolic novelty?

JASON RAYMOND, ERIC ALSOP AND MATTHEW KELLOM

School of Earth & Space Exploration, Arizona State Uni.

A combination of prolific biological diversity and steep physical and geochemical gradients make hydrothermal ecosystems outstanding environments for understanding the dynamic interplay between life and environment. Our work investigates taxonomic (e.g. 16S rRNA), metagenomic, and transcriptomic profiling of microbial communities in extreme environments. One such study focuses on communities occurring along a 40+ degree C temperature gradient in a geochemically well-characterized alkaline hot spring in Yellowstone National Park (YNP). The communities along this single outflow channel show changes in community organization, metabolism, and (taxonomic) biodiversity that can be directly related to changes in the geochemistry of their aqueous environments.

One unexpected result of this work comes at the so-called photosynthetic fringe, where "hot" chemotrophic metabolism gives way to "cool" phototrophy. This transition occurs between 55 and 73 degrees C in alkaline YNP springs—an apparent upper temperature limit on photosynthesis that is still poorly understood. While in general, biodiversity increases as temperature decreases, 16S analysis reveals that community diversity—quite unexpectedly—peaks not below but rather just above the onset of photosynthesis, tapering off at both higher and lower temperatures. This increase in biodiversity is not simply the union of lower T photosynthetic and higher T chemotrophic communities; intringuingly, new species not observed in any other communities occur only at this intersection.

We are integrating molecular genetic data with geochemical analyses to investigate several plausible hypotheses for this boost in diversity. Furthermore, this integrated approach provides unprecedented resolution of how the onset of photosynthesis in complex, natural communities results in a dramatic shift not only in the overall numbers but also in the distinct types of biomolecules able to be synthesized by the community at large. Whereas taxonomic diversity is at a maximum above the photosynthetic fringe, biochemical and metabolic diversity is highest below the fringe, where the energetic supercharge provided by photosynthesis makes accessible new and otherwise costly metabolic capabilities.

Finally, we hypothesize that the transitions associated with the photosynthetic supercharge may provide important insights into how the invention of photosynthesis (oxygenic photosynthesis in particular) provided the molecular underpinnings for early life on Earth to achieve new levels of complexity and stands as the single most important biological innovation since the origin of life itself.

STXM characterization of fossil organic matter from the Montceau-les-Mines Lagerstätte (France)

A. RECANATI[1], S. BERNARD[1], D. GERMAIN[2], S. CHARBONNIER[2] AND F. ROBERT[1]

[1]LMCM, UMR 7202, MNHN and CNRS, Paris, France (arecanati@mnhn.fr, sbernard@mnhn.fr, robert@mnhn.fr)
[2]CR2P, UMR 7207, MNHN and CNRS, Paris, France (scharbonnier@mnhn.fr, germain@mnhn.fr)

The fossil record contains key information regarding the evolution of life and environment on Earth. However, decoding this record can be quite challenging as biogenic organic matter (OM) is inevitably altered during fossilization processes. The combination of transmission electron microscopy (TEM) with synchrotron-based scanning transmission X-ray microscopy (STXM) and X-ray Absorption Near Edge Structure (XANES) spectroscopy now offers valuable capabilities for the *in situ* characterization of heterogeneous and organic-rich samples such as fossilized remains [1]. TEM provides spatially-resolved information on organic constituent texture at the sub-nanometer scale, and allows for crystallographic determination. STXM and XANES enable spatially-resolved characterization of organic constituent speciation at the 15 nanometer scale.

Here we report the multiscale characterization of exceptionnally preserved soft-bodied plants and animals fossilized within carbonate concretions from the Carboniferous Montceau-les-Mines Lagerstätte [2]. SEM and TEM investigations have revealed mineralogical and textural heterogeneities at all scale of observations, likely explaining the exceptional morphological preservation of the investigated fossils. STXM experiments (performed using the 5.3.2.2. ALS STXM Polymer beamline [3]) have allowed to evidence the similar molecular signatures of the OM composing the vegetal and the animal remains. We interpret this surprinsing homogeneity as resulting from the replacement of the initial biogenic OM by newly condensed recalcitrant geopolymer compounds during early diagenesis. Altogether, this study illustrates the capabilities of synchrotron-based STXM and XANES spectroscopy to provide molecular-level information on natural OM.

On some feedback-coupling relations between fluid flow, igneous Intrusion, metamorphic / metasomatic events and deformation during low-P high-T regional thermal metamorphism. An example from the Osor high-grade complex (Catalan Coastal Ranges. NE Iberia)

JOAN RECHE[1] AND FRANCISCO J. MARTÍNEZ[1]

[1]Departament de Geologia. Universitat Autònoma de Barcelona, 08193 Bellaterra (Cerdanyola del Vallés) Barcelona, Spain. (joan.reche@uab.cat)

Bulk composition (BC) controls assemblages and rheology of metamorphic rocks. BC changes are expected in deep crustal levels due to advective phenomena such as pervasive to channelized fluid or melt flows. Imperatively the following coupled phenomena should be investigated: a) How BC changes influence mineral assemblages b) How resulting rheological changes influence deformation regimes, and c) How subsequent P-T evolution occurs.

In the Osor complex we found evidence for sin-D2 fluid flow during a LP/HT thermal metamorphic event at c. 320 my (age of syn-D2 Susqueda diorite) and also retrograde fluid flow related to leucogranite crystalization at c. 300 my. Prograde flow may have produced modal depletion in q and K-Na phases (mu or pl), and modal increase in fibrolite giving sil-enriched D2 foliation planes, through carrying away SiO_2 and alkalis. Local migmatization and genesis of peraluminous granitoid melts probably contributed also to the silica and alkalis depletion. Retrograde fluids from crystallization of sin-D3 granitoid veins recycled silica and alkalis back to the series and produced growth of blastic mu, bi and Na-rich pl. The recycled silica is found as sets of late q-rich veins. The final result are altered surmicaceous, q-poor rocks with different rheological properties with respect to the original metapelites. The genesis of this rheologicaly week lithology would have enhanced late gravitational instability [1] during the final stages of D2. Subsequent deformation (D3) shows SCC foliation planes, fish-like micas and porhyroclastic albite, which are features related to uplift-exhumation of the Osor high-grade core.

A Simple Method to Filter Arsenic From Water using CuO Nanoparticles

K.J. REDDY AND K.J. MCDONALD[1]

[1]Department of Ecosystem Science and Management, University of Wyoming, Laramie, WY 82071, USA (katta@uwyo.edu)

A continuous flow-through reactor with CuO nanoparticles (NPs) was developed to filter arsenic (As) from groundwater samples. Natural groundwater samples as well as spiked with 100 µg/L of As were passed through (1L per hr) the flow-through reactor to filter As. Samples from the flow-through reactor were collected at a regular interval and analyzed for As and other chemical components (e.g., pH, major and trace elements). The CuO NPs adsorbed with As were regenerated with a sodium hydroxide (NaOH) solution and tested again in the flow-through reactor. The continuous flow-through reactor was effective in filtering As from spiked or natural groundwater samples. The regenerated CuO NPs were also effective in filtering As from groundwater. The CuO nanoparticle treatment did not show any discernible effects on the chemical quality of groundwater samples. Results of this study suggest that CuO NPs show potential for developing a simple process for field applications to remove As from water (Table 1) [1].

Time (min)	Volume (L)	CuO NP (As, µg/L)	RegenCuO NP (As, µg/L)
0	Control	109	110
5	0.1	1.5	<1.0
30	0.5	2.5	<1.0
180	3.0	3.0	<1.0
600	10.0	12.5	5.0
900	15.0	19.0	10.0
1200	20.0	23.0	14.0
Composite		12.5	6.0

Table 1. Effect of CuO NPs in removal of As from groundwater samples with continuous flow-through system.

Empirical palaeoceongraphic proxies typically exploit geochemical signiatures in biominerals, such as the shells ('tests') of foraminfera. Correlations between quantities such as Mg-content of the whole shell and the physico-chemical environment in which the shell was laid down by the planktonic organism are used to chart, for example, ocean temperature. Data off tests obtained from ocean floor sediment cores allow the proxy measurement of paleotemperatures back through geologic time.

Implicit here is the assumption that Mg substitutes into the calcite lattice of the shell. Links between XRD results for high-Mg-calcites of foram tests and inorganic high-Mg-calcites lend support to his assumption, but are, of necessity, made from crushed and averaged powder samples of whole shells. The Mg-contents of most formainifera (0-10 mmol/mol Mg/Ca) are lower than the detection limits of XRD, however. Furthermore, previous LA-ICP-MS and nanoSIMS mapping of elemental concentrations in forma tests indicate banding and chemical heterogeneity.

We have exploited the nanometre scale resolution of STXM methods at the ALS, Berkeley, to determine elemental concentrations and chemical environments (coordination states) of key targets, such as Mg, B and S in foraminifera test. STXM and related methods, such as PEEM, (potentially) ptychography provide unique insights into the chemical state of important geochemical proxies within mineral lattices. We find that Mg is indeed incoporated into the crystalline lattice of CaCO3, but with some potential indication of clustering. Results show that compositional banding in one element can be compared directly with other key elements.

The role of diagentic alteration in old foram tests has been explored through synchrotron tomography at Diamond Light Source. Additional capabilities such as coherent diffraction imaging technieus offer future prospects for further exploring the relationship between proxy element distributions and mineral nanostructure.

Partial melting and melt loss: Migmatites from Val Strona di Omegna (Ivrea Zone, NW Italy)

CHARLOTTE REDLER[1]

[1]Institute of Earth and Environmental Sciences, Mineralogy-Petrology-Geochemistry, University of Freiburg, Albertstrasse 23b, D-79104 Freiburg, Germany (charlotte.redler@minpet.uni-freiburg.de)

The mid to lower crustal field gradient through amphibolite to granulite facies rocks in the Ivrea Zone [1] offers the potential to study classical high-grade metamorphic processes such as partial melting and melt loss. Metapelitic rocks in Val Strona di Omegna show a progressive development in structures, starting with typical amphibolite facies mica-schists at lowest grades that change to metatexites with rare isolated leucosome veins at medium grades and diatexites in high-grade granulite facies rocks.

The first field evidence for partial melting is given by narrow discontinuous leucosomes that coincide with the fluid-absent breakdown of muscovite and the prograde appearance of K-feldspar. Towards high grades the consumption of biotite lead to more extensive melting and the formation of garnet-bearing leucosomes. Zones of diatexite in the highest-grade rocks indicate that melt loss was inefficient and/or accumulation of melt occurred. These zones are common at boundaries between diatexitic metapelitic rocks and metatexitic metagreywacke and may indicate that the metagreywacke formed a low-permeability barrier that restricted melt flow.

Field and petrographic evidence for melting can also be seen by crossing the position of the modelled wet solidus, which is consistent with the small amounts of melt predicted to occur by H_2O-saturated melting. In addition, calculated *P–T* pseudosections show that the metapelitic rocks have produced up to 30-40 mol.% melt at peak metamorphic conditions of around 11 kbar and 900°C. Modelling of granulite facies samples suggest a significant melt loss prior to cooling by showing elevated solidi. This is consistent with a depletion in SiO_2, Na_2O and K_2O and an enrichment in FeO, MgO and TiO_2 relative to amphibolite facies samples.

Peloid mud maturation, a mineralogical and health hazard point of view.

MARCO REDOLFI[1]*

[1]Dipartimento di scienze, Univ. Roma3, Roma 00146 Italia (*correspondence: marco.redolfi@uniroma3.it)

One of the main topic in medical spa is understanding the health hazard correlated to the presence of heavy metal cations in the thermal mud that can be absorbed by the skin associated with the more desirable cations who have beneficial property for some chronic diseases. I develop a standard protocol for analysis of the thermal mud during the maturation for better understanding the characteristic and eventually change in mineralogical and metal available parameter.

I used a maturation protocol developed at Salsomaggiore Terme [1] Italy, mixing a common clay, obtain in Tor Caldara Regional park, Anzio with 11 thermal water collected in the Lazio region in Italy plus distillated water. These mud has been put at 40°C in sealed container for all the maturation perid.

After one month and three month of maturation I sample the mud for XRD analysis and heavy metal sequential extraction plus “sweat” extraction [2] to understand the change in these parameter with the progress of the maturation process. These parameter were compered each other, to see the modification of the mineralogy and heavy metal availability during the different stage of mud maturation.

The first data are under integration with new data obtain in these days. But avaiable data demonstrate the formation of gypsum inside the clay, and the partial reduction of some more complex mineral, like plagioclase. The data of the metal and “sweat” extraction are under processing phase and will be ready for the end of June.

Active and Total Microbial Community Structure in relation to Metal Availability within Subsurface Sediments

BRANDI KIEL REESE[1], LAURA ZINKE[2], HEATH J. MILLS[3] AND KATRINA EDWARDS[1]

[1]Department of Biological Sciences, University of Southern California, Los Angeles, CA (brandi.reese@usc.edu)
[2]Department of Earth Sciences, University of Southern California, Los Angeles, CA (laurazinke@neo.tamu.edu)
[3]Department of Oceanography, Texas A&M University, College Station, TX (hmills@ocean.tamu.edu)

To understand the role of biology over geologic time scales and to appreciate past, current and future processes, the total microbial community (including metabolically active and dormant populations) must be characterized. The total microbial community is composed of varying metabolically active and dormant populations based on geochemical conditions. While metabolically active populations change the current geochemical conditions, understanding the total community structure can determine the potential processes available when geochemical conditions change in the future or when geochemical conditions were different in the past. Unlike surface populations that may experience rapid geochemical shifts, timescales for change in the deep subsurface may be over geologic time scales. Thus, dormant populations may become members of a seed bank, which can contribute to the diversity of future microbial communities while remaining examples of past conditions.

Sediment was collected during IODP Expedition 336 on the western flank of the mid-Atlantic ridge (North Pond) and was immediately cryogenically frozen. DNA and RNA were simultaneously isolated from the same sample at eight depths downhole using a uniquely developed extraction method. The V1-V3 region of the 16S gene and gene transcript was targeted using universal *Bacteria* specific primers. This approach targeted the active microbes via rRNA transcripts and the total population (live, dormant, dead) via DNA targets. X-ray Absorption Spectroscopy (XAS) was also used to map elements within the sediment samples chosen for molecular analysis. 16S rRNA gene transcripts extracted were quantified using quantitative rt-PCR. Greater microbial activity was observed at the sediment surface and diversity decreased with depth into the sediment. A majority of the lineages detected were heterotrophic, despite reduced metal species being present, suggesting the overall influence of very low carbon concentrations on community structure and function.

Holocene climate variability from Rio Martino Cave (Western Alps, northern Italy)

The Alpine region of Europe currently experiences complex climatic conditions and this is also apparent during the Holocene. With this in mind, several flowstone cores were retrieved from Rio Martino Cave (Piemonte, Northern Italy, ca. 1530 m a.s.l.) in the western Alps, where the climate is dominated by North Atlantic synoptic systems. U/Th dating of several flowstones indicates that deposition started at the beginning of the Holocene. One core has been intensively studied using a multi-proxy approach (stable isotopes and rock magnetism). The $\delta^{18}O$ record show substantial variability through the Holocene, which is interpreted as changes in rainfall $\delta^{18}O$ recharging the cave catchment. Variations in $\delta^{13}C$ instead are interpreted as different degrees of soil development. A long-term trend in $\delta^{18}O$ is apparent, with relatively low values persisting from the commencement of deposition until ca. 6 ka. From 6 to 3 ka the $\delta^{18}O$ increases gradually before decreasing again from 3 ka onward. $\delta^{13}C$ shows a good degree of correlation with $\delta^{18}O$. This long-term trend may be related to changes in the seasonal patterns of precipitation. Superimposed on this trend there are numerous centennial scale oscillations which may reflect alternating periods of drier and wetter conditions.

Both stable isotope records and magnetic susceptibility, which mainly depend on the detrital content, show good correlations with lake level record and flood events in Lake Ledro.

[4]Deltares, Utrecht, The Netherlands
[5]Nikola Poushkarov Institute of Soil Science, Sofia, Bulgaria
[6]University of Sheffield, Sheffield, UK

Soil physical properties such as aggregate stability and porosity are crucial for the soil's agricultural productivy, carbon sequestration capacity and water holding capacity. The formation of soil aggregates is the result of complex interactions between biological, chemical and physical soil processes. Therefore, multi-disciplinary research on Critical Zone Observatories (CZO's) is needed to unravel the key-factors controlling aggregate formation [1].

We will discuss the role of soil chemical and biological processes in the formation of soil aggregates. These data are the result of the joined efforts from soil chemists and biologist collaborating within the SoilTrEC project [2]. We show that organic-mineral interactions and solution chemistry are important for formation of primary soil aggregates. Especially Fe-(hydr)oxides play a crucial role because of their strong interactions with organic substances in the soil [3]. Macro-aggregates are formed when both organic matter, clay minerals and Fe-(hydr)oxides are present in sufficient amounts. These soil macro-aggregates act as habitats for micro-organisms which may in turn alter the organic substances within the soil aggregates. The microbial communitities within the macro-aggregates are affected by the land use. Furthermore, land use shows pronounced effects on the structure of the pores within the soil macro-aggregates.

Overall, we want to highlight the importance of multi-disciplinary research in understanding the complex interactions between chemical and biological processes within the critical zone.

Reconstructing subducted sediment fluxes using ancient arc lavas

MARCEL REGELOUS[1], CHRISTOPH BEIER[1] AND KARSTEN HAASE[1]

[1]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Schlossgarten 5, 91054 Erlangen, Germany (correspondence: marcel.regelous@fau.de)

Previous studies have shown that there exists a relationship between the fluxes of trace elements contained in subducting sediments at active subduction zones, and the trace element composition of the associated arc lavas, after correction for melting and fractionation effects [1]. This relationship apparently holds despite the wide range in thermal structure of present-day subduction zones resulting from variations in subduction rate, slab dip and the age of the subducting plate and could be used, together with trace element analyses of ancient arc lavas, to estimate past sediment fluxes at former subduction zones.

This method might be used to test the hypothesis that high atmospheric CO_2 concentrations in the late Mesozoic-early Cenozoic was maintained by subduction and decarbonation of large volumes of carbonate-rich sediment deposited in the former Tethys Ocean [2-4]. If this were the case, then ancient arc lavas from the margins of Tethys would be expected to have relatively high Sr and Ba, and low Th normalised concentrations. The approximate mass of carbonate subducted could be estimated from the Sr concentration of Tethyan carbonate.

The volume and average composition of deep-sea sediment available for subduction at ancient subduction zones has likely varied over time-scales that are long compared to the average age of the oceanic crust (~60 Ma) [5]. Biogenic sediments, which are important hosts of some trace elements, would not have been available for subduction before 500 Ma. The mid-Mesozoic proliferation of planktic calcifiers resulted in a larger carbonate component in deep-sea sediments available for subduction. If carbonate makes up 7-15% of average subducting sediment and has Sr contents an order of magnitude higher than the detrital fraction, then sedimentary Sr fluxes into subduction zones may have been ~50% lower than present before 500 Ma (i.e. for much of Earth's history).

Occurrence and distribution of natural occurring radioactive materials at a geothermal facility in the North German Basin

SIMONA REGENSPURG[1], JÖRG DILLING[2], JÜRGEN MIELCAREK[2], RUDOLF NAUMANN[1] AND UWE-KARSTEN SCHKADE[2]

[1]Helmholtz Centre Potsdam, German Research Centre for Geosciences, Telegrafenberg, D-14473 Potsdam, Germany; regens@gfz-potsdam.de
[2]Federal Office for Radiation Protection, Köpenicker Allee 120-130, D-10318 Berlin, Germany

The occurrence of mineral precipitates with elevated activity concentrations of radionuclides of natural origin is a well known observation from wells of the oil and gas industry. Similar natural occurring radioactive materials (NORM) were found at some deep geothermal facilities. Presumably, these radionuclides are transported with the geothermal fluids and co-precipitate upon change of thermodynamic conditions with the respected oversaturated mineral.

On the one hand, the occurrence of NORM offers the identification of geochemical processes, but on the other hand elevated activities might lead to an enhanced exposure due to radiation. At the geothermal research facility in Groß Schönebeck (North German Basin) the mobility of potassium (^{40}K) and radionuclides of the natural uranium- and thorium decay series was intensively monitored. Radionuclide concentrations were measured by gamma-ray spectrometry in samples from reservoir rocks, scalings, filter residues and fluids. Additionally the ambient gamma dose rate of several plant components was monitored. It was found that the content of natural radioactivity in the reservoir rocks is relatively low, whereas a strong enrichment was detected for ^{210}Pb and especially for the radium isotopes ^{226}Ra and ^{228}Ra in the filter residues of the plant. Filter residues and fluid samples were not in equilibrium with respect to these nuclides.

Since these residues consist mainly of the mineral barite ($BaSO_4$) and Ra is known as substitute for barium in minerals, barite precipitates apparently act as scavenger for these radionuclides. Further, it was found, that in sandstone reservoir rocks the radionuclides ^{226}Ra and ^{210}Pb are in deficiency compared to their parent ^{238}U.

REE mobility in carbonatites: insights from the trace-element composition of dolomite

E.P. REGUIR* AND A.R. CHAKHMOURADIAN

[1]Department of Geological Sciences, University of Manitoba, Winnipeg, MB, Canada, R3T 2N2 (*correspondence: umreguir@cc.umanitoba.ca)

Dolomite is a principal constituent of many carbonatites. Whereas the major-element chemistry of this mineral has been studied reasonably well, its trace-element variations have not. Here, we examined the trace-element composition of dolomite from carbonatites at Aley (British Columbia, Canada) to improve the current understanding of the processes that affected these rocks after their emplacement.

The examined dolomite shows extremely variable levels of Mn, Co, Sr, Ba, Sc and REE (900-13500, 0-15, 22-7000, 0-600, 0-60 and 0-400 ppm, respectively). Late-stage rhombohedral dolomite associated with quartz and chlorite (± REE minerals) is consistently enriched in REE relative to the groundmass. The pattern of enrichment varies from light-REE dominated to heavy-REE dominated. The former type correlates with enrichment in Mn, Sr, Co and Ba. Late-stage dolomite enriched in heavy REE contains lower levels of these elements. There is a general increase in REE content from the core of rhombohedral crystals toward their rim. The groundmass dolomite is characterized by relatively flat chondrite-normalized profiles, which are, in some cases, interrupted by a small negative Y anomaly. With the exception of one sample, REE patterns of the late-stage dolomite show appreciable positive Eu and Y anomalies.

The observed trace element characteristics of dolomite indicate an influx of REE, possibly scavenged from fluorapatite and transported by F-bearing crustal fluids under reducing conditions. The trace-element composition of the late-stage dolomite was further influenced by the precipitation of other associated phases, such as monazite and chlorite.

Crustal thickness estimation from GOCE satellite mission gravity data

M. REGUZZONI[1] AND D. SAMPIETRO[2]*

[1]DICA, Politecnico di Milano, Piazza Leonardo Da Vinci, 32 20133, Milano, Italy (mirko.reguzzoni@polimi.it)
[2]GReD - Geomatics Research & Development srl, via Valleggio 11, 22100, Como, Italy (*correspondence: daniele.sampietro@g-red.eu)

The boundary between Earth crust and mantle, the so called Moho, is commonly estimated by means of seismic or gravimetric methods. The former methods can be locally very accurate since seismic profiles give an almost direct observation of the actual crustal structure, but can be quite far from reality in large regions where no data are available. The latter methods, although often based on simplified hypotheses to guarantee the uniqueness of the solution, are nowadays becoming more and more important thanks to the improved knowledge of the gravitational field. In particular satellite gravity missions, like the European Space Agency mission GOCE (Gravity field and steady-state Ocean Circulation Explorer) [1], provide a very accurate and spatially homogeneous dataset that can be used to validate the existing global crustal models or to estimate a new one by constraining the relation between Moho depth and crustal density.

In this work a new crustal model (GEMMA model) with a spatial resolution of 0.5°x0.5° and constrained with GOCE observations is computed. For this purpose several additional external information has been used, such as topography, bathymetry and ice sheet models from SRTM, a recent 1°x1° sediment global model and some prior hypotheses on crustal density. In particular the main geological provinces, each of them characterized by its own relation between density and depth, have been considered. A model describing lateral density variations of the upper mantle is also taken into account. Starting from this prior information, an inversion algorithm is applied to the GOCE space-wise grid of second radial derivatives of the gravitational potential [2] to estimate the bottom of the crust. The computed Moho global model is well consistent not only with other global/regional models, but also with the actual gravity field, thus overcoming the main limitation of seismic Moho models (e.g. CRUST2.0).

[7]Center for Environmental Nanoscience and Risk, University of South Carolina, USA

Studies of biological uptake and environmental fate of manufactured nanoparticles (NPs) are often hampered by the difficulty of distinguishing these materials from the normal background levels of elements and natural NPs in environmental samples. Needed are methods for tracking engineered NPs in bulk samples from exposures that are carried out at realistic particle concentrations rather than the much higher levels that are often dictated by the lack of suitable analytical protocols. For metal and metal oxide NPs, this can be achieved by stable isotope tracing, employing NPs that are prepared from a single isotope of the target element.

We are currently investigating stable isotope labeling and tracing for ZnO, CeO_2 and Ag NPs, all materials that have a wide range of applications in industrial and consumer products. Using suitable isotopes and NP preparation methods, stable isotope labeling is cost-effective for these elements. When combined with high precision mass spectrometry for detection, the methodology provides unprecedented sensitivity for NP tracking. For example, biological uptake of ZnO NPs can be detected even at Zn background levels, which exceed the NP concentrations by more than a factor of 10,000.

The application of such methods enables accurate tracing of NP fate and transfer in a wide range of exposure systems and biota. Importantly, the results are able to directly address the key question of whether organisms take up nanoparticles directly or whether the elements are taken up only after particle dissolution.

[5]Dept of Environment, Earth and Ecosystems, The Open University, Milton Keynes MK7 6AA, UK
[6]Dept of Earth Sciences, University of Oxford, Oxford OX1 3AN, UK

Research in isotope geo- and cosmochemistry is often driven ahead by investigations that interrogate novel isotope systems or particularly 'difficult' sample types, whereby analytical challenges are frequently addressed by the use of advanced instrumentation and/or new techniques of sample preparation and data acquisition. Testament to this are the numerous isotopic 'methods' articles that are published by geochemists and the even more frequent contributions that present and discuss novel data from, prominently, studies of (still) 'non-traditional' stable isotope systems, extinct radionuclides and nucleosynthetic isotope anomalies.

Such leading edge work faces similar but distinct analytical difficulties and additional metrological challenges. In particular, it cannot rely on well-characterized pure-element isotope standards and geological or environmental reference materials (RMs), for evaluation and documentation of data quality. The geochemical community has, however, been very adept in finding pragmatic solutions to such challenges in quality control, through innovative work of individual laboratories, critical peer review of journal articles and, most importantly, generally good-natured competition and extensive collaboration, both formal and informal, between research groups.

With regard to reference materials and method validation, geochemists and metrologists share a common interest in improving data quality and intercalibration but communication and collaboration between these communities on isotopic research is often limited. This is unfortunate because both sides could readily profit from improved interaction, for example in the preparation, characterization and distribution of RMs.

Field Sampling for Porewater Mercury and Methylmercury using DGT

DANNY REIBLE[1]*, PAUL BIRETA[2], ARIETTE SCHIERZ[1], JAMES GRUNDY[2] AND RICH LANDIS[3]

[1]Center for Research in Water Resources, University of Texas at Austin, Austin, TX, USA, reible@mail.utexas.edu (*presenting author)
[2]Civil, Architectural and Environmental Engineering Department – EWRE, Universtiy of Texas at Austin, Austin, TX, USA
[3]DuPont, 974 Centre Road, Wilmington, DE, USA

Dissolved porewater concentrations have the potential to better relate to mercury methylation rates than bulk mercury sediment loadings. The diffusive gradient in thin film (DGT) technique is applied to determine aqueous mercury and methyl mercury vertical porewater concentration profiles. DGT probes were deployed in the South River (Virginia, USA) where previous industrial activities had led to mercury contamination. The river is primarily a sand and gravel stream with limited microbial productivity. The DGTs were used to evaluate methylation rates and extent and identify locations contributing significantly to methyl mercury. A potential remedial option of biochar amendment was evaluated in a small floodplain pond. The DGTs were used to measure the performance of the sediment amendment including changes to available mercury and methyl mercury. Sampling of bulk sediment, surface water, porewater, and biota was carried out in parallel. Specific redox couples were also measured over depth using cyclic voltammetry. Conclusions were drawn as to the sources of significant methylation and relationship to sediment geochemistry.

The microstructure and trace metal geochemistry of pyrite from porphyry Cu deposits

M. REICH[12,*], A. DEDITIUS[3] AND F. BARRA[12]

[1]Dept. of Geology, University of Chile, Santiago, Chile (*email: mreich@ing.uchile.cl)
[2]Andean Geothermal Center of Excellence (CEGA), University of Chile, Santiago, Chile
[3]Graz University of Technology, Graz, Austria

Porphyry copper deposits (PCDs) are currently the world's largest source of copper and molybdenum, and are also among the largest reservoirs of gold in the upper crust. Despite the fact that pyrite is a ubiquitous mineral phase in these deposits, the major and trace element chemistry of pyrite from PCDs remains poorly understood.

Here we report the first comprehensive trace element database of pyrite from the Dexing deposit, China's largest porphyry Cu deposit, determined using a combination of electron microprobe analysis (EMPA) and secondary-ion mass spectrometry (SIMS). Results show that the concentrations of precious metals (e.g., Au, Ag), metalloids/chalcogens (e.g., As, Sb, Se, Te), and base/heavy metals (e.g., Cu, Co, Ni, Zn, Hg) in pyrite from a PCD are more significant than previously thought (e.g. ~6 wt.% Cu, ~3 wt.% As, ~0.25 wt.% Au, and ~0.2 wt.% Ni).

EMPA-WDS elemental mapping and SIMS depth profiling reveal that some of these metals occur exclusively in solid solution in the pyrite structure (e.g., As, Ni) or are present in solid solution and also in micro- to nano-sized inclusions (e.g. Cu and Au). The mineralogical occurrences are associated with complex textural and chemical features such as oscillatory growth zoning and sector zoning with variable porosity, where Cu-rich, As-(precious metals)-poor zones alternate with As-(precious metals rich)-rich, Cu-poor zones, and with barren pyrite zones.

These observations point toward a decoupled behavior of Cu and As in this porphyry system, strongly suggesting that selective partitioning of metals into pyrite is most likely the result of changes in fluid composition, probably caused by fluid mixing and repeated and intermittent pulses of Cu and As-bearing fluids of magmatic/ hydrothermal origin. Despite the fact that more studies are needed to increase our knowledge about metal partitioning in sulfides during the hydrothermal stages of PCDs formation, the observations and data presented here support an important role of pyrite as a record of fluid variations, and as a host of precious and base metals, metalloids/chalcogens and potentially PGEs.

The disparate crystal records of the Youngest Toba Tuff, Indonesia

M.R. REID[1]* AND J.A.VAZQUEZ[2]

[1]Northern Arizona University, Flagstaff, Arizona 86011, USA (*correspondence: Mary.Reid@nau.edu)
[2]U.S. Geological Survey, Menlo Park, California 94025, USA

The 74 ka Youngest Toba Tuff (YTT) is the product of a giant eruption (>2800 km^3) from the Toba Caldera Complex of Sumatra, Indonesia. The YTT sample suite spans the compositional range of 63-75 wt.% SiO_2, with most >68.8 wt.% SiO_2. The narrower compositional range of quartz-hosted melt inclusions suggests that YTT compositional heterogeneity may reflect a spectrum of crystal-liquid mixtures [1]. Quartz from high silica rhyolites are relatively unzoned whereas those from low silica rhyolites have Ti, and therefore temperature, reversals late in their crystallization history. Limited diffusional relaxation across these bands suggests rim crystallization within a few ka of eruption [2]. In contrast, allanite from a high silica rhyolite grew extensively over >35 ka and are not reversely zoned at the rims [3]. ^{238}U-^{230}Th-^{206}Pb zircon crystallization dates range to even older ages but mainly predate eruption by <400 ka. Despite the strong crustal signature of the YTT ($^{87}Sr/^{86}Sr$ ~ 0.714), bonafide xenocrysts are relatively rare. Growth on individual zircon grains occurred over a protracted time interval (>100-500 ka), and was likely episodic. Zircon ages in high silicic rhyolites may span a more limited range. Zircon from individual rocks exhibit a significant Th/U compositional range and evidently crystallized from a plumbing system with a wider range in thermochemical conditions than those characterized by YTT matrix glasses. Cores nucleated over at least a 300 ka interval, often from relatively unevolved magmas. Zircon rims grew from host melts and yield ages that range from ~80 ka to ~115 ka. Compositional reversals are recorded by rims in zircon from low silica rhyolite but not high silica rhyolite. Considered collectively, ages and age ranges otained from YTT phases decrease in the order zircon > allanite > quartz, a sequence that parallels that for attainment of phase saturation conditions. Minerals stable in more diverse magmatic compositions apparently persisted longer. Crystals were apparently remobilized intermittantly by magmatic rejuvenation rather than being incorporated by foundering of roof rocks at the time of eruption. Domains that ultimately erupt as low silica rhyolites were remobilized beginning 40 ka before eruption – based on the zircon/allanite ages – with the most recent reheating occurring within a few thousands years of eruption [2].

Assessment of a gold absorbing resin in natural groundwaters for mineral exploration

N. REID[1]*, D.J. GRAY[1] AND A. LUCAS[2]

[1] Deep Exploration Technologies Cooperative Research Centre, CSIRO Earth Science and Resource Engineering, Kensington, Western Australia, Australia (*correspondence: nathan.reid@csiro.au)

[2]School of Earth and Environment, University of Western Australia, 35 Stirling Highway, Crawley 6009, Western Australia

One of the most important elements for mineral exploration is gold, and yet it is one of the hardest to accurately measure in groundwater. Recent successes in regional hydrogeochemistry in Australia [1] has highlighted the potential of using activated carbon via both grab sampling and a newly modified Diffusive Gradients in Thin films (DGT) technique [2] to gain low level detection of Au (and other elements) as increasing concentraions of Au can vector to large mineral systems. A question we are addressing is whether the Au signal can be concentrated and/or improved by the use of specific Au absorbing resins.

We used Micro-CT tomography to determine how a specific resin, Purolite A100, absorbs both ionic and metallic Au from solutions, and precipitates it both on and within the resin structure.

Preliminary results show that Purolite A100 absorbs more Au (and also Ag, Bi, Pt and Pd) than activated carbon and gives more consistent results at higher concentrations.

Further research is still required for improving the absorbance of Au at lower Au concentrations.

Investigating the physicochemical gradients in oil sands wastes

THOMAS REID[1]*, RYAN BOUDENS[1] AND CHRIS WEISENER[1]

[1]GLIER - University of Windsor, Windsor, Ontario, Canada *(reid11c@uwindsor.ca)

The Athabasca Oil Sands contain one of the world's largest oil reserves consisting of approximately 178 billion barrels of oil[1]. With 20% recoverable through open pit mining methods, this extraction process produces a considerable amount of fluid fine tailings (FFT) waste material, which must be deposited on site in tailings ponds. These ponds allow the waste sands, clays, residual bitumen and water to settle out, allowing for the water to be recycled for use again in the extraction process. It is vital to understand the physicochemical gradients which form in these tailings ponds over time, with the goal of remediation once the ponds are no longer needed.

To study the influences of biotic and abiotic processes on fresh and mature FFT, sensitive microsensor profiling techniques are being used to measure hydrogen sulphide (figure 1), oxygen, Eh, and pH profiles over a 1 year period. These profiles are accompanied by pore water extraction methods to analyse cation, anion and pore water gas expression. To compliment these static experiments, dynamic simulations will investigate shear forces (wave action and turbulence) on the water-sediment interface in each of the biotic and abiotic microcosms, under controlled atmospheric conditions.

This holistic study provides insight regarding biotransformation and physicochemical controls effecting sediment oxygen demand associated with remediated wetlands & end pit lake development.

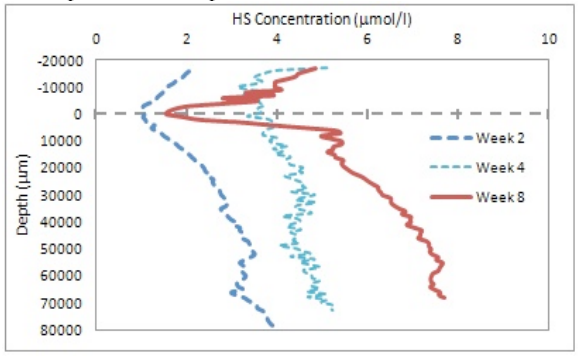

Figure 1: HS^- concentration profiles of mature FFT at 2, 4, and 8 weeks, extending from cap water down into the FFT sediment; dashed line is the sediment-water interface

Adsoption of Eu(III) onto minerals in the presence of humic acids: effects of various solution parameters and sorptive fractionation on modelling and spectroscopy

P.E. REILLER,[1] N. JANOT[2] AND M.F. BENEDETTI[2]

[1]CEA/DEN/DANS/SEARS/LANIE, Gif-sur-Yvette, France
[3]Institut de Physique du Globe de Paris, Université Denis Diderot, Paris, France
pascal.reiller(at)cea.fr

Adsorption of metals on minerals with humic acids is always under predicted [1]. The case of Eu(III) in ternary system including purified Aldrich humic acid (PAHA) and α-Al_2O_3 was measured, modelled and probed using time-resolved laser-induced luminescence spectroscopy (TRLS). Each binary system was studied independently [2,3,4], and the luminescence properties of Eu(III), luminescence spectra and decay times (τ), were aquired and compared [5]. Influence of ionic strength and PAHA concentration was also evaluated.
The typical luminescence behaviour of Eu(III)-HA system, showing a bi-exponential decay, was also found in the ternary system Eu(III)/PAHA/α-Al_2O_3, but with marked differences. Luminescence spectra and faster decay τ_1 are the same in both system at pH < 6, but with higher τ_2 indicating a rigid environment for Eu(III). For pH > 6, modifications of Eu(III) luminescence spectra and decrease of τ_2 are showing a progressive influence of α-Al_2O_3. The non-variation of τ_1 suggests the on-going influence of PAHA, notwithstanding its progressive desorption.

Comparing with previous data on sorptive fractionation of PAHA [2,3,6], and with the TRLS evolution of the system [5], an operational modelling was proposed [4], which implies that alumina-sorbed PAHA is showing a stronger interaction towards Eu(III) compared with non-sorbed PAHA even at pH > 7. This stronger interaction is due to the sorptive fractionation which reveals stronger binding sites [1,4,7].

Geochemistry of European bottled water

CLEMENS REIMANN[1], MANFRED BIRKE[2] AND ALECOS DEMETRIADES[3]

[1]Geological Survey of Norway, P.O. Box 6315, Sluppen, 7491 Trondheim, Norway
[2]Federal Institute for Geosciences and Natural Resources, Wilhelmstrasse 25 – 30, 13593 Berlin, Germany
[3]IGME, 1 Spirou Louis Street, Entrance C, Olympic Village, 136 77 Acharnae, Athens, Hellas

To obtain a first impression of the geochemistry and quality of ground water at the European scale bottled mineral water was used as a sampling medium. In total, 1785 bottled waters were purchased from supermarkets of forty European countries, representing 1247 wells/drill holes/springs at 884 locations. All bottled waters were analysed for 72 parameters at the laboratories of the Federal Institute for Geosciences and Natural Resources (BGR) in Germany. The result provide a first impression of the natural variation of chemical elements in ground water at the European scale. Maps demonstrate that geology is one of the key factors influencing the observed element concentrations for a significant number of elements. Examples include high values of (i) Cr clearly related to the occurrence of ophiolites; (ii) Li (Be, Cs) associated with areas underlain by Hercynian granites; (iii) F (K, Si) related to the occurrence of alkaline rocks, especially near the volcanic centres in Italy, and (iv) V indicating the presence of active volcanism and basaltic rocks. The natural variation of element concentrations in the bottled water covers usually between three to four orders of magnitude and reaches up to 7 orders of magnitude for a few elements (e.g., Li, U). A comparaison with the chemistry of European tap water, surface water and Norwegian ground water shows surprising similarities in terms of median and variation. This proves that bottled water can be taken as a proxy for European ground water quality for the majority of elements/parameters. The bottled water samples showed, however, exceptionally high concentrations for a few elements typical for deep, hydrothermal sources (e.g., B, Be, Br, Cs, F, Ge, Li, Rb, Te and Zr).

Fortunately less than one percent of all samples returned values that were above the currently valid European maximum admissible concentrations (MACs) for drinking and/or bottled water (e.g., for As, Ba, F, Se, NO_3 and NO_2). It is, however, an important observation that currently there exist no water action levels for some of the elements that show an exceptionally high natural variation (e.g., Li and U).

Chemistry of Europe's agricultural soils - the GEMAS project

CLEMENS REIMANN[1], ALECOS DEMETRIADES[2] AND MANFRED BIRKE[3]

[1]Geological Survey of Norway, P.O. Box 6315, Sluppen, 7491 Trondheim, Norway
[2]IGME, 1 Spirou Louis Street, Entrance C, Olympic Village, 136 77 Acharnae, Athens, Hellas
[3]Federal Institute for Geosciences and Natural Resources, Wilhelmstrasse 25 – 30, 13593 Berlin, Germany

Geochemical Mapping of Agricultural and grazing land Soil (GEMAS) is a cooperative project between the Geochemistry Expert Group of EuroGeoSurveys and Eurometaux. During 2008 and until early 2009, a total of 2108 samples of agricultural (ploughed land, 0-20 cm) and 2023 samples of grazing land (0-10 cm) soil were collected at a density of 1 site/2500 km^2 each from 33 European countries, covering an area of 5,600,000 km^2. All samples were analysed for 52 chemical elements following an aqua regia extraction, 41 elements by XRF (total), and soil properties, like CEC, TOC, pH (CaCl2), following tight external quality control procedures. In addition, the agricultural soil samples were analysed for 57 elements in a mobile metal ion (MMI®) extraction, Pb isotopes and magnetic susceptibility. The GEMAS project thus provides for the first time fully harmonised data for element concentrations and soil properties known to influence the bioavailability and toxicity of the elements at the continental (European) scale. The provided database is fully in compliance with the requirements of the European REACH Regulation (Registration, Evaluation, Authorisation and Restriction of Chemicals). It also provides valuable information for other European pieces of legislation related to metals in soil.

The results demonstrate that robust geochemical maps of Europe can be constructed based on low density sampling. At the European scale element distribution patterns are still governed by natural processes, most often a combination of geology and climate.

An Iceland-like Setting for Generation of Earth's Earliest Known Crust

REIMINK, J.R.,[1]* CHACKO, T.,[1] STERN R.A.[12] AND HEAMAN, L.M.[1]

[1]Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton T6G 2E3, Canada (reimink@ualberta.ca)
[2]Canadian Centre for Isotopic Microanalysis, University of Alberta, Edmonton T6G 2E3, Canada

The Acasta Gneiss Complex (AGC) contains the oldest rocks on Earth with U-Pb zircon ages indicating crust formation between 3.6-4.03 Ga [1-3]. Here we report whole rock geochemistry along with SIMS U-Pb, trace element, and O-isotope compositions of zircon from a >4.0 Ga tonalite unit identified during detailed mapping of the AGC.

Unlike typical Archean TTGs [4], this unit is characterized by moderate silica contents (58-62 wt % SiO_2), strong Fe-enrichment (12-15 wt% FeO), and low Mg numbers (13-18). REE patterns are relatively unfractionated (La/Yb_N ~2.5) and contain a significant negative Eu anomaly. These features strongly suggest that, unlike deep-seated Archean TTG magmas [4], the evolution of this AGC tonalite was dominated by shallow-level fractionation processes involving plagioclase.

Zircons from this well preserved unit document complex morphological patterns, very similar to previously described pre-4.0 Ga zircons from the AGC [1]. Two phases of igneous zircon growth, centers and mantles, are compositionally distinct but record indistinguishable U-Pb ages >4.01 Ga. Oxygen isotopic compositions from zircon centers and mantles document a decrease in $\delta^{18}O$ from a mean of 5.6±0.1‰ to a mean of 4.7±0.1‰. This center to mantle decrease in $\delta^{18}O$ can be explained by late-stage assimilation of hydrothermally altered crust.

Collectively, these data for the >4.0 Ga AGC tonalite are strikingly similar to those reported for intermediate rocks from Iceland (e.g., icelandites), which are thought to have formed by a combination of shallow-level basaltic magma fractionation and assimilation of surface-water altered crust [e.g., 5]. Thus, Iceland may serve as a suitable analogue for the generation of Earth's earliest proto-continental crust.

Toward an *in-situ* bioremediation strategy for acidic *in-situ* leach uranium mining

B.C. REINSCH[1]*, M. DESCOSTES[2], R. BERNIER-LATMANI[1] AND P. ROSSI[1]

[1]École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland,
(*correspondence : brian.reinsch@epfl.ch)
[2]AREVA, Paris, France

In Kazakhstan, *in-situ* leach (ISL) mining of uranium utilizes the oxidizing power of pH < 2 sulfuric acid solutions to liberate and mobilize uranium from the ore's naturally reducing conditions. Although ISL has the potential to be less environmentally impactful than physical mining techniques, it includes the risk of groundwater contamination. A detailed geochemical and microbiological analysis and comparison of pre-, mid-, and post-mining conditions is warranted in order to assess and potentially mitigate that risk.

A theoretically ideal remediation strategy for ISL would be one that re-equilibrates the pH, immobilizes uranium as U(IV) precipitates, and does not require physical disruption of the surface. The strategy proposed here is *in-situ* biostimulation. The injection of carbon-based electron donors into the subsurface would, in theory, promote the growth of indigenous bacterial communities able to reclaim the subsurface. The proposed mechanism is that stimulated sulfate and/or iron reducing bacteria can return the pH to its original value and re-establish reducing conditions more rapidly than the commonly practiced strategy of natural attenuation. Biostimulation could also utilize the existing configuration of pumps and pipes, originally used to inject acid.

The objectives of this study are: 1) to characterize the impact of the injection of sulfuric acid on the subsurface geochemistry, 2) to probe changes in the subsurface microbial communities as a result of mining operations, 3) to identify through laboratory-based studies which electron donors may promote Fe- and/or sulfate-reducing microbia communities post-mining, and 4) to ascertain the composition of the microbial community post-remediation. The results presented here represent the initial stages of a pioneering study to understand the effects of uranium ISL on the environment and to design and implement an *in-situ* bioremediation strategy in Southern Kazakhstan.

Geochemistry of Biotite of The Vila Nova Plutonite (Central Portugal)

A.I.M. REIS[1]

[1]Department of Earth Sciences, University of Coimbra, 3000-272 Coimbra, Portugal (aimreis@gmail.com)

The Vila Nova plutonite intruded phyllites and metagraywackes of Neoproterozoic-Cambrian Beiras Group in Central Iberian Zone of Iberian Massif which is the SW segment of the European Variscan Belt and occurs in a group of seven plutonites of similar age and particular features related to a major strike slip shear zone.

The Vila Nova plutonite has a compositional variability of tonalite-granodiorite-granite. Its a rock of fine to medium grained, muscovite>biotite. The $\delta^{18}O$ values are 11.09_{tn}-11.54_{gd}- 12.65_{gt} ‰. The plagioclase An(%) contents are 13.2_{tn} - 13.6_{gd} - 14.6_{gt} and feldspar Or(%) contents are 86.2_{gd} - 93.2_{gt}. The tonalitic lithotype do not contain feldspar.

Biotite is often altered to chlorite associated with acicular rutile and opaque minerals such as pyrite and is absent in granitic composition with tourmaline.

They are magmatic except in microgranular enclaves where they are reequilibrated, the X_{FeO} is 0.74_{Tn} - 0.71_{Gd} - 0.73_{Gt}[1] and are ferriferous biotites[2] with aluminopotassic trends[3] evidence of peraluminous magma.

The biotite in surmicaceous xenolithes, stretched on alternated reeds with muscovite, occur in the tonalitic composition and have less content of Si, Ca, Na and higher content of Al^{IV} and Zn and, in the microgranular enclaves in the granodioritic composition the dispersed and subhedral biotite have less conten of Ti, Zn, K and higher contens of Fe^{3+}, Ca and Na than others biotites. In these textural heterogeneities some elements have opposite behavior from center to rim. The biotites in the evolutionary trend have a decrease of Fe^{3+}, Fe^{2+}, Mn, Li, Ca, Rb, OH, Li/Mg, $Rb10^3$/K and Fe^{2+}/Mg and an increase of Mg, Na, Cs, F, Si/Ca.

Chromitites from the Andriamena greenstone belt, Madagascar: Hints of a mid-Archean ophiolite?

LAURIE REISBERG*[1], MARYSE OHNENSTETTER[2] AND CATHERINE ZIMMERMANN[1]

[1]Centre de Recherches Pétrographiques et Géochimiques, UMR 7358, CNRS, Université de Lorraine, BP 20, 54501 Vandoeuvre-lès-Nancy, France. (*correspondence: reisberg@crpg.cnrs-nancy.fr)

[2]GéoRessources, UMR 7359, CNRS, Université de Lorraine, BP 70239, 54506 Vandoeuvre-lès-Nancy, France

The Andriamena greenstone belt of Madagascar contains massive chromitite bodies of likely ophiolitic affinity, composed of about 90% chromite and 10%, mostly secondary, gangue minerals (talc, green amphibole, orthopyroxene, Ca and Mg carbonate). Arguments in favor of an ophiolitic origin for the chromitite include the high Cr# (0.67-0.74), coupled with relatively high Mg# (0.6-0.78) of the constituent chromite. In addition, these phases display very low TiO_2 contents (<0.25%), which are also characteristic of ophiolites and possibly suggestive of an arc environment. Though in most places the chromitite is in tectonic contact with a variety of igneous lithologies, remnants of apparently cogenetic ultramafic rock types, including dunites, harzburgites, and some pyroxenites are sometimes immediately juxtaposed with the chromitite. The very high Fo content of the olivine in the dunite, as high as 0.95, also attests to an ophiolitic provenance.

Platinum group element (PGE) and Os isotopic analyses were performed on several chromitite samples. Chondrite normalized PGE spectra display marked depletions in PPGE relative to IPGE, with $(Pt/Ir)_N$ ranging from ~0 to 0.09, though Pd contents are somewhat less depleted than those of Pt. The observed PPGE depletion is another feature characteristic of ophiolitic chromitites. The IPGE enrichment is consistent with the presence of laurite microinclusions in the chromite revealed by SEM. Os isotopic compositions are tightly clustered, with $^{187}Os/^{188}Os$ ranging from 0.1057 to 0.1059, corresponding to T_{RD} model ages of ~ 3.2 Ga, assuming primitive upper mantle parameters [1]. $^{186}Os/^{188}Os$ measurements are in progress.

If the ophiolitic nature of the chromitites is confirmed, our results might imply that mechanisms similar to present-day tectonic processes may already have been active in the mid-Archean.

Biogeochemical cycling of Au and Pt - Integrating field studies, micro-analyses and molecular biology

FRANK REITH[1]*, CARLA ZAMMIT[1], DIETRICH H. NIES, GORDON SOUTHAM[3] AND JOËL BRUGGER[1]

[1]The University of Adelaide, School of Earth and Environmental Sciences, Adelaide SA5005, Australia (*correspondence:frank.reith@csiro.au)

[2]Martin-Luther University Halle-Wittenberg, Institute of Biology/Microbiology, Halle, Germany.

[3]The University of Queensland, School of Earth Sciences, Brisbane, QLD 4072, Australia

The biosphere catalyzes a variety of biogeochemical reactions that transform Au and Pt. Studying these interactions from the nano- to the macro-scale requires a well-integrated set of tools ranging from field studies to micro-analytical, synchrotron- and omic approaches. Gold and Pt grains are rare, hard to find and getting access to prospecting sites often requires a great deal of 'field diplomacy'. To study biofilms living on grain surfaces, Au and Pt grains need to be collected under field-sterile conditions and frozen, refrigerated or fixed immediately after collection for genomic-, culturing- or electron microscopic studies, respectively. In particular, FIB-SEM-EBSD/EDXA has been useful in understanding the distribution and structure of biominerals and biofilms, as well as their effect on the (trans)formation of Au and Pt grains. In addition, FIB-SEM has been used to study analogue Au and Pt biominerals formed in laboratory experiments by organisms (i.e., *Cupriavidus metallidurans*) identified on Au grains. Synchrotron spectroscopy techniques (μXRF, μXANES and μEXAFS) allow us to map the distribution and speciation of Au and Pt in individual *C. metallidurans* cells. This has led to an understanding of the fate of environmentally important mobile Au- and Pt-complexes (identified with HPLC-ICP-MS), upon contact with cells. To understand the reaction of cells to the toxic complexes transcriptome microarrays and 2-D SDS-PAGE was used. Important determinants of Au and Pt resistance and sensitivity were studied using deletion mutagenesis and (LA)-ICP-MS analyses of cells and proteins enriched in Au. Specific Au-binding proteins have been identified with MALDI-TOF-TOF, and can be used as biosensors for in field quantification of Au. To investigate the distribution of these important determinants in surface to depth environments high-density phylogenetic and functional microarrays (e.g., PhyloChip, GeoChip) are used. Understanding the determinants of biogeochemical cycling of Au and Pt may explain the formation of large supergene deposits have formed, and provide the basis for novel approaches in exploration, bio-hydrometallurgy and bio-remediation.

Quantifying the relative contribution of natural gas fugitive emissions to total methane emissions in Colorado, Utah, and Texas using mobile $\delta^{13}CH_4$ analysis

CHRIS W. RELLA*[1], RENATO WINKLE[1], ERIC CROSSON[1], GLORIA JACOBSON[1], ANNA KARION[23], GABRIELLE PETRON[23] AND COLM SWEENEY[23]

[1]Picarro Inc., 3105 Patrick Henry Drive, Santa Clara, California 95054 USA.*correspondence: rella@picarro.com

[2]National Oceanic and Atmospheric Administration, Earth System Research Laboratory, Global Monitoring Division, Boulder, CO, USA

[3]University of Colorado, Cooperative Institute for Research in Environmental Sciences, Boulder, Colorado

Fugitive emissions of methane into the atmosphere are a major concern facing the natural gas production industry. Because methane is more energy-rich than coal per kg of CO_2 emitted into the atmosphere, it represents an attractive alternative to coal for electricity generation, provided that the fugitive emissions of methane are kept under control. A key step in assessing these emissions is partitioning the observed methane emissions between natural gas fugitive emissions and other sources of methane, such as from landfills or agricultural activities. One effective method for assessing the contribution of these different sources is stable isotope analysis, using the $\delta^{13}CH_4$ signature to distinguish between natural gas and landfills or ruminants. We present measurements of mobile field $\delta^{13}CH_4$ using a spectroscopic stable isotope analyzer based on cavity ringdown spectroscopy, in three intense natural gas producing regions of the United States: the Denver-Julesburg basin in Colorado, the Uintah basin in Utah, and the Barnett Shale in Texas. Mobile isotope measurements of individual sources and in the nocturnal boundary layer have been combined to establish the fraction of the observed methane emissions that can be attributed to natural gas activities. The fraction of total methane emissions in the Denver-Julesburg basin attributed to natural gas emissions is 78 +/- 13%. In the Uinta basin, which has no other significant sources of methane, the fraction is 96% +/- 15%. In addition, preliminary results in the Barnett shale, which includes a major urban center (Dallas), are presented.

Experimental characterization of replacement symplectites: The influence of temperature and small amounts of water on microstructure evolution

PATRICK REMMERT[1]*, BERND WUNDER[1], LUIZ MORALES[1], WILHELM HEINRICH[1] AND RAINER ABART[2]

[1]GFZ Potsdam, Telegrafenberg, 14473 Potsdam, Germany (*patrick.remmert@gfz-potsdam.de)

[2]University of Vienna, Althanstrasse, 1090 Wien, Austria

Symplectite microstructures are a widespread phenomenon in a multitude of different parageneses in metamorphic rocks. The aim of this study is to characterize the formation of symplectites and to investigate experimentally the influence of temperature and water content on the evolution of symplectite microstructures.

Synthetic monticellite (Mtc) crystals with an excess forsterite (Fo) component of about 8 mole% were annealed in a piston-cylinder apparatus at 1.2 GPa, 950 - 1200°C, run durations of 5min - 24h and water contents of 0 - 1.0 wt.% H_2O using Al_2O_3 as a pressure medium. At these conditions Mtc breaks down into two types of fine-grained symplectite microstructures.

The two symplectite microstructures can be explained by two types of cellular segregation reactions: (a) The Mtc precursor phase (Mtc I) is replaced by a symplectite (type I) consisting of Fo rods in a Mtc matrix without excess Fo component (Mtc II). (b) A symplectite (type II) consisting of a lamellar intergrowth of merwinite (Mw) and Fo is formed. In both cases replacement of the Mtc precursor phase by the symplectite implies chemical diffusion within the advancing reaction front.

The lamellar spacing of both symplectites shows a strong temperature dependence. At identical run durations the spacing of Sy I increases from 450 nm at 1000°C to 1200 nm at 1100°C, whereas the Sy II spacing increases from 250 to 400 nm. Both symplectite microstructures could only be produced in experiments with at least minute amounts of water. Adding H_2O to the experiment strongly increases the reaction rate of the symplectite formation.

Applying the formalism introduced by Degi *et al*. [1] yields a diffusion coefficient for MgO and CaO within the reaction front of around $7*10^{-13}$ m^2/s for the formation of the Sy II indicating very fast diffusion inside the reaction front.

The vapour-brine partitioning of uranium in boiling ore systems

KIRSTEN U. REMPEL [1]*, WILHELM HEINRICH [2], AXEL LIEBSCHER [3] AND PETER DULSKI [4]

[1]Dept. of Applied Geology, Curtin University, Australia (*correspondence: kirsten.rempel@curtin.edu.au)
[234] GFZ GeoForschungsZentrum, Potsdam, Germany
[2](whsati@gfz-potsdam.de); [3] (alieb@gfz-potsdam.de)
[4](dulski@gfz-potsdam.de)

Uranium is found in ore systems associated with high-temperature H_2O-CO_2 fluids of probable magmatic origin, such as skarns and iron oxide-Cu-Au-U deposits. At P-T-X conditions of vapour-liquid (V-L) coexistence, the exsolved magmatic fluids undergo boiling, so uranium mobility in the ore fluid is dependent on its partitioning between V and L. In an experiment using a pressure vessel equipped with dual sampling lines, we have determined the partition coefficients ($D_{V/L}$) for U at 400°C between coexisting CO_2-rich vapour and NaCl brine. $D_{V/L}$ increases linearly from $1.5x10^{-4}$ to $2.0x10^{-1}$, with increasing P from 263-356 bar.

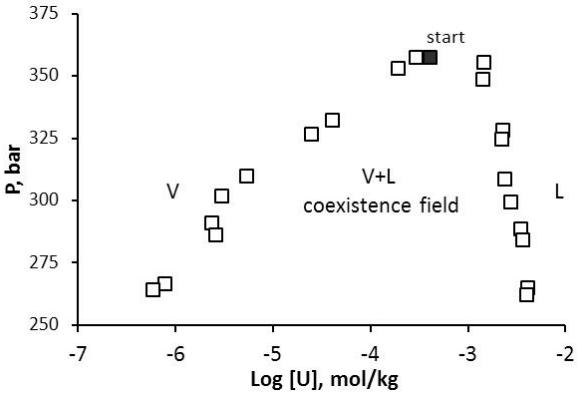

Figure: Uranium concentrations in vapour and liquid sample pairs taken at equivalent P, from a starting P-T-X of 356 bar, 400°C, and bulk composition of $4.2x10^{-4}$ m (100 ppm) U, 2.3 m CO_2 and 0.5 m NaCl (filled square).

The results of this study suggest that boiling may be instrumental to the production of zoned uranium orebodies, as the majority of U is carried in the denser brine rather than in the coexisting CO_2-rich vapour. However, at conditions approaching the critical curve, increasing concentrations of U are partitioned into the vapour (e.g., 1% of the total U at 325 bar, rising to 20% at 357 bar). This study presents the first experimental data on the V-L partitioning of U and its mobility in H_2O-CO_2 vapour.

Different D-rich organic reservoirs in unequilibrated ordinary and carbonaceous chondrites

LAURENT REMUSAT [1], SYLVAIN BERNARD [1], LAURETTE PIANI [2], JEAN-YVES BONNET [3] AND ERIC QUIRICO [3]

[1]LMCM, UMR CNRS 7202, MNHN, Paris, France
[2]CRPG, UMR CNRS 7358, Université de Lorraine, France
[3]IPAG, UMR CNRS 5274, UJF, Grenoble, France

Insoluble organic matter (IOM) contained in chondrites is known to host large D-enrichments [1]. The distribution of D in carbonaceous chondrites (CC) appears to be heterogeneous at the sample, micrometer and molecular scales [1-3]. The isotopic signature is influenced by primary (pre-accretional) processes, including low temperature chemistry occurring in the outer protosolar nebula or in the parent molecular cloud [4] and secondary processes during the evolution of the parent body [1]. On the other hand, the distribution of D in the IOM of ordinary chondrites (OC) remains cryptic. Most of the OC have been subjected to thermal metamorphism. Surprisingly, the D-content of IOM in OC and CC exhibit an opposite evolution with increasing temperature of the parent body [1]. While more high temperature CC have a lower D/H compared to pristine or hydrated CC, the D/H ratio of OC IOM increases with increasing temperature.

To better understand this striking observation, we have subjected the IOM of Orgueil (CC) and GRO 95502 (OC) to thermal heating without oxygen (pyrolysis). Then, we have evaluated the evolution of each IOM upon heating by NanoSIMS (to assess the D/H distribution), STXM (molecular structure) and Raman (organization degree). In CC, the D-content decreases, while in the meantime the IOM undergoes the carbonization process (loss of heteroatoms and formation of larger aromatic structures). In OC, the D/H ratio increases likely due to the loss of a D-depleted organic component.

We conclude that in CC the D-rich organic component is thermally sensitive whereas in OC it is thermally refractory. This clearly indicates different organic moieties that may have distinct origins. Organic radicals were suggested to be the carrier of the D-excess in CC [3]. In OC, another organic component, yet unidentified has to be invoked. It might have been formed in the interstellar medium [4]. The opposite behavior of the organic D-rich component in CC and OC may induce distinct evolutions of the D/H of their IOM upon thermal metamorphism.

The nitrogen isotopic composition of the organic matter trapped within the calcite shells of planktonic foraminifera (FB-$\delta^{15}N$) has been explored as a new proxy in ocean sediment records to reconstruct past changes in the marine nitrogen cycle, but information on its generation and preservation is so far minimal. In this study, we report measurements of the $\delta^{15}N$ of foraminiferal biomass from Sargasso Sea net tow material and shell-bound N from shallow sediments collected in different open ocean regions. The annual average biomass $\delta^{15}N$ of three euphotic zone dwelling species, *G. ruber*, *G. sacculifer*, and *O. universa* in the Sargasso Sea surface is around 2‰, similar to but slightly lower than the thermocline nitrate $\delta^{15}N$, as well as their shell-bound $\delta^{15}N$ in the surface sediment. We observe large seasonal variations in the biomass $\delta^{15}N$. $\delta^{15}N$ is lowest in fall to winter, followed by a $\delta^{15}N$ rise during the spring bloom. Our global data set of FB-$\delta^{15}N$ from surface sediments in the oligotrophic regions shows a strong correlation between FB-$\delta^{15}N$ and changes in the subsurface nitrate $\delta^{15}N$, which is the dominant source of new N to the euphotic zone. In the subarctic North Pacific and the eastern equatorial Pacific, where nitrate is abundant at the surface, FB-$\delta^{15}N$ in the surface sediment closely tracks changes in surface nitrate $\delta^{15}N$ and is thus anticorrelated with nitrate concentration. These results are strong evidence that FB-$\delta^{15}N$ is a reliable proxy for tracing the $\delta^{15}N$ of the N supply to surface waters in oligotrophic regions and for reconstructing surface nitrate utilization in high-nutrient regions. We will also examine the interspecies differences in terms of depth habitat and and trophic level.

Heavy metal availability in contaminated soils:complementary insights from isotopic exchange, DMT, and sequential extractions

Z. L. REN[1,2], J. DAI[2], Y.SIVRY[1] AND M. F. BENEDETTI[1]*

[1]Université Paris Diderot- Sorbonne Paris Cité - IPGP, UMR CNRS 7154, Paris, France 75205 (*correspondence: benedetti@ipgp.fr)
[2]College of Resources and Environment, South China Agricultural University, Guangzhou, China 510642

Contaminated calcareous topsoils were sampled from paddy fields around a lead/zinc mine in Lechang, Guangdong Province, South China. The soil pH was 7.8, total heavy metal contents were 768 mg Pb kg^{-1}, 715 mg Zn kg^{-1}, 58.7 mg Cu kg^{-1} and 22.6 mg Ni kg^{-1}.

Donnan membrane technique (DMT) and stable isotopic exchange kinetic (SIEK) technique were performed to determine the concentration of free metal ion (FMI) in soil solution and the available metal pool (isotopically exchangeable metal, *E* value) in soil. Traditional sequential extractions were also used to assess the metal distribution among the geochemical compartments of soil solid phase.

DMT results showed that quite few FMIs were presented in the soil solutions. At soil:solution ratio = 100 g L^{-1}, the total dissolved Pb, Zn, Cu, Ni were only 0.91, 3.29, 3.34, 0.07 μg L^{-1}, while large proportion of Pb, Cu and Ni were complexed. A good agreement was found between the FMIs concentration measured by experiments and calculated by NICA-Donnan model.

However, multi-SIEK results indicated that the isotopically exchangeable pool of Pb, Cu and Zn were large. After 12-day equlibrium, E_{Pb}, E_{Cu}, and E_{Zn} value were 302, 13, and 106 mg kg^{-1}, which were up to 39%, 22% and 15% of metal total content, respectively. In contrary, E_{Ni} value was only 1 mg kg^{-1} (i.e. 1.5% of total Ni).

Combined with the metal distribution in solid phases given by sequential extractions, the larger Pb available pool may be attributed to the high carbonate-bound and Mn oxides-bound fractions. A large proportion of Ni in the so-called residual fraction (i.e. 75% of total Ni) may explain the lower E_{Ni}.

Therefore, such combination of different techniques can give a more comprehensive insight into the heavy metal availability, thus it can provide implications to risk assessment and long term remediation.

Broader impacts of geochronology

PAUL R. RENNE*[1,2]

[1]Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley, CA 94709, USA (*correspondence: prenne@bgc.org)
[2]Dept. Earth and Planetary Science, Univ. California, Berkeley, CA 94720, USA

Few Earth and/or planetary scientists need convincing that geochronology is fundamentally important to quantitative knowledge of planetary and biotic evolution. However, to non-scientists or even scientists from other disciplines, geochronology may be perceived as an esoteric or arcane pursuit with little "practical" value. On the contrary, geochronology plays a vital role in mineral and petroleum resource exploration. Perhaps less well-known outside the Earth science community are applications to natural hazard evaluation, particularly those due to volcanism and seismicity. In validating the cyclic orbital forcing of earth's climate, geochronology facilitates the discrimination of anthropogenic versus endogenous climate change, and permits quantification of the rate of change. Geochronology has even played a critical role in nuclear forensics. It is fair to anticipate that technological innovations will continue to improve the precision and scope of various geochronometric techniques in the future. Consequently, geochronology will likely have increasing importance to societal issues in addition to underpinning new discoveries about how the Earth works and interacts with the rest of our Solar System.

Stepwise calibration of the Alder Creek sanidine $^{40}Ar/^{39}Ar$ dating standard to the historical 79 CE eruption of Vesuvius

RENNE*[12], PAUL R. AND DEINO[2], ALAN D.

[1]Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley, CA 94709, USA (*correspondence: prenne@bgc.org)
[2]Dept. Earth and Planetary Science, Univ. California, Berkeley, CA 94720, USA

Interlaboratory variations in argon isotope data for standards remains a significant problem for $^{40}Ar/^{39}Ar$ geochronology. A bellweather for the problem is the ca. 1.2 Ma Alder Creek sanidine (ACs) standard, for which a range of ca. 2 % in $^{40}Ar^*/^{39}Ar_K$ has been reported by various laboratories. To address this problem we are calibrating ACs against sanidine (79Vs) from the 79 CE eruption of Vesuvius, whose age is known from analysis of the writings of Pliny the Younger and other sources to within 3 months [1] in 1934 years, i.e., a relative uncertainty of ±0.013%. Direct calibration of ACs against 79Vs involves measuring a ratio of $^{40}Ar/^{39}Ar$ (R'-ACs/79Vs) between the two samples of ca. 600, which admits the possibility of bias from detector non-linearity and differential sensitivity to memory. Hence we use a third sample (X) of intermediate age to provide a stepping stone between ACs and 79Vs and make use of the fact that (R'-ACs/79Vs) = (R'-ACs/X) x (R'-X/79Vs). Neglecting atmospheric ^{40}Ar, the optimal values of (R'-ACs/X) = (R'-X/79Vs) = 24, corresponding to an age of ca. 46 ka. Accordingly, we have selected sanidine from the ca. 40 ka Campanian ignimbrite (CIs) in the Campi Flegrei as the stepping stone. Previous studies of CIs have yielded satisfactory reproducibility and no evidence of extraneous argon. Preliminary data suggest that this approach will yield a value of (R'-ACs/79Vs) with <2% relative uncertainty, hence will contribute to clarifying the absolute age of ACs.

A new Cenozoic Record of Sulfur Isotopes from Foraminiferal Calcite.

VICTORIA RENNIE[1]*, GUILLAUME PARIS[2], JESS F. ADKINS[2] AND ALEXANDRA V. TURCHYN[1]

[1]Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK, vcr22@cam.ac.uk (*presenting author)

The sulfur isotope composition of marine sulfate ($\delta^{34}S_{SO4}$) reflects the balance between the weathering and burial fluxes of both evaporite minerals and pyrite, and their isotopic composition. These are the dominant fluxes into and out of the marine sulfur cycle, and thus a change in the seawater $\delta^{34}S_{SO4}$ would reflect a change in the global sulfur cycle. The importance of the sulfur cycle lies in its potential to help elucidate the subsurface remineralization of organic carbon and, indirectly, the oxidation state of Earth's surface environment.

Reconstructions of seawater $\delta^{34}S_{SO4}$ have previously been made using marine barite (limited to the past 130Ma) and discontinuous evaporite deposits. However, carbonate-associated sulfate (CAS), sulfate that has been incorporated into the carbonate lattice, has potential to act as an alternative archive for seawater S-isotope history and can provide information on regional and global variations in the S-cycle over geological time.

We present CAS $\delta^{34}S_{SO4}$ results from single species foraminifera, using a new sulfur isotope analytical technique optimised for mass limited samples [1]. We report an interspecies variability of up to 1‰ in planktonic forams and a large decrease in $\delta^{34}S_{SO4}$ variability upon the choice of shell cleaning. This method also allows us to identify contaminant phases with greater ease than in bulk studies. Our $\delta^{34}S_{SO4}$ record for the Cenozoic, using a species-specific approach, is in agreement with the coeval barite $\delta^{34}S_{SO4}$ record, engendering confidence in CAS as a proxy for $\delta^{34}S_{SO4}$.

[3]Géosciences Environnement Toulouse UMR 5563, CNRSUniversité Paul Sabatier IRD, Toulouse, France

Contamination of river sediments by metal(loid)s originating from mining activity is a worldwide problem. Because the transport of metals associated with sediments can represent more than 90% of the total flow of metals in rivers, identify their sources and evaluate their potential mobility are particularly important.

The purpose of this work was to assess past and present influence of mining activity on metal(loid) enrichment in sediments of a former mining watershed now industrialized and urbanized, the Gardon River watershed (France).

Samples of a sedimentary archive and current sediments of the Gardon River and its tributaries were characterized combining geochemical analyses, zinc isotopic analyses and sequential extractions.

Considering metal(loid) concentrations in sediments upstream from the mining sites and in bottom sediments of the archive, natural background values were proposed. Based on these values, enrichment factors (EF) were calculated. Several tributaries were highly impacted by old mining sites (EF values up to 250 for Pb, 160 for Cd, 60 for Zn, 70 for As and 1850 for Sb) and by industrial activity. These polluted tributaries impacted metal(loid) content of the main stream sediments. EF values increased in Gardon River sediments downstream from old Pb/Zn mines about 3-fold for Pb, Cd and 2-fold for Zn, As and downstream from old Sb mines about 5-fold for Sb. Interelement relationships were used to distinguish the main contaminant sources. Although Zn isotopic signatures differed significantly for mining impacted tributaries (δ^{66}Zn~0.08‰) and for industrial impacted tributary (δ^{66}Zn~0.31‰), Zn isotopic composition remained homogeneous in the main stream sediments of the Gardon River watershed (δ^{66}Zn values around 0.20‰). Finally, the percentage of metal(loid)s present in the "mobile" pool, as estimated by sequential extraction, was: Sb (1-5%) < As (1-22%) < Zn (10-65%) = Pb (15-68%).

[4]Laboratoire de Météorologie Dynamique, Jussieu, Paris, France

The triple isotope composition of atmospheric oxygen ($\delta^{18}O$, $^{17}\Delta$) integrates the signature of various mass dependent processes associated with hydrological cycle, biological cycle and non mass dependent photochemical reactions in the stratosphere, both on orbital and millennial timescales: changes in global seawater, hydrological cycle, relative humidity, vegetation distribution and C3/C4 plants partition. At the orbital timescale, tropospheric $\delta^{18}O$ bears a strong orbital precession signal while at the millennial timescale, d18O depicts a clear decrease in phase with Greenland InterStadial events. $^{17}\Delta$ ($\ln(\delta^{17}O+1)-\lambda*(\delta^{18}O+1)$) is more directly related to variations in the global biospheric productivity with a main variability associated with the glacial – interglacial changes.

Here we make use of a global model integrating changes in climate, biosphere productivity, water isotopic composition to quantify the contribution of the different processes to $\delta^{18}O$ and $^{17}\Delta$ signals at relevant orbital periods (snapshots of pre-industrial period, Last Glacial Maximum (LGM), Heinrich event). The model accounts for the latest fractionation ratios between ^{18}O /^{16}O and ^{17}O/^{16}O associated with oxygen respiration processes and leaf transpiration, oceanic net primary production (simulated by PISCES model), the spatial and temporal variation of vegetation distribution (simulated by ORCHIDEE model), climatic conditions and isotopic composition of meteoric water and water vapor (LMDZ global circulation model)

Bacterial diversity in Baltic Sea sediments from Skagerrak and Bothnian Bay

CAROLINA REYES[1]*, OLUWATOBI ONI[1], OLAF DELLWIG[2], MICHAEL E. BÖTTCHER[2] AND MICHAEL W. FRIEDIRCH[1]

[1]Leobener Strasse, NW2, D-28359 Bremen, Germany (*correspondence: reyes@uni-bremen.de)
[2]Leibniz-Institute for Baltic Sea Research, Seestrasse D-18119 Rostock, Germany

The biogeochemical cycling of iron is a key process in terrestrial and aquatic systems including marine environments. However, limited information exists about the diversity and metabolic pathways of microorganisms linked to the iron cycle in ocean sediments. The goal of this study was to determine the bacterial community diversity in sediment samples from Skagerrak (SK) and Bothnian Bay (BB) using pyrosequencing as a first step in characterizing microorganisms potentially involved in iron reduction at these two sites. DNA was extracted from various depths from sediments collected in SK and BB. Porewater profiles of relevant electron acceptors showed that sulfate was ~28 mM and ~ 2 mM in in SK and BB sediments, respectively. H_2S was below detection in both sediments, and Fe^{2+} and Mn^{2+} levels reached ~ 140-150 μM in SK sediments between 6-7 cm depth and ~300 μM within the first 2 cm in BB sediments. V1-V3 regions of the 16S rRNA gene were used for 454 titanium pyrosequencing and sequences were analyzed using QIIME (1). Proteobacteria dominated these sediments and potential iron- and manganese-reducing bacteria included *Desulfurmonadales*, *Alteromonadales*, *Geobacteraceae*, *Pelobacteraceae*, *Shewanellaceae*, *Myxcoccocales*, *Oceanospirillales,* and *Campylobacterales*. Additionally, *Actinobacteria,* and *Bacteroidetes* were also dominant. These results imply that marine systems are likely to harbor more metabolically diverse iron and manganese reducing microorganisms than the traditional *Shewanella* and *Geobacter* model systems.

Igniting flare-up events in Sistan Suture Zone, Iran

M. REZAEI-KAHKHAEI[1] AND F. CORFU

[1]Department of Geoscience, Shahrood University, Iran (*correspondence: Rezaei@shahroodut.ac.ir)
[2]Department of Geosciences, University of Oslo, PB 1047 Blindern, N-0316 Oslo, Norway (fernando.corfu@geo.uio.no)

Sistan Suture Zone (SSZ) was undergone a number of important short-lived tectonic events from the middle Cretaceous to recent: (i) rifting of a large continental mass in the middle Cretaceous produced the Lut and Afghan blocks with an intervening marine basin (flysch) accumulated; (ii) northeastward subduction under the Afghan block by the Maastrichtian; (iii) collision between the Lut and the Afghan blocks terminated subduction by the middle Eocene; and continued convergence between the Lut and Afghan blocks resulted in widespread conjugate strike-slip faulting [1]. Zahedan–Saravan granitoides are parts of SSZ and occurred after closure of the ocean with a northwest–southeast trend (figure). The granitoides can be separated into two groups based on detailed age, major and trace-element geochemistry and field work. They are dominated by biotite granites at about 50km away from subduction place (ophiolitic rocks) with ~ 43Ma in age and granodiorites at 70-90km away from subduction place with 30Ma in age. The granitoides were cut by lots of andesitic and rhyolitic dykes at ~ 29Ma before they completely cold. U–Pb dating and geochemical analyses reveal: (1) a shift between the ages of biotite granites near the subduction place and the granodiorites farther than biotite granites from the subduction place; (2) Relative to granodiorites, biotite granites are richer in CaO, MgO, TiO_2, Ni, Cr, Co, Zr, Yb, Cs and Lu; and (3) an apparent flare-up in the SSZ from 43 to 29Ma.

Figure: Geological map of Zahedan–Saravan granitoides.

Dependence of Sulfur Cycling and Mobility in Peat Soil on the Water Table Regime

F. REZANEZHAD[1]*, R-M. COUTURE[12], C. PARSONS[1], R. KOVAC[1], D. O'CONNELL[1] AND P. VAN CAPPELLEN[1]

[1]Ecohydrology Research Group, University of Waterloo, Waterloo, Canada (*correspondence: frezanez@uwaterloo.ca)
[2]Norwegian Institute for Water Research, Oslo, Norway

Water table fluctuations change the soil redox environment and hence, affect the metabolism of electron donors and acceptors by the native microbial community. To investigate the role of water table dynamics on biogeochemical transformations and fluxes in soils, an automated column system was developed to simulate the interactions between groundwater and surface waters under controlled conditions. In this system, the position of the water table is imposed using a computer-controlled, multi-channel pump connected to a hydrostatic equilibrium reservoir and a water storage reservoir. We compared two water table regimes: i.e., fast (4 days) vs. slow (16 days) water table fluctuations. The pulse of oxygen introduced by lowering the water table caused a partial and temporal oxidation of previously reduced species. As expected, draining and rewetting of the soil columns resulted in a significant re-oxidation of reduced sulfur species, changes in pore water SO_4^{2-} concentration and microbial sulfate reduction rates. However, the dual-porosity structure of the peat soil was found to strongly modulate the sulfur cycling and mobility. This study supports the importance of water table dynamics and soil texture on biogeochemical functioning of peat soil environment.

Caprock's nanoporus structure modification by supercritical CO_2/water interaction:A contribution of adsorption techniques

D. RHENALS[1,2] ,S.LAFORTUNE[1] , H. SOULI[2] AND P. DUBUJET[2]

[1]French National Institut for Industrial Environment and Risks, Parc Technologique Alata, BP 2, Verneuil-en-Halatte, 60550,France-david-rhenals@ineris.fr
[2]National School Engeeniers of Saint Etienne, 58 rue Jean Parot, Saint-Etienne, France

CO_2 storage is envisioned as a technique which reduces large quantities of CO_2 rejected in the atmosphere because of many human activities.

The effectiveness of this technique is mainly related to the storage capacity as well as its safety. The safety of this operation is primarily based on the conservation of petro-physical properties of the caprock, which prevents the transport of CO_2 through it. However when CO_2 reaches the reservoir/caprock interface due to buoyancy effects, the interaction between interstitial fluid and injected fluid creates a series of dissolution/precipitation reactions affecting the properties of containment of the caprock, which is generally characterized by low transport properties.

This study aims to assess the impact caused by CO_2/interstitial fluid interaction on the nanostructure of the caprock under geological storage conditions. In order to do this, degradation experiments in a well characterized shale have been conducted using batch reactors for two months.

Adsorption-desorption isotherms showed an increase in the sorption capacity as well as a variation on pore size distribution. BJH and Dubinin Stoeckli distributions showed an increase in porous density lower than 10 nm, which is mainly attributed to dissolution of carbonates and some aluminosilicates detected initially with XRD techniques. Chemical water analysis showed an increase in Ca,Mg,Na,K,Si concentration, which is consistent with porous structure variation determined by physical adsorption.

Composition of the shallow aqueous fluids released beneath the SE Mariana Forearc Rift

JULIA RIBEIRO[1], ROBERT J. STERN[1], KATHERINE A. KELLEY[2], ALISON SHAW[3], FERNANDO MARTINEZ[4] AND YASUHIKO OHARA[5]

[1]Geosciences, University of Texas at Dallas, USA.
[2]GSO, University of Rhode Island, USA.
[3]Depart. of Geology and Geophysics, WHOI, USA.
[4]SOEST, University of Hawai'i at Manoa, USA.
[5]Hydrographic and Oceanographic Depart. of Japan, Japan.

Fluids released from subducted slabs are thought to be more aqueous beneath forearcs than are the fluids released beneath arc volcanoes; however, investigating their composition is challenging as the cold forearc mantle generally does not melt. Basaltic lavas of the Southeast Mariana forearc rift (SEMFR) provide an unusual opportunity to examine basalts affected by such fluids. SEMFR extends from arc volcanoes nearly to the Mariana trench and was generated by forearc seafloor spreading ~2.7–3.7 Ma ago. SEMFR basalt compositions are similar to backarc basin basalts and contain olivines with unusually depleted basaltic melt inclusions. These OL-MI were captured by unusually refractory olivines (Fo_{90-93}), and we interpret them to have formed as hydrous melts trapped in the forearc mantle. Fragments of this mantle (OL xenocrysts and Cr-spinel) were entrained with SEMFR basalt magmas during their ascent. SEMFR glassy rinds and Ol-MI have variable volatile contents (mean H_2O=1.85±0.26 wt%, S=757±109 ppm, Cl=334±169 ppm, F=94±31 ppm, CO_2=144±137 ppm). SEMFR Ol-MI and their host basaltic glassy rinds have unusually high ratios of volatiles and fluid-mobile elements (FMEs; mean H_2O/Ce=10096±3901, Cl/Nb=1238±516, Cs/Th=6±5, Ba/Th=523±203, Rb/Th=79±38 for the Ol-MI; and mean H_2O/Ce=4953, Cl/Nb=838, Cs/Th=0.84±0.66, Ba/Th=265±97, Rb/Th=27±14 for the glassy rinds) ever recorded in the Mariana intraoceanic arc (mean H_2O/Ce=1705±1125, Cl/Nb=429±414, Cs/Th=0.39±0.16, Ba/Th=264±150, Rb/Th=15±3), indicating that the shallow fluids have distinctive FMEs/Th and volatile/incompatible ratios. SE-NW gradient in these ratios demonstrate that the aqueous fluids and the volatile fluxes are the highest at ~50–100 km slab depth, suggesting that hydrous minerals in the subducted slab mostly break down beneath the arc.

Contact-metamorphic effects of the Santa Eulália Plutonic Complex (Southern Portugal): Litological and structural constraints

RIBEIRO, M.A.[1(*)], SANT'OVAIA; H.[1] AND CRUZ, C.[1]

[1]Centro Geologia, Faculdade de Ciências, Univ. Porto R. Campo Alegre, 4169-007 Porto, Portugal (*correspondence maribeir@fc.up.pt)

The Santa Eulália Plutonic Complex (SEPC) is a late-variscan granitic pluton in SW sector of the Iberian Orogen. This granite with 400 km^2 cross-cuts the regional NW-SE variscan structures, namely a major high-grade and high-strain shear zone in the contact between two axial geotectonic zones of the iberian varican belt. The host rocks of SEPC are composed by low to high grade metamorphic rocks from Upper Proterozoic to Lower Paleozoic. In the NE-sector of the shear zone a low grade metasedimentary Ediacaran unit (Série Negra) composed by siliciclastic rocks, including black cherts, is located adjacently to a high grade unit (migmatites and gneiss). In the SW-sector of the shear zone, a low-grade metasedimentary and metavolcanic Cambrian sequence has quartz-pelitic, carbonate and volcanic rocks. The lithostratigraphic units are also tectonic units bounded by major high-strain transcurrent faults placing side by side different rock types and different metamorphic grades, but always characterized by a well-developed vertical foliation. Both at east or at west, the host rocks are phyllite and quartz-phyllite, in chlorite zone conditions, without any thermal effects even at short metric distance from the contact. The metapelitic rocks show millimetric veins (2mm thick) with biotite, quartz, chlorite and apatite, concordant with foliation, without exhibiting any thermal effects on the walls. The Cambrian carbonate rocks outcropping in narrow bands near the ESE border of SEPC did not show any post-kinematic thermal effect. Unlike, in the western sector of SEPC the thermal effect is marked in the metasedimentary roof pendants, by metamorphic and metasomatic paragenesies in pelitic and carbonate hornfels, the later with large wollastonite crystals.

Our results highlight that the thermal effects of the SEPC in the host rocks are restricted to the roof pendants and the metasomatic effects are constrained by the carbonate rocks. The shape of the pluton, the absence of lateral thermal effects, the smooth bend of the vertical host rocks around the pluton in easthern border suggest a small thickness of the massif in the western border, and a deep rooting in the major vertical shear zone at the eastern border.

Diverse capacity for 2-methylhopanoid production correlates with specific niches

JESSICA N. RICCI[1], MAUREEN L COLEMAN[1], PAULA V. WELANDER[2], ALEX L. SESSIONS[1], ROGER E. SUMMONS[2], JOHN R. SPEAR[3] AND DIANNE K. NEWMAN[1,4]*

Molecular fossils of 2-methylhopanoids (2-MeBHPs) are important geological biomarkers and have often been interpreted as proxies for cyanobacteria and their main metabolism oxygenic photosynthesis [1]. However, substantial culture and genomic-based evidence indicates that organisms other than cyanobacteria can make 2-MeBHPs [2, 3]. Yet, these lines of evidence do not address which organisms produce 2-MeBHPs in the environment. In this study, we use metagenomic and clone library methods to address the environmental diversity of *hpnP*, the gene encoding the C-2 hopanoid methylase. We show that *hpnP* copies from alphaproteobacteria and unknown origin are found in diverse modern environments, including some representative of those preserved in the rock record, while cyanobacterial *hpnP* genes are more rare and localized to specific habitats. Moreover, *hpnP* diversity in any given locale can be spatially and temporally heterogeneous, stressing the need to sample environments rigorously before drawing general conclusions. Additionally, we asked if *hpnP* is overrepresented in organisms or environments with a specific metabolism or associated with a particular niche. We found the presence of *hpnP* to be significantly correlated with organisms and environments known to support plant-microbe interactions. Our results indicate that 2-MeBHPs can no longer be used as unambiguous biomarkers for cyanobacteria and hints at a potential interpretation for 2-MeBHPs separate from oxygenic photosynthesis that underpins the observed enrichment of *hpnP* in these contexts.

Thermodynamic analysis of water-rock-hydrocarbon interactions in petroleum systems

LAURENT RICHARD

Geoquímics dels Àngels, Carrer dels Àngels 4-2-1, 08001 Barcelona, Spain

Throughout their evolution across the crust of the Earth, minerals and organic compounds interact in many geological processes ranging from the low-temperature early diagenesis of marine sediments to the metamorphism of pelitic schists. The geochemical cycles of iron, sulfur or nitrogen (among other elements) are governed by such interactions, which correspond to oxidation-reduction reactions. Well-documented examples include the decarbonation of siderite in the presence of carbonaceous matter [1], the formation of sulfur-rich organic matter in carbonate sediments [2], or the exchange of nitrogen isotopes among petroleum and clays in clastic reservoirs [3].

It is the purpose of the present communication to illustrate how thermodynamic properties published for solid and liquid hydrocarbons and sulfur- and nitrogen-bearing compounds of geochemical interest [4,5] can be used to develop quantitative models for the evolution of water-rock-hydrocarbon systems, as well as to make reasonable estimates regarding the composition of petroleum fluids as a function of temperature, pressure, the fugacities of CO_2, H_2S, NH_3 and H_2, and their mineralogical and aqueous environment. Conversely, I will show how compositional data for crude oils can in some instances be used to evaluate or retrieve thermodynamic data.

The role of arc magmas and subduction-modified lithosphere in ore formation

JEREMY P. RICHARDS[1]

[1]Dept. Earth and Atmospheric Sciences, University of Alberta, Edmonton, Alberta, Canada, T6G 2E3
Jeremy.Richards@ualberta.ca

Arc magmas are a unique source of subduction-derived volatiles (water, sulfur, and chlorine: mostly derived from seawater-altered oceanic lithosphere), plus water-soluble elements (alkalis and large-ion lithophile elements) and chalcophile and siderophile metals. Upon emplacement in volume in the upper crust, these magmas may generate porphyry Cu±Mo±Au and epithermal Au±Cu deposits. However, during their ascent through the upper plate lithosphere, they interact with these rocks to form hybrid calc-alkaline magmas, and fractionate to leave ultramafic to mafic, amphibolitic cumulate residues at the base of the crust (MASH process of Hildreth and Moorbath, 1988).

Over the life of an arc (typically ≤10–15 m.y.), the mantle wedge above the subduction zone becomes increasingly hydrated and oxidized as slab fluids cause progressive metasomatism, leading to partial melts that also increase in water content and oxidation state over time. Early primitive magmatic fluxes entering the upper plate lithosphere may leave considerable amounts of metals behind in cumulate zones as sulfides separated from relatively reduced (ΔFMQ ≈ 0) magmas (Lee *et al.*, 2012). However, increasing oxidation state in later magmas (ΔFMQ ≈ 1–2) suppresses sulfide-saturation, and leads to efficient transport of metals in magma fluxes reaching the upper crust (Botcharnikov *et al.*, 2011). Consequently, major porphyry-forming events are commonly relatively late in the evolution of a given arc.

The deep crustal residues of arc magmatism are relatively fusible (amphibole-rich) and likely contain small amounts of metal sulfides. Re-melting of these residues during later tectonic events, such as collision or rifting, may generate metalliferous magmas with similar chemical and isotopic characteristics to normal arc magmas, which may go on to form post-subduction porphyry Cu±Mo±Au deposits. Their derivation from partial melting of deep crustal garnet-amphibolites gives these magmas adakite-like high Sr/Y and La/Yb ratios, but they are not formed by slab melting.

Rhizogenic C-Fe Redox Cycling: Sleeping Couple No Longer

D. DEB. RICHTER[1]*, A.R. BACON[1], M.L. MOBLEY[2], M. OELZE[3] AND F. VON BLANKENBURG[3]

[1]Duke University, Durham, NC 27708 USA (*correspondence: drichter@duke.edu)
[2]University of Wyoming, Laramie, WY 82072 USA
[3]German Research Center for Geosciences, D-14473, Potsdam, Germany

Nearly all soil data derive from bulked collections that homogenize soil heterogeneity [1, 2]. We therefore have limited understanding of biogeochemical processes, properties, and gradients that may contrast greatly amongst the many micro-environments that exist within soil profiles. Rooting can affect the upper several meters of soils and especially subsoil rhizospheres are hotspots of biological and chemical activity. In upland soils, distinctive redoximorphic features often visually illustrate microenvironments that contrast not only in color, but in chemistry, physics, and biology. Such redoximorphic features are often interpreted as being relic features of past ecosystems [3]. We hypothesize that mottles are both relic and active microsites in which organic-reductant enriched rhizospheres are periodically reduced when saturated, when the C-Fe redox cycle is associated with carbon stabilization, FeIII reduction, mineral dissolution reactions, and colloidal translocation.

Depth-dependent sampling of redoximorphic microsites in three upland soils was combined with chemical and physical analyses to investigate processes, properties, and time scales on which these rhizogenic microsites operate. In all three soils, we attribute C enrichment and Fe depletion in rhizospheres to result from electron acceptors periodically switching from O_2 to FeIII and other redox-active species, when subsoils become periodically saturated due to wet conditions and low hydraulic conductivity. Both $\Delta^{14}C$ and $\delta^{56}Fe$ [4] data indicate that the rhizogenic C-Fe redox cycle operates in the contemporary forest ecosystem, thus redoximorphic features are both relic and active. Large contrasts in clay and crystalline Fe concentrations among these microsites demonstrate large but local-scale mobility of Fe and colloidal materials. The significance of the upland rhizogenic C-Fe redox cycle is underscored by the deep and extensive rooting and mottling of many upland soils across a range of plant communities, lithologies, and climatic regimes.

Kinetic isotope fractionation at the frontier of modern geochemistry

FRANK RICHTER

The Univ. of Chicago, Chicago, IL USA [richter@geosci.uchicago.edu]

Geochemistry can claim a special place in the Earth sciences because it provides distinctive insight into both processes and the time scale over which they operated. I will review recent developments both from experiments and natural settings that illustrate how stable isotope fractionations are being used to identify the process responsible for chemical zoning, and that when the zoning is unambiguously shown to be due to diffusion, can it be used to provide a measure of time. To make this case for the role of stable isotopes the first thing one needs to demonstrate is that mass transport by diffusion in silicate systems is easily recognized by the fact that it produces isotopic fractionations that are large compared to modern analytical methods. The state of affairs in terms of the results of laboratory experiments involving chemical diffusion in melts [1-4], minerals [5], and metal alloys [6] is that in every case so far studied large kinetic isotope fractionations were found and thus they do provide a "fingerprint" with which to distinguish mass transport by diffusion from other mechanisms. What makes this especially relevant is that what has been found in the laboratory experiments has also been found in numerous natural settings ranging from quenched contacts between mafic and silicic melts [7], minerals from mantle xenoliths [8], from lava flows both on Earth and from Mars [9,10] and from a lava lake [11]. A corollary to the above arguments is that when one finds chemical zoning that does not have correlated stable isotope fractionations, one should avoid any temptation to interpret these as providing a measure of time. Thus kinetic isotope fractionations can both give special insight into the causes of chemical zoning, but equally importantly, spare us from the embarrassment of using diffusion kinetics to infer cooling rates from chemical zoning caused by some process other than diffusion.

A history of inhibition: thresholds and echinoderm Mg/Ca

R. E. M. RICKABY[1], M. VICKERS[1], H. C JENKYNS[1], A. S. GALE[2], P. BOTS[4] AND S. SHAW[3]

Oscillations between an ocean which generates a primary abiotic precipitate of calcite or aragonite have been identified throughout the Phanerozoic and attributed to variability in the major ion chemistry of the ocean (magnesium, calcium and sulphate concentrations as lead candidates). Such variability represents fundamental changes to Earth surface processes, notably the balance among continental weathering, sedimentation, and volcanic activity. These cycles in seawater chemistry and primary mineralogy of marine carbonates have implications for reconstructing the drivers of changes in atmospheric CO_2, for the feedbacks in the global carbon cycle, and for the evolution of biomineralising life. Yet the record of precisely how, when and what these major changes have been is scant at best. Further definition of the chemical thresholds and a quantitative reconstruction and mechanistic understanding of the drivers of these fundamental ocean chemistry changes remains elusive.

First we shall explore how the combined effects of chemical inhibitors can alter the potential thresholds for a change in primary marine carbonate precipitate (Bots *et al*., 2011). We then employ an established method (Dickson, 2002) to provide insight into refining the Meso-Cenozoic history of the dominant kinetic inhibitor of calcite precipitation, namely magnesium. We demonstrate the utility of a uniquely pristine sample compilation of echinoderm fragments collected from clay hosted sediments to preserve a history of seawater Mg/Ca. Our reconstructed history of seawater Mg/Ca is largely concordant with existing results except for a part of the middle Jurassic which appears to be characterised by much lower Mg/Ca ratios than predicted by most models.

Boundary addition of Hf and Nd in the Southern Ocean

J. RICKLI[1], M. GUTJAHR[2], D. VANCE[1], C.D. HILLENBRAND[3], G. KUHN[4] AND M. FISCHER - GÖDDE[5]

[1]ETH Zurich, Institute of Geochemistry and Petrology, Switzerland (joerg.rickli / derek.vance@erdw.ethz.ch)
[2]GEOMAR Helmholtz Centre for Ocean Research Kiel, Germany (mgutjahr@geomar.de)
[3]British Antarctic Survey, Cambridge, UK
[4]Alfred Wegener Institute, Bremerhaven, Germany
[5]Westfälische Wilhelms Universität, Münster, Germany

Hf and especially Nd isotopes are increasingly used to reconstruct past ocean circulation. Many of these applications rely on their quasi-conservative behaviour impyling that the key process that governs their distribution is circulation. Here, we report new elemental (Hf, Zr, Nd) and isotope data (εHf, εNd) from the Pacific sector of the Southern Ocean, which document the relative significance of circulation vs boundary processes on the Hf and Nd distribution adjacent to Antarctica. Seawater depth profiles were sampled in the Ross Sea, along the West Antarctic continental rise and in the vicinity of the Marie Byrd Seamounts offshore the Amundson Sea Embayment (ASE). In addition, several samples were taken within 1.5 m to the seabed in the ASE. The samples were not filtered, which implies that some of the observations may be accentuated by contributions from the leaching of particulates during sample acidification.

The key observations for Nd include (a) the shift to radiogenic εNd and elevated Nd concentrations in the ASE (εNd up to -5.4), (b) a gradual increase in εNd with depth from 1000 m to 3000 m water depth in the open ocean (-9 to -7.8) along the entire West Antarctic margin and (c) distincly more radiogenic deep waters beneath 3000 m, especially at the Haxby seamount (up to -3.1). (a) is indicative of boundary release of Nd. (b) probably reflects the mixing of freshly forming boundary affected deep waters with circumpolar deep water (CDW) upon sinking. (c) indicates that, in addition to the shelf, the deep ocean floor and basaltic seamounts act as sources of radiogenic Nd.

Hf isotopes are relatively homogenous in the data set (εHf mostly between +2 and +3.8). Boundary release is, however, evident from elevated Hf and Zr concentrations in the embayment. In addition, distincly unradiogenic εHf of -1 are observed in deep waters at the Haxby Seamount. The data thus suggests that relatively unradiogenic Hf is released from Antarctica in the sampling area, which probably also accounts for the slight but systematic difference between measured εHf of CDW and deep waters of the eastern Pacific compared to the Atlantic sector of the Southern Ocean.

Is this a good time to be burning fossil fuels?

ANDY RIDGWELL [1]

[1]University of Bristol, Bristol, UK, andy@seao2.org

The basic for any sane analysis and discussion of the biotic response to past ocean acidification is, of course, identifying that there has been ocean acidification in the first place. But outside of the relatively recent geological past, the measurement and interpretation of direct proxies for the key parameters involved – pH and carbonate ion concentration (saturation state) becomes increasingly challenging. This is important as only the closely coupled decline in both these parameters together constitutes a future-relevant marine environmental change. One can resort to analysis of the size and duration of carbon isotopic changes and if really desperate … models, in order to make estimates of the magnitude of carbon release and perturbation, but often such thinking takes place in a conceptual framework delineated by observations of how the modern carbon cycle works.

What I would like to explore here is whether the sensitivity of ocean chemsitry to perturbation could have been much greater ealier in the Phanerozoic compared to today. For instance, following the advent and proliferation of planktic (carbonate) biomineralization during the Mesozoic: did the emergent deep sea carbonate 'buffer' preclude ocean acidification driven mass extinction? And what would it take in terms of fossil fuel CO_2 emissions to overwhelm it today?

Evolution of the oceans biological pump

ANDY RIDGWELL [1]

[1]University of Bristol, Bristol, UK, andy@seao2.org

Earth history is punctuated by a huge variety of transitions and perturbations in climate and global biogeochemical cycling. These may be linked to major extinctions or evolutionary innovations, and may exhibit evidence for greenhouse warming and CO_2 release and hence potentially hold direct future-relevant information. In interpreting the geological record it is common to assume the presence in the ocean of a strong vertical 'pump' of carbon and associated trace elements and isotopic properties. Proxies for past environments and perturbations are duely interpreted on this basis. However, evolutionary innovations have the potential to change the ground rules and give rise to non uniformitarianism behaviors of the global carbon cycle in deeper time. For instance, the cycle and reservoir of dissolved organic in the ocean may have been dominant in the past and has been invoked to explain a number of prominent features of the geological record. But is even this thinking too constrained by our familiary with the modern? Just how radically different might the biological pump have been at different times since the the advent of photosynthesis? When was a biological pump of any sort first developed?

In this talk I'll start by summerizing the known knowns and known unknowns surrounding the marine carbon cycle as it exists today, as we need to be clear at the outset about what key processes are incompletely understood. I will then piece together a potted history of how today's carbon cycle might have arisen in relation to the various evolutionary developments and transitions over the past ~2 Ga and discuss the implications for how we interpret the geological record.

Surface Complexation Modeling of cation adsorption by TiO_2 nanoparticles

MOIRA K. RIDLEY[1]*, MICHAEL L. MACHESKY[2] AND JAMES D. KUBICKI[3]

[1]Texas Tech University, Dept. of Geosciences, Lubbock, TX, USA, moira.ridley@ttu.edu (* presenting author

[2]University of Illinois, Illinois State Water Survey, Champaign, IL, USA, machesky@illinois.edu

[3]The Pennsylvania State University, University Park, PA, USA jdk7@psu.edu

Surface Complexation Models (SCM) provide a means to quantify the specific adsorption of ions, the interaction of electrolyte ions, and the pH-dependent charging at mineral-aqueous solution interfaces. Additionally, SCMs provide a thermodynamic framework for predicting surface protonation equilbria. The charge distribution (CD) and MUSIC model facilitates the integration of molecular-scale information with macroscopic data to describe the interface behavior of ion-mineral systems.

In this presentation, we will dicuss the application of the CD and MUSIC model to provide a thermodynamic description of the primary charging behavior of a suite of monodisperse, nanocrystalline anatase particles in NaCl media. Additionally, the CD-MUSIC model has been used to evaluate the interaction of Sr^{2+} and Ca^{2+} ions with the same suite of nano-anatase samples.

The adsorption of cations onto nano-anatase was evaluated over a wide range of pH, surface loading, and ionic strength. Complementary DFT-MD molecular simulations were also completed to evaluate the bonding geometries of all cations on the predominant (101) anatase surface. The adsorption behavior for the two divalent cations onto the anatase surface are broadly similar; although, Ca^{2+} first adsorbs at slightly low pH values and has slightly steeper charging curves than Sr^{2+}. The variations in the macroscopic charging curves for the interaction of Sr^{2+} and Ca^{2+} with anatase reflect the differences in binding geometries identified at the molecular-level. The DFT-MD optimizations show inner-sphere binding for all cations; however, the most stable binding geometries are different for each ion. The Na^{+} and Sr^{2+} ions have bidentate coordination geometries, with Na^{+} ions coordinated to two bridging oxygen (BO) surface sites and Sr^{2+} coordinated to two terminal oxygen surface sites. Conversely, Ca^{2+} ions are coordinated to three BO sites. This molecular-scale information was used explicitly to constrain all CD-MUSIC model fits.

Organic carbon and trace element mobilization from a biochar amended arable soil: A soil column study

THOMAS RIEDEL[1], JENNIFER GEILICH[1] AND S ASCHA IDEN[1]

[1]Technische Universität Braunschweig, Institut für Geoökologie

The addition of charred biomass (biochar) to agricultural soils is currently attracting attention as a means for sequestering carbon and as a potentially valuable method to improve soil fertility. Because some uncertainty remains about the possible impacts of biochar additions on organic carbon and trace element cycling in arable soils we conducted a soil column study to investigate the mobilization of trace elements (Mn, Fe, Cu, Zn) and organic carbon.

Amendments of 1% (w/w) of grounded and finely dispersed biochar resulted in a net reduction of organic carbon, Cu and Zn leaching from the saturated soil columns. The organic carbon leaching from the amended soil was less phenolic indicating that sorption to biochar was compound specific. A more detailed characterization of the organic matter with ultra-high resolution mass spectrometry revealed that the most non-polar compounds detectable with this method were retained by the biochar likely because of hydrophobic interactions.

Cu and (to a lesser extend) Zn were associated with the organic matter retained by the biochar as revealed by gel-permeation liquid chromatography hyphenated with inductively coupled plasma mass spectrometry. Complexation with organic matter may therefore play an important role in the interactions of some metals with biochar in soils. The elution behavior of Fe and Mn was almost unaffected.

After two weeks of flow interruption the water-logged soil columns had turned anoxic. Under these conditions the elution behavior of the trace elements changed markedly. Mobilization of Fe and Mn increased strongly, but the increase was less pronounced for the biochar amended soil indicating that sorption of Fe(II) and Mn(II) to the biochar had occurred. Zn and organic carbon on the other hand showed almost no difference to the oxic elution indicating no redox sensitivty.

Our results show that charred biomass affects the quantity and quality of organic matter as well as the quantity and speciation of trace elements leaching from agricultural soils.

Tectonically enhanced deep subsurface microbial carbon cycling in the Nankai Trough, Japan

N. RIEDINGER[1]*, M. STRASSER[2] AND T.W. LYONS[1]

[1]Dept. of Earth Sciences, Univ. of California, Riverside, CA 92521 USA (*correspond.: natascha.riedinger@ucr.edu)
[2]Geological Institute, ETH Zurich, 8092 Zurich, Switzerland

The occurrence and activity of microbial communities in deep subsurface environments are highly investigated. However, the abundance of microbial life and the source of energy necessary for these microorganisms remain controversial and under explored.

Here we investigate the impact of depositional and tectonic events on those deep microbial processes in sediments at IODP (Integrated Ocean Drilling Program) Site C0006, drilled and sampled during IODP Expedition 316 at the Nankai Trough, Japan. The observed methane isotope profiles indicate that active microbially mediated methane production occurs in sediments below 450 mbsf. This observation is supported by alkalinity measurements, indicating a source of inorganic carbon into the pore water as a by-product of deep in situ methane production. Thus, our data provide evidence for carbon cycling in these deep subsurface sediments. This is likely related to the highly dynamic tectonic regime at Nankai Trough, where tectonically induced temporary temperature increase can re-stimulate organic matter at distinct depths.

While tectonic activity can lead to the reactivation of recalcitrant organic matter, the variable sedimentary system provides niches for microbial abundance. The newly available/accessible organic carbon compounds fuel the microbial community – resulting in an onset of microbial methane production several hundred meters below the seafloor. This process is also captured in the isotope signal of methane, and thus methane isotopes can help us pin down locations of active microbial processes in deeply buried sediments.

Accurate isotope composition measurements by a miniature LMS system designed for in situ space research

A RIEDO[1]*, M. NEULAND[1], S. MEYER[1], M. TULEJ[1] AND P. WURZ[1]

[1]Physics Institute, Space Research and Planetary Sciences, Sidlerstrasse 5, 3012 Bern, Switzerland (*correspondence: andreas.riedo@space.unibe.ch)

A miniature laser ablation reflectron time-of-flight mass spectrometer designed for in situ space research for sensitive and accurate measurements of the elemental and isotopic composition of extraterrestrial material is described and its performance for accurate in situ measurements of isotope composition is demonstrated [1-4]. A ns- (266 nm, 5 ns, 20 Hz) [1-2] and a fs-laser ablation ion source (775 nm, 190 fs, 1kHz) [3] were used to investigate figure of merits (mass resolution, dynamic range, detection sensitivity and accuracy of measurements). The studies are performed with a high spatial resolution by focusing the pulsed laser radiation to spot of about Ø20 and 40 µm, respectively on the sample surface. The measurements are conducted with high dynamic range of at least 10^8 and a mass resolution ($m/\Delta m$) of up to 800-900, as measured at ^{56}Fe [1]. High detection sensitivity is achieved in measurements of both, metallic and non-metallic elements (tens of ppb) [1]. While ns-laser ablation ion source have to be calibrated with appropriate NIST standard reference materials (SRM), the relative sensitivity coefficients (RSC) were determined to be close to one when the fs-laser ablation ion source was applied [3]. Hence, the coupling of LMS with a fs laser system is preferable and is of considerable interest for the development of standard-less instruments. We developed a measurement procedure, which will be disscussed in detail, that allows LIMS to measure isotope composition of elements, e.g. Ti, Cr, Pb, etc., with a measurement accuracy and precision in the per mille and sub per mille level for the first time and is comparable to the performamce of other well-known and accepted measurement techniques (TIMS, SIMS and LA-ICP-MS) [2-3]. High performance of the LMS instrument offers versatile applications regarding in situ investigations of the chemical composition (elemental and isotopic) of extraterrestrial surface material [1-4].

Insight into biotite weathering rate using U-series isotopes

S.RIHS*[1], A. GONTIER[1], M.P. TURPAULT[2], D. LEMARCHAND[1], A. VOINOT[1] AND F. CHABAUX[1]

[1]LHyGeS/Université de Strasbourg (UMR 7517), Strasbourg, France (* correspondence: rihs@unistra.fr)

[2]Lab. Biogéochimie des Ecosystèmes Forestiers, (UR INRA 1138), Champenoux, France (turpault@nancy.inra.fr)

While the chemical weathering rate of silicates is a key parameter for several geochemical processes, field measurement of these rates remains challenging. Uranium- and Th-series nuclides were used to investigate biotite weathering in a soil profile. Some crystal-habits of biotites (including the alteration products) were hand-picked from five horizons (20 to 140 cm) of a soil profile from the experimental Breuil-Chenue site (France). Additionally, biotites from a seemingly 'fresh' block of the granitic bedrock were also recovered. Chemical analyses and XRD data allow quantifying the fraction of biotite remaining in these crystal-habits (91% to 9%). The extraction of the 'fresh' biotite interlayer demontrates the lack of U and Th in this interlayer.

Unexpected behaviour of U and Th nuclides was recorded in these biotites An unambiguous loss of ^{232}Th occurs during the transformation of the biotite to its alteration products, whereas little U loss (similar to Fe) was observed, implying an efficient redistribution of U between the primary mineral and the alteration products (mainly kaolinite and vermiculite) within the crystal-habit The measured U-series activity ratios show a ordered evolution, consistent with an increased weathered stage in these samples. However, this "U-series-derived-weathered-stage" is not always coherent with the location of the sample within the soil profile, i.e.: the 'fresh' biotite from the granite bedrock actually diplays some U-series activity ratios typical of significantly weathered samples, suggesting an incongruent leaching of U and Th isotopes. These results highlight that the U- and Th-series nuclides are probing some water-mineral interactions occuring before macroscopic mineral transformation.

Using an open-system leaching model, the coupled (^{234}U/^{238}U), (^{234}U/^{230}Th), and (^{226}Ra/^{230}Th) disequilibria measured in the samples permit to calculate a weathering duration ranging from 12 to 50 ka for the most altered biotite of this soil profile. The biotite weathering rates deduced from these data are consistent with the range of field rates previously reported [1], suggesting a valuable use of U-series isotopes for mineral-weathering field rate determination.

Dissolved Mo, W, V in Atlantic surface water

M. RIMSKAYA-KORSAKOVA*, E. BEREZHNAYA AND A. DUBININ

P.P.Shirshov Institute of Oceanology RAS, Moscow, Russia (*correspondence: korsakova@ocean.ru)

Molar ratio of Mo/W is about 1800:1 in the Pacific Ocean water, while in the Earth's crust Mo/W ratio is close to 1. Tungsten was preferentially scavenged by hydrogenic Fe-Mn oxyhydroxides in oceans relative to Mo, that enriches ocean water. In sediments of South Atlantic one can see gradual decrease of Mo/W ratio in the past. It is not clear what drives the directional changes of Mo/W ratio. To investigate the factors controlling the behavior of these elements in the Earth's history (a record in the sediments), their variations should be studied in the modern ocean water.

The concentration of W in open ocean water is extremely low (about 50 pmol/L). So we developed the technique for solid phase extraction preconcentration of dissolved W together with Mo and V from ocean water with ICP-MS detection. The concentration factor is 50; the detection limits are 0.31 nmol/kg for Mo, 6 pmol/kg for W and 40 pmol/kg for V. The precision of the determination is 2.7% for Mo, 3.4% for W and 3.5% for V in seawater (n=6).

The concentrations of the above mentioned elements in 16 surface water samples of submeridional profile (from 36ºN to 36ºS) across the Atlantic Ocean have been determined using the developed technique. The ranges of studied elements concentrations were: Mo – 90-110 nmol/kg, W – 54-93 pmol/kg and V – 28-35 nmol/kg along the profile. Concentrations of studied elements are not clearly correlate to salinity. Mo content shows strong correlation with V content. Distribution of W differs from that of Mo and V. The Mo/W ratio in the surface water changes from ca. 1100 to 1800 along the profile in Atlantic Ocean.

Regional scale OA oxidation observed over the Po Valley basin (Italy), at Mt. Cimone (2165 m asl)

M. RINALDI[1], S. GILARDONI[1], S. DECESARI[1], S. FUZZI[1], P. CRISTOFANELLI[1], P. BONASONI[1], S. FERRARI[2], V. POLUZZI[2] AND M.C. FACCHINI[1]

[1]Istituto di Scienze dell'Atmosfera e del Clima, Consiglio Nazionale delle Ricerche, Bologna, 40129, Italy (*correspondence: m.rinaldi@isac.cnr.it)

[2]Centro Tematico Regionale Aree Urbane, Arpa Emilia-Romagna, Bologna, 40138, Italy

High resolution time of flight aerosol mass spectrometer (HR-ToF-AMS) measurements have been performed, for the first time, at Mt. Cimone GAW station (44°12' N, 10°42' E, 2165 m asl) from 11 June to 9 July 2012, under the framework of the EU project PEGASOS and the Emilia-Romagna Region project SUPERSITO.

The peculiar character of the site allows the investigation of organic aerosol (OA) ageing occurring at regional scale over the Po Valley. In fact, particles sampled during the day are representative of the early stages of aerosol atmospheric oxidation, comprising processed primary OA and secondary OA formed in the Po Valley basin, being the site within the planetary boundary layer (PBL). During the night, the aerosol sampled at Mt. Cimone is representative of more processed conditions, as the site is in the free troposphere (FT), containing aerosols with an age from several hours to days.

Elemental analysis performed with high resolution mass spectra [1], revealed decreasing average H/C and increasing O/C ratio from PBL to FT samples. As a consequence, the OM/OC ratio passes from 1.83±0.05 in PBL, to 1.94±0.08 in FT samples.

These results evidence the progressive oxidation of OA over the Po Valley basin, from few hours after their emission/formation to one or more days of atmospheric processing. On a Van Krevelen space, the data produce a slope of ~ –1, suggesting that the observed regional scale oxidation processes occur mainly through the addition of carboxylic functional groups [2]. This is further confirmed by the analysis of the HR mass fragments, showing that, from PBL to FT samples, the average contribution of fragments containing carbon, hydrogen and more than one oxygen atom (CHO>1) passes from 25% to 33%, while both CH and CHO fragments decrease their contribution.

Sr^{2+} and Mn^{2+} incorporation during $CaCO_3$ cementation on calcitic and aragonitic shells

T. RINDER[1]*, M. DIETZEL[2] AND A. DEDITIUS[2]

[1]GET/CNRS, 14 avenue Édouard Belin, 31400, Toulouse(*correspondence: rinder.thomas@gmx.net)

[2]TU Graz, Institute of Applied Geosciences, Rechbauerstr. 12, Graz, Austria

Precipitation of calcium carbonates may cause significant changes in the porosity, permeability and overall physical properties of sedimentary rocks. For instance in sandstone the loss of permeability and porosity negatively influences the potential quality of the hostrock as a hydrocarbon or groundwater reservoir [1]. In recent years more attention to cementation issues is received for the increasing efforts to reduce CO_2 emission into the atmosphere and the possibility of long term storage by means of underground fixation in carbonates [2].

In the present study flow through experiments were carried out to investigate carbonate cementation of primary unconsolidated shell material by investigation of the spatial distribution and trace element incorporation of the precipitated material. $NaHCO_3$ – Na_2CO_3 – $CaCl_2$ solutions supersaturated with respect to calcite were pumped through columns packed with shell fragments of a grain size between 0.5 and 1mm. Sr^{2+} and Mn^{2+} addition was used to trace the temporal and spatial evolution of newly formed precipitates in the pore space.

Overall distribution coefficients calculated from aqueous bulk solutions result in a D_{Sr} of 0.68 and D_{Mn} of 6.08 for the precipitated $CaCO_3$. These coefficients are in good agreement with literature values within the given proportions of precipitated calcite and aragonite. However, apparent measured distribution coefficients in the newly formed $CaCO_3$ solids derived from electron microprobe analysis are highly heterogeneous and results in a maximum D_{Sr} and D_{Mn} value of 18 and 163, respectively.

Alternating trace element rich and poor growth zones were discovered in our experiments carried out at a constant solution composition, temperature and flow rate. We suggest that the incorporation behaviour depicted by bulk ratios which serve as proxies for the reconstruction of environmental conditions during precipitation of $CaCO_3$ is not necessarily valid on the microscale. The actual locally occurring trace element incorporation into $CaCO_3$ can significantly exceed or fall below the average bulk incorporation.

Using TOF-SIMS isotope mapping for studying dissolution and precipitation processes at mineral grains in an experimental CO_2-sequestration setup

S. RINNEN[1], A. RISSE[2], C. OSTERTAG-HENNING[2] AND H.F. ARLINGHAUS[1]

[1]Physikalisches Institut, University of Muenster, Wilhelm-Klemm-Str. 10, 48149 Muenster, Germany (stefan.rinnen@wwu.de)

[2]Bundesanstalt fuer Geowissenschaften und Rohstoffe, Hannover, Germany

CCS (Carbon dioxide capture and sequestration) is a technique investigated for its possible employment in the reduction of the amount of anthropogenic CO_2 gas emitted into the atmosphere. Deep saline aquifers are one option for storing CO_2 gas streams produced e.g. by the combustion of fossil fuels at power plants. These gas streams contain different impurities depending on their origin, among them O_2, NO_x, SO_x in addition to the CO_2. We have used ToF-SIMS to determine the influence of these impurities on dissolution and precipitation processes at the minerals.

Experiments under in situ pressure and temperature conditions of possible geological storage sites were performed at the German Bundesanstalt fuer Geowissenschaften und Rohstoffe (BGR) in flexible Dickson-type gold-titanium cells and small gold capsules.

Minerals common in the deep saline aquifers (e.g. siderite, calcite) were placed in small reaction cells of thin gold foil in a reactor vessel and exposed to isotopically enriched water ($H_2{}^{18}O$) or carbon dioxide ($^{13}CO_2$) during the experiments.

To facilitate the determination of the amount of dissolved ions incorporated into newly formed precipitates within the reaction chambers, a database of positive and negative ToF-SIMS spectra for a variety of rock-forming minerals were set up to identify minerals and mineral alterations. In addition, preparation techniques were developed for high-resolution measurements of the incorporation of isotope-labeled elements/ions (e.g. ^{18}O) into mineral precipitates. The results show that ToF-SIMS can simultaneously image the elemental, isotopic, and molecular compositions of these minerals with high spatial resolution. Also, elemental and isotopical distributions as a function of depth can be monitored.

Carbonatitic Magmas? A Mineralogical and Isotopic Approach

DEBORA C. RIOS[1,2]*, DONALD DAVIS[2], HERBET CONCEIÇÃO[3], MARIA DE LOURDES S. ROSA[3], AND CÂNDIDO A.V. MOURA[4]

Massive deep orange calcites are intensely colored, coarse grained rocks, in contact with silicate rocks that exhibit centimetric crystals of phlogopite, occurs at Serrinha Nucleus (SerN), Brazil. Occeli are a common feature, composed of euhedral fluorapatite, diopsidic pyroxenes and barite. Associated creamy coloured rocks are composed of >90% calcite, 3-8% green-olivine and diopside, 1-2% euhedral sulphides and well developed crystals of purple-spinel and blue-fluorapatites, as well as rounded mafic enclaves composed of amphibole, biotite and pyrite. Coarse calcite veins and/or dykes also cut the 2.1 Ga syenite-lamprophyre association and the meta-gabbros of Itapicuru Greenstone, demonstrating a clear interrelation between carbonates and silicate minerals including Fe-Mg-Mn calcite, diopside, apatite, quartz and Fe-Ni oxides. Rutile, few zircons and pyrite were described from the heavy mineral concentrates.

C and O preliminary results for $\delta^{13}C$ (PDB) between +12 e +13 per mil, $\delta^{18}O$ (PDB) of -10 per mil, and V-SMOW of +20, suggest the involvement of different magmatic or hydrothermal phases in these rocks formation. LA-ICP Pb-Pb analyses of calcites yielded model ages of ~1950 Ma and U-Pb ages from 2 zircons are (i) 2.11 Ga, close to that of SerN syenites and lamprophyres, suggesting that these rocks may be comagmatic and (ii) a clear core-border relationship showing ages of 2.7 and 2.5 Ga, respectively, similar to those reported for zircon xenocrysts in syenites and kimberlites.

Our results show that these rocks are calcite carbonatites, fairly well exposed, and that have not been metamorphosed. The occellar texture suggests liquid immiscibility, indicating silicate magma droplets. Although further work remains to be done, the isotopic data suggest an emplacement age of ~2.0-2.1Ga, coeval with emplacement of the syenites and lamprophyres and to the gold mineralization at Itapicuru Greenstone. This syenite-lamprophyre-carbonatite association is closely related to Au in many Archean cratons worldwide.

Investigation of reactive transport with closed-flow column experiments and parallel factor analysis (PARAFAC) of fluorescence data

THOMAS RITSCHEL* AND KAI UWE TOTSCHE

Institute of Geosciences, Friedrich-Schiller-University Jena (*correspondence: Thomas.Ritschel@uni-jena.de)

The study of biogeochemical interfaces is crucial to understand soil functioning [1]. The sorption of solutes and colloids to these interfaces results in the phenomenon of retardation. Besides the interactions at the sorbent-solution-interface, the sorption rate depends also on the spatial structure of the pore network (size distribution, connectivity, topology). Column experiments allow for the consideration of the structure and thus for a quantification of possible rate limitations. We focus on column experiments run in closed-flow mode. There, a typical oscillation in the "breakthrough" of solute concentration, which conveys additional information about the flow regime (dispersivity, water content, immobile water) as well as the effective interaction kinetics, can be observed. Another major feature of the closed flow design is the conservation of tracer mass inside the column setup. Therefore, the investigation of sorption characteristics can be simplified by using mass balances.

Our objective was to study the interaction between different solutes (conservative tracers, e.g., NaCl and reactive tracers, e.g., acetate, oxalate and vanillic acid) and artificial porous media (composed of quartz, illite, goethite and charcoal in a well defined grain size distribution). The reactive tracers were chosen to probe specific reactive surfaces, which allowed for a consideration of involved sorption mechanisms and an estimation of sorbent surface coverage. The concentration-time profile of solutes was measured with non-consuming techniques (fluorescence spectroscopy or electrical conductivity measurements). PARAFAC analysis of fluorescence data was used for the quantification of aromatic compounds in complex background solutions. Since the reconstructed sorption characteristics are influenced by physical and chemical non-equilibrium and possible sorption sites were unavailable due to aggregate formation and immobile regions in the porous medium, we were able to estimate the amount of void volume and the availability of sorption sites of goethite.

Hydrogeochemical modeling and noble gas analysis of spring waters from Poços de Caldas, MG-Brazil

RITTER S.M.[1], ISENBECK-SCHRÖTER M.[1]*, FREUNDT F.[2], AESCHBACH-HERTIG W.[2] AND BONOTTO D.M.[3]

[1]Inst. of Earth Sciences, Heidelberg Univ., INF 236, 69120 Heidelberg, Germany (*corr: Margot.Isenbeck@geow.uni-heidelberg.de)

[2]Inst. of Env. Physics, Heidelberg Univ., INF 229, 69120 Heidelberg, Germany (aeschbach@iup.uni-heidelberg.de)

[3]Instituto de Geociências e Ciências Exatas, UNESP- Campus of Rio Claro, Av 24-A, n°1515 Bela Vista 13506-900 - Rio Claro, SP - Brazil (dbonotto@rc.unesp.br)

Thermal and non-thermal spring water samples from the city of Poços de Caldas were analysed with respect to their chemical composition and dissolved noble gas contents. The objective is a better understanding of the hydrogeochemical evolution, maximum reservoir temperature, groundwater age and possible heat sources of the low-enthalpy thermal system.

The genesis of the thermal alkaline waters (Na-K-(H)CO_3-SO_4-F-type) could be approached by an inverse model of water-rock interactions with PhreeqC. The model favours four main processes to take place in thermal water formation: (I) pyrite oxidation; (II) CaF2 or NaF dissolution; (III) calcite precipitation; (IV) Na-K-alumosilicate weather-ing; (V) equilibrium at depth of Na and K with Na-K-alumosilicates (e.g. orthoclase and nepheline). Thoroughly chosen chemical Geothermometers, calculated with the computer program SolGeo [1], indicate maximum equilib-rium reservoir-temperatures of 105-130°C, which offer estimates on the circulation depth of 2.6-3.3 km.

Dissolved noble gas contents and their isotopic ratios in the water samples generally support previous assumptions [e.g. 2] of (i) different aquifer sources for the springs; (ii) the occurrence of mixing of thermal and non thermal water during ascent; and (iii) relatively long residence times of the curculating meteoric water in the geothermal system. Further noble gas data examamination could lead to obtain age constraints derived by ^{4}He accumulation and more information about the heat source of the geothermal system.

Early mantle composition and evolution inferred from ^{142}Nd and ^{182}W variations in Isua samples

H. RIZO*[1,2], M. TOUBOUL[2], R.W. CARLSON[1], M. BOYET[3], I.S. PUCHTEL[2] AND R.J. WALKER[2]

The composition and evolution of the early terrestrial mantle is largely unknown due to the sparse geological record preserved from Earth's infancy. The short-lived ^{146}Sm-^{142}Nd chronometer applied to Eoarchean Greenland rocks led to the discovery of the oldest known mantle reservoir. Samples derived from this reservoir have ^{142}Nd excesses of 10-20 ppm compared to modern samples, which combined with ^{147}Sm-^{143}Nd systematics suggest that their source was depleted in incompatible elements, and formed in the first 150 Ma of Solar System history [1-4]. Recently, ^{182}W excesses of ~+13 ppm relative to terrestrial standards were also detected in rocks from the same area [5], as well as in the mantle sources of 2.8 Ga komatiites [6]. ^{182}W excesses could reflect imperfect mixing of late-accreted materials into the mantle during the period between 4.5 and 3.8 Ga. Given the short half-life of ^{182}Hf, these excesses could instead reflect Hf/W fractionations during the first tens of Ma of the Solar System history. In this case, ^{182}W and ^{142}Nd signatures would indicate that early-formed mantle reservoirs were not erased during the Moon-forming giant impact. Re-mixing of early-formed Greenland reservoirs likely started during the Hadean and the obliteration of these heterogeneities with respect to ^{142}Nd seems to have been completed by 3.3 Ga [7], whereas the ^{182}W anomalies detected in 2.8 Ga komatiites imply that W isotopic heterogeneities persisted in the mantle until at least the late Archean [6]. We present new highly siderophile element and ^{182}W data for 3.8 Ga to 3.3 Ga old Isua samples, previously analyzed for ^{142}Nd. This dataset may help constrain the composition of the Archean mantle as it evolved through time, and may allow modeling the mixing rate of late accreted meteoritic material in the mantle.

[4]Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, 50121 Firenze, Italy

We performed a noble gases investigation of fluid inclusions hosted in olivines and pyroxenes from mafic enclaves contained in the 1570 and 1925 A.D. dacitic magmas erupted at Nea Kameni. These enclaves are a portion of mafic magma batches that replenished the shallow chamber of the plumbing system hosting cooler and more silicic melts. Their Sr-Nd isotope ratios are quite similar to those measured in the host dacitic rocks, implying a common parental magma. Therefore, the analysed enclaves may be considered representative of the historic magma erupted at Nea Kameni which could be still present in the volcano plumbing system feeding the crater fumaroles.

Gases extracted from fluid inclusions are affected by an appreciable air contamination, as their ^{4}He/^{20}Ne and ^{40}Ar/^{36}Ar ratios are near to the typical atmospheric signature. The ^{3}He/^{4}He ratios of olivines, once corrected for air contamination (3.1-3.6 Ra), show higher and more reliable values than the cogenetic pyroxenes. These values partially overlap those of the gases (3.5-4.0 Ra) collected from Nea Kameni fumarolic field and from bubbling springs at Palea Kameni. The range of ^{3}He/^{4}He ratios (3.1-4.0 Ra) is appreciably lower than typical arc volcanoes (R/Ra ~7-8), implying that a contamination by ^{4}He-rich fluids occurred either directly in the mantle and/or in the plumbing system. Comparison of ^{3}He/^{4}He and ^{4}He/^{40}Ar* ratios measured in enclaves with those of fumarolic gases, as well as long-term monitoring of R/Ra in the latters, coherently indicate that magma involved in the 2011-2012 unrest is likely more primitive and ^{3}He-rich than the mafic enclaves. This would imply that the Santorini magma presently available for eruption has a lower explosive potential than in the recent historic eruption of Nea Kameni.

The relative distribution of volatile elements (e.g. H, C, F, Cl, S) in the different Earth's various reservoirs provides strong constraints on the understanding of the Earth's history. This study aims to access the mechanism and proportion of halogens that may be accomodated in minerals of Earth's Transition Zone (TZ; 410 to 660 km depth). The storage of water in the TZ is thought to be important due to its high solubility (up to 3.3 wt% water [1,2]) in wadsleyite (Wd) and ringwoodite (Rw), the two main phases of the TZ (60 % of its volume). As the halogen and water cycle are often linked (see the review after [3]), we investigate whether the TZ could be a deep reservoir for F and Cl. Therefore, we are measuring the F and Cl solubilities in Wd and Rw. F and Cl doped Wd and Rw samples were synthesized in multi-anvil press to reach the conditions of pressure and temperature of the TZ (14 to 22 GPa; 1100 to 1450°C). The obtained crystal sizes were greater than 10 μm, allowing precise mesurement of halogen contents in individual crystals. The synthesis were performed under both anhydrous and hydrous conditions to study the influence of water on the F and Cl solubilities. F and Cl quantification was realized by ion beam analysis: we used μ-PIGE (μ-Particle Induced Gamma Ray Emission) for F; and μ-PIXE (μ-Particle Induced X-ray Emission) for Cl. We show that F and Cl can be incorporated in Wd and Rw in significant amounts. F solubility decreases with the presence of water. This suggests that F (possibly Cl) and water (OH) are accommodated on the same crystallographic sites in Wd and Rw. If we assume that the transition zone would store significant amounts of Cl and F, it means that (1) the TZ has been continuously supplied by Cl and F-bearing subduction materials, or (2) TZ is a hidden deep light halogen elements reservoir which never exchanges with the rest of the mantle.
In both cases, F and Cl bulk silicate Earth contents may have been underestimated. If confirmed, the Earth's accretion models may have to be revisited.

Mass independent isotope fractionation in Ozone

REINHARDT, P.[1] AND ROBERT, F.[2]

[1]Laboratoire de Chimie Théorique, UMR-CNRS 7616, UPMC, 4 place Jussieu, F 75252 Paris, France
[2]Laboratoire de Minéralogie et Cosmochimie du Muséum, UMR CNRS 7202, MNHN, Paris 75005, France.

We propose that the average lifetime of an activated O_3* complex yielding ozone and formed by collisions involving distinguishable isotopes in the reaction O + O_2, is not equal to the average lifetime of the same complex but formed by collisions involving indistinguishable isotopes. We ascribe the mass independent isotopic fractionation factor $\boldsymbol{\eta}$ [1] to the average lifetime ratio of complexes formed by reactions involving dis- and indistinguishable isotopes.

Calculated average lifetimes of the O_3* complexes in a thermal gas were obtained by classical trajectories of collisions O + O_2, where all atoms have the same mass (16 amu). Simulations have been carried out in an ab-initio potential surface [2] of three oxygen atoms in a singlet ground state. We derive the mass-dependent fractionation as measured in laboratory experiments [3] by including differences in the zero-point energies of involved O_2 molecules. The numerical results account well for the measured isotopic fractionation in ozone [3, 4], as reported in the Table 1.

Reactions		Complex	ΔZPE	α(M.D.)	η	α(calc.)	α(mes.)

New insights into the evolution of a stagnant magma chamber- magma loss and liquid evolution in the Upper Zone of the Bushveld Complex

R. JAMES ROBERTS[1]

[1]University of Pretoria; james.roberts@up.ac.za

The Upper Zone (UZ) of the Bushveld Complex is the final magma chamber to be emplaced and crystallised during the evolution of the mafic portion of Bushveld magmatism. Though isotopic evidence indicates that no magma was added to the UZ during its crystallisation history, numerous studies have postulated the loss of large volumes of magma (20-40% of the original volume[1,2]) from the magma chamber. These estimates are problematic in that volcanic material related to the Upper Zone has never been identified. This new study utilises Zr and K bulk rock data to argue that the Upper Zone has experienced little or no magma loss. Previous estimates of Zr abundance have been too low, as researchers have assumed that Zr was incompatible in the UZ; in fact, zircon is a cumulus phase in the UZ, and is especially abundant in the magnetitite and nelsonite layers in the sequence. The new estimate of <5% magma missing from the original magma is conformable with global studies on intrusion/extrusion rates for mafic magmas[3], and has consequences for the evolution of the liquid line of descent (LLD) for the UZ. A new multi-part LLD for the UZ was constructed and tested using MELTS. The modelled liquid and the actual sequence of minerals present in the UZ is extremely close, indicating that the UZ separated into a number of separate magma packets which then crystallised independently of one another. It is noted that despite the good correlation between the model and the actual rocks, the high Fe, low Si bulk liquid calculated for the UZ is unlikely to occur in nature, and that a portion of the UZ magmatic sequence is likely to be hidden underneath the roof rocks of the Bushveld Complex.

Distinguishing between advection and source changes recorded by Nd isotopes in the NE Atlantic

N. L. ROBERTS[1]* AND A. M. PIOTROWSKI[1]

[1]University of Cambridge, Cambridge, UK,
(*correspondence: nr297@cam.ac.uk)

Nd isotopes, measured on authigenic sediment phases, are a powerful tracer of past changes in ocean circulation [1]. Recent method developments have shown that planktonic foraminifera, which have not been chemically cleaned, preserve the Nd isotope signature of bottom water, and thus are an alternative phase to sediment leachates, avoiding possible contamination by volcanic phases [2, 3]. However, interpretation of downcore changes in Nd isotope records, in terms of past changes in water mass proportion, relies on the accurate reconstruction of the endmember composition of water mass source. Records from Fe-Mn crusts [4] and corals [5] from the NW Atlantic, and a sediment leachate record measured on core ODP 980 in the NE Atlantic [6] suggest the Nd isotope composition of the northern source endmember remained constant between the last glacial and the Holocene. However, a recent study comparing sediment leachate and uncleaned foraminifera Nd isotopes from a core close to ODP 980 indicates that sediment leachate data from this region are not reliable [7], thereby calling into question the invariant nature of the northern source endmember composition.

We present Nd isotope records, measured on unclean planktonic foraminifera, from a depth transect of cores in the northern NE Atlantic, which today are bathed by a mixture of overflow waters and Labrador Sea water. Our records sample Nd isotope composition from 1 – 4 km depth, and from 0 - 30ka. We compare our Nd isotope records with previously published benthic $\delta^{13}C$ and B/Ca records, measured on the same cores, and used to infer past changes in ocean circulation [8]. We use the observed decoupling between these three proxies to distingish between endmember source changes in the Nd isotope composition and circulation controlled changes, with implications for interpreting changes in the Nd isotope sigatures recorded elsewhere in the N Atlantic.

Linking Iron and Nitrogen Cycles in Lake Sediment

ELIZABETH ROBERTSON[1] AND BO THAMDRUP[1]

[1]Nordic Centre for Earth Evolution, Institute of Biology, University of Southern Denmark, Odense M, Denmark

In anoxic environments, iron reduction can function as a significant pathway for organic matter oxidation, resulting in the production of ferrous iron. This Fe^{2+} can potentially be re-oxidised by nitrogen species formed in surface sediment (e.g. nitrate; NO_3^-, nitrite; NO_2^-). The fate of such oxidized nitrogen compounds is of particular importance to nitrogen availability in microbial communities – determining whether nitrogen is retained in the environment in a bioavailable form (NH_4^+) or effectively 'lost' as N_2. Although both freshwater and marine microbial strains have been isolated which are capable of coupling NO_3^- reduction to iron oxidation, the role of such processes for either iron or nitrogen cycling in natural environments is largely unknown.

The potential interactions of iron with NO3- reduction pathways were investigated in anoxic incubations with iron-rich sediment from a shallow, mesotrophic Danish lake. ^{15}N tracing methods were used to determine contributions of denitrification and dissimilatory nitrate reduction to ammonium (DNRA) and how Fe^{2+} potentially influences the partitioning between these processes. DNRA was found to be the dominant nitrate reduction process and appeared to be further stimulated by addition of Fe^{2+} to incubations. These results suggest that NO_3^- reduction coupled to Fe^{2+} oxidation in this sediment yields NH_4^+ as opposed to N_2 as previously described in several culture studies; resulting in nitrogen being retained in the system as a bioavailable substrate. Whether our findings are more generally applicable to aquatic systems such as marine sediments and anoxic waters where Fe2+ and oxidized nitrogen species co-occur is currently being explored.

Identifying carbon pools in heterogeneous materials: Use of peak fitting and TGA-DSC-MS data

S.A. ROBERTSON[1]*, E. LOPEZ-CAPEL[2], D.A.C.MANNING[2], N. FINLAY[1] AND K.L.JOHNSON[1]

[1]School of Engineering and Computing Sciences, Durham Univ, DH1 3LE, UK (*correspondence: steven.robertson@durham.ac.uk)

[2]School of Civil Engineering and Geosciences, Newcastle Univ, NE1 7RU (elisa.lopez-capel@newcastle.ac.uk)

Thermogravimetry-differential scanning calorimetry (TG-DSC) is an effective tool for the analysis of modelable carbon pools (including labile, recalcitrant, resistant and inorganic carbon) in soils [1,2]. Coupling of the TG-DSC instrument with a quadrupole mass spectrometer to give a TG-DSC-MS arrangement allows the temperature dependent evolution of low molecular weight species such as carbon dioxide and methane to be monitored at the same time as mass losses [2].

A TG-DSC-MS analytical run from 100 to 1000 °C in an atmosphere of 20% O_2 80% He_2 produces data that can be interpreted using GRAMS-AI software (Thermo Scientific). After ruling out potential interferences, monitoring the m/z 44 ion shows the evolution of CO_2 at different temperatures during the TG-DSC-MS run and a semi-automated peak fitting process has been developed, whereby the proportions of labile, recalcitrant, resistant and inorganic carbon in a sample can be estimated. By defining a range of temperatures over which each carbon pool might be expected to thermally decompose, and running multiple iterations of GRAMS-AI's peak fitting algorithm, a composite "best fit" of the four individual carbon pool peaks to the m/z 44 trace can be produced. The relative peak areas indicate the proportion of each type of carbon in the sample and parallel use of an elemental analyser allows estimation of carbon masses.

The approach adds utility to the TG-DSC-MS approach where heterogeneous materials are under investigation and has been used to investigate man-made soils [3] and to study organic rich residuals from the drinking water industry [4]. It appears to have general applicability in cases where rapid estimation of the size of the four carbon pools is required.

Characterization of Gas-Phase Air Pollutants and their Public Health Impact

ROBERTS-SEMPLE D

dawn_semplea@yahoo.com

Air pollution can have deleterious effects on human health. This study examines the role of meteorological factors on air pollution concentrations and their cumulative effects on public health in Hackensack Meadowlands, New Jersey. Ambient concentrations of nitrogen oxides (NO_x) and ground-level ozone (O_3) were measured and meteorological variables were monitored at the Meadowlands Environmental Research Institute (MERI) from June 2007 to May 2008, to characterize the temporal and seasonal variations of gas-phase air pollutants. Health records of respiratory hospital admissions were obtained from the New Jersey Department of Health and Senior Services (NJDHSS). Statistical analyses were conducted by using time series, multiple linear and principal component regression techniques. The meteorological conditions and air pollutants that may be associated with human respiratory health effects were analyzed.

The results show that ambient levels of NO_x and O_3 are influenced by certain meteorological conditions in the Meadowlands, and there is a strong relationship between hospital admission and personal exposure to NO_2. There is no direct relationship between O_3 and hospital admission (r=-0.092), whereas hospital admission and NO_x correlate (r=0.317) but more strongly with NO_2 (r=0.359) at a significance level of 0.01. Hospital admission rates are indirectly affected by relative humidity (r=-0.077). The seasonal dependence of pollutants is caused mainly by low wind speed and differences in chemical processing, making them interdependent. Seasonal variations of NO_x were less distinct with strong diurnal patterns of traffic-related peaks during the early morning rush hour. There was a strong association between NO_x and respiratory hospital admissions in the fall, winter and spring seasons. The variability of NO_x and O_3 was altered by distinct atmospheric conditions and chemical inter-conversions of the pollutants. There was an inverse relationship between concentrations of NO_x and O_3; the latter was dominant in summer and specific time of the day (early afternoon). For O_3, association with hospital admissions was strongest at 2 lag days. Both climate-induced and pollution-induced health effects of NO_x and O_3 suggest that current national standards may not adequately provide a safe threshold for air pollutants from a public health perspective.

Uranium isotopes as a novel tracer of paleo-hydrology?

LAURA F ROBINSON [1] JOHN M SWARTZ [2] AND WILLIAM G THOMPSON [3]

[1]University of Bristol, BS8 1RJ, Bristol UK (laura.robinson@bristol.ac.uk)
[2]Institute for Geophysics | J.J. Pickle Research Campus, Austin, TX (jmswartz@gmail.com)
[3]Woods Hole Oceanographic Institution, Woods Hole, MA 02543 USA (wthompson@whoi.edu)

Uranium series isotopes provide unique insights into the rates and amplitude of geologic processes through their range of chemical behaviours in different environments, and their radioactive decay. In this case we use ^{234}U and ^{238}U isotopes to examine and quantify the controls of uranium input to rivers with an emphasis on watershed precipitation and discharge. First we show data from contrasting hydrological zones in two dynamic regions: New Zealand and Chile. After controlling for lithology and physical weathering caused by uplift we show that the strength of the hydrologic cycle plays a distinct role in controlling the $^{234}U/^{238}U$ ratio in river waters as they move through a water shed. Hydrothermal systems, subsurface processes and lakes may also act to affect the final ratio as rivers discharge into the ocean. The hydrologic cycle is thought to have changed markedly over millennial and glacial interglacial timescales leading to the possibility of a shift in the $^{234}U/^{238}U$ ratio of rivers, groundwater and seawater. Terrestrial speleothem $^{234}U/^{238}U$ records appear to provide supporting evidence for a lower regional hydrologic cycles during the last glacial period. By contrast, a compilation of seawater $^{234}U/^{238}U$ recorded in corals point to a shift in the opposite direction.

Structure and Radiation Damage in $Y_2Ti_2O_7$ and Y_2TiO_5

M. ROBINSON[1], N.A. MARKS[1]*, D.J. CARTER[1], M.J. QIN[2], S.C. MIDDLEBURGH[2], G.J. THOROGOOD[2], E.Y KUO[2], R.O. AUGHTERSON[2] AND G.R. LUMPKIN[2]

[1]Nanochemistry Research Institute, Curtin University, Australia (*correspondence: N.Marks@curtin.edu.au)
[2]Australian Nuclear Science & Technology Organisation, Locked Bag 2001, Kirrawee DC, 2232, NSW, Australia

Yttrium titanate is a rich solid-state system with important applications in a nuclear context. When it takes the stoichiometry $Y_2Ti_2O_7$ yttrium titanate adopts the pyrochlore form, a crystal structure which has been extensively studied as an immobilization matrix for nuclear waste. Y-Ti-O nanoparticles are also key ingredients in high-performance oxide-dispersion-strengthened (ODS) steels needed for next-generation fission and fusion reactors. The structure of these nanoparticles is complex and not fully clear, spanning a range of possibilities including enriched clusters, defective rocksalt-type TiO phases as well as stoichometric $Y_2Ti_2O_7$ and Y_2TiO_5 [1,2]. The Y_2TiO_5 structure itself is poorly understood, with the phase diagram thought to comprise a low-temperature orthorhomic phase, a high-temperature cubic phase, and a hexagonal phase at intermediate temperatures [2].

Here we develop a new interatomic potential for yttrium titanate and apply it to both the determination of structure and irradiation response. The potential employs partial charges and is fitted to lattice parameters, internal coordinates and elastic constants obtained from density-functional-theory. For both $Y_2Ti_2O_7$ and orthorhombic Y_2TiO_5 the potential provides a substantial improvement over existing literature models.

Recent experiments [3] have shown that cubic Y_2TiO_5 exhibits a pyrochlore-derived superstructure involving a tripling of the unit cell along 111 directions. To determine its structure, Monte Carlo simulations were performed to order the cations and anions within a large 3×3×3 tiling of the 88-atom unit cell. Experimental diffraction reflections were used to arrange the cations by calculating the structure factor, while the potential was used to order vacancies on the oxygen sub-lattice. The potential was also employed in Molecular Dynamics calculations of threshold displacement energies, thermal spikes and radiation damage cascades in $Y_2Ti_2O_7$ and Y_2TiO_5. Using these simulations we interpret experimental studies of amorphization and quantify the role of anti-sites and structure in radiation response.

A new model for the formation of podiform chromitites in ophiolites

PAUL T. ROBINSON[1]*, JINGSUI YANG[1], MEI-FU ZHOU[2] AND FAHUI XIONG[1]

[1]Chinese Academy of Geological Sciences, Beijing, China (*correspondance: paulrobinson94@hotmail.com)
[2]Department of Earth Sciences, Univ.of Hong Kong, Hong Kong, SAR, China (mfzhou@hku.hk)

Podiform chromitites occur in the upper mantle sections of ophiolites where they are typically surrounded by dunite envelopes formed by melt-rock reaction. Both high-Cr and high-Al varieties are common, but rarely in the same ophiolite. In contrast, residual chromite grains in the host peridotites and dunites show a wide range of composition. The podiform chromites are generally thought to be magmatic precipitates from suprasubduction (SSZ) melts migrating through the mantle wedge However, the recent confirmation of diamonds in both podiform chromitites and peridotites of several ophiolites, and evidence suggesting depths of formation >300 km for some of the chromites, challenges this model. All UHP minerals would be destroyed if they were exposed to SSZ melts at shallow mantle levels. We suggest that residual chromites first crystallize as discrete grains in mantle peridotites beneath mid-ocean spreading centers near the top of the transition zone, where they encapsulate diamonds and highly reduced phases carried by fluids from greater depths. These would be high-Al chromites, indicating relatively low degrees of partial melting of the host peridotites. Some of these chromite-bearing mantle sections in which diamonds occur are eventually trapped in suprasubduction zones where they are infiltrated by hydrous SSZ melts, either arc tholeiitic or boninitic in composition. As these melts migrate through the mantle wedge they react with the host peridotites, dissolving pyroxene, precipitating olivine in dunite 'channels', and becoming progressively enriched in Cr. These melts react with and locally remobilize the 'residual' chromite grains, increasing their Cr#. The residual chromite grains are not melted but become more Cr rich by diffusion. The remobilized chromite grains are carried to shallow levels by the rising melts where they are deposited, along with newly precipitated grains, as podiform chromitites. The UHP minerals within the chromite grains are not destroyed because they are protected from the melts. This model accounts for the fact that podiform chromitites are found only in ophiolites and for the preservation of UHP minerals in both podiform chromitites and residual chromites within the host peridotites.

The age of the Moon from U-Th-Pb systematics on terrestrial and lunar primitive mantles

KACEM ROCHD

Chouaib Doukkali University, El Jadida, Morocco
rochdkacem@yahoo.com

U-Th-Pb systematics of the primitive mantles reflect early mantle differentiation and core formation processes and may provide key constrain on the genetic relationship between the different planets. Here, we show that the Pb data for the terrestrial and lunar primitive mantles define a system of isochrons centred on unequilibrated primitive meteorites (e.g.; Mezo Madaras meteorite), which suggests that the Earth and Moon were formed at different times by direct accretion from the solar nebula. Following this result, we determine the age of the Moon to be exactly 5.13 Gyr. In principle, this new method of portraying a solar system by secondary isochrons centred on unequilibrated primitive meteorites can be used for precise dating all other objects in the solar system provided they are formed by direct accretion from the collapse of solar nebula and have experienced core-mantle segregation early in their planetary evolution. An other example is Mars whose Pb data for its primitive mantle might be available in the near future**.**

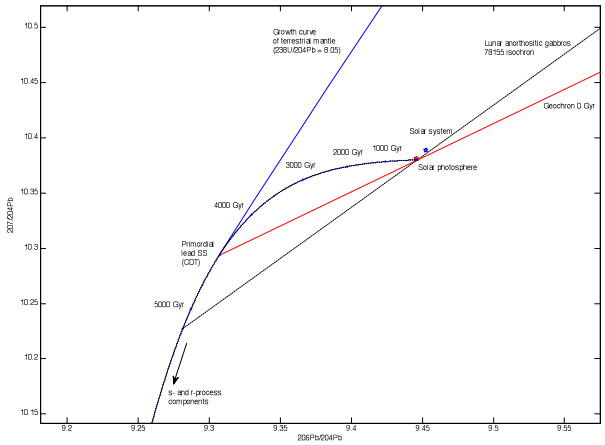

Figure 1: $^{206}Pb/^{204}Pb$ vs. $^{207}Pb/^{204}Pb$ plot for 4.55 Gyr geochron, including data point of terrestrial mantle calculated with μ = 8.05 (Rochd, 2009), and 5.13 Gyr lunar isochron, including data points of plagioclase ($\rho < 2.89$) from Apollo 17 anorthositic gabbro 78155 (Nunes, 1975).

Carbonation of cement within a repository for radioactive wastes: Impact of CO_2 on cement mineralogy and permeability

C.A. ROCHELLE*[1], G. PURSER[1] AND A.E. MILODOWSKI[1]

[1]British Geological Survey, Keyworth, Nottingham, NG12 5GG, UK
(*correspondence: caro@bgs.ac.uk)

Large quantities of cementitious materials will be used for radioactive waste repository construction and buffer/backfill. Degradation of organic material within the waste will produce CO_2, leading to cement carbonation. This will reduce its capacity to maintain highly alkaline conditions, thus possibly aiding radionuclide migration. Conversely, some carbonation reactions might improve material properties, e.g. by reducing cement permeability. Currently, it is unclear whether the overall changes due to carbonation will be beneficial or deleterious to long-term radionuclide immobilisation.

As part of the pan-European FORGE project we have undertaken a laboratory study to examine the impact of carbonation on 'Nirex reference vault backfill' (NRVB) cement. Aims for the work were to quantify changes in cement mineralogy, structure, porosity/permeability, and the composition of coexisting aqueous fluids. Lab investigations exposed samples of cement to free phase and dissolved CO_2 under a range of potential *in-situ* conditions; 20°C or 40°C, 4 MPa or 8 MPa, 'young' (Na/K/Ca-rich) or 'evolved' (Ca-rich) cement porewaters. The experiments involved static and flowing experiments lasting 10-365 days.

Reaction was rapid in all experiments, with samples increasing in weight by up to 9% with no change in overall size. Key reactions were breakdown of portlandite and calcium silicate hydrates and formation of carbonates and silica. Reaction fronts moved through the cement over time, demarking regions of low, partial and full carbonation. The fully carbonated zone showed evidence for higher-density carbonate-filled fractures and concentric 'relic' reaction fronts, which separated areas having lower-density and high porosity. Appreciable amounts of a Cl-rich phase formed in the partially carbonated zone.

Controlled flow-rate experiments revealed decreases in overall sample permeability for gaseous, supercritical and dissolved CO_2. Carbonation was fastest with supercritical CO_2, but the greatest permeability reduction occurred with dissolved CO_2. Permeability decreases reflect porosity reduction due to conversion of portlandite and CSH to secondary carbonate minerals. The greatest reductions in porosity and permeability occurred in a very narrow zone at the leading edge of the visible alteration front.

Design Overview of the Potsdam 1280-HR SIMS Instrument

A. ROCHOLL[1] *AND M. WIEDENBECK[1]

[1]Helmholtz-Centre Potsdam, GFZ, German Research Centre of Geosciences, Telegrafenberg, 14473 Potsdam, Germany (*correspondence: Alexander.Rocholl@gfz-potsdam.de)

The Helmholtz Zentrum Potsdam is currently installing a CAMECA 1280-HR SIMS, which will begin producing user data in the autumn of 2013. This state-of-the-art, ultra-high sensitivity and large geometry ion microprobe will function as an open user facility, in accordance with the Helmholtz Society's support of the global scientific community through providing access to top-end infrastructure. The new 1280-HR instrument will be integrated into the Helmholtz SIMS network, whereby the activities in the Potsdam laboratory will be closely coordinated with new SIMS infrastructure currently being installed in both Dresden (accelerator SIMS) and Leipzig (NanoSIMS 50L). While the 1280-HR is intended mainly for geoscience studies, the facility will also support a limited number of well defined material science investigations as well as serving as a platform for instrumentation development work. This abstract provides a brief overview of the new facility's design and operational goals.

The instrument currently being installed consists of the basic 1280-HR design, including the five trolley multi-collection system along with a Resistive Anode Encoder, thus making the system optimized for both low uncertainty isotope ratio determinations (e.g., $\delta^{13}C$, $\delta^{18}O$ and $\delta^{34}S$) as well as quantification and distribution mapping of low concentration elements in minerals, glasses or biological materials. The possibility of very high mass resolution of $M/dM \geq 25{,}000$ allows the separation of isobaric masses, such as ^{40}Ca and ^{40}K. The sample loading system consists of the standard 2-positon carousel; a high capacity 500 l/s turbo pump with vibration damping provides improved vacuum in the sample source chamber. The most significant design modification unique to the Potsdam instrument is the addition of 5 flanges in the coupling and projection sections of the machine, including one intended for the integration of a total ion current measuring capability. Factory testing has shown a repeatability for $\delta^{18}O$ determination (n= 10) of ± 0.25 ‰ (1sd) on a quartz disk, with further improvements in analytical uncertainty expected once the instrument enters routine service. Envisioned key analytical topics include H, B, C, O, S and Pb isotopic studies, geochronological applications and the quantification of volatile elements in geological materials.

Trace-elements distribution in tourmaline, micas and K-feldspar from the Berry-Havey pegmatite (Maine, USA): implications for the pegmatitic evolution

E. RODA-ROBLES[1], W. SIMMONS[2], A. PESQUERA[1], P. P. GIL-CRESPO[1], J. NIZAMOFF[2] AND J. TORRES-RUIZ[3]

[1]Dpto. Mineralogía y Petrología, UPV/EHU, Bilbao, Spain, encar.roda@ehu.es

[2]Earth and Environmental Sciences, University of New Orleans, USA. wsimmons@uno.edu

[3]Dpto. Mineralogía y Petrología, Universidad de Granada, Spain. jotorres@ugr.es

The Berry-Havey pegmatite (Oxford pegmatite field, Androscoggin County, Maine, USA), is a highly evolved pegmatite enriched in Li, F, B, Be and P. The pegmatite has a complex internal structure, with four texturally and compositionally different zones, which show an increasing degree of evolution inwards: wall zone, intermediate zone, core margin and core zone, where gemmy tourmaline-bearing pockets are common. The main minerals are quartz, feldspars, Al-micas (muscovite-lepidolite series), tourmaline (schorl-elbaite-rossmanite), and minor Fe-micas (biotite and zinnwaldite). Garnet, beryl, amblygonite-montebrasite, and apatite are common accessory minerals.

Most trace elements do not show a clear preference for any of the main minerals. However, Li, Cs, Mn, Ba, Nb, and Ta mainly partition into the Fe-mica, whereas Be, Sn, W and Zr partitions preferably into the Al-mica. P and Sr partition into the K-feldspar. Tourmaline is the poorest of the four phases in trace elements. Li content increases from the wall zone to the core in all the phases. Rb, Cs and Ba show a similar trend for micas and K-feldspar, with Rb and Cs increasing gradually from the wall zone to the core zone, simultaneously to the decrease of Ba. In tourmaline Li, Be, Mn, Sn, Nb and Ta contents increase from the wall zone to the core zone, and finally decrease in the gemmy tourmaline from the pockets. Overall, REE contents are very low. The origin of these differences relates to the concentration of the elements in the melt and the variations in the compatibility of these elements between the minerals and melt during fractional crystallization, which in turn depends on the behavior of major elements. Micas, K-feldspar and tourmaline are good geochemical monitors using trace elements such as Li, Rb, Be, Sr and Ba, to understand the petrogenesis of pegmatites.

[4]Nordic Center for Earth Evolution (NordCEE)

Due to its redox-sensitivity, the chromium isotope system is an interesting paleoclimatic tracer particularly powerful in recording fluctuations of atmospheric oxygenation and continental weathering [1]. Here we seek to investigate detailed $\delta^{53}Cr$ records associated with intense climatic changes during Neoproterozoic glaciations.

We present a $\delta^{53}Cr$ record of late Neoproterozoic marine carbonates stretching from the Chuos (746±2Ma[2]) to the the Ghaub Fm (635.6±0.5Ma[3]), exposed in northern Namibia, covering shallow water sedimentation during the Cryogenian glaciations. The $\delta^{53}Cr$ stratigraphy was complemented with $\delta^{13}C_{carb}$ as well as major and trace element concentrations. The Chuos $\delta^{53}Cr$ signal is close to mantle inventory [4], but recovers rapidly to positive values after the glacial sequence, indicating a sufficiently oxygenated atmosphere. Prior to the Ghaub glaciation, $\delta^{53}Cr$ values are positively fractionated (+0.12±0.02‰) and correlate to $\delta^{13}C_{carb}$, while in post-Ghaub carbonates $\delta^{53}Cr$ values decrease to ~-0.08‰, similar to drops observed in post-Chuos sediments, and accompanied by increased Cr, Sc, and Ti concentrations. These $\delta^{53}Cr$ results suggest increased continental-derived detrital input as a consequence of enhanced weathering periods related to rapid climate change, elevated post-glacial pCO_2[5], proximity to the continent and/or increased hydrothermally-derived Cr input.

The observed $\delta^{53}Cr$ fluctuations indicate sufficiently high atmospheric oxygen levels to oxidize and mobilize Cr during weathering processes on land prior and after the major Neoproterozoic glaciations. Increased weathering due to rapid post-glacial rise of pCO_2 render the $\delta^{53}Cr$ signal unfractionated, also potentially indicating the predominance of accumulated hydrothermally-derived Cr in the shallow seawater pool during the Ghaub aftermath.

A new experimental approach to silicic magma differentiation

CARMEN RODRIGUEZ[1]*, ANTONIO CASTRO[2] AND ANTONIO SÁNCHEZ-NAVAS[3]

[1]University of Huelva Campus El Carmen, 21071 Huelva, Spain (*correspondence: carmen.rodriguez@dgeo.uhu.es)
[2]Unidad Asociada de Petrología Experimental, CSIC-University of Huelva, Campus El Carmen, 21071 Huelva, Spain (dorado@uhu.es)
[3]University of Granada Campus Fuentenueva 18071

The separation of fluid and crystals from melt at diverse stages in the evolution of magmatic systems is inferred on the basis of thermomechanical modelling [1], geochemical relations of zoned silicic plutonic bodies [2] and phase equilibrium studies [3]. However, experimental tests dealing with magmatic differentiation of natural magmas at real pressures and temperatures are very scarce [4, 5].

In our laboratory experiments, gravity effects are separated from those imposed by thermal gradients, which simulate natural conditions of crystallization in a cooling magma chamber. Major and trace element distribution profiles result from the thermal gradient for water-bearing magma systems. The observed profiles are exclusively explained by diffusion in the liquid and boiling-assisted crystal-liquid separation, without invoking gravity crystal settling. These experiments confirm the key role of fluids in silicic magma differentiation and their implications on explosive volcanism and ore deposit generation.

Origin of Grande Ronde Basalts, Columbia River Basalt Group

SEDELIA RODRIGUEZ[1] AND GAUTAM SEN[2]

[1]Florida International University, Miami, FL, USA
[2]Amrican University of Sharjah, Sharjah, UAE, gsen@aus.edu

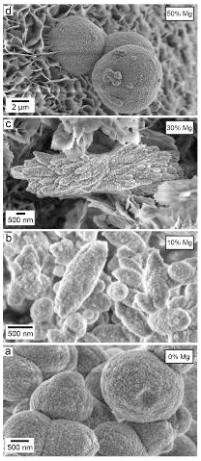
The Grande Ronde Basalt lavas contain 0-5% phenocrysts of plagioclase, augite, pigeonite, and olivine. Plagioclase hygrometry shows that the erupted lavas contained less than 0.3% dissolved H_2O. The presence of rare An_{96} plagioclase megacrysts suggests ~4.5wt% dissolved H_2O in some parent magmas. All magmas degassed during ascent and eruption. Size of plagioclase phenocrysts suggests an average phenocryst residence time in magna of 160 years. Ignoring hiatuses between eruptions, we estimate that the 110 flows of the GRB erupted over a cumulative time of 17,600 years, with an average eruption rate of about 8.6 km^3/year. The average interval between eruptions is estimated to be 3658 years. Model simulations and petrological reasoning indicate that the primary melts were generated from spinel peridotite at 1.5 GPa, perhaps under hydrous conditions. Extensive melting of lithospheric eclogite may have played a role as well; however, this is not constrained by our simulations. Magmas underwent contamination, mixing, and partial crystallization during and prior to their short residence within shallow (6 km) intrusives. Our petrologic conclusions lead us to present a petrotectonic model that supports the hypothesis that the CRBG magma generation was greatly aided by a thinned lithosphere and H_2O that may have come off the mantle wedge.

The role and effect of Mg on the formation of carbonates

JUAN DIEGO RODRIGUEZ-BLANCO[1,2]*, SAMUEL SHAW[1,3], PIETER BOTS[1,3] AND LIANE G. BENNING[1]

[1]School of Earth and Environment, University of Leeds, Leeds LS2 9JT, UK. (* presenting author)
[2]Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmmark.
[3]School of Earth, Atmospheric and Environmental Sciences. The University of Manchester.

Mg is the most abundant divalent cation in seawater. It plays an important role in the crystallization of $CaCO_3$-based biominerals that control the marine global carbon cycle. However, the mechanisms of $CaCO_3$ crystallization from solution in the presence of Mg are still poorly understood. Here we show that a spherulitic growth mechanism often controls the nucleation, growth and crystallization of Ca-Mg carbonate polymorphs produced with variable Mg contents (0-50%) and at different temperatures (7.5-220°C). Combining *in situ* and realtime synchrotron-based diffraction and scattering with time-resolved UV-Vis spectrophotometry and high-resolution imaging we quantitatively evaluated the kinetics and mechanisms of the formation and crystallization reactions in the Ca-Mg-CO_3 system.



Under all conditions an initial, variable Mg containing, poorly-ordered, nanoparticulate precursor (amorphous calcium carbonate, ACC) forms from solution and transforms to various nanocrystalline intermediates via a spherulitic growth mechanism. In turn these intermediates crystallize via a dissolution and reprecipitation mechanisms to end products. The composition, kinetics of formation, local structure and stability of the ACC are dependent on the initial Mg/Ca/CO_3 ratio, the temperature, supersaturation and pH of the reactions. At 0% Mg, pure ACC rapidly (<2 min at 21°C) crystallizes to vaterite via spherulitic growth (image ***a***, bottom) and later transforms slower (hours) into calcite through dissolution-reprecipitation [1,2]. With 10% Mg, ACC is ~1 order of magnitude more stable than pure ACC, and transforms to Mg-calcite with no vaterite intermediate [3] (***b***). Higher Mg contents further stabilize the ACC for hours to days. These high Mg-ACC phases crystallize spherulitically either to monohydrocalcite (***c***; Mg/Ca> 0.25; T<60°C; [4]), dolomite (***d***; at Mg/Ca ~1; T>60°C; [5]) or various Mg-rich carbonates (e.g., at Mg/Ca>1 hydromagnesite).

Enhanced *in situ bio*denitrification (EIB) is a feasible technology to clean up nitrate-polluted groundwater and achieve drinking water standards. We developed a reactive transport model that considers biogeochemical processes as well as isotope fractionation to enable better monitoring and management of this technology. In this work, we applied this model to interpret data from batch experiments on EIB. Furthermore, 2-D simulations at field scale are in progress to model an EIB pilot conducted in a fractured aquifer system. The used codes were PHREEQC for batch scale and PHAST for field scale. The fractured media were modeled as equivalent continuum media with two hydraulic conductivity zones. The flow model was validated with experimental data from a tracer test with bromide. The reactive transport model at batch and field scale was validated with experimental values of Vidal-Gavilan *et al*. (2013) [1]. The preliminary results show that parameters determined in batch experiments can be used as first estimates to reproduce field observations provided groundwater flow is well known. Moreover, the inclusion of isotope fractionation processes allowed to determinate the real scope and exact degree of EIB at field scale.

Uptake of $Pb^{2+}_{(aq)}$ by baryte-celestine solid-solution crystals

R. M. RODRÍGUEZ-GALÁN, J. CARNEIRO AND M. PRIETO

Department of Geology, University of Oviedo, Spain

The interaction of dissolved toxic metals with minerals frequently leads to dissolution-coprecipitation processes in which the metal ion incorporates into the solid phase substituting for the major ion in lattice positions. The fact that the solubility of a minor constituent in a solid solution is smaller than the solubility of its equivalent pure solid explains the environmental relevance of these coprecipitation reactions. Interaction studies are typically carried out by using stoichimetric minerals as host phases. However, in most cases the effectiveness of this removal mechanism could be significantly increased using suitable solid-solutions instead of pure minerals. In this work we study the interaction of Pb-bearing aqueous solutions with baryte ($BaSO_4$) and intermediate (5-15 % molar Sr) members of the $(Sr,Ba)SO_4$ solid solution.

Compositionally homogeneous crystals of the solid solution were obtained by precipitation & aging in a closed reactor at 90ºC. The obtained precipitates were checked for compositional homogeneity by considering the full width at half maximum intensity values (FWHM) of some selected reflections of the XRD patterns. The precipitate compositions were determined by analyzing the remaining solutions by ICP-AES. Moroever, samples of each precipitate were analyzed by SEM-EDS.

The interaction experiments were carried out in closed reactors at 25ºC. The aqueous composition was analyzed repeated times during the experiments, which lasted one month. In the case of the interaction with strontian baryte, lead incorporates into the solid phase while some barium and a large proportion of strontium incorporate to the aqueous solution. As result the aqueous solution becomes depleted in lead at a significantly greater extent than during the interaction with pure baryte.

Future work will deal with the implementation of an equilibrium model for the $(Pb,Sr,Ba)SO_4$-H_2O system. An added implication is related to the effectivenes of Sr-bearing baryte as a sequestring phase for radium. The interaction with baryte leads to a significant removal of dissolved Ra^{2+}, but the depletion could be considerably greater using strontian baryte.

Biomineralization of Mg-rich Calcite ($Mg_xCa_{1-x}CO_3$) by *Proteus mirabilis*

YUL ROH[1]*AND SERKU KANG[2]

[1]Chonnam National University, Gwangju, Korea, (*correspondence: rohy@jnu.ac.kr)
[2]Chonnam National University, Gwangju, Korea, (chodang02@naver.com)

Recently bacterially induced carbonate precipitation has been proposed as an environmentally friendly method to apply CO_2 sequesteration and fixation [1]. The objectives of this study were to investigate biomineralization of the carbonate minerals using microorganisms enriched from rhodoliths and to identify environmental factors that control the formation of calcite by the microorganisms.

Carbonate forming microorganism (CFM) was enriched from rhodoliths using D-1 medium for microbial activity and aerobically cultured at 25℃ using D-1 medium with containing 30:30 mM Ca-:Mg-acetate concentrations to confirm formation of carbonate minerals. Enriched microorganisms were analyzed by 16S rRNA gene DGGE analysis to confirm microbial diversity. Various ratios of Ca and Mg-acetate concentrations (60:0, 60:20, 20:60, 0:60 mM) were added to D-1 medium to examine how different Ca and Mg ratios affect the biomineralization of carbonate minerals. Mineralogical characteristics of bio-precipitates were determined by XRD and SEM-EDS analyses.

A 16S rRNA sequence analysis showed the enriched microorganisms contained CFM such as *Proteus mirabilis* [2]. XRD analyses showed that the precipitates were calcite with Ca-:Mg-acetate (60:0, 60:20 mM), Mg-rich calcite with Ca-:Mg-acetate (30: 30, 20:60 mM) and huntite with Ca-:Mg-acetate (0:60 mM) were formed, whereas any carbonate minerals were not formed without the microorganisms in D-1 medium. Also, through various ratios of Ca/Mg concentrations, we observed that the formation of Mg-rich calcite and huntite occurred when the level of Mg ion was much higher than that of Ca ion in D-1 medium. SEM-EDS analyses showed that the carbonate minerals formed by the microorganisms were a rhombohedron shape consisted of Ca, Mg, C. and O and irregular shaped extracelluar polymeric substance (EPS) with Ca, Si, and Mg componet.

These results indicate that the microorganisms induce precipitation of carbonate minerals on the cell walls and EPS via the accumulation of Ca and/or Mg ions on the cells. Therefore, microbial precipitation of carbonate minerals may play one of important roles in metal and carbon biogeochemistry as well as carbon sequestration in natural environments.

Redox processes in the Earth's mantle

ARNO ROHRBACH[1]

[1]Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Germany, arno.rohrbach@uni-muenster.de

Redox reactions are crucial for many geological processes, but especially how Earth's surface and atmosphere became oxidized enough to form a habitable planet is a key question. To understand redox controls in Earth's mantle is of prime importance, because oxygen fugacity (fO_2) regulates the biogeochemical cycles of volatiles such as C-O-H or S and their respective fO_2-dependent species. These volatiles also link deep mantle reservoirs and Earth's surface because they promote mantle convection and initiate volcanism through solidus depression in various tectonic settings.

The redox state of the mantle may be reconstructed, for instance, by investigating mantle melts. Subduction related basalts (IAB) have higher Fe^{3+}–ΣFe ratios than mid-ocean ridge basalts (MORB) or ocean island basalts (OIB) [1]. A matter of debate is, whether these higher redox states are a source signal from the mantle wedge with higher Fe^{3+}–ΣFe compared to the MORB source [2], or, if IAB melts are affected by post genetic oxidation at some stage between early crystallization and solidification. Fe^{3+}–ΣFe ratios in basalt glasses correlate with H_2O content [1] but differ from results based on other redox proxies such as V/Sc [3,4], Zn/Fe_T [5], or Fe isotopes [6]. Key problems, e.g., if and how subduction related fluids oxidize the mantle, if subduction causes a secular variation in mantle fO_2, or if the mantle is buffered with respect to fO_2 remain highly controversial.

Oceanic crust, lithosphere and overlying sediments are generally more oxidized than the ambient mantle if subducted to depths >100 km, because cratonic lithosphere and potentially also the asthenosphere become increasingly reduced with increasing depth [7,8]. The redox contrast between delaminated oxidized blocks from the slab and reduced ambient mantle sets the frame for hydrous and carbonatitic redox melting processes in the deeper mantle [9,10].

Palaeozoic biosphere and climate: Modes of marine primary production and methane cycling feedbacks

MEGAN ROHRSSEN[1], GORDON D. LOVE*[1] AND CHRISTOPHER T. REINHARD[2]

[1]Department of Earth Sciences, University of California, Riverside, CA, 92521, USA; *Correspondence: glove@ucr.edu

[2]Departmentof Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA, 91125, USA

Lipid biomarker records of microbial community structure during the Late Ordovician through Early Silurian (~449-439 Ma) indicate substantial differences in the balance of bacterial versus algal primary production through the Late Ordovician, largely in response to climatic change associated with the Hirnantian glaciation ([1]. Our biomarker records suggest that these warm Palaeozoic intervals were associated not only with elevated atmospheric pCO_2 (~4-16x preindustrial atmospheric levels, PAL), but also with a higher average flux of oceanic methane, exerting a potential positive feedback on hothouse climates in the Paleozoic. To refine the assessment of a methanotrophic contribution to lipid biomarkers, we have conducted compound-specific carbon isotope analyses on hydrocarbon extracts from Anticosti Island (Canada) the Vinini Formation (USA), the Maquoketa Formation (USA), and OM9 drill core (Estonia).

Recent models have demonstrated that a relatively modest increase of 4-5x preindustrial pCH_4 can generate 2-3ºC of warming [2]. Methane cycling feedbacks on climate must have been of similar or greater impact in the Palaeozoic, a period of warm conditions and reduced oxidant availability [3] which may have driven a larger proportion of remineralized organic matter through microbial methanogenesis and attenuated the efficacy of combined anaerobic methane oxidation processes as a throttle for methane fluxes to the atmosphere. Because the loss rate of atmospheric methane scales inversely with atmospheric methane abundance [4], increased fluxes to the atmosphere will often translate into higher steady-state concentrations. We explore the possible effects of this for Palaeozoic times with a series of simple mass balance calculations given a range of carbon flux and anaerobic remineralization scenarios.

[3]CIEMAT, Research Centre for Energy, Environment and Technology, Madrid, Spain

Radionuclide sorption and solubility in cementitious systems can be affected by the presence of organic ligands. Gluconic acid (GLU) is a poly-hydroxocarboxylic acid expected in repositories for low and intermediate–level radioactive waste as a component of cementitious materials. The formation of very stable An(III)–GLU complexes has been reported in the literature, although in contrast to An(IV) no ternary species Ca–An(III)–GLU have been described so far. These species may play a relevant role in cementitious and saline environments, where high Ca^{2+} concentrations are expected in certain scenarios.

Undersaturation solubility studies with $Nd(OH)_3$(am) were conducted in inert gas (Ar) gloveboxes at 22±2ºC. Samples were prepared in dilute NaCl (0.1 M) and $CaCl_2$ (0.1 and 0.25 M) solutions as background electrolytes. Parallel experimental series were prepared with pH_c = constant ~12 and $10^{-6} \leq$ [GLU] $\leq 10^{-2}$ M, and with [GLU] = constant = 10^{-3} M and $9 \leq pH_c \leq 13$. TRLFS measurements were performed with ~10^{-7} Cm(III) per sample, with NaCl (0.1 M) and $CaCl_2$ (0.1 and 0.25 M) as background electrolytes. In the NaCl systems, three different concentration levels of Ca^{2+} were considered: 0, 10^{-3} M and 10^{-2} M. The initial concentration of GLU in all samples (10^{-6} M) was increased to $3 \cdot 10^{-3}$ M by step–wise additions of NaCl-NaGLU or $CaCl_2$-$CaGLU_2$ solutions of appropiate ionic strenght.

The solubility of $Nd(OH)_3$(am) remains unaffected by GLU in 0.1 M NaCl solutions. On the other hand, solubility of $Nd(OH)_3$(am) in 0.1 and 0.25 M $CaCl_2$ solutions is clearly increased by GLU under hyperalkaline conditions. The species forming are pH–dependent and unequivocally involve the participation of Ca^{2+}, with the likely formation of a Nd–GLU complex with stoichiometry 1:2. No further increase of Nd(III) concentration is observed at [GLU]tot $\geq 10^{-3}$ M, resulting in an upper solubility limit at [Nd] ~ $10^{-6.5}$ M which suggest the formation of a new Ca–Nd–GLU solubility limiting solid phase. Consistently with Nd(III) solubility data, TRLFS confirms the key role of Ca^{2+} in the complexation process, with the likely formation of a Ca–Cm(III)–GLU complex with Ca:GLU ratio 1:1. Two Ca–Cm–GLU species are further identified in 0.1 M and 0.25 M $CaCl_2$ solutions.

Importance of reference materials and of the determination of matrix effects for precise and accurate measurements by SIMS

C. ROLLION-BARD[1] AND NANCY ION MICROPROBE TEAM[1]

[1]Centre de Recherches Pétrographiques et Géochimiques, Univ. de Lorraine, UMR 7358, 15 rue Notre Dame des Pauvres, F-54500 Vandoeuvre-lès-Nancy, France, rollion@crpg.cnrs-nancy.fr

SIMS technique (Secondary Ion Mass Spectrometer) has been used for several decades to examine element and isotope compositions at micrometer scale in various geological samples [1]. But SIMS measurements are subject to matrix effect at the time of sputtering process. To overcome these matrix effects in the order to achieve precision and accuracy of the analyses, reference materials are needed. These reference materials must have the same chemical composition and mineralogy of the sample, or at best, must be the closest possible.

We will show different examples of determination of matrix effect for oxygen isotopes: in $CaCO_3$ polymorphs, in different carbonates (magnesite, dolomite, siderite, rhodochrosite and ankerite, [2]), and in a solid-solution, i.e. Fe-Ca-Mg garnets [3,4]. We will highlight the importance of the choice of the reference materials and the determination of possible matrix effect. When all the precautions regarding these effects are taken, a precision better than 0.5 ‰ can be achived, the more complex the correction, the worse precision is reached.

Differentiating magma sources from conglomerate and breccia clasts, IODP Site U1349, Ori Massif, Shatsky Rise Oceanic Plateau

I.V. ROMANOVA* AND D.T. MURPHY

School of Earth, Environmental and Biological Sciences, Queensland University of Technology, 4001, Brisbane, Australia (*correspondence: i.romanova@qut.edu.au)

Shatsky Rise in the northwestern Pacific is one of the largest (~500,000 km^2) and oldest (145-135 Ma) Large Igneous Province on the oceanic floor. Studies of magnetic lineations and bathymetry showed that Shatsky has an elongated structure with three edifices (Tamu, Ori, Shirshov) progressively decreasing in age and in volume [1]. Integrated major and trace elements and Sr-Nd-Pb-Hf isotopes for the Shatsky Rise basalts show 4 distinct magma types and MORB-like compositions with trends towards the enriched plume(?)-source for Ori and Shirshov Massifs [2-4]. Deciphering deep plume vs. shallow mantle contributions to the Shatsky magmatism remains a fundamental problem.

During the IODP Expedition 324, site U1349A penetrated Ori massif near its summit [5] and recovered volcaniclastic sandstones, volcanic breccia, a clay-rich layer and polymictic volcaniclastic conglomerate (Unit III, ~20 m) between sedimentary layers and igneous basement. The breccia clasts range in size from 2-20 mm and the conglomerate clasts from 2-80 mm. These fragments represent eroded volcanic material originating from locally sourced portions of the Ori Massif.

All clasts are heavily altered picritic and tholeiitic basalts with little or no primary magmatic minerals preserved and significant enrichments in fluid mobile elements (Ca, Na and K). For the fluid immobile element Ti the concentration of TiO_2 ranges from 1.8-4 wt. %, whereas the Shatsky Rise basement lavas have no TiO_2 contents higher than 2.7 wt. %. This implies that the clasts are derived from different lavas with distinct petrogenesis and geochemistry relative to the rest of the basement lavas sampled to date. Thus, at least 5 magma types compose Ori Massif. Trace element and Nd-Hf isotope data on the new High-Ti magma type will allow further investigations into source heterogeneities.

A 2000-year rainfall record from the Eastern Tropical Pacific and ENSO variability during the Common Era

LIDIA ROMERO VIANA[1,2], ULRIKE KIENEL[2] AND DIRK SACHSE[1]

[1]University of Potsdam, Institute of Earth and Environmental Science, Karl-Liebknecht-Str. 24-25, 14476 Potsdam-Golm, Germany

The ENSO is the dominant mode of interannual tropical climate variability with widespread global teleconnections. Understanding its natural variability is a key factor to evaluate its effect on the internal variability in the global climate system. We present a 2000-year rainfall reconstruction from the Eastern Tropical Pacific based on a calibrated lipid biomarker ratio, the DiTe index [1], using the annually laminated sedimentary sequence of a crater-lake located in Isabel Island (Mexico). In the region, the highly seasonal rainfall pattern is dominated by ENSO dynamics, resulting in drier/wetter conditions during positive (El Niño)/negative (La Niña) anomalies. Our inferred past rainfall variability shows negative anomalies at millennial and centennial scale coinciding with periods of high frequent and strong El Niño events being coherent with other hydroclimatic records, based on independent proxies within the target region. Our record of subdecadal resolution allows for detailed evaluation of regional rainfall variability during key periods, such as, the Medieval Climate Anomaly and Solar minima and therefore, contributes to the understanding of climatic variability in the Tropical Pacific. Are the anhydrite and gypsum carbonatation pathways the same?

T. RONCAL-HERRERO[1], P. BOTS[1,2], J.D. RODRIGUEZ-BLANCO[1,3], J.M. ASTILLEROS[4,5]*, M. PRIETO[6], L.G. BENNING[1] AND L. FERNÁNDEZ-DÍAZ[4,5]

Coupled dissolution-recrystallization reactions during interactions between carbonate-bearing fluids and calcium sulphate minerals lead to de novo formation of $CaCO_3$ polymorphs. The carbonation of anhydrite (ANH, $CaSO_4$) and gypsum (GYP, $CaSO_4.2H_2O$) produces dramatic changes in both textural and chemical properties of the starting calcium sulphate phase (e.g., porosity, composition etc.). However, our understanding of such processes is still fragmented.

Here we present an experimental study comparing the carbonation of ANH and GYP at 25 ºC. In both cases, the formation of various $CaCO_3$ polymorphs occurred immediately upon contact between the solid phase and a Na_2CO_3 solution. However, differences in textural features and reaction pathways were observed between both systems. GYP carbonation produces a large volume of porosity with a prominent gap between parent and product phases. Conversely during ANH carbonation such a gap does not form and porosity generation is minimal. Furthermore, the produced $CaCO_3$ polymorphs are spatially differently distributed on ANH *vs*. GYP surfaces and within the replaced layer indicating that the nature and reactivity of the parent phases control the $CaCO_3$ polymorph and the evolution of textural features during carbonation. These results have implications for biomineralization, CO_2 sequestration and industrial applications.

Opal-CT precipitation in a clayey soil explained by geochemical transport model of dissolved Si (Blégny, Belgium)

B. RONCHI[1]*, A.L. BARAO[2], F. VANDEVENNE[2], N. VAN GAELEN[1], D. VERHEYEN[1], R. ADRIAENS[1], O. BATELAAN[1], A. DASSARGUES[1], E. STRUYF[2], J. DIELS[1] AND G. GOVERS[1]

[2]UA, Campus Drie Eiken, D.C.116, Universiteitsplein 1, 2610 Wilrijk, Belgium

Dissolved Si (DSi) exported by rivers are controlled by geological, hydrological and biological cycle processes [1]. The DSi concentrations measured in a river of an upstream catchment in eastern Belgium (Blégny, Land of Herve) don't vary seasonally (6.91±0.94mgL^{-1}; n=363). Si concentrations in pore water are often higher and vary more (8.65±3.65mgL^{-1}; n=128). The decrease of DSi along the flowpath of water is due to sink processes, i.e. precipitation, adsorption or uptake by vegetation. As the DSi in the river does not show any seasonal variation, uptake by vegetation can be ruled out [1] whereas precipitation or adsorption can control the DSi drained by the stream water. This hypothesis is confirmed by XRD and DeMaster analysis. At 0.1m depth the soil is constituted of 62% quartz, 7% K-feldspar, 6% plagioclase, 3.2% carbonates, 18.9% Al-clay, 1.47% Kaolinite, 0.63% Chlorite and 0.2% amorphous Si, probably of biogenic origin. At 1.5m depth, the amounts of several minerals (35.8% quartz, 0.6% K-feldspars, 0.9% plagioclase, Al-clay 14.7%) drop drastically. Carbonates, chlorite and kaolinite are absent whereas 40.4% opal-CT appears. The precipitation of opal-CT controls the DSi export of this catchment.

To describe DSi export from a catchment a geochemical transport model is developed in HP1 which couples the water flux model Hydrus with the geochemical model PHREEQC [2]. Our model is based on the conceptual model developed in [3]. First results show different DSi export dynamics in the unsaturated zone than in the aquifer due to different pCO_2 values and varying soil moisture conditions. Further development of the model will help to find out the reason of opal-CT precipitation in this setting.

Constraining the origin of sulfur isotopic variability through the end-Ordovician Hirnantian glaciation and mass extinction

CATHERINE V. ROSE[1*] AND DAVID A. FIKE[1]

[1]Department of Earth & Planetary Sciences, Washington University, St. Louis, MO 63130, USA *(crose@eps.wustl.edu)

Geochemical records of the end-Ordovician Hirnantian Stage show parallel positive excursions in the stable isotope compositions of sedimentary pyrite sulfur ($\delta^{34}S_{pyr}$), organic carbon, and carbonate carbon; these isotope excursions coincide with the end-Ordovician glaciation and mass extinction. An increase in pyrite burial attributed to marine anoxia has been proposed to explain the sulfur isotope excursion and link oceanic redox conditions to the extinction of marine fauna. Such an increase in pyrite burial would generate a parallel excursion of equal magnitude in the isotopic composition of coeval marine sulfate. However, paired sulfur isotope data from the Hirnantian Stage of Anticosti Island, Quebec, do not covary, which suggests enhanced pyrite burial is not the cause of the Hirnantian $\delta^{34}S_{pyr}$ excursion and questions the role of anoxia in the mass extinction. We present new high-resolution paired sulfur isotope data from carbonate-associated sulfate (CAS) and pyrite during the Hirnantian Stage from the Girardeau Formation, Missouri, USA, to test these hypotheses. The results show a 28‰ enrichment in $\delta^{34}S_{pyr}$ but no parallel excursion in $\delta^{34}S_{CAS}$, indicating that enhanced pyrite burial did not generate the Hirnantian $\delta^{34}S_{pyr}$ excursion. These observations may best be explained by a transient reduction in the expressed isotopic fractionation during microbial sulfate reduction associated with Hirnantian sulfur cycling possibly caused by: a change in actual biological fractionation; a shift in the chemocline leading to restricted exchange of porewater sulfate; or glacio-eustatic sea-level drawdown corresponding to syndepositional sediment reworking and increased oxidation.

Fe Isotope Fractionation During Reduction of Fe(III) to Fe(II)

A.D. ROSENBERG*, C.E. HODIERNE AND S.G. JOHN

Dept. of Earth and Ocean Sciences, University of South Carolina, USA (*correspondence: arosenberg@geol.sc.edu)

Phytoplankton growth, and thereby primary productivity, is limited in many regions of the ocean by insufficient iron (Fe) availability. In seawater iron exists in two different oxidation states – Fe(III) and Fe(II). While Fe(III) is thermodynamically stable in oxic environments, it can be reduced to Fe(II) by photochemical or biological reduction. In the ocean release of Fe(III) from ligands by reduction to Fe(II) is often necessary for Fe to become bioavailable to phytoplankton. Recently, techniques have been developed to measure dissolved Fe stable isotope ratios (δ^{56}Fe) in seawater and marine plankton, opening the door to using δ^{56}Fe as a tracer for biologically important Fe redox cycling in the oceans.

In order to clarify the impact that various reduction pathways have on Fe isotopic fractionation, the natural reduction of Fe(III)-L to Fe(II) was simulated in the lab by the reduction of Fe(III)-EDTA to Fe(II) in three ways: photochemically, chemically, and electrochemically. During photochemical reduction, Fe(III)-EDTA was reduced upon exposure to direct sunlight which promotes ligand-to-metal charge transfer. Chemical reduction was achieved by the addition of a reducing agent such as hydroxylamine hydrochloride. Electrochemical reductions were carried out using a rotating-disc electrode at a variety of overpotentials. Following reduction, Fe(II) was collected and purified for Fe isotope analysis by MC-ICPMS.

The reduction pathway has a large impact on the observed isotope effect. Photochemical reduction produces positive δ^{56}Fe values (+0.95 to +1.03 ‰) while chemical reduction produces negative δ^{56}Fe values (-1.73 to -2.20 ‰) with electrochemical reduction iron isotope ratios (-0.28 to -0.94 ‰) falling in between the two. Further investigation into isotopic fractionation during reduction of Fe(III) to Fe(II) may provide insight into the pathways by which Fe(III) is reduced and made bioavailable to phytoplankton in the oceans, leading to an overall greater understanding of marine iron cycling.

Linking nutrient and contaminant dynamics in rhizopheres of hyperaccumulators

C.E. ROSENFELD[1]*, R.L. CHANEY[2], A. LANZIROTTI[3] AND C.E. MARTÍNEZ[1]

[1]Pennsylvania State University, Department Ecosystem Science and Management, University Park, PA, USA, cer196@psu.edu (* presenting author), cem17@psu.edu
[2] USDA ARS Environmental Chemistry Laboratory, Beltsville, MD, USA Rufus.Chaney@ars.usda.gov
[3]Consortium for Advanced Radiation Sources, University of Chicago, Chicago, IL, USA lanzirotti@uchicago.edu

Trace metal contamination in soils is a global problem, causing plant and microbial toxicity, diminished crop production or decreased land cover. Some plants can grow, and even thrive, in heavily polluted soils though it is generally unclear how. Our goal was to elucidate linkages between contaminant and nutrient uptake in plants grown in metal contaminated soil.

We examined two ecotypes (Ganges and Prayon) of the metal hyperaccumulator, *N. caerulescens* (formerly *Thlaspi caerulescens*) grown on field-contaminated soil. Both ecotypes are known zinc (Zn) hyperaccumulators, while only the Ganges ecotype hyperaccumulates cadmium (Cd). At harvest, rhizosphere and plant thin sections were obtained for synchrotron-based μ-X-ray fluorescence (μ-XRF) and Zn-μ-X-ray Absorption Near Edge Structure (Zn-μ-XANES) spectroscopy.

Substantial Zn was accumulated by the plants (1390 mg Zn/kg), though there was no significant difference between ecotypes. Cadmium uptake, was significantly greater in the Ganges ecotype (750 mg Cd/kg) than the Prayon ecotype (90 mg Cd/kg). There was also greater Cd root-to-shoot translocation (root:shoot ratio = 0.13) than Zn (root:shoot ratio = 0.81). The Ganges ecotype took up significantly less Ca, which was also evident by the reduced rhizosphere Ca/Zn correlation in that ecotype. All rhizosphere soil regions investigated contained spectral features consistent with a combination of ZnS and ZnO, while bulk soil regions only occasionally contained such features. Inside the Ganges root, Zn speciation was most consistent with complexation by soft ligands (e.g. cysteine or histidine) while the Prayon roots contained Zn in a combination of mineral ZnO/$Zn(OH)_2$-like forms and hard-ligand (e.g. organic acids) complexes.

Nutrient biogeochemical cycles are often linked to differential metal accumulation in plants, as nutrient acquisition may be enhanced or inhibited because of contaminant uptake. In our plants, increased Cd uptake was correlated with decreased Ca uptake, decreased Zn-Ca co-location, and altered Zn speciation. On a larger scale, shifting Zn complexation in roots and the rhizosphere may impact Zn bioavailability to other organisms and mobility within contaminated ecosystems.

We compare age spectra from a multi-year sampling effort on the Mississippi-Atchafalaya River System (MARS), in which several different discharge regimes were sampled, the Narayani River in Nepal, and the Colville River Delta, for application of ramped pyrolysis ^{14}C analysis to samples from different basin types. The emerging picture from the MARS is one of consistency, with some variability related to flood provenance and discharge. Large river systems such as the MARS are integrative of a range of different lithologies and carbon sources. In contrast, the Narayani River, where high incision rates erode old carbonaceous rocks more efficiently during high discharge events, shows more variability and wider overall age spectra. Limited sedimentary storage of watershed primary productivity in the Narayani River watershed results in substantially wider age spectra than from the MARS system. It is likely that the Narayani River is less consistent in time than the MARS as contributions of old carbonaceous material are likely driven by discharge regime. We add to this comparison density-separated fractions from POC samples of the Arctic Colville River to further test a recent conceptual model of basin-control on POC age structure (Blair and Aller, 2012).

The fate and behaviour of volatiles during subduction of oceanic crustal material towards the deep mantle

A. ROSENTHAL[1]* AND D.J. FROST[1]

[1]Bayerisches Geoinstitut, University of Bayreuth, 95440 Bayreuth, Germany (*correspondence: Anja.Rosenthal@Uni-Bayreuth.de)

Knowledge of the abundance and distribution of H_2O in the Earth's deep interior (i.e. mantle and core) remains highly controversial.

The chief means of replenishment of the Earth's interior with volatiles over much of geological time is subduction (i.e. the transport of crustal material into the deep Earth by large-scale tectonic processes) but constraints are very poor as natural samples from the deep Earth's interior subduction zones are inaccessible. High pressure experimental investigations however can overcome that problem by simulating deep mantle conditions and processes.

The aim of this study is to experimentally determine the maximum storage cpacity, solubility and behaviour of H_2O in hydrous and nominally anhydrous minerals (NAMs) during subduction of hydrated oceanic crustal material into the deep upper mantle. We apply a novel experimental approach, which will for the first time enable determination of maximum H_2O contents of NAMs (and hydrous phases) in equilibrium with the full phase assemblage in subducted oceanic crust. This was not achieved in numerous previous studies which concentrated on simple, monomineralic systems.

Here, we present first results of experimentally determined melting and phase relations of an altered oceanic basalt composition GA1 [1] containing varying amounts of water (<1 wt%) at varying temperatures (sub-solidus to near solidus) and pressures (6-9 GPa; i.e. ~200 to ~300 km depth) using multi anvil apparatuses at University of Bayreuth, Germany.

Outcomes will allow constraints to be placed on the fluxes of H_2O recycled into the mantle at subduction zones, a critical step in the Earth's overall volatile budget.

[6]Laboratoire Magmas et Volcans, Clermont Université.

Iron isotopic variations are commonly reported in materials produced in high temperature environments such as planetary mantles. However, a reliable database of equilibrium fractionation factors between melts and igneous minerals is still lacking to interpret the rock record. In the case of iron, these factors can be directly derived from Nuclear Resonant Inelastic X-ray Scattering (NRIXS) experiments at a synchrotron facility [1, 2] through the determination of mean force constants. This method is insensitive to kinetic effects during mineral and glass synthesis, contrasting with conventional experimental approaches [3].

Because iron is a multivalent element, its isotopes could be good tracers of redox conditions during melting [4, 5]. To establish Fe isotope systematics as a redox proxy, we used NRIXS to measure mean force constants of synthetic ^{57}Fe-labelled olivine and silicate glasses synthesized at different oxygen fugacities in a gas mixing furnace and in piston-cylinders at different pressures with and without dissolved water.

At a given Fe^{3+}/Fe^{2+} ratio, the force constants of tholeitic to andesitic glasses are almost identical. For all samples, the force constant increases linearly with Fe^{3+}/Fe_{tot}. The effect of pressure and water content is moderate. Thus, for mafic melts, there is little structural control; redox effects seem to dominate. Our data demonstrate that even at high temperature (1100 °C), the equilibrium δ^{56}Fe fractionation between the two oxidation states of iron in MORBS is large (+0.25 ‰). The iron isotopic fractionation factors derived from NRIXS data may explain the heavy iron isotopic compositions measured in MORBS.

Approaching real uncertainty estimates for δ^{11}B data

MARTIN ROSNER[1] AND JOCHEN VOGL [2]

[1]IsoAnalysis UG, martin.rosner@isoanalysis.de
[2]BAM Ferderal Institute of Materials and Testing, jochen.vogl@bam.de

The measurement uncertainty is an indispensable quality criterion of isotope ratio data and sets important limits for the general use and geochemical interpretation of such data. Despite traceability to the International System of Units (SI) or an accepted standard an uncertainty statement allows the direct comparison of isotope data which have been obtained in different laboratories and/or using different procedures. To realise traceability and comparability of isotope data a realistic uncertainty statements should include uncertainty contributions from all influence quantities. In isotope geochemistry, however, often the term uncertainty is used for terms describing the statistical dispersion of measurement results such as precision, repeatability or reproducibility. Because an measurement uncertainty must include all influence quantities even the so-called external precision or reproducibility will underestimate the overall uncertainty. Without uncertainty statement traceability and comparability of measurement results cannot be established. In cases where no uncertainty for isotope ratio data is presented it is highly recommended that at least the measurement results of a quality control sample with known isotope composition are presented which can be used to evaluate the accuracy and roughly estimate uncertainty.

Here we present an approach to calculate uncertainty budgets for δ^{11}B data which can easily be used for other δ-values. Our approach considers uncertainty components from the mass spectrometric isotope ratio determination (repeatability and reproducibility), the chemical preparation (contamination, isotope fractionation) and the isotope reference material (or δ-zero material). Having quantified the single uncertainty components the identification of the most important contributors to the overall uncertainty is possible and strategies to improve the measurement uncertainty can be investigated. The here presented expanded uncertainties for δ^{11}B values between 1.2 and 0.4 ‰ of matrix standards (IAEA B1-3) and processed isotope reference materials (NIST SRM 951, ERM-AE101) show that typically intense sample preparation is the biggest uncertainty contributor. Uncertainties derived from unprocessed reference materials or standards will therefore significantly underestimate the uncertainty of real samples.

Effect of Fluid Salinity on Subcritical Crack Propagation in Calcite

ROSTOM F, RØYNE A, DYSTHE D AND RENARD F

fatma.rostom@ens-lyon.fr

The slow propagation of cracks, also called subcritical crack growth, is a mechanism of fracturing responsible for a ductile deformation of rocks under crustal conditions. In the present study, the double-torsion technique was used to measure the effect of fluid chemistry on the slow propagation of cracks in calcite single crystals at room temperature. Time-lapse images and measurements of force and load-point displacement allowed accurate characterization of crack velocities in a range of 10^{-8} to 10^{-4} m/s. Velocity curves as a function of energy-release rates were obtained for different fluid compositions, varying NH_4Cl and NaCl concentrations. Our results show the presence of a threshold in fluid composition, separating two regimes: weakening conditions where the crack propagation is favored, and strengthening conditions where crack propagation slows down. We suggest that electrostatic surface forces that modify the repulsion forces between the two surfaces of the crack may be responsible for this behavior.

Halogens in the early Solar System inferred from meteoritic phosphates

J. ROSZJAR[1]*, T. JOHN[2], M. J. WHITEHOUSE[3], A. BISCHOFF[4] AND G. D. LAYNE[5]

[1]Institut für Geowissenschaften, FSU Jena, Germany (*correspondence: julia.walter-roszjar@uni-jena.de)
[2]Insitut für Mineralogie, WWU Münster, Germany
[3]Swedish Museum of Natural History, Stockholm, Sweden
[4]Institut für Planetologie, WWU Münster, Germany
[5]Department of Earth Sciences, Memorial University, St. John's, NL Canada

Although F, Cl, Br, and I are relatively abundant elements in the Solar System, their distribution, abundances and the related fractionation processes in early formed meteoritic material is poorly constrained. Owing to different condensation temperatures, the halogens each have different volatility, which makes them suitable for constraining early Solar System processes such as degassing and fluid-rock interactions. The halogen budget of individual meteorite samples appears dominantly controlled by apatite, which preferentially incorporates halogens. However, merrillite, if present, also contributes to the bulk halogen budget. Although these phases are accessory rock components, they are widely distributed among meteorite classes. Fluorine, Cl, Br, and I concentrations together with the stable Cl isotope composition of individual apatite and merrillite grains were determined in ordinary (OC) and Rumuruti chondrites (RC), primitive achondrites (PA), eucrites (EUC), and silicate-bearing IAB iron meteorites. Petrography and chemistry of phosphate grains were determined using SEM and EPMA. Halogen concentrations and stable $\delta^{37}Cl$ values were determined using a Cameca IMS 1280. $\delta^{37}Cl$ values of most meteorite groups are in the range of -0.05±1.20 ‰ (2σ), consistent with results from [1], but with an evolutionary trend from chondritic to more evolved differentiated rocks. The EUC apatite is in the range of -4.49±0.33 ‰ to +11.93±0.33 ‰, similar only to the Moon. For the latter dry fractionation processes were discussed [2]. Thus, the EUC parent body was either as dry as the Moon, or other mechanisms such as metasomatism [3] may fractionate the Cl isotopes. The same evolutionary trend is seen for halogen concentrations, which are dominated by Cl- and Br-rich apatite in OC, and IAB irons, and F- and I-enriched EUC apatite, with PA being intermediate. Compared to apatite, merrillite halogen concentrations are an order of magnitude lower, with limited Cl variation, except for EUC, consistent with a parent body halogen fractionation process.

Evidence for volatiles on Mercury

D. A. ROTHERY[1]*, R. J. THOMAS[1] AND L. KERBER[2]

[1]Dept of Physical Sciences, The Open University, Milton Keynes, MK7 6AA, UK (*correspondence: d.a.rothery@open.ac.uk)

[2]Laboratoire de Météorologie Dynamique du CNRS, Université Paris 6, Paris, France

Several independent lines of evidence provided by MESSENGER suggest that Mercury is surprisingly rich in volatiles: (i) Gamma-ray spectroscopy reveals a high K/Th ratio in its surface regolith similar to Mars, and very much higher than the Moon [1]. (ii) Xray spectroscopy reveals 2-5% S in its surface regolith [2]. (iii) It has recognisable pyroclastic deposits around vents, requiring explosive exsolution of an unknown magmatic volatile phase in the range 3600-13,000 ppm [3]. (iv) It exhibits patches of steep-sided, flat-bottomed 'hollows' (10s of m deep and 100s of m to km wide) associated with a spectrally distinct (blue, high albedo) unit that appear to form by sublimation, or some similar process capable of dispersing material to space [4]. (v) Neutron spectrometer measurements [5] show a hydrogen-rich phase, interpreted as water-ice, within permanenently-shadowed polar craters [6].

Polar-ice (v) is probably cold-trapped from on-going cometary impacts, but (i)-(iv) are likely to reflect volatiles intrinsic to Mercury. It has been argued [7] that (i) and (ii) could result from low oxygen fugacity affecting geochemical affinities rather than demonstrating volatile-richness on a volumetric planetary scale. Nevertheless it is clear from study of volcanic vent architecture, pyroclastic deposits and hollows that migration of volatile phases from the interior to and through the surface plays a major role in sculpting Mercury' surface. We look forward to enhanced insights when Bepi Colombo achieves orbit.

Heavy noble gases in type 3 enstatite chondrites. Implications for the Earth primordial signature and its evolution.

C. ROUBINET* AND M. MOREIRA[1]

[1]IPGP 1, rue Jussieu 75005 Paris (*correspondence : roubinet@ipgp.fr) (moreira@ipgp.fr)

Enstatite chondrites have often been proposed as possible building rocks of telluric planets and in particular of the Earth [1]. This hypothesis is based firstly on the coincidence of their respective formation zone (inner part of solar system [2]) and also on the similarity of their isotopic composition (O, N, Ni, Mo, Ru, Os, $^{53\text{-}54}$Cr…) [1]. Moreover, enstatite chondrites of type 3 in particular are the only chondrites to display close ^{142}Nd/^{144}Nd ratio to Earth [3]. Thus their study may bring information about primordial composition of the Earth concerning noble gases.

Analysis of E3s by mass spectrometry coupled to stepwise heating allows us to highlight that their primordial composition for Xe and Kr is related to phase Q. So, regarding the ubiquity of this phase, its resistance to high temperatures and also its high noble gases content, it seems appropriate to consider it is the most likely primordial signature of the Earth.

We will discuss the possibility of a terrestrial evolution starting with a phase Q composition, as nowadays, Earth's mantle and atmosphere don't display the same isotopic signature. This discrepancy can be due first to fractionation during accretion process as it has been suggested for Nd ([4]) or to post-accretionnal processes like partial loss of primary atmosphere [5] and also noble gases subduction which can have modified in the long run mantle's signature [6].

Decoupling of the sub-basinal CO_2 and He mantle fluxes as evidenced by intense $CO_2/^3He$ fractionation of natural gases from Brazilian south Atlantic margin basins

VIRGILE ROUCHON[1], EUGENIO VAZ DOS SANTOS NETO[2], AND ERICA TAVARES DE MORAIS[2]

[1]IFP Energies Nouvelles, Rueil-Malmaison, France. virgile.rouchon@ifpen.fr
[2]PETROBRAS R&D Center, Rio de Janeiro, Brazil

Fluxes of mantle CO_2 in sedimentary basins are of present concern regarding deep basin oil and gas exploration. Such degassing of the mantle, although of lower amplitude than that of MOR and convergent margin magmatism, has some influence on the global carbon cycling and on the carbon mass balance of sedimentary basins.

Nearly 150 samples of various basins of the Brazilian Atlantic margin have been analyzed for their molecular composition, stable isotopic ratios of carbon, hydrogen and of the nobles gases ($^3He/^4He$, $^{40}Ar/^{36}Ar$). The gases analyzed show a full compositional range corresponding to the mixing of thermogenic gas (average $\delta^{13}C_{CH4\text{-}PDB}$ = -39‰) with inorganic CO_2 (average $\delta^{13}C_{CO2\text{-}PDB}$ = -5.5‰), with CO_2 contents from 0.1 up to 78%. The $^3He/^4He$ ratio shows a consistent increase with the CO_2 concentration from $3.4e^{-7}$ up to $8.9e^{-6}$. The $CO_2/^3He$ ratio of the richest CO_2 samples is reaching that of MORB between $1.2\text{-}1.6e^9$. A decreasing trend in the $CO_2/^3He$ ratio defined by the whole sample set correlates with decreasing $^3He/^4He$ ratio and CO_2 abundance. The data support a large scale loss of CO_2 (of up to 99%) from an initial mantle fluid during its ascent towards the surface, in addition to mixing of this fractionated fluid with thermogenic gases from within the basins.

The potential loci and processes of this fractionation are discussed along with their consequence for the relative fluxes of mantle C and He to sedimentary basins.

Interactions of Arsenic and Chromium with Struvite During Mineralization

ASHAKI A. ROUFF* AND NING MA

School of Earth and Environmental Sciences, Queens College, CUNY, Queens NY 11367, USA
The Graduate Center, CUNY, 365 Fifth Ave., New York, NY 10016, USA
(*correspondence:Ashaki.Rouff@qc.cuny.edu)

Struvite ($MgNH_4PO_4{\cdot}6H_2O$, MAP) recovered from wastes may be a viable alternative to phosphate fertilizers [1]. However, the potential for sorption of trace elements in wastes with struvite has not been fully addressed. This study evaluates the sorption of arsenic (As) and chromium (Cr) with struvite as impacted by oxidation state, pH and initial solution concentration [2, 3]. The As content of struvite precipitated in the presence of As(V) as AsO_4^{3-} and As(III) as AsO_3^{3-} increased with pH from 8-11. Struvite recovered from As(V) solutions had As concentrations greater than fertilizer limits over the entire pH range. X-ray absorption fine structure (XAFS) analysis revealed that As(V) was coprecipitated into the struvite structure, and that As(III) was adsorbed to the mineral surface. Oxidation state also dictated Cr sorption with struvite precipitated in the presence of Cr(III) as Cr^{3+} and Cr(VI) as CrO_4^{2-} at concentrations of 1-100 μM. Less Cr was associated with struvite recovered from Cr(VI) solutions compared to Cr(III) solutions over the range of concentrations. For struvite formed in the presence of Cr(III), XAFS confirmed the formation of adsorbates at low initial Cr concentrations, with surface precipitates dominating at higher solution concentrations. Where surface precipitates were detected, the Cr content of struvite exceeded the limit for fertilizers. Fourier transform infrared analysis (FT-IR) suggested that Cr(VI) may be adsorbed and/or coprecipitated with struvite. The extent and mechanisms of sorption for As and Cr have implications for the use of struvite as a fertilizer. Coprecipitated As(V) and precipitated Cr(III) are likely to be delivered to agricultural soils along with struvite, introducing contamination to soils and plants. Conversely, low concentrations of As(III) and Cr(VI) pose less of a risk, and adsorbates may be removed from the struvite surface prior to application.

A 30ka Sponge-Diatom Silicon Isotope Record of Dissolved Silicon Concentration in Subantarctic Mode Water

J.ROUSSEAU[1]*, M.J.ELLWOOD[1], H.BOSTOCK[2], H.NEIL[2], AND S.FALLON[1]

[1]Research School of Earth Sciences, Australian National University, Canberra, Australia (*correspondence: u4406548@anu.edu.au)

[2]National Institute of Water and Atmospheric Research, Wellington, New Zealand

Here we present silicon isotope records for biogenic sponge ($\delta^{30}Si_{sponge}$) and diatom ($\delta^{30}Si_{diatom}$) silica from Southern Ocean sediments. For two cores located in Subantarctic Mode Waters (SAMW) on the Campbell Plateau, NZ, we observe a decrease in $\delta^{30}Si_{sponge}$ values from the late Holocene through to the mid-deglacial period. From the mid-deglacial $\delta^{30}Si_{sponge}$ values increase through to the LGM. $\delta^{30}Si_{sponge}$ results for a core located within Antarctic Intermediate Waters (AAIW) generally follow the same trend during the Holocene, but are consistently and expectedly more negative than the shallower SAMW values. During the deglacial period the difference between Intermediate Water and Mode Water depth $\delta^{30}Si_{sponge}$ is variable suggesting large changes in silicon utilisation within the Subantarctic Zone during this time. A diatom silicon isotope record ($\delta^{30}Si_{diatom}$) from the Macquarie Ridge, located further south and upstream of the sponge records, suggests a similar degree of silicon utilisation between the Holocene and the LGM and higher utilisation for a short period during the deglacial.

Modelling dissolved Silicon concentration ([DSi]) in SAMW from a comparison of the Macquarie Ridge $\delta^{30}Si_{diatom}$ and Campbell Plateau $\delta^{30}Si_{sponge}$ records we find that [DSi] in SAMW may have been 100-150% higher in the LGM compared to the Holocene, which is consistent with the Silicic Acid Leakage Hypothesis. This prediction however is not corroborated by a model using a more distal Indian Ocean $\delta^{30}Si_{diatom}$ record for the comparison, pointing towards significant regional differences in SO Silicon dynamics over this period.

Dynamics of chemical characteristics of solubilized organic matter in wetland soils under aerobic or anaerobic conditions.

ASMAA ROUWANE, ISABELLE BOUVEN, MARION RABIET, GILLES GUIBAUD AND MALGORZATA GRYBOS

Groupe de Recherche Eau-Sol-Environnement, Université de Limoges, 123 av. A. Thomas, Limoges, 87060, France.

Soil organic matter plays an important role in the release and potential transport of metal(loid)s[1,2]. Wetlands are a large terrestrial carbon pool, thus understanding the chemical quality of dissolved organic matter (DOM) in wetland soils is crucial.

Controlled incubations of a wetland soil (Roselle catchment, France) were carried out under aerobic and anaerobic conditions (simulating temporarily and permanently flooded soil). Solubilized organic matter was quantified and characterized. Anaerobic incubation involved strong releases of dissolved organic carbon (DOC) to the soil solution (2 mg of C per g of soil), which was correlated with an increase of solution pH (from 6.0 to 7.3) and Fe reduction. In contrast, aerobic incubation (preventing soil reduction) at pH 6.0 induced a smaller DOM release (0.8 mg of C g per g of soil). Released DOM under both experimental conditions had an increasing trend in aromaticity* with incubation time. Indeed after 500 h of anaerobic incubation, DOM exhibited aromaticity of 60% whereas the aromaticity of DOM released in aerobic experiment was 40%. Using size exclusion chromatography coupled to UV and fluorescence detection, three main size fractions (labeled i, ii, iii) of released DOM were identified. The first fraction (i) with an apparent molecular weight (aMW) >10kDa was constituted of protein-like compounds and had a disappearance trend with incubation time. The second fraction (ii) with an aMW from 1kDa up to 10kDa, exhibited aromatic characters and was composed of a mixture of protein-like and humic substances-like compounds. The fraction (ii) had an increasing trend with incubation time with a higher release of humic substances-like compounds under anaerobic conditions. The third fraction (iii) with an aMW <1 kDa, composed of protein-like and humic substances-like compounds, had a decreasing trend with incubation time whatever experimental conditions.

In conclusion, evolution of DOM solubilization in reduced wetland soils comparing to DOM released under aerobic conditions is different in terms of chemical characteristics and of MW distribution.

Non-traditional Stable Isotope Systematics of Seafloor Hydrothermal Systems

OLIVIER ROUXEL[1]

[1]IFREMER, Centre de Brest, 29280 Plouzané, France

Seafloor hydrothermal activity at mid-ocean ridges is one of the fundamental processes controlling the chemistry of the oceans and the altered oceanic crust. Past studies have demonstrated the complexity and diversity of seafloor hydrothermal systems and have highlighted the importance of water-rock reactions and subsurface environments in controlling the composition of hydrothermal fluids and mineralization types. In addition, the far-field consequences of hydrothermal venting on deep oceanic metal reservoirs, in comparison to other marine sources, is just starting to be recognized.

Isotope ratios of various metals and metalloids, such as Fe, Cu, Zn, Ge, Se, Cd and Sb have recently provided new approaches for the study of seafloor hydrothermal systems. Here, I will present new results of non-traditional isotope systematics of seafloor hydrothermal systems, in particular:

(1) the mechanisms of metal isotope fractionation in hydrothermal chimney environments through paired isotopic analysis of mono-mineralic sulfides in contact with hydrothermal fluid;

(2) the controlling parameters of metal isotope signatures of hydrothermal vent fluids through the study of mid-oceanic and back-arc hydrothermal vent fields, spanning wide ranges of pH, temperature, metal concentrations and contributions of magmatic fluids enriched in SO2.

(3) the potential role of high-temperature seafloor venting in affecting deep sea metal isotope composition through the investigation of metal isotope systematics in hydrothermal plume.

Ultimately, the use of complementary stable isotope systems should help identify the complex interactions between fluids, minerals, and potentially organisms in seafloor hydrothermal systems and constrain metal sources in marine environments.

Mineral and Melt Inclusion Geochemistry of the Nea Kameni Dacites, Santorini, Greece

ROWE, M.C.[1], ELLIS, B.S.[2] AND KYRIAKOPOULOS, K.[3]

[1]University of Auckland, School of Environment, Auckland, New Zealand. Michael.rowe@auckland.ac.nz

[2]ETH Zurich, Institute for Petrology and Geochemistry, Zurich, Switzerland. Ben.ellis@erdw.ethz.ch

[3]Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, Athens, Greece. ckiriako@geol.uoa.gr

Since the voluminous 3.6 ka Minoan eruption, the Santorini volcano has been periodically erupting small volumes of dacitic magma forming the Kameni islands. This study focuses on variations in mineral geochemistry of lavas spanning from 46-47AD to 1950 to better understand the temporal evolution of silicic magmatism at the Santorini volcano. In addition to feldspar geochemistry, this study utilizes silicate melt inclusion analyses to document melt compositions associated with different feldspar populations. On a bulk level, the dacites of Nea Kameni have remained compositionally homogeneous while containing a mixture of mafic grains and crystal clots. The Kameni dacites contain two populations of feldspar, one An_{38-65} interpreted as crystallising from the dacitic liquid and a second An_{86-94} derived from a mafic magma. The two feldspar populations are distinct in terms of $^{87}Sr/^{86}Sr$ as determined via LA-ICPMS with the higher anorthite plagioclase having higher $^{87}Sr/^{86}Sr$. The same two isotopic populations appear to be contributing to the Kameni magmatic system for the past 1900 years.

Analysis of glassy melt inclusions from the 1940 eruption preserve a similar bimodal distribution of glass compositions consistent with host compositions. Interestingly, despite their assumed cumulate nature, high-An feldspar retain euhedral, undegassed glassy melt inclusions. High-An plagioclase contain mafic melt inclusions whereas the lower An plagioclase contains melt inclusions more similar to the groundmass glass. Pre-eruptive volatiles (S, Cl, H_2O) are maintained in both populations of melt inclusions.

The 87Sr/86Sr data indicate that the dacitic magmas cannot represent fractionated equivalents of the mafic input to the Kameni system (similar to the Minoan eurption). The presence of abundant glassy clasts of dacite as lithics within the Minoan deposits suggests that prior to the last catastrophic eruption a similar period of relative quiescence may have occurred. Kameni-style volcanism may be a common occurrence at Santorini, just with low preservation potential.

Distribution of ^{230}Th and ^{232}Th along the Bonus GoodHope section in the SouthEast Atlantic Ocean

M.ROY-BARMAN[1], S. MARCHANDISE[1], F. THIL[1], LOUISE BORDIER[1], SOPHIE AYRAULT[1], E. GARCIA-SOLSANA[2] AND C. JEANDEL[2]

[1]Laboratoire des Sciences du Climat et de l'Environnement, France. (*correspondence : Matthieu.Roy Barman@lsce.ipsl.fr)

[2]Laboratoire d'Etudes en Géophysique et Oceanographie Spatiale, France.

Dissolved concentrations of ^{230}Th and ^{232}Th have been measured in seawater on 5 profiles along the Bonus GoodHope (GEOTRACES/IPY) section in the SouthEast Atlantic Ocean.

Most dissolved ^{232}Th concentrations range from 5 to 98 pg•kg^{-1}. There is a genral increase of the ^{232}Th concentration from the surface to the deep waters. A strong ^{232}Th gradient exists between the stations located off the African continents (where stong ^{232}Th inputs occur) and the stations located in the middle of the section. A distinctly high ^{232}Th concentration of 283 pg•kg^{-1} is found at the bottom of the station closest to the African coast, likely linked to an input from the sediment.

Dissolved ^{230}Th concentrations range from 0.7 to 36.4 fg•kg^{-1}. The ^{230}Th data of the Bonus GoodHope section compare well with the ^{230}Th data of ANT III section obtained near the Polar Front [1]. There is a general increase of the ^{230}Th concentration with depth. In the Cape basin, concentrations increase linearly, with a lower scavenging rate north of the subtropical front than south of it. At the Polar front level, a distinctly low ^{230}Th concentration is found in the deepest sample (9 fg•kg^{-1} at 4300 m against 15 fg•kg^{-1} at 3048 m) suggesting occurrence of boundary scavenging. South of the Polar Front, upwelling of deep waters create non linear profiles.

Particulate samples collected with in situ pumps are under process for the determination of ^{230}Th and ^{232}Th.

Dissimilatory Sulfate Reduction in Hypersaline Environments: What is regulating sulfate uptake?

A.N. ROYCHOUDHURY[1]* AND D.PORTER[2]

[1]Dept. of Earth Sciences, Stellenbosch University, Stellenbosch 7602, South Africa (*correspondence: roy@sun.ac.za)

[2]Department of Genetics, University of Pretoria, Pretoria, South Africa

Microbes in engineerd systems such as wastewater treatment facilities and mine tailings are often subjected to extremes of salinities. Little is known; however, about the activity and survival mechanisms of sulfate reducers in such extreme environments. Hypersaline pans, a prototype for engineered systems, are used here to understand sulfate uptake and regulatory mechanisms among sulfate reducers.

Thermodynamic and kinetic parameters for dissimilatory sulfate redution (DSR) were quantified in five hypersaline coastal saltpans located in South Africa. Compared to normal marine environments, salinity and sulfate concentration at the studied saltpans was higher by up to 10 and 20 times, respectively. Determined apparent activation energies (28 – 62 kJ/mol) and Q_{10} values (2.0 – 2.3) for DSR suggest no gross physiological adaptations in bacteria, such as changes in membrane structure, to temperature.

Sulfate uptake affinity, quantified in terms of apparent half-saturation concentration (K_s); however, indicates adaptation with respect to high ionic status of the saltpans. The K_s values (64 – 780 mM) for sulfate reduction determined for the first time from hypersaline environments are two to three orders of magnitude larger than those determined for normal marine ecosystems. This indicates that in hypersaline environments there exists a third transport mechanism, which attenuates even the low-affinity system observed among marine sulfate reducers. We propose that the observed extremely low-affinity, high accumulation system is a consequence of increased regulation of sulfate uptake and accumulation because of adaptation mechanisms employed by halophiles to survive under extremes of salinity.

Redox chemistry profiling in the Kara sea sediments (from the Ob-river to the Saint Anna trench)

ALEXANDER ROZANOV

P.P. Shirshov Institute of Oceanology. Nakhimovsky prosp. Moscow. 117997. e-mail: rozanov@ ocean.ru

Submeridional redox profile across the bottom sediments of the Kara sea from the Ob ' river (71 N) to the St. Anna trench (77 N) was studied in the course of the Russian expedition on the R / V «Akademik Mstislav Keldysh» in September 2007. Redox profile is formed under the influence of diagenetic reactions in sediments with organic matter (OM), produced into the sea and brought from the shore. The main oxidants involving microorganisms consistently are oxygen, nitrates, oxyhydroxides of manganese and iron, sulphates and carbon dioxide, while in the pore water accumulate NH3, Mn2+, Fe2+, H2S and CH4. The content of the OM, which is a fundamental characteristic of sediments, is more than 1.5% (dw) Corg in the Ob' delta (71 N), close to 1% in the estuary (72 N), 0.5-0.75% in the sediments of inner and outer shelf (72-75 N), as well as in the slope (75-76 N), 2% in the sediments of the of the St. Anna trench (77 N). OM in the deltaic part is mainly terrigenous, in the northern part of the profile the cause of increased OM content is the primary production of plankton. On the border of the estuary and the shelf there is a sharp decrease of suspended matter in the surface waters (from 7 to 1 mg/l), the Corg and many metals of the river runoff in the sediments reach maximum values (Mn 0.3%, Fe 7% dw). The growth of OM stimulates the reduction processes, as reflected in higher concentrations of the dissolved components in the pore water (Mn2+ up to 260, Fe2+ to 100 uM) and derivatives of H2S (up to 0.3 %) in the sediments. Dissolved Mn remove from the sediments to the bottom water, dissolved Fe is oxidized by oxygen of the bottom water and forms a thin oxidized layer on the surface. Recycling of Mn and Fe is accompanied by formation of ferromanganese nodules. Sedimentation in central and northern part of the profile, adjacent to the St. Anna trench are characterized by lower content of Mn due to both long distance from the river outflow and diagenetic removal of Mn from the sediments of higher Corg content. In this part of the profile derivatives of H2S are mainly represented by organic forms, which are very typical for Arctic sediments in contrast to the bottom sediments of the temperate and tropical zones, in which among H2S-forms prevails diagenetic pyrite.

Effects of lead and strontium on radium uptake by barite: Atomistic simulations and thermodynamic assessment

K. ROZOV[1], V. L. VINOGRAD[1,2]*, D. A. KULIK[3], F. BRANDT[1], B. WINKLER[2] AND D. BOSBACH[1]

[1]Institute of Energy and Climate Research (IEK-6), Forschungszentrum Jülich, Germany
[2]Institute of Geosciences, Goethe University, Frankfurt, Germany (*correspondence: v.vinograd@fz-juelich.de)
[3]Nuclear Energy and Safety Research Department, Paul Scherrer Institute, Villigen, Switzerland

Experimental studies related to safety issues of the long-term disposal of spent nuclear fuel in deep geologic formations suggest that Ra released from the fuel can be efficiently immobilized as a constituent of a barite-rich solid solution (SS) [1,2]. Here the uptake of Ra by barite is investigated using the Gibbs free energy minimization method [3] at variable fractions of $PbSO_4$ and $SrSO_4$ in the SS. The SSs were modelled as ternary $(Ba,Sr/Pb,Ra)SO_4$ regular mixtures. The mixing parameters (W_{BaPb}= 5.4, W_{PbRa} = 1.5, W_{BaRa} = 2.5, W_{BaSr}= 8.9, W_{SrRa}= 19.6, W_{SrPb} = –0.3 kJ/mol) were computed from first principles with the aid of the single defect method [4]. The system contained 0.00214 moles of $Ba_{1-x}(Sr/Pb)_xSO_4$, 0.1 *m* of NaCl, $5.0 \cdot 10^{-6}$ *m* of $RaCl_2$ and 1 kg of H_2O. The concentration of Ra(aq) decreases with the $(Sr/Pb)SO_4$ fraction in the system due to the common anion effect. However, in the $SrSO_4$ case, after the fraction of $SrSO_4$ exceeds ~0.01, the concentration of Ra(aq) starts to grow due to the corresponding increase in the mole fraction of $RaSO_4$ in barite. This effect is suppressed by the decomposition of the SS in Ba- and Sr-rich phases; the concentration of Ra(aq) remains less than that in the Sr-free system up to the Sr/Ba ratio of ~10. Therefore, at certain conditions, an admixture of $PbSO_4$ or $SrSO_4$ in barite would lead to a more efficient immobilization of Ra. The study is funded by BMBF-IMMORAD project through the grant 02NUK019E.

Fracture propagation driven by crystal growth and the role of interfacial fluid chemistry

A. RØYNE[1]*, P. MEAKIN[12], A. MALTHE-SØRENSSEN[1], B. JAMTVEIT[1] AND D.K. DYSTHE[1]

[1]Physics of Geological Processes (PGP), University of Oslo (*correspondence: anja.royne@fys.uio.no)
[2]Carbon Resource Management Department, Idaho National Laboratory

Crystals that grow confined in pores and cracks may exert a force on their surroundingsand thereby drive crack propagation in rocks and other materials. Of particular importance for engineering and cultural heritage is the degredation of building stones due to salt crystallization. The opening of fractures due to crystal growth may also open new pathways for transport of reactive fluids and therefore serve to accelerate the rate of advanement of weathering or replacement fronts.

In order for a growing crystal to actively displace the walls of the confining pore, there must be a liquid film present between the crystal face and the surface of the pore. This film acts as the transport pathway for growth units to the crystal face. The normal stress between the crystal face and the confining wall is transmitted through the disjoining pressure in the liquid film, and the maximum stress which can be excerted is determined by the fluid chemistry and surface properties. The same confined fluid is also present at the crack tip, where it plays a large role in determining the fracture threshold and velocity at low tensile stresses [1,2].

We use a theoretical model of crystal growth in an idealized crack geometry to study how the kinetics of crystal growth and crack propagation are coupled through the confined fluid and the stress in the surrounding bulk solid [3]. The rate of initial crack propagation is found to be limited by subcritical crack growth, while crystal growth becomes the rate limiting step when the crack has grown to sufficient length. The cross-over length is determined by crystal and crack tip kinetics, fluid supersaturation and elastic properties of the surrounding material.

Integration of U-Pb dating, trace elements and oxygen isotopes at the microscale

DANIELA RUBATTO[1], LAURE GAUTHIEZ-PUTALLAZ[1], AND KATHERINE BOSTON[1]

[1]Research School of Earth Sciences, Australian National University, 0200 Canberra, Australia. Daniela.Rubatto@anu.edu.au

The U-Pb chronology of metamorphic events has greatly benefited from the high spatial resolution achievable with microbeam techniques that allows to date individual growth zones in accessory phases. The capability to retrieve trace elements and isotopoic information at the same scale has allowed relating ages to metamorphic processes. With the newly developed capacity to analyse oxygen isotopes at the same scale as U-Pb ages, the application of this method to metamorphic fluid-rock interaction is particualrly exciting.

The robustness of zircon makes it a prime candidate for retrieving the oxygen composition of pre-metamorphic history. Zircon in high pressure rocks of the Western Alps show different degrees of metamorphic recrystallization. Their age and oxygen composition constrain the timing of fluid circulation and offer insight into its origin and degree of fluid-rock interaction.

Monazite is particulary promising as monitor and timer of fluid-rock interaction as experimental and field studies have shown that monazite readily recrystallizes in the presence of fluids. Analytical protocols and standards have been developed for in-situ oxygen analysis of monazite using the SHRIMP ion microprobe. Accurate measurements require an additional correction for matrix effect due to the variable composition of monazite. This effect is found to be proportional to the Th content of monazite and produces a shift of circa in $\partial^{18}O$ of 1‰ every 10 wt% of Th. Oxygen isotopes combined with trace element analysis to relate monazite to major mineral offer new opportunities for monazite geochronology in metamorphic rocks.

Allanite preserves multiple growth zones and retains its U-Pb age up to temperatures of at least 700°C. Geochronology of allanite requires adequate corrections for initial Pb composition, particularly for metamorphic domains formed in sub-solidus conditions. For ion microprobe data, robust results are obtained with Th-Pb isochrons. Even in allanite with high amounts of initial Pb (60-95%) isochrons return reasonably accurate and robust ages. Oxygen isotope analysis of allanite is still hampered by significant matrix effects for which a correction scheme is work in progress.

Accretion and chemical evolution of the terrestrial planets

D.C. RUBIE[1]*, D.P.O'BRIEN[2], A. MORBIDELLI[3], S.A. JACOBSON[1,3] AND E.D. YOUNG[4]

[1]Bayerisches Geoinstitut, Bayreuth, Germany (dave.rubie@uni-bayreuth.de)
[2]Planetary Science Institute, Tucson, USA (obrien@psi.edu)
[3]Observatoire de la Cote d'Azur, Nice, France (morby@oca.eu)
[4]Dept. of Earth and Space Sciences, UCLA, Los Angeles, USA

Classical dynamical models of planetary accretion have been successful in reproducing the general characteristics of the terrestrial planets of the solar system [1]. However, they have been less successful in reproducing the small mass of the outermost terrestrial planet, Mars, which appears to require a strong depletion of mass beyond ~1 AU [2]. The recent "Grand Tack" model, based on the early inward and then outward migration of Jupiter and Saturn, provides a solution to this problem [3]. We are using a geochemical approach to test the validity of the Grand Tack and other accretion models. Accretion occurs through impacts between growing planets and smaller bodies. Each impact delivers energy (magma ocean formation) and metal and thus an episode of core formation. The chemical evolution of the mantles and cores of growing bodies is modeled based on the bulk composition of the accreting material combined with a mass balance/element partitioning approach [4]. The main constraint is the composition of Earth's primitive mantle and the FeO contents of the mantles of Mercury and Mars (3-4 wt% and ~18 wt% respectively). Bulk composition is defined in terms of solar system (CI) relative abundances of the non-volatile elements with an oxygen content that determines the metal-silicate ratio. Accretion simulations that produce synthetic planets closely resembling those of the solar system are tested. Model parameters (metal-silicate equilibration pressure, starting compositions of embryos and planetesimals) are refined by a least squares regression in order to produce a synthetic Earth that matches Earth's mantle chemistry.

The mantle chemistries of Earth and Mars can be reproduced well when the compositions of bodies that originate in the inner solar system (<~1.6 AU) are highly reduced and those forming further out are more oxidized. However, the current Grand Tack simulations result in an inner planet ("Mercury") that accretes too much material from the outer regions of the planetesimal disk and is thus too massive and too oxidized.

The first active boninite eruption was observed by ROV in 2009 at West Mata, a small, submarine rear-arc volcano in the NE Lau Basin. Globally, boninite is a rarely erupted, arc-fluid-enriched magma. We examine rates and processes of W. Mata boninite generation, ascent, and storage, with implications for arc magma and volatile source-to-surface transport. A number of characteristics indicate magma differentiation during rapid ascent from the mantle within a poorly developed magma storage system: large, very short-lived ^{210}Pb-^{226}Ra disequilibria of 20-40% in glasses, Ni diffusion profiles in olivine, and a complex range of mineral textures, including rapid crystal growth and magma reactions. Geochemical and petrological studies of fresh-appearing lavas collected in 2009 and on two subsequent cruises indicate limited lithological variability throughout the volcano. W. Mata erupts a highly vesicular, crystal-rich (ca 40%) magma, having opx>>cpx>ol and a continuum of mineral compositions (e.g., opx and ol Mg# 92-82). Whole rocks (WR) are boninite sensu strictu but have more evolved coexisting glass (WR and glass have MgO=11-15 and 3.5-6.5 wt%, SiO_2=54-57 and 55-58 wt%, TiO_2=0.3-0.45 and 0.4-0.6 wt%). Older, non-summit lavas define distinct but similar major element trends, with variable radiogenic isotope and trace element ratios. Slab influence is indicated by glasses with extreme ^{238}U-^{230}Th disequilibria (40% excess U), high Fe oxidation (Fe3+/∑Fe=0.2-0.25), strong fluid-mobile element enrichments (Ba and U to 160 ppm and 0.4 ppm), high Cl/K, plus up to 3 wt% H_2O in melt inclusions.

Itrax™ Core Scanner as a quick screening tool for polluted coastal sediments

B. RUBIO *, D. REY, I. RODRÍGUEZ-GERMADE, P. ÁLVAREZ-IGLESIAS AND A.M. BERNABEU

Research group GEOMA. Departamento de Geociencias Marinas y Ordenación del Territorio, Universidad de Vigo, Vigo (Spain).
*Correspondence: brubio@uvigo.es

The traditional techniques for the study of chemical composition of sediment cores, are, among others, the X-ray fluorescence (XRF) and the spectrometry (ICP) applied on discrete samples. The development of non-destructive continuous analysis as the XRF scanners as the Itrax™ core scanner [1], which analyses humid core-sections with a millimetric resolution, have supposed a great advance in the study of sediments and rocks. These instruments are able to detect the majority of the elements from the Al to the U, in a low concentration, depending on the acquisition conditions.
Until now, the majority of the works with these scanners have been focused on palaeoceanographic or palaeoclimatic reconstructions, both in marine and continental sediments, being much more scarce the studies based on discrimination of pollution.

We have analysed with the ITRAX from the University of Vigo and varying time-acquisition conditions, sediment cores from the inner Galician Rías Baixas (NW Spain). These are highly organic, but not very heavily polluted environments, however ITRAX was able to detect Hg concentrations lesser than 0.6 μg g^{-1} and Cd concentrations in the order of 1 μg g^{-1}. These values were confirmed by total digestion and subsequent analysis by ICP and by conventional XRF of pressed pellets, obtaining a good relationship for most of the trace elements (Zn, Pb, Cu, etc.) and confirming the presence of Cd and Hg. Pollution by these elements was restricted to the upper 10-15 cm, approximately ranged between 30-50 yr based on ^{210}Pb and ^{137}Cs datings obtained by gamma spectrometry. Only Pb and Hg showed concentrations above the sediment quality guidelines that could be associated with measures of adverse effects. Several sequential extraction protocols (BCR and NWR) of selected samples were also applied in order to get information about the bioavailability of these elements. The data confirms the predominance of oxides and residual fractions in the case of Pb and oxidizable forms (organic-matter and sulphides) in the case of Hg. Our results confirms that ITRAX represent a fast and high-resolution tool for identify pollution in these environments not heavily affected.

Aerosol ageing and effect on their optical properties by a new broadband aerosols spectrometer

MICHEL FLORES[1], NIR BLUVSHTEIN AND YINON RUIDCH[1,*]

[1]Department of Environmental Sciences, Weizmann Institute of Science, Rehovot, 76100 Israel (Flores@weizmann.ac.il, Nir.bluvshtein@weizmann.ac.il
*correspondence: yinon.rudich@weizmann.ac.il)

The optical properties of complex aerosols, important in determining their radiative forcing in the atmosphere and, subsequently, their impact on climate, are extensively examined. There is an abundance of natural and anthropogenic organic compounds in the atmosphere that can be released as primary aerosols or form secondary organic aerosols (SOAs) via photochemical reactions with OH, NO_3, and O_3.

Aerosols can undergo further processing in the atmosphere with oxidizing species, changing the chemical, physical, and optical properties of the particles. Particle internal structure and composition have important implications for their optical properties. Despite their acknowledged importance, the internal structures of aerosols, mechanisms of formation, atmospheric aging, and heterogeneous reactivity remain poorly understood and yet their environmental role cannot be quantitatively determined.

In this talk we will describe new studies that investigate the changes in optical properties of different model aerosols. We will describe a new broadband aerosol spectrometer that can retrieve aerosol optical properties between 360 and 420 nm, a less explored wavelength range. As examples, we will present the effect of nitration of organic aerosols on aerosol absorption, and the effect of aging on the optical properties of SOA that form from the ozonolysis of biogenic and anthropogenic VOCs. The effect of structure on the optical properties, and how core/shell structure differs from homogenous structure will be demonstrated.

Glacial tillites reveal temporal evolution of upper continental crust

ROBERTA L. RUDNICK[1], RICHARD M. GASCHNIG[1] AND WILLIAM F. MCDONOUGH[1]

[1]Dept. Geology, University of Maryland, College Park, MD 20782, U.S.A., rudnick@umd.edu

Defining the absolute composition of the continental crust, and its lateral and vertical variations, are essential parameters needed in extracting the geoneutrino signal from the mantle and thereby place constraints on the Earth's present-day radioactive power. K, Th, and U are strongly concentrated in the upper continental crust (UCC) so refining its composition and deriving uncertainties is important to neutrino geoscience.

UCC estimates generally rely on reference suites of shales, pelites, and loess (e.g., Hu and Gao, 2008: HG08). Here we use modern to Archean glacial tills and tillites to determine the average UCC composition through time and then we compare them with HG08. Paleoproterozoic tillites are systematically enriched in transition metals (Sc, Cr, Co, Ni) relative to post-Archean tillites and average UCC, indicating more mafic contribution to the Archean upper crust (as previously documented in shales). However, in contrast to shale data, we find no systematic differences in Th/Sc as a function of age in tillites, implying that Th is not systematically depleted in Archean UCC as sampled by the glaciers. Th/U of the tillites correlates with their age: Th/U ~3 in modern tills, and Carboniferous and Paleoproterozoic tillites, whereas Neoproterozoic tillites and HG08 have Th/U ~6. The high Th/U of the Neoproterozoic tillites can be linked to intense weathering (and U leaching) attending the snowball Earth glaciations. The lack of a significant difference in the abundances of heat producing elements in Archean and post-Archean average UCC may imply that the lower surface heat flow in Archean cratons compared to post-Archean regions may be related to differences in Moho heat flux.

Resolving gas transport through compacted sand/bentonite material by using noble gases

J. RUEEDI[1], R. SENGER[2] , DONATELLA MANCA[3], KARAM KONTAR[4] AND P. MARSCHALL[1]

[1]NAGRA, 5430 Wettingen, Switzerland
[2]Intera Inc., 5408 Ennetbaden, Switzerland
[3]EPFL ENAC IIC LMS, 1015 Lausanne, Switzerland
[4]Solexperts, 8617 Mönchaltorf, Switzerland

Gases (hydrogen, methane, carbon dioxide) may accumulate in the emplacement caverns of a geological repository for low/intermediate-level waste due to the corrosion and degradation of the wastes. Nagra is evaluating the concept of an engineered gas transport system (EGTS), aimed at providing an additional transport pathway for gas release if overpressures were to be developed. Gas permeable tunnel seals are among the main design elements of the EGTS, consisting of sand/bentonite (S/B) mixtures with a bentonite content of 20% to 30%.

It is expected that material heterogeneities at repository scales will, at least to some extent, lead to a water saturation and a gas invasion behaviour that differs from those observed in small-scale lab experiments. Past applications of probabilistic two-phase flow models tried to assess the influence of material heterogeneities on water and gas transport in clay material. The models revealed complex two-phase flow patterns during gas imbibition and after gas breakthrough. It is thought that these patterns are mainly driven by the material properties and associated heterogeneity. However, there is little experimental evidence to constrain the large number of possible model realisations.

In 2010, a laboratory column was filled with a S/B mixture (80% sand and 20% MX80 bentonite) and compacted to a density of 1.5 g/cm^3. The column was then saturated with distilled water for a few weeks and a hydro test was performed to determine the hydraulic permeability of the material and to confirm saturation. A gas test was performed by injecting N_2 at increasing pressures until breakthrough. After breakthrough the gas flow was kept constant and the N_2 gas was replaced by a gas mixture (N_2, He, Ar, Xe, SF_6) and the breakthrough pattern of the different gases was monitored continuously using a mass spectrometer. The choice of the gas tracers was made based on their different physical properties – i.e. solubility in water and diffusivity in both gas and liquid phases.

The observed partitioning of the different gas tracers provides unique experimental evidence for the determining the dominating transport processes within the partially saturated material and thus help constrain probabilistic models for two-phase flow and transport through S/B material.

(* correspondence: micha.ruhl@earth.ox.ac.uk)

Past global marine mass extinction events are often linked to terrestrial Large Igneous Province (LIP) volcanism, but exact mechanisms driving extinction are often not well constrained.

We studied two of Earth's largest mass extinction events, at the Triassic-Jurassic (~201.4 Ma) and Permian-Triassic (~252 Ma) boundaries, which coincide with Central Atlantic Magmatic Province (CAMP) and Siberian Trap volcanism, respectively. The Triassic-Jurassic mass extinction is often contributed to carbon release driven ocean acidification while the Permian-Triassic mass extinction is suggested to be related to widespread ocean anoxia.

We compare Permian-Triassic and Triassic-Jurassic ocean redox change along continental margins in different geographic regions (Permian-Triassic: Greenland, Svalbard, Iran; Triassic-Jurassic: UK, Austria) and discuss its role in marine mass extinction.

Speciation of iron [(Fe_{HR}/ Fe_T) and (Fe_{PY}/ Fe_{HR})] and redox-sensitive trace element concentrations (e.g. Mo, V etc.) show that the Triassic-Jurassic marine mass extinction directly coincides with a rapid shift to anoxic and euxinic conditions at the onset of CAMP volcanism and increased atmospheric pCO_2. Biotic recovery after the extinction event only commences when redox-conditions return from a euxinic to a ferruginous state and stabilization of marine ecosystems only commences after decreasing atmospheric pCO_2 and a return to more oxic marine conditions.

Iron-speciation at both the Triassic-Jurassic and Permian-Triassic mass extinctions however shows 2 phases of euxinia along continental margins, with an initial short peak at the onset of volcanism followed by a shift to ferruginous conditions, possibly due to a strongly diminished ocean sulphate reservoir because of massive initial pyrite burial. $D^{34}S_{pyrite}$ suggests that following prolonged (several 100kyr) euxinic conditions only commence when the ocean sulphate reservoir is replenished by the release of sulphur from volcanism.

Geochemistry of cassiterite and wolframite from quartz veins in Central Iberian Zone (Spain)

CASILDA RUIZ [1]*AND CONCEPCIÓN FERNÁNDEZ-LEYVA[2]

[1]Technical University of Madrid (UPM). Spain (*correspondence: casilda.ruiz@upm.es)

[2]Geological Survey of Spain. Madrid 28003 (c.fernandez@igme.es)

Sn- and Sn-W-bearing quartz veins in the Central Iberian Zone mainly cut across the granites. Some of these veins were mined during the last century. The paragenetic sequence corresponds to two oxide-silicate stages and a sulfide stage in that order. Massive crystalline quartz is the main mineral of the three stages. Stage 1 consists of muscovite, cassiterite and arsenopyrite, stage 2 of wolframite and arsenopyrite, and stage 3 of small amounts of sulfides: arsenopyrite, pyrite, pirrotite, sphalerite and chalcopyrite.

Cassiterite from Sn- and Sn-W-bearing quartz veins shows Ti> Fe> Mn content, and Ti replaces Sn. The chemical variation of cassiterite crystals is controlled by the direct substitution of Sn^{4+} by Ti^{4+}. Cassiterite generally shows lighter and darker zones, and Nb content is higher in darker than in the lighter zones. Wolframite consists almost entirely of FeO, MnO, and WO_3, with less than 1% Ta_2O_5, Nb_2O_5, and TiO_2. It shows Mn and Fe substitution. Wolframite individual crystal shows a decrease in the hübnerite component from core to rim. Likewise, Nb increases toward the rim of the wolframite crystal. Ta content of cassiterite and wolframite is generally higher than Nb content. Cassiterite has a higher Nb and Ta content than wolframite [1].

Tungsten is carried as H_2WO_4, WO_4^{2-} [2] and wolframite can be precipitated by the cooling of an Fe-W-bearing fluid, without wall rock reaction [3]. Mineralizing fluid deposites cassiterite, associated with muscovite selvages in the paragenetic stage 1. This fluid evolves and precipitates wolframite, mainly within quartz veins in stage 2.Tungsten shows different behavior from that of tin and consequently, cassiterite is generally not associated with wolframite.

Geochemical modelling of Sn and W in granites from Central Iberian Zone (Spain)

CASILDA RUIZ [1]*AND CONCEPCIÓN FERNÁNDEZ-LEYVA[2]

[1]Technical University of Madrid (UPM). Spain
(*correspondence: casilda.ruiz@upm.es)
[2]Geological Survey of Spain. Madrid 28003
(c.fernandez@igme.es)

Field and petrographic observations of the quartz veins mineralization in relation with granites in Central Iberian Zone (CIZ) [1], show that cassiterite and wolframite occur in quartz veins principally. It seems that quartz deposition is before the cassiterite one and wolframite is deposited after cassiterite. Processes that form mineral deposits associated with granitic rocks can have a close relationship with magmatic processes. Geochemical calculations applied to Sn and W have been performed to investigate if magmatic processes have been the mechanism by which the mineralisation was generated in the (CIZ).

Complex linear mixing models show that Sn and W increase their concentration in the fractionation stages while modal extracted muscovite is reduced. Sn and W are concentrated in the residual liquid when the modal quantity of extracted muscovite is ≤ 5%. Starting from an initial leucogranitic composition, concentrations of Sn can reach up values over 100 ppm after high degrees of fractionation. On the other hand, the calculated W concentrations are much lower. The same results suggest models for equilibrium and fractional crystallisation [2]. Complex linear mixing models show that crystallisation processes generated mineralizations by concentrations of Sn, whereas W does not reach the levels required for generating ones.

The pH influence on barite nucleation and growth

CRISTINA RUIZ-AGUDO[1], CHRISTINE PUTNIS [2] AND ANDREW PUTNIS [3]

[1]c_ruiz02@uni-muenster.de
[2]putnisc@uni-muenster.de
[3]putnis@uni-muenster.de

Barite (BaSO4) scale formation is a problem in many industrial processes, especially in oilfields where mixing sea water with reservoir water can result in solid layers of barite scale that can completely block pipes. Organic compounds (e.g. organophosphonates) have been used as inhibitors for barite precipitation. The effectiveness of these compounds is pH-dependent, usually more effective at high pH where they are highly deprotonated. Thus to be able to determine the performance of organic additives as barite scale inhibitors, we have first studied the influence of pH on barite nucleation and growth.

To determine the influence of pH on growth, AFM observations of barite growth on a barite cleavage surface were carried out under conditions of constant supersaturation, temperature, Ba/SO4 ratio and ionic strength but changing growth solution pH.

The effect of pH on nucleation was studied with turbidimetry and conductivity experiments complemented with FESEM observations to determine changes in morphology and size of the barite precipitated. Induction times were determined by monitoring the variation in absorbance due to barite precipitation and this enabled the estimation of potential changes in interfacial tension. Conductivity experiments allowed us to determine the onset of nucleation (i.e. induction time) as well as the supersaturation reached at that point and how both parameters vary with pH.

It was found that increasing the pH of the growth solution results in shorter induction times and lower values of interfacial tension. These changes can be explained considering the effect of increasing hydroxyl ion concentration on barium hydration.

Porosity development during carbonation reactions

ENCARNACIÓN RUIZ-AGUDO[1], CHRISTINE V. PUTNIS[2] AND ANDREW PUTNIS[2]

[1]Department of Mineralogy and Petrology, University of Granada, Granada, Spain. encaruiz@ugr.es
[2]Institut für Mineralogie, University of Münster, Münster, Germany. putnisc@uni-muenster.de

The reduction in industrial emissions of CO_2 is one of the major challenges of this century. Anthropogenic CO_2 capture and injection into geological formations is considered a promising strategy for the permanent storage of this greenhouse gas. This process is based on the dissolution of silicate rocks in contact with CO_2-rich fluid and the precipitation of carbonates, so that CO_2 is trapped as a stable mineral phase. The generation of product layers on the surface of the carbonating material occurs by an interface-coupled dissolution-precipitation reaction (Putnis, 2009). The study of the processes of dissolution and carbonation of portlandite, $Ca(OH)_2$, is crucial due to the great potential of this reaction for CO_2 capture and storage, as well as for understanding the carbonation behavior of artificial mineral associations such as mortars or cements.

A critical aspect to consider in mineral replacement processes described above is the porosity evolution. The porosity created depends on the difference between the molar volumes of reagent and the product as well as the relative solubility of the two phases in the reaction fluid. The generation of porosity enables the progress of the replacement reaction, providing pathways for the fluid to be in permanent contact with the reacting solid. On the contrary, if porosity does not form during the reaction, fluid advancement is hampered and the reaction stopped. The maximum capability of CO_2 storage in a geological formation will thus depend on the porosity generated during the carbonation reaction.

This work is aimed at determining how certain physicochemical parameters of the solutions (hydrodynamic conditions, pH or composition) may affect the development of porosity during replacement reactions. Geochemical modelling and experimental studies of the replacement of wollastonite ($CaSiO_3$) and portlandite by calcite ($CaCO_3$) are used for illustrating the influence of such parameters.

Toxic element balances in small scale wood combustion systems

H. RUPPERT* AND T. SEIDEL

Geosciences Center & Interdisciplinary Center for Sustainable Development, University of Goettingen, Goldschmidtstr. 3, D-37077 Goettingen, Germany (*correspondence: hrupper@gwdg.de)

In Europe, wood combustion in stoves and boilers is widely applied for residential heating. In Germany, approximately 15 million of 40 million households own small-scale wood-burning furnaces, which deliver 7% of Germany's heat consumption. Using state-of-the-art small-scale combustion systems, we investigated how the air quality changes due to the emissions of harmful elements and organic pollutants during the combustion of wood and straw.

Beside the fuel, we analysed all the originating ashes – grate ash, heat exchanger ash, and fly ash – to reconstruct element fluxes. As the input/output balance calculations show, some elements – such as cadmium, zinc, tin, thallium, lead, bismuth and antimony – may also be retained within the cooler zones of the furnace, in the chimney, or in the refractory lining material where samples could not be taken (Fig. 1). The elements collected by filters correspondent to the element amount in the flue gas, which is emitted into the ambient air. At most, these element portions represent 30 percent of the amount contained in the fuel [1, 2].

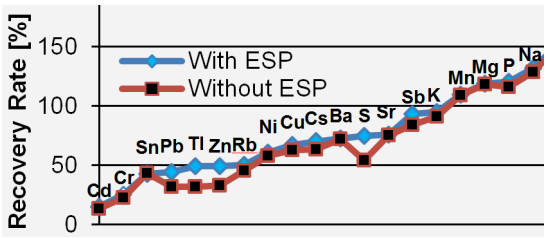

Figure 1: Element recovery rates with and without electrostatic precipitator ESP (combined element amounts in all ashes divided by the amounts contained in the combustred wood)

The pollutants are bound in fine (< 1 μm) particles or gaseous compounds and may enter the lungs' alveoli and contaminate the body. Clearly, effective emission reduction measures are necessary.

The architecture of the intermediate-sized Quizapu magma system

PHILIPP RUPRECHT[1]*, GEORGE BERGANTZ[2], KARI COOPER[3] AND OLIVIER BACHMANN[4]

[1]LDEO of Columbia University, Palisades, NY, USA, (*correspondence: ruprecht@ldeo.columbia.edu)
[2]Dept. of Earth and Space Sciences, University of Washington, Seattle, WA, USA
[3]Dept. of Geology, University of California, Davis, CA, USA
[4]Inst. für Geochemie und Petrologie, ETH Zürich, Switzerland

While high melt fraction magma chambers may be transient features in the crust, magmatic mushes represent the long-lived counterparts of the crustal magmatic factory. Together they source largely variable andesitic to dacitic composite volcanic cones and stratovolcanoes and manifest the continuous presence of silicic magma in the crust above convergent margins. Silicic magmas are ultimately fed and their eruption triggered by magmas generated in the mantle. How intermediate-sized (tens of km^3) magmatic systems are assembled and what kind of crustal-scale architecture results from that assembly, requires an integrated approach of crystal-scale geochemistry, petrology, and fluid dynamics.

Utilizing such a combined approach provides tight constraints on the magmatic architecture beneath Volcán Quizapu (Chile), a magmatic system that produced two ~ $5km^3$ large historic eruptions. The shallowest part of the Quizapu system is dominated by high-melt fration dacites with minimal evidence for hybridization. This eruptible dacite lense is generated by crystal-melt separation from an andesitic mush of intermediate temperature. Hybridization – common for arc systems – is limited to the andesitic mush, while hot recharge magmas interact only in rare cases directly with the shallow dacite magma [1]. Such mafic recharge leads to mixing and eruption and diffusion modeling of elemental zonation in phenocrysts at Quizapu (e.g., Mg in plagioclase) suggests that recharge, mixing, and eruption occured within days to a few weeks [2]. Moreover, we consider the thermal effects on the mixing and eruption dynamics associated with hot mafic recharge and find (i) that overall mixing efficiency for the erupted volume is set early during the recharge events – limiting the extent of hybridization [1] – and (ii) that short-term reheating leads to significant viscosity reduction in the resident dacite magma. We argue that late-stage reheating may reduce the potential for Plinian eruptions as water-saturated dacites degas efficiently during ascent [3].

Are long-lived stratovolcanos low-pass filters for magma transport?

PHILIPP RUPRECHT[1]* AND TERRY PLANK[1]

[1]LDEO of Columbia University, Palisades, NY, USA, (*correspondence: ruprecht@ldeo.columbia.edu)

Arc stratovolcanoes localize magmatic activity for 10s to 100s kyr, leading to self-cannibalization and the emergence of polybaric subvolcanic magma storage regions. Partial melts accumulate within mush zones and sills at various levels in the crust. Dense primitive mantle-derived magmas that ascend from mantle source regions encounter those density barriers on their way to the surface, leading to stalling and an evolution to more buoyant magmas through fractionation, mixing, and assimilation. It is therefore not surprising and well-known through geochemical and isotopic studies that primitive magma compositions typically do not reach the surface within voluminous arc magma systems. This view suggests that long-lived arc stratovolcanoes act as low-pass filters for primitive magmas from the mantle, where the frequency of magma addition from the mantle is converted in the crust to a slower integrated ascent rate as magmas stall, evolve and accumulate. Isotope and geochronology studies on crystal cargo provide evidence for such prolonged magma processing. While some stalling and processing in the crust is commonly agreed upon, magma transit times at middle to lower crustal levels are particularly unconstrained. A contrasting view is that magmas rise rapidly (potentially adiabatically), resorb any crystal cargo upon ascent, and crystallize at shallow depth.

Combining geochemical data from primitive crystals (e.g., Fo90), observations of upward earthquake migration beneath long-lived volcanic centers, and thermal constraints on magma transport in the crust, we show that slow processing (low-pass filtering) may not be as ubiquitous as it is assumed for large stratovolcanoes [1]. Instead, a second mode of fast magma transit from the mantle to the surface must coexist. Some phenocrysts in arc magmas record in their crystal zoning mixing eposides of primitive magmas at Moho depth (e.g., >1000 ppm Ni variations in olivines of constant Fo), and provide an upper limit on ascent rates of primitive magmas. In fact, thermal models for dike transport and trace element diffusion calculations for Ni zoning constrains integrated Moho-to-surface ascent rates for the fast mode to ~ 0.1-1 km/day, well in line with seismic observations from migrating earthquake swarms. Such ascent rates require primitive magmas to bypass or transit effectively most middle to lower crust magma storage regions.

Hydrothermal-sedimentary lithogenesis

V.YU. RUSAKOV

V.I. Vernadskiy Institute Geochemistry and Analytical Chemistry, RAS (rusakov@geokhi.ru)

The model of the hydrothermal-sedimentary lithogenesis rests on data of suspended and settled matter of 'black smokers', proximal and distal metalliferous sediments (MS), as well as the Paleozoic hydrothermal-sedimentary deposits. Recent hydrothermal fields (Broken Spur (<1 kyr), TAG (~40-50 kyr), Krasnov (~120 kyr), Semenov ore cluster (~37-124 kyr)) and ancient VMS deposits of the Urals (Molodezhnoye, Yaman-Kasy, Safiyanovskoe) was selected as an illustration of the model. Moreover, the manganiferous deposits of the Urals (Kyzil-Tash, South-Faizulinskoe, Bikkulovskoe) was also included in this model as an ancient propotype of distal hydrothermal-metalliferous sediments.

On the basis of study of sediment strata on the Krasnov field [Rusakov *et al*., 2011; 2012] and Semenov ore cluster [Rusakov *et al*., 2013 in press] was found that epicenter part of the hydrothermal-sedimentary strata in form of ore-bearing sediments, covered ore-bodies, reflects a zone of interrelation between ore-bearing solutions (infiltration-metasomatic processes) and seawater (halmyrolysis). At the distance of the zone the ore-bearing sediments are transformed into proximal MS, ore part of which is completely presented by Fe-oxyhydroxides. Main part of Mn is precipitated on great distance from the hydrothermal field from non-buoyant plumes.

On the basis of study of ferruginous rock around VMS deposits enable to reveal main stages of the meta-sediment formation: (1) sedimentation, (2) infiltration-metasomatic, (3) halmyrolysis, (4) lithification. The infiltration-metasomatic impact of hydrothermal solutions and oxidizing action of seawater leads to copper redistribution within sediment strata and formation of secondary minerals (pyrite is replaced by chalcopyrite, chalcopyrite is replaced by siderite, as well as formation of secondary calcite and chlorites). The main mechanism of lithification of MS is sediment dehydration, expressed in replacement of Fe-oxyhydroxides by hematite and silica by quartz. In spite of such transformations, original lateral zoning of rock is remained indicating on effect of hydrothermal-sedimentary genesis.

Origin of Earth's Earliest Continental Crust: A Combination of Partial Melting and Fractional Crystallization?

T.RUSHMER[1]* AND J. ADAM[1]

[1]Department of Earth and Planetary Sciences, Macquarie Univeristy, Sydney, AUS (*Tracy.Rushmer@mq.edu.au)

The origin of tronalite-trondhjemite-granodiorite (TTG) plutonic complexes continues to be a major focus of research as these suites make up a majority of Earth's earliest continental crust. Partial-melting experiments were conducted (at 900-1100 ºC and 0.5-3.0 GPa) on two greenstones from the Nuvvuagittuq Complex, Quebec, Canada and on PC-103, a 3.66 Ga tonalite that encloses the mafic rocks of the Nuvvuagittuq Complex. At 1.5-3.0 GPa and 950-1100 ºC, the experimentally produced melts are compositionally similar to Archaean TTGs (including PC-103). But the degree of melting needed to produce these melts is high (> 30 %) and so the relative concentrations of most incompatible elements in the melts are similar to those of their greenstone parent rocks. These greenstones have compositional affinities with modern subduction zone magmas. Thus, arc-like mafic rocks appear to have been selectively involved in TTG formation, implying the involvement of crustal recycling in TTG genesis. The results of experiments on the tonalite PC-103 suggest either equilibrium of its original magma with a garnet pyroxenite residue at ~1050 °C and 3.0 GPa, or compositional control by the plagioclase-pyroxene cotectic at ≤ 900 °C and < 1.0 GPa. The latter option is more consistent with the compositional trends of Archaean TTGs. In either case, a high degree of inheritance is involved implying a role for early crustal recycling.

Green River CO_2 natural analogue, Utah: insights into Fe mobilisation from jarosite fracture mineralisation.

J. C. RUSHTON[1], D. WAGNER, G. PURSER, J. M. PEARCE AND C. A. ROCHELLE

British Geological Survey, Environmental Science Centre, Keyworth, Nottingham NG12 5GG [1] jere1@bgs.ac.uk

Outcrop samples of the Jurassic Entrada Sandstone in the Green River area of Utah, USA, have been studied as part of a CO_2 storage natural analogue study (CRIUS consortium). These rocks are locally bleached, the pattern of which is enigmatic but commonly associated with sub-vertical fractures. In some locations these fractures are pathways to recent carbonate travertine deposits. Of key interest is the fate of Fe, whose reduction and mobilisation is implied by the host rock bleaching patterns and which is present in travertine deposits, and CO_2-rich springs and geysers in the area.

Petrographic analysis has revealed a complex and unusual textural and mineralogical assemblage in the fractures. Jarosite ($KFe_3(SO_4)_2(H_2O)_6$) has been identified; its formation is typically associated with oxidative alteration of sulphide minerals and acid mine drainage[1]. Cubic pseudomorphs mostly comprising goethite, centrally concentrated in the fractures and containing rare pyrite relics, suggest pyrite was the primary fracture mineralisation, and may indicate that S-bearing reducing fluids are responsible for the host rock bleaching patterns.

Expansive textures associated with the jarosite suggest that it formed with minimal overburden, and that the oxidative fluids were a near-surface episode. Zones of complete and then partial dissolution of diagenetic carbonates in the host sandsones adjacent to the fractures, associated with Al oxide / hydroxide mineralisation, are consistent with low pH fluids resulting from sulphide oxidation. Gypsum- and calcite-cemented fractures cross-cut the jarosite mineralised textures; these later events relate to current CO_2-rich fluid movements since they can be observed to form part of the feeder system linking directly to travertine deposits at some locations. This paragenesis shows that the same fracture flowpaths have been used by several generations of fluids.

Petrographic observations, together with an experimental study of Fe mobilisation from the Entrada Sandstone, suggest that dissolved Fe in the modern regional CO_2-rich fluids is largely derived from the fracture mineral assemblage, rather than through current alteration and beaching of the host rock.

Aerosol particles in the marine boundary layer include primary organic and salt particles from sea spray and combustion-derived particles from ships and coastal cities. The Eastern Pacific Emitted Aerosol Cloud Experiment (E-PEACE) 2011 was a targeted aircraft campaign to assess how different particle types nucleate cloud droplets. Particle sources included shipboard smoke-generated particles with 0.05-1 μm diameters (which produced tracks measured by satellite and had drop composition characteristic of organic smoke) and combustion particles from container ships with 0.05-0.2 μm diameters (which were measured in a variety of conditions with droplets containing both organic and sulfate components) [1]. Three central aspects of the collaborative E-PEACE results are: (1) the size and chemical composition of smoke particles compared to cargo ship emissions as well as background marine particles, (2) the characteristics of cloud track formation for smoke and cargo ships, as well as the role of multi-layered low clouds, and (3) the implications of these findings for quantifying aerosol indirect effects. For comparison with the E-PEACE results, the preliminary results of the Stratocumulus Observations of Los-Angeles Emissions Derived Aerosol-Droplets (SOLEDAD) 2012 provided evidence of the cloud-nucleating roles of both marine organic particles and coastal urban pollution, with simultaneous measurements of the effective supersaturations of the clouds in the California coastal region.

Analogue experiments on volatile escape from crystal-rich magmas

A. RUST[1], K. CASHMAN[1], J. OPPENHEIMER[1] AND I. BELIEN[2]

[1]School of Earth Sciences, University of Bristol, UK glkvc@bristol.ac.uk
[2]Exxon Mobil Upstream Research, Houston, TX

The low water content of granitoid bodies requires effective escape of the volatile phase during crystallization of mushy magma. We explore the physical mechanisms for volatile migration in crystal-rich magmas with experiments on three-phase analogue mixtures of syrup, solid particles and gas. The liquid+particles was either placed in a vertical tube or sandwiched between two glass plates; gas was injected into the suspension, or generated throughout the suspension by chemical reaction or by decompression. The proportions of phases, syrup viscosity, particle sizes, and rate of gas injection/expansion were varied. Experiments were videoed and monitored with gas pressure data.

Comparisons with crystal-free experiments indicate that crystals in mushes strongly inhibit buoyancy-driven bubble migration, but can facilitate the formation of temporary connected gas pathways, allow degassing of permeable gas flow at much lower volume fractions of gas than the crystal-free system. The experiments with parallel glass plates facilitate visualization of the gas phase. Three regimes are identified by gas distribution patterns, and are found to be related to the volume fraction of solids: (1) At low particle concentrations the gas forms smooth fingers that intrude steadily; (2) At ~55% particles, the gas penetrates the suspension in bursts, and forms thin "fractures"; (3) At solid fractions sufficient to lock the particles in place, the gas pushes liquid out through the particle network.

In all three regimes the measured gas pressure increases smoothly and does not decrease until, or shortly before, the gas reaches the edge of the liquid+particle mixture. In the fracturing regime, the pressure increase is steady even during bursts of motion; this indicates that the ductile but sudden fracture formation rearranges the gas phase but does not create episodes of pressure buildup and release. Once a fracture has released gas to the outside, however, there are subsequent fluctuations in pressure as the initial fracture heals (viscously) and closes the system until a new fracture reaches the suspension boundary, at which point the process is repeated in a new location (because in hetrogenous suspensions fractures preferentially propagate into areas with relatively high solid contents). This mechanism would allow effective open-system degassing of crystallizing volatile-saturated magma, without leaving textural evidence of the volatile phase.

Calculation of Mass-Dependent Isotope Fractionation in Aqueous-Mineral Systems: In Pursuit of 1-permil Accuracy

JAMES R. RUSTAD[1]

[1]University of California, Davis, Davis, CA 995615 (correspondence: jrrustad@ucdavis.edu)

Calculation of mass-dependent isotope fractionation in geochemical systems is probably the single most successful application of computational chemistry to geochemistry. The accuracy of these calculations is highly system dependent. For heavy isotopes with fractionations between minerals and aquo ions on the 1-2 permil level, first principles calculations are highly challenging, and computational requirements differ considerably between anionic and cationic systems. Aquo ions need large basis sets, particularly anions, which require basis sets of aug-cc-pVTZ (or better) quality. Aquo cations can be represented using continuum solvent models beyond the second shell, while aquo anions cannot. When density functional theory is used, the choice of the exchange-correlation functional has a strong effect on the results. This exchange-correlation variation, together with the basis set variation, can easily result in steps taken through basis-set XC functional that vary over a range of more than ~3 permil, with no apparent consensus on which functionals work best. Thus while past success has often been impressive, reliable prediction of fractionation at the sub-1 permil level will remains a highly challenging, though not unattainable, goal. Examples are taken from BOH_3(aq)-BOH_4^-(aq), Mg^{2+}(aq)-calcite, Ca^{2+}(aq)-calcite, Fe^{3+}(aq)-hematite, $(H)CO_3^-$(aq)-carbonate, perovskite-ferropericlase, chlorophyll, and amino acid systems.

Polyoxoions as Model Systems for Mineral Surface Chemistry

JAMES R. RUSTAD[1]

[1]Corning Incorporated, Sullivan Park Research Center, Corning, NY 14831, USA
(correspondence: rustadjr@corning.com)

Polyoxometalate ions (POMs) have structures similar to condensed oxide phases and can be used as representative molecular models of the oxide/water interface. Oxygen atoms in POM exchange with water molecules at different rates. At present there is no basis for predicting how the coordination environment and metal substitution influences rates and mechanisms. Lability of oxygen in POMs is governed by low-energy metastable configurations that form from the breaking of weak bonds between metals and underlying highly coordinated oxygen atoms, followed by facile hydroxide, hydronium or water addition. The mediation of oxygen exchange by these stuffed structures suggests a new view of the relationship between structure and reactivity at the oxide/solution interface.that de-emphasizes local bond ruptures and activated transition states. Reaction rates are governed by pathways for the formation and destruction of oxygen-stuffed intermediate states, not specific oxygen site chemistry, as has long been assumed. These intermediates form from ring-opening reactions that allow isotopic exchange and, by extension, dissociation and dissolution. As for the Keggin-type polyoxocations, the common feature of these intermediates is the breaking of a weak bond between a surface metal and the deeper, highly coordinated oxygen. The relative energies of the intermediate structures are similar across the range of substituted decaniobates, supporting the experimental observation that metal substitution at a specific site does not change the relative order of reactivity of the different types of oxygen atom. Unlike the Keggin-type polyoxocations, metal substitutions in the decaniobate POMs affect rates mainly by modifying the Broensted acid/base properties of the molecule.

Combining geochemistry with thermal infrared remote sensing to characterize glacial weathering

A.M. RUTLEDGE*, P. CANOVAS, E. SHOCK AND P.R. CHRISTENSEN

School of Earth and Space Exploration, Arizona State Univ., Tempe, AZ 85281 USA
(*correspondence: allie.rutledge@asu.edu)

Subglacial and englacial weathering of geologic materials contributes to the solute flux in meltwater, provides feedback in the global carbon cycle, and is a potential source of energy to chemotrophic microbes [1]. Thermal infrared (TIR) remote sensing has been used to identify geologic materials and study weathering processes [2]. In this study, we characterize the weathering processes occurring in a glaciated silicate-carbonate system by linking Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) infrared spectroscopy to in-situ rock and sediment samples, and compare our results with aqueous geochemical data. Our major objective is to link *in situ* samples with remote sensing capabilities.

Robertson Glacier (115°20'W, 50°44'N) drains the northern flank of the Haig Icefield in Peter Lougheed Provincial Park, Kananaskis Country, Alberta, Canada. The glacier rests on Upper Devonian impure limestones, dolostones, and shales [3]. Samples of glacially altered rock and sediments were collected at the glacier in 2010 and 2011. TIR laboratory spectroscopy was used to determine the composition and abundance of minerals present. Ice and water samples were also collected at similar locations and analyzed for major and minor elements. TIR imagery of the region was collected with the ASTER satellite instrument.

Dissolved Ca^{+2} and SO_4^{-2} increase downstream in the outflow channel. This is consistent with earlier studies of this system – these increases are interpreted to be due to acid hydrolysis of calcite fuelled by CO_2 dissolution and by pyrite oxidation [4], which is likely to be microbially mediated. Both ASTER- and lab-scale spectroscopic analyses show evidence for calcite leaching. Lab TIR analyses demonstrate the presence of calcite-depleted weathering rinds on hand samples. ASTER analyses show similar spectra on a regional scale; freshly revealed glacial till is seen to be depleted in calcite relative to the surrounding bedrock. This TIR remote sensing method has wide application to studies of glacial weathering, especially those focusing on less accessible regions of the world.

Monitoring the 40Ar/39Ar irradiation parameter 'J' without using geological age standards

DANIEL RUTTE*[1], SEPP UNTERRICKER[2], JÖRG A. PFÄNDER[1] AND RAYMOND JONCKHEERE[1]

[1]Institut für Geologie, TU Bergakademie Freiberg, Germany, [*daniel.rutte@geo.tu-freiberg.de]

[2]Institut für Angewandte Physik, TU Bergakademie Freiberg, Germany

One of the major error components in $^{40}Ar/^{39}Ar$ geochronology is the irradiation parameter J. Its associated error is based on the accuracy of the independent age of the geological age standard and the inhomogeneity of the neutron fluence in the irradiation channel. To tackle both problems, we included independent fluence monitors (Ni and Co foil) in two of our irradiation containers, one irradiated under Cd-shielding in the research reactor Geesthacht FRG1 (Germany), the other without Cd-shielding in the research reactor Řez LVR-15 (Czech Republic). The irradiation containers were placed in rotating positions. Based on the activation reaction $^{58}Ni(n,p)^{58}Co$, gamma-spectroscopy of the resulting decay of ^{58}Co to ^{58}Fe provided the means to calculate absolute fast neutron fluences. The relative variation of the calculated fast neutron fluence at different points in the irradiation container is in agreement with the J-values measured from geological age standards within 1 sigma errors. For the irradiation in the research reactor LVR-15, the calculated neutron fluence varied systematically by 2.5% over an axial distance of 6 cm and by 1.9% over a radial distance of 3 cm. From the calculated absolute fast neutron fluences we calculated J-values, independent of geological age standards. In a first approach, the calculated J-values are about 12% higher than the J-values determined using geological age standards. The relative 1 sigma errors of the calculated J-values are on average 0.15%, as determined by a Monte Carlo method, which takes into account the weighing error of the Ni- and Co-monitors, as well as counting statistics of the gamma-spectrometer.

Halogen Systematics of the Manus Spreading Center.

L. RUZIÉ[1,*], D. CHAVRIT [1], R. BURGESS [1], P. CLAY[1], B. JOACHIM[1], D. R. HILTON[2] , J. M. SINTON[3] AND C.J. BALLENTINE [1]

[1]University of Manchester, UK (*lorraine.ruzie@manchester.ac.uk)

[2]Scripps Institution of Oceanography, California, USA

[3]University of Hawaii, Honolulu, USA

The incompatibility of the heavy halogens (Cl, Br, I) combined with relatively high concentrations and distinct elemental compositions in surface reservoirs makes the halogens good tracers to detect the recycling processes in the different mantle sources. However, the halogen systematics in mantle reservoirs remains poorly constrained mainly because of their very low abundance in materials of interest. An innovative analytical technique, involving neutron irradiation of samples to convert halogens to noble gases then measured using conventional noble gas mass-spectrometry, provides detection limits unmatched by any other technique [1].

We focus on the halogen contents in the glassy margins of basalts erupted along the Manus Spreading Center (MSC), which lies in a back-arc basin setting. Samples consist of both MORB-type lavas and back-arc basin basalts (BABB) [3]. The major and trace elements, as well as $^{3}He/^{4}He$ ratios, water concentrations and δD have already been determined [2].

The halogen concentration range is between 160 and 1500 ppm Cl, 600 and 5700 ppb Br and 10 and 60 ppb I. The lower concentrations found in MORB-type samples are similar to E-MORB contents from Central Indian Ridge [4]. The higher concentrations are found in BABB samples. A strong negative correlation is apparent between I/Cl and both H_2O/Ce and δD: (1) the lower I/Cl wt. ratios measured in BABB ($4.1 \pm 1.4 \times 10^{-5}$) are associated with the higher H_2O/Ce ratios (2,150 ±580) and δD (-52 ±15‰), (2) the higher I/Cl wt. ratios measured in MORB-type lava ($7.2 \pm 2.5 \times 10^{-5}$) are associated with lower H_2O/Ce ratios (750 ±130) and δD (-94 ±11‰). From these results, we infer that our suite of samples from MSC are explained by mixing a seawater-derived component of the actual slab and the Manus underlying mantle. Considering both the MSC distance to the arc (240 km) and the slab slope, we conclude that a seawater-derived component can be preserved below 100 km depth.

Ge and Ge-bearing mineral phases in gabbrodolerites of Mt. Ozernaya trap intrusion (Siberian platform)

V.V. RYABOV[1] AND L.V. AGAFONOV[1]

[1]V.S.Sobolev of Institute Geology and Mineralogy SB RAS, Novosibirsk, 630090, Russia; e-mail: trapp@igm.nsc.ru

Native iron(-platinum) ores [1] are associated with the Mt. Ozernaya trap intrusion, which is a part of the large volcano tectonic structure. Small (5-25 μm) isometric grains and subhedral crystals of Ge and Ge-bearing oxygen-free and oxygen-containing mineral phases are observed in interstices of olivine-bearing gabbrodolerites of this intrusion. The phase composition was determined on LEO 143OVP scanning microscope and on GEOL JXA-8100 electron-microprobe. Because of small sizes of the grains, it was not possible to determine X-ray parameters of the mineral phases. The element composition in Ge and Ge-bearing mineral phases varies within the wide range: Ge (1.0-37.6%), Ni (24.8-72.2%), Co (0.9-5.1%), Fe (1.3-42.9%), Sb (0-20.2%), As (0-39.8%), and S (0-15.7%). Individual grains contain Cu (0.6-5.9%), Pd (4.5-19.9%), and Sn (10.7-18.0%). The ideal formulas of mineral phases are Ni2Ge, Ni2(Ge,Sb), Ni2(S,Ge), and Ni2(Ge,As).

Three analyses of the oxygen-containing Ge mineral phases show the variation: 41.41, 40.65 and 40.94 GeO2, 56.98, 51,84 and 51.62 FeO; 0.00, 4.33 and 4.94 MgO; 1.61, 1.65 and 1.61 NiO; 0.00, 0.38 and 0.55 Co; 0.00, 1.12 and 1.08 CuO, respetively. The sums are 100, 99.97 and 100.74, respectively. Their ideal formula is Fe2GeO4.

In association with the Ge and Ge-bearing phases, the following constituents are observed in interstices of gabbrodolerites: graphite, iron, cobalt, camacite, taenite, awaruite, NiCoFe-intermetallic compounds, silver, wustite, hercynite, chalcopyrite, cubanite, bornite, pentlandite, heazlewoodite, troilite, acantite, maucherite, nickeline, as well as fayalite, biotite, hastingsite, garnet, demidovskite, breakdown solid solution structure Wo2En47Fs51 - Wo40En42Fs18, and circon.

Formation of the mineral phases is assumed to occur under highly-reductive conditions involving organoelement compounds. [2]

Variations in modes and rates of long-term denudation in carbonate terrains under Mediterranean to hyper-arid climates

U. RYB[1]*, A. MATMON[1], Y. EREL[1], I. HAVIV[2] AND L. BENEDETTI[3]

[1]The Fredy and Nadine Herrmann institute of Earth Sciences, Admond J. Safra Campus, Givat Ram, Jerusalem, 91904, Israel. (*corrospondance: uri.ryb@mail.huji.ac.il)

[2]Ben-Gurion University of the Negev, Be'er-Sheva 84105, Israel

[3]Aix-Marseille Université, CNRS-IRD-Collège de France, UM 34 CEREGE, Technopôle de l'Arbois, BP80, 13545 Aix-en-Provence, France

Using ^{36}Cl measurements in >100 carbonate bedrock and sediment samples we calculate long-term denudation rates in two drainage basines that drain the western and eastern flanks of the Judean mountain range (central Israel). A sharp climatic gradient from Mediterranean to hyper-arid conditions characterizes the transition from the western to the eastern flank of the range, due to rain shadow effects. Moving from the Mediterranean to the hyper-arid climate zones, denudation rates of interfluves drop by an order of magnitude from ~20 to 1-3 mm kyr^{-1} and are linearly dependent on precipitation, indicating that carbonate dissolution is the dominant erosional process. Conversely, denudation rates become increasingly dependent on hillslope gradient only in the dryer climate zone, and thus delineate the dominant control of mechanical processes on denudation within this zone. We demonstrate that the transition between chemically-controlled denudation to mechanically-controlled denudation occurs between mean annual precipitations values of 100 and 200 mm yr^{-1}. The growing contribution of mechanical processes to hillslope erosion is also evident in the increase of denudation rates calculated from sediments, collected from the eastern drainage, between the Mediterranean (16-18 mm kyr^{-1}) and the hyper arid (30-48 mm kyr^{-1}) regions. This study demonstrates that carbonate terrains have the capacity to switch between mechanical and chemical weathering regimes in response to changes in precipitation. Similar transitions in response to changes in temperature or the level of tectonic activity have been reported in the past. It is suggested that the abrupt nature of such transitions is a reflection of the competition between surface and subsurface drainage systems in carbonate terrains, derived from the congruent nature of carbonate dissolution processes.

Sub-sea tailings deposition leach modeling

P. RZEPKA[1]*, I.F. WALDER[1], P. BOŻĘCKI[2] AND G. RZEPA[2]

[1]Kjeøy Research & Education Center, Kjeøy, 8412 Vestbygd, Norway;
(*correspondence: przemyslaw.rzepka@gmail.com)
[2]AGH University of Science and Technology, Department of Mineralogy, Petrography and Geochemistry, al. Mickiewicza 30, 30-059 Kraków, Poland.

The sub-sea/deep sea tailings deposition is a controversial method for disposing of mine wastes. Hazardous chemicals used during processing and deposited metal sulfides may dissolve, affecting the sea environment.

The overall objective for this project is to evaluate the copper leaching potential from tailings on the example of the proposed submarine tailing disposal in Repparfjorden discharged from 2 deposits - Nussir and Ulveryggen, mined by Nussir ASA. This experiment gives better understanding of the reactivity of sulfide minerals in saline system during sub-sea deposition.

Several kinetic tests were run based on recirculation of the leachate (batch experiments) using a constant flow rate over the tailings material of 1-2 m/h. The columns were run at approximately 10 °C (Fig. 1).

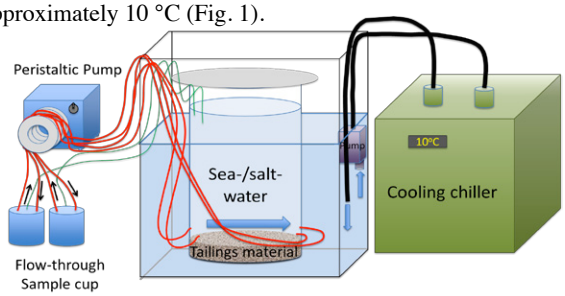

Fig. 1. Scheme of sub-sea tailing deposition leach test model.

There is a distinct increase in copper concentration during the experiments; while other hazardous elements (like Se, As, Ni) do not reveal changes. Copper leaching is a two-stage process: (1) initial rapid dissolution of secondary minerals formed from sulfide oxidation, related to the tailings material disposing period, and (2) long term slow leaching of available surface material of tailings settled on the bottom. Copper concentrations reached 0.02 mg/l after 100 days. Towards the end of experiments (from 70-100 days) the leaching rate leveled off (approximately 2.8 mg/m^2/year) with time. Cu content data indicated that there were no further increase or leaching. These experiment results are potentially overestimating sub-sea tailings deposition natural conditions.

δD in lunar volcanic glasses and melt inclusions: A Carbonaceous chondrite heritage revealed

A.E. SAAL[1]*, E.H. HAURI[2], J.A. VAN ORMAN[3] AND M.J. RUTHERFORD[1]

[1]Dept. of Geol. Sc., Brown University, RI, 02912, USA (*correspondence: asaal@brown.edu)
[2]DTM, Carnegie Institute of Washington, DC, 20015, USA
[3]Dept. of Geol. Sc., Case Western Reserve University, OH 44106, USA

Water is perhaps the most significant molecule in the solar system, and determining its origin and distribution in planetary interiors has important implications for understanding the evolution of planetary bodies. Here we present the isotopic composition of hydrogen dissolved in lunar volcanic glasses and in their olivine-hosted melt inclusions to establish the source of the lunar magmatic water. These volcanic glasses, returned by the Apollo 15 and 17 missions, represent some of the best-studied and most primitive magmas generated within the Moon. The D/H ratios and H_2O contents were measured simultaneously in the center of the exposed interiors of individual lunar volcanic glass beads and olivine-hosted melt inclusions, using a Cameca NanoSIMS 50L multicollector ion microprobe. We examined very-low Ti and low-Ti glasses from Apollo 15 15426/27 and high-Ti glasses from Apollo 17 74220. The Apollo 17 high-Ti glasses contain olivine-hosted melt inclusions, small samples of magma trapped within the olivine that grew in the magma before eruption. By virtue of their enclosure within their host crystals, melt inclusions are protected from loss of volatiles by degassing during eruption. After consideration of cosmic ray spallation and degassing processes our results demonstrate that lunar magmatic water has an isotopic composition that is indistinguishable from the bulk water in carbonaceous chondrites and similar to terrestrial water, implying a common origin for the water contained in the interiors of the Earth and Moon. The Moon must have received its water during or shortly after its accretion, before the formation of a robust lunar lithosphere ≤100 My. Data for highly siderophile elements [1] suggest that a late veneer of meteoritic material delivered to the Moon was too small to be responsible for the lunar volatile budget. Therefore, the simplest scenario consistent with our observations is that the Earth was wet at the time of the Moon-forming event, as predicted by dynamic models [2,3], and that the water was not completely lost during this giant impact.

Fluid-mineral reactions during CO_2-based geothermal energy extraction

MARTIN O. SAAR, XIANG-ZHAO KONG, BENJAMIN M. TUTOLO, ANDREW J. LUHMANN AND WILLIAM E. SEYFRIED, JR.[1]

[1]Department of Earth Sciences, University of Minnesota, 310 Pillsbury Dr. SE, Minneapolis, MN 55455, USA. saar@umn.edu

Geothermal energy extraction with groundwater as the subsurface heat extraction fluid can result in substantial scaling (mineral precipitation) in pipes, heat exchangers, power conversion equipment, and the subsurface reservoir. A potential solution to this problem is to utilize carbon dioxide (CO_2) as the subsurface heat extraction fluid. During this approach, CO_2 from an emitter, such as a coal-fired power plant, biofuel plant, or concrete factory, is injected into a geothermal reservoir such as a sedimentary basin or a hydrofractured rock. In the case of the sedimentary basin approach, large amounts of CO_2 are permanently stored underground in the form of a CO_2 plume while a small portion of the geothermally heated CO_2 is circulated back to the surface for power production before reinjection into the reservoir along with the main CO_2 stream. This is referred to as a CO_2-Plume Geothermal (CPG) system.

When CO_2 is injected into deep saline aquifers, the CO_2 largely displaces the brine although there is a small degree of dissolution at the CO_2-brine interface. The result is a multicomponent-multiphase plume environment that ranges from virtually pure CO_2 in the center of the plume to CO_2 with dissolved water on the CO_2 side of the CO_2-water interface, to brine with dissolved CO_2 on the brine side of the interface, to brine with no CO_2 away from the plume.

Here, we present results on the reactions of some of the above described fluid components with various reservoir minerals that are based on flow-through reaction cell experiments under realistic T and P conditions. Pre- and post-experiment X-Ray Computed Tomography analyses provide 3D images of pore-space geometry changes due to the reactions. The 3D images are then used as input in lattice-Boltzmann fluid flow simulations to determine permeability field changes due to the fluid-mineral reactions. The ultimate objective of this work is a parameterization of permeability changes as a function of fluid and mineral chemistry for typical host rocks and T-P conditions which can be included into geothermal reservoir simulators such as TOUGH2.

Evaluation of different RNA preservation methods to study the active microbial communities in oil sand tailings ponds

SABARI PRAKASAN M.R[1]*, NADINE LOICK[2] AND CHRIS WEISENER[1]

[1]GLIER, University of Windsor, Windsor, Canada (*mullapus@uwindsor.ca)
[2]Rothamsted Research, Hertfordshire, England

Analysis of RNA is the best approach to understand active microbial populations in an environment. In contrast to DNA, which can persist in soil for several days, RNA is an unstable macromolecule making it more suitable to investigate metabolically active microbial communities. Due to its susceptibility to degradation, the preservation of a sample containing RNA is an important step in molecular studies. In the field of Oil Sand Tailings Research sample-preservation is especially important as due to logistical limitations the extraction of nucleic acids may only be possible days after the samples are taken. The aim of this study is to evaluate the ability of different methods to preserve RNA in Oil Sand Tailings samples both short term (5 days) and long-term (30 days). In our study different preservation solutions including LifeGuard™ Soil Preservation Solution (MoBio Laboratories, Inc.), RNAlater® (Ambion), glycerol and liquid nitrogen are compared to find the best preservative method for soil RNA preservation.

Analysis of different RNA samples shows that all four preservation methods provide significant amounts of RNA for further analysis. After cDNA synthesis T-RFLP analysis is used to compare community structure derived from the differently treated samples. Additionally, during RNA-extraction co-precipitated DNA is also analysed. The community structure data derived from cDNA and DNA provides information on the ability and comparability of the different techniques to preserve microbial communities and demonstrates the importance of RNA (cDNA) in microbial ecology.

Interaction of Eu(III) with calcium carbonate: Spectroscopic characterization

A. SABĂU[1,2], N. JORDAN[3], C. LOMENECH[2], N. MARMIER[2,*], V. BRENDLER[3], A. BARKLEIT[3], S. SURBLÉ[4], N. TOULHOAT[5,6], Y. PIPON[5], N. MONCOFFRE[5], E. GIFFAUT[1]

[5]IPNL, CNRS/Université Claude Bernard Lyon
[6]CEA/DEN Saclay, 91191 Gif sur Yvette, France

The present work investigated irreversible sorption processes in the Eu-CO_2-NaCl-$CaCO_3$ system, by combining macroscopic with TRLFS and RBS spectroscopic studies.

Powders and single crystals were used due to spectroscopic tools requirements. Sorption of europium was investigated by varying the initial concentration in europium concomitant with the contact time (few hours up to 6 months). TRLFS identified two lifetimes and therefore two species at the calcite/water interface. Lifetimes allow an unambigous discrimination between sorption processes and incorporation. Values of the lifetimes are comparable to the literature [1] and the total loss of water molecules is a distinctive sign of Eu(III) species incorporation .

RBS confirmed that Eu(III) is associated in two different states with calcite:

(1) heterogeneous (supported by SEM) surface accumulation, i.e. as a surface precipitate, after 1 month contact time
(2) incorporation up to depths greater than 160 nm after 1 month.

Monazite anamnesis – providing a quantitative timeframe for metamorphic petrogenetic processes

GAVRIL SĂBĂU[1], ELENA NEGULESCU[1] AND THOMAS THEYE[2]

[1]Geological Institute of Romania, RO-012271 Bucharest, (g_sabau@yahoo.co.uk)
[2]Institut für Mineralogie und Kristallchemie, DE-70174 Stuttgart, (thomas.theye@imi.uni-stuttgart.de)

Monazite is a privileged phase in metamorphic assemblages, as it has a wide p-T stability field, a complex chemical composition, incorporates high concentrations of radioactive elements and is remarkably refractory to diffusion. Its chemical substitutions represent a very sensitive response to mineral reactions triggered by changing conditions, being recorded and preserved in grain zonations, as well as in regular chemical variations in the monazite populations. Connecting age data with chemical features allows not only dating monazite growth, but also a sometimes surprisingly accurate insight in the concurrent mineral reactions.

We performed several hundred microprobe analyses on monazite in pelitic and gneissic rocks from the South Carpathian basement units, for both chemical characterization and dating. The chemical characterization included structural formulae, ternary plots, normalized plots and elemental ratios therefrom. Relating age point data to compositional trends reveals homogeneous compositional and age domains, as well as regular chemical shifts, having a counterpart in mineral reactions involving monazite, and in variations in the crystallization versus resorption rates of monazite itself.

Monazite acts as a LREE and Th scavenger from decomposing REE-bearing phosphates, carbonates and silicates, and Th (U)-bearing silicates, phosphates and oxides, recording high Th (+Ca, U) and LREE contents in the initial growth stages. Oppositely, monazite resorption is typically indicated by its Nd and Sm enrichment. LREE correlations are variable, reversing differently in different samples with increasing atomic number, whereas the corresponding ratios indicate changes in modal abundance. Y content is buffered by coexisting xenotime and melt, being also markedly fractioned in coexisting garnet, as Y variation strongly and inversely reflects changes in modal garnet abundance. Eu is fractioned in plagioclase (metamorphic or crystallizing from melts) and U in coexisting melts. Heavier MREE are partitioned in xenotime. Monazite chemistry holda thus valuable keys for both identifying and dating thermometamorphic processes, especially those involving melting episodes and garnet growth and decomposition.

Towards Quantitative Paleohydrology: Reconstructing changes in relative humidity from lipid biomarker δD values

DIRK SACHSE[1], OLIVER RACH[1], ANSGAR KAHMEN[2], HEINZ WILKES[3] AND ACHIM BRAUER[3]

University of Potsdam, Institute of Earth and Environmental Science, Karl-Liebknecht-Str. 24-25, 14476 Potsdam-Golm, Germany
[2]ETH Zurich, Institute of Agricultural Sciences, Universitätsstrasse 2, 8092 Zürich, Switzerland
[3]GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany

The stable isotopic composition of meteoric waters, recorded through the hydrogen isotopic composition of lipid biomarkers is an integral of a number of hydrological parameters, such as condensation temperature, precipitation amount, evaporation, moisture pathway. It is often difficult to disentangle these parameters for a true quantitative reconstruction of hydrological variables, such as precipitation amount and relative humidity. Here we review the current state of knowledge of the factors driving leaf wax δD values and evaluate how terrestrial plant lipid biomarker δD values in combination with plant physiological modelling can be used to quantitatively reconstruct changes in relative humidity (rH).

We present a proof-of-concept for this approach by estimating relative humidity changes during the Younger Dryas cold period in Western Europe from the analysis of lipid biomarker δD values from the annually varved sediments of Lake Meerfelder Maar. We use the isotopic difference between aquatic and terrestrial lipid biomarkers as a measure of mean leaf water isotope enrichment. We parameterized a Craig-Gordon leaf water isotope model with plant physiological parameters estimated from available vegetation cover information from palynological records and climate proxy data (such as temperature) and solved this model for rH. Our reconstruction of Younger Dryas rH changes documents profound hydrological changes - likely as a consequence of changes in atmospheric circulation due to the position of North Atlantic Sea Ice - which were the ultimate trigger for the observed environmental changes. While supporting previous suggestions of a dry Younger Dryas in Western Europe our new biomarker and modelling approach delivers for the first time quantitative estimates of hydrological changes (i.e. relative humidity changes), which can be directly compared to the output from climate models.

The role of organic matter in genesis of sedimentary-hosted stratiform copper deposits in Nahand-Ivand area, NW Iran

*SADATI N.[1], YAZDI M.[1], BEHZADI M[1]. ADABI M.H[1]. AND MOKHTARI A.A[2]

[1]Department of Geology, Faculty of Earth Science, Shahid Beheshti University, Tehran, Iran (*correspondence: sadati_sn@yahoo.com)
[2]Department of Geology, Faculty of Earth Science, Zanjan University, Zanjan, Iran([2] mokhtari1031@gmail.com)

The study area is located in part of Arasbaran- Sabalan zone in the northwestern part of Iran. Cu mineralization in Nahand - Ivand area is observed in sandstone rock units belonging to the Ghom Red beds Formation of Miocene age[1]. The Ghom Red beds Formation include alternations of red oxidized (iron oxide minerals) sandstones and conglomerates that partly convert to reduced clastic such as sandstone, siltstone, shale, conglomerate, limestone, dolomite and marl, which may contain carbonaceous or organic matter. Also Evaporites such as gypsum and salt are commonly associated. In this study, zones of reduction (grey, white, green) within oxidized red-bed sedimentary rocks are the most favored host rocks. The color of the host rocks ranges from light gray to black, reflecting their high organic matter content.

Mineralization is localized in the organic-rich and pyrite-containing gray rocks that replace the red rocks along the vertical and lateral directions[2].The main ore minerals in the deposit are copper carbonates such as malachite, azurite and some copper sulfides such as chalcocite[3]. During this study 44 samples were collected from the Ghom Redbeds Formation. Host rock and mineralized samples were analyzed for major and trace element contents by Inductively Coupled Plasma–Mass Spectrometry (ICP- MS). The results showed that In addition to copper, precious metals such as silver are less focused. In this area maximum grade of samples are up to 5.2% Cu with an average of 1.4% Cu. Copper precipitation was possibly promoted by reduction zones from organic matter such as woody fragments and plant fossils[4]. It seems that during the formation of the copper deposits, organic matter played an important role in adsorbing and gathering metallic elements [5].

REE contents in soils and sediments from the GEMAS and FOREGS data-bases: comparison between different geological contexts in Italy and Sweden

M.SADEGHI[1], P.PETROSINO[2], M.ANDERSSON[1], S. ALBANESE[2], A.LADENBERGER[1], G. A. MORRIS[1], J.UHLBÄCK[1] , A. LIMA[2] AND B. DE VIVO[2]

[1]Geological Survey of Sweden, BOX 670, S-75128 Uppsala, Sweden (* correspondance : martiya.sadeghi@sgu.se)
[2]Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università degli Studi di Napoli Federico II, L.go S. Marcellino 10, 80138 Napoli

Rare Earth Elements (REEs) are rapidly gaining attention as important chemical resources thanks to the increasing number of high-tech applications in which they are required and, as a consequence, scientific interest on REE-bearing minerals and resources is increasing. In this study, REE data from the FOREGS database of solid media chemistry (topsoils, subsoils, stream sediments, floodplains) have been used to constrain elemental distribution maps. Principal Component Analysis (PCA) has been applied to identify patterns within the data set. Detailed investigation of the distribution of REEs in all media for both countries shows the prominent role played by geogenic components. Despite similar REE concentrations in the underlying bedrocks, several significant differences emerge between the two countries driven by climate, morphology of the territory, age of the deposits, presence of mineralisation, type of soils and presence/absence of till.

The same approach has been applied to the GEMAS database to compare the REE distribution in agricultural and grazing land soils, using the same statistical approach as used for solid media from the FOREGS database. In general, high pH alkaline soils show higher REE concentrations. Certain specific anomolies can be correlated to known phosphate and REE mineralizations. The fingerprint of anthropogenic activity, both agricultural fertilizer use and cattle feed, does not influences the geogenic signal. In both Italy and Sweden, REE concentrations in agricultural and grazing land soils are comparable with those obtained for topsoils sampled from unoccupied and indisturbed areas. The main difference between the elemental distibution of REEs is more closely related to the geochemical behaviour of invidual elements and their extractability as affected by the source of the elements in the sample media.

Partitioning behavior of Cs in the matrix of simulated ash residues

A. SAFFARZADEH[1]* AND T. SHIMAOKA[1]

[1]Kyushu University, Fukuoka 819-0395, Japan
(*correspondence: amir@doc.kyushu-u.ac.jp)

Tohoku great earthquake and tsunami of March 11, 2011 caused massive explosions at Fukushima I Nuclear Power Plant. Such incidents led to the dissemination of fission products (such as ^{131}I, ^{134}Cs, ^{137}Cs) in a broad geographic area [1, 2]. These radionuclides concentrated in the surrounding natural environments [3] as well as in the debris left from the disaster. Incineration of combustible fraction of disaster debris resulted in the higher level of radioactivity (Cs-related) in the generated ash residues (up to 100,000 Bq/kg in fly ash in some areas), thus banned landfilling.

To model the behavior of radioactive Cs in the ash residues, simulated ash was produced by fusing RDF and Cs salts (non-radioactive) at high temperatures (800-1000 °C). The products mainly consist of glassy matrix (silicate) and a variety of crystalline phases (Fig 1). Microbeam analysis indicates that Cs is essentially distributed within the glassy matrix of the ash with little or no partitioning within the crystalline phases (Table 1). Binding of Cs in the silicate structure of the glass is a good evidence for the entrapment of analogous radioactive Cs. Additional experiments are underway to examine the chemical form of Cs and to improve the ash quality in order to meet the standards for landfilling.

The H_2O-CO_2-(K, Na)Cl fluids, melting of the tonalite gneiss, and the A-type granitic magmas: Experimental evidence for connection

OLEG SAFONOV

Institute of Experimental Mineralogy, Russian Academy of Science, Chernogolovka, Russia, oleg@iem.ac.ru

The A-type (anorogenic) granites, a specific variety of ferroan granitic rocks forming predominantly during crustal extension, are distinct by their medium-to-high peralkalinity (low Al_2O_3 and high K_2O+Na_2O contents), low CaO, elevated contents of F and Cl. Partial melting of the Archean TTGs in the continental basement is discussed among models to explain origin of these granites. However, neither fluid-absent nor hydrous melting of TTGs at pressures up to 15 kbar can fully satisfy the required parameters of the melts. The influx of K and Na seems to be needed for the formation of the A-type granites. Data on the melting of TTGs in presence of the H_2O-CO_2 fluids containing alkali salts are absent, so far. In order to trace variations of mineral assemblages and melt composition in dependence on temperature, concentration of salts and K/Na ratio in the fluids, the experiments on interaction of a biotite-hornblende tonalite gneiss with the H_2O-CO_2-(K, Na)Cl fluids at 5.5 kbar and 750 and 800^{O}C were performed. The H_2O-CO_2-KCl fluids provoke melting only at 800^{O}C. Addition of NaCl assists to melting at 750^{O}C. The increase of the chloride/(H_2O+CO_2) ratio in the fluids results in formation at 800^{O}C of the rhyolitic melts with Al_2O_3 < 13.5 wt. %, CaO < 2 wt. %, K_2O+Na_2O > 7 wt. %, FeO/(FeO+MgO) > 0.8, K_2O/Na_2O > 1, moderately enriched in Cl (0.2-0.6 wt. %). The melt composition correlate with the coexisting mineral assemblages, varying in the sequence Opx+Amp+Pl+Ti-Mt+Ilm→Opx+Cpx+Ilm→Cpx+Kfs+Ilm. Stabilization of Cpx and Kfs at the high chloride/(H_2O+CO_2) ratio in the fluids corresponds to the decrease of CaO and Al_2O_3 contents in the melts, while increase of the Cl content in these melts promotes the FeO/(FeO+MgO) ratio. Stability of pyroxenes at moderate and high chloride/(H_2O+CO_2) ratios in the fluids reflects low a_{H2O} in the melts, i.e. their apparent "dryness". These characteristics are similar to the A-type granites. At 750^{O}C, the H_2O-CO_2-(K, Na)Cl fluids produce trachytic melts, which model syenites, monzonites and other alkalic basic counterparts of the A-type granitic complexes. The experiments support the model for formation of these complexes by crustal melting during high-grade metamorphism in presence of the aqueous-carbonic-salt fluids fluxing in the extensional environments.

Arsenic contamination in pond sediment of central India

B. L. SAHU[1], K. S. PATEL[1], I. WYSOCKA[2] AND I. JARON[2]

[1]School of Studies in Chemistry, Pt. Ravishankar Shukla University, Raipur-492010, CG, India, bharatred007@gmail.com
[2]Polish Geological Institute, Rakowiecka, Street-00-975, Warsaw, Poland, iwys@pgi.gov.pl

The pond is widely used for the fish culture and other house hold activities in India. The environment of the Kaudikasa, central India is one of the most arsenic contaminated sites in the World [1]. In this work, the contamination of arsenic and other 33 elements in eight pond sediments (N 20º51' and E 80^{0}45') is described. The sediment samples were collected in summer 2012, and the crushed sample (≤ 0.1 mm) was digested in the micro-oven with acids. The acid extracts were analyzed by using techniques: ICP-AES and ICP-MS. Among 34 elements analyzed, eight elements i.e. Na, K, Mg, Ca, Al, S, P and Fe occurred at macro levels, ranging from 0.01 – 0.06, 0.21 – 0.45, 0.17 – 1.08, 0.18 – 0.76, 1.41 – 3.14, 0.01 – 0.06, 0.02 – 0.03 and 2.8 – 6.3% with mean value of 0.01±0.01, 0.33±0.07, 0.43±0.30, 0.38±0.14, 2.12±0.48, 0.03±0.01, 0.03±0.01 and 4.2±0.9%, respectively. Tweve metals i.e. As, Ba, Sr, Ti, V, Cr, Mn, Co, Ni, Cu, Zn and Pb was present at milligram levels, ranging from 48 - 256, 129 – 264, 12 – 30, 62 – 735, 38 – 144, 29 – 732, 388 – 1109, 12 – 42, 23 – 108, 35 – 73, 40 – 100 and 17 – 40 mg kg^{-1} with mean value of 111±52, 192±32, 20±5, 226±151, 72±25, 77±49, 646±177, 23±8, 48±21, 53±9, 66±17 and 24±6 mg kg^{-1}, respectively. Twelve metals i.e. Li, Rb, Cs, Be, Ga, Tl, Sn, Sb, Bi, Mo, Ag, Cd, Th and U present at lower milligram levels with mean value of 11, 31, 1.3, 1.7, 10, 0.2, 1.5, 0.5, 0.2, 0.8, 0.6, 0.13, 11.7 and 1.24 mg kg^{-1}, respectively. Arsenic content was correlated well with the P, Pb and Zn content. The arsenic concentration was found to be several folds higher than the recommended value of 5 mg kg^{-1}. The arsenic content in the pond sediment of this region was found to be much more higher than other region of the World [2].

[4]Air Quality Research Center, University of California, Davis, USA, yjzhao@ucdavis.edu

The impact of aerosols on regional air quality necessitates improved understanding of their emission and microphysical properties. The size distributions of black carbon (BC) and light scattering particles (LSP) were measured with a single particle soot photometer on board the NASA DC-8 aircraft during the ARCTAS mission 2008. Air sampling was made in the air plumes of both urban and forest fire emissions over California during the CARB (California Air Resources Board) phase of the mission. Air plumes were identified using tracers for fossil fuel (FF) combustion and biomass burning (BB). Enhancements of BC and LSP in BB plumes were signficantly higher compared to those in FF plumes. The average mass concentration of BC in BB plumes was more than twice that in FF plumes. Distinct ***emission ratios of*** BC/CO_2, BC/CH_3CN, CH_3CN/CO, and CO/CO_2 were estimated for the plumes from the two sources. The size distributions of BC and LSP also showed different behaviours. The BC count median diameter of 115 nm in FF plumes was smaller compared to 141 nm in the BB plumes. BC aerosols were thickly coated in BB plumes as the average shell/core ratios were 1.47 and 1.24 in BB and FF plumes, respectively.

U-Th systematics and chronology of of CH_4-derived $CaCO_3$ crusts of the Barents Sea

DIANA SAHY[1]*, AIVO LEPLAND[2,3], STEPHEN R. NOBLE[1], DANIEL J. CONDON[1], HARALD BRUNSTAD[4].

[1]NERC Isotope Geoscience Laboratory, Keyworth, UK (*correspondence: dihy@bgs.ac.uk)
[2]Geological Survey of Norway, Trondheim, Norway
[3]Tallinn University of Technology, Tallinn, Estonia
[4]Lundin Petroleum, Oslo, Norway

$CaCO_3$ crusts forming due to methane oxidation at seafloor seepage sites serve as archives of past fluid flow and methane discharges into ocean and atmosphere. U incoporation into $CaCO_3$ during precipitation offers the opportunity to date the crust formation and growth via U-Th systematics (e.g., Aharon et a., 1997; Teichert *et al*., 2003).

We present U-Th and $^{87}Sr/^{86}Sr$ data obtained on such $CaCO_3$ crusts recovered from the Barents Sea floor using a remotely operated vehicle. $CaCO_3$ phases occur in different modes within the crusts – disseminated within the siliclastic matrix, porosity- and late cavity- filling. These $CaCO_3$ domains, sampled by microdrilling, display $[^{230}Th/^{232}Th]_{AR}$ from 0.9 up to ~200 and ^{232}Th concentrations from ~10 to 7000 ppb. Intra-crust U-Th dates range from ~13.1 ± 0.4 to 8.9 ± 0.4 ka. Older dates come from $CaCO_3$ disseminated within the sediment matix while younger dates are from late cavity filling $CaCO_3$. Layered cavity fills yield resolvable growth histories on the order of 1.0 kyr. Combined such dating results can be used to constrain the histories of CH_4 seepage in the Barents Sea.

$^{87}Sr/^{86}Sr$ has been analysed on aliquots drilled adjacent to U-Th sample sites. For the majority of crust samples both $^{87}Sr/^{86}Sr$ and $\delta^{234}U$ are close to expected values for modern/Holcene seawater. In addition, a sample of a matrix-dominated tubestone representing a subsurface carbonatized fluid conduit, has more radiogenic $^{87}Sr/^{86}Sr$ values and $\delta^{234}U$ closer to secular equilibrium. Such contrasts in $^{87}Sr/^{86}Sr$ and initial $\delta^{234}U$ reflect distinctly different fluid chemistries forming surface and subsurface $CaCO_3$ precipitates. These data, together with crust data from from other seeps, demonstrate the utility of U-Th for constraining CH_4 seepage duration and absolute timing.

The use of mass spectrometry based proteomics has the capability for direct measurement of proteins produced by microbial life. These proteins can include biomarkers for nutrient stress or microbial taxonomy, as well as enzymes that are responsible carrying out biogeochemical reactions. Most biogeochemically-relevant enzymes require one or more metal atoms for catalytic activity. We report on the analyses of samples collected from a range of depths in the Equatorial Pacific and Eastern Tropical South Pacific. Analyses involved total protein extractions, enzymatic digestion, multi-dimensional chromatographic separation, mass spectrometry analyses, peptide mapping by high performance computing, and quantitative estimates. Proteins of interest will be discussed with a particular focus on metalloenzymes that contain nickel, cobalt, copper, and iron.

Origin of atmospheric dust and the associated anthropogenic lead around Omura Bay, West Japan

YU SAITOH[1]*, YU UMEZAWA[2], KAZUAKI KAWAMOTO[2], MASAHARU TANIMIZU[3] AND TSUYOSHI ISHIKAWA[3]

[1]CAMCR, Kochi University, B200 Monobe, 783-8502, Japan (*correspondence: jm-yu-saitoh@kochi-u.ac.jp)
[2]Graduate School of Fisheries Science and Environmental Studies, Nagasaki University
[3]Kochi Institute for Core Sample Research, JAMSTEC

In order to evaluate the responsibility of the cross-border pollution to the atmospheric environment in West Japan, we measured the trace element concentration and Sr-Pb isotope ratios of aerosol particles collected at the eastern hill of Omura Bay with temporal high resolution from May 2011 to June 2012. The acid-soluble component of the aerosol samples contain more than 10 times the amount of Cd and Pb that the residual dust components contain. This suggests that these elements are mainly of anthropogenic origin. The $^{87}Sr/^{86}Sr$ of silicate component is high in winter and spring (0.712-0.714), and is lowest in summer (0.706). These high and low ratios are typical of Asian dust and the local sediment, respectively. The seasonal change is considered to reflect the difference of dominant wind direction between winter and summer. Although the correlation between $^{87}Sr/^{86}Sr$ and soluble Cd and Pb ($r>0.7$) suggests that the anthropogenic components are transported with the Asian dust, the isotope ratios of soluble Pb ($^{206}Pb/^{207}Pb$: 1.16 , $^{208}Pb/^{207}Pb$: 2.44) suggest that their origin is Japan in spring, when much amount of Asian dust arrives, while those in fall and winter ($^{206}Pb/^{207}Pb$:1.13-1.15 , $^{208}Pb/^{207}Pb$: 2.42-2.43) suggest far-east Russian and/ or Central Asian origin. Perhaps because dust particles act as adsorbent, lead concentration is highest in the season of Asian dust. Cross-border pollution is highlighted in winter when the coal combustion for heating is at the peak under the wintry atmospheric pressure pattern around East Asia.

Melting history of the Pozantı-Karsantı ophiolite, Turkey: Implications from whole-rock and mineral compositions

SAMET SAKA[1]*, IBRAHIM UYSAL[1], R. MELIH AKMAZ[2] AND MELANIE KALIWODA[3]

[1]Karadeniz Technical University, Trabzon, Turkey (*correspondence: sakasamet61@gmail.com)
[2]Bülent Ecevit University, Zonguldak, Turkey
[3]Mineralogical State Collection Munich, Germany

Pozantı-Karsantı ophiolite, from the eastern Tauride, Turkey, is represented by mantle unit and overlying crustal sections composed of ultramafic to mafic cumulates and isotropic gabbros. Harzburgitic to dunitic mantle peridotites are characterized by low Al_2O_3 (0.11–1.01 wt%) and CaO (0.10–1.07 wt%) contents. The low whole rock Al and Ca values are consistent with their high Cr# of spinel values, ranging between 44 and 78. These spinels are generally have low TiO_2 (<0.06% wt%) contents, although spinel in some samples show enrichment up to 0.25 wt%. Chondrite-normalized whole rock and clinopyroxene REE contents show depletion towards HREE to MREE. However, all peridotite samples show marked enrichment of LREE compared to MREE. Both whole rock and clinopyroxene HREE patterns of some peridotite samples follow the melting residue lines, and are modeled ~25–27 fractional melting in spinel stability feld. However, depletion of MREE compared to HREE is stronger in some samples and the HREE to MREE patterns do not follow the melting lines produced by various degree of fractional melting in spinel stability field. These samples can be modeled by 5 to 10% fractional melting started at garnet stability field and followed in spinel stability field with additional 22 to 15% melting. The melting degrees obtained from whole rock and clinopyroxene REE data as well as spinel composition are consistent with each other, and confirm that the mantle unit of the Pozantı-Karsantı ophiolite is represented by up to 27% melting at different pressure conditions. The LREE enrichment observed in whole rock and clinopyroxene as well as higher TiO_2 contents of high-Cr# spinels in some samples do not suggest that the mantle unit of the Pozantı-Karsantı ophiolite is the simple melting residue. However, these feature of the peridotites is suggested to be due to the interaction of LREE and TiO_2 rich melts/fluids with formerly depleted peridotites. This interaction, taking place at suprasubduction zone environment, may increase the LREE contents of the peridotites and also cause the equilibration of Ti-depleted spinel to Ti-richer composition.

Correction of initial-disequilibrium on U-Th-Pb system for dating of young zircons

SHUHEI SAKATA[1]*, SHINSUKE HIRAKAWA[1], HIDEKI IWANO[2], TOHRU DANHARA[2] AND TAKAHUMI HIRATA[1]

[1]Laboratory for Planetary Sciences, Kyoto University, Kyoto, Japan (junchan@kueps.kyoto-u.ac.jp)
[2]Kyoto Fission Track Co. Ltd., Kyoto 603-8832, Japan

Major analytical problems associated with U-Pb age determination of the young zircons (e.g. < 1 Ma) is the initial-disequilibrium in the U-Th-Pb decay systems through the crystallization of zircon in source magma. To correct the effect of initial disequilibrium, the ratio of the distribution coefficient between source magma and zircon crystal (D) for Th and U ($f_{Th/U}$ =D^{Th}/D^{U}) must be defined [1]. To achieve this, we have determined both the ^{238}U-^{206}Pb and ^{232}Th-^{208}Pb ages obtained for three tephra zircon samples collected from Kirigamine rhyolite (Ar-Ar age is 0.945±0.005 Ma [2]), Bishop tuff (Ar-Ar age is 0.7589±0.0036 Ma [3]) and Toga pumice (Ar-Ar age is 0.42±0.01 Ma [4]) by means of laser ablation-ICPMS technique. The resulting ^{232}Th-^{208}Pb ages were 0.940±0.010 Ma for Kirigamine, 0.759±0.016 Ma for Bishop, and 0.4296±0.0066 Ma for Toga, demonstrating that the resulting ages were consistent with the previously reported values. The $f_{Th/U}$ values could be calculated based on the measured ^{232}Th-^{208}Pb ages and $^{206}Pb/^{238}U$ ratios, and the resulting $f_{Th/U}$ values agreed well within the analytical uncertainties. The disequilibrium-corrected ^{238}U-^{206}Pb age can be calculated under the assumption that the $f_{Th/U}$ value did not vary significantly among the zircons. To evaluate this, we have measured the ^{238}U-^{206}Pb and ^{232}Th-^{208}Pb ages for zircons from Sanbekisuki tephra [5]. The $f_{Th/U}$ values used for the correction was based on the average of three $f_{Th/U}$ values obtained here ($f_{Th/U}$ = 0.51 ± 0.11). The corrected ^{238}U-^{206}Pb age was 92.1 ± 8.4 ka, which agreed with the ^{232}Th-^{208}Pb age (90.4 ± 9.5 ka) within the analytical uncertainties. The good agreement in the corrected ^{238}U-^{206}Pb age and ^{232}Th-^{208}Pb age demonstrates clearly that the present $f_{Th/U}$ value for the Sanbekisuki zircon was consistent with the averaged $f_{Th/U}$ value calculated above. In conclusion, we can construct more accurate and effective U-Th-Pb dating method based on the $f_{Th/U}$ value defined in this study, especially for the young zircons (0.1 – 1 Ma).

Application of geochemical and statistical approach to assess metal contaminantion in marine sediments

FANI SAKELLARIADOU[1]

[1]University of Piraeus, Dept of Maritime Studies, fsakelar@unipi.gr

The two principal sources for heavy metals at the sea are lithogenic and anthropogenic ones. Sediments are considered as physical traps for many environmental pollutants [1]. At the present study, sediment samples from Lavrio port (located 60km SW of Athens, in Greece) were analyzed for the determination of metal content. The area is well known for the presence of mixed sulphide mineralisation (galena, sphalerite and pyrite) hosted within marbles and limestones. Samples were digested with a mixture of conc. acids at high temperature [2]. Metal contents were measured by AAS. Data set was treated with multivariate and geostatistical approach. The dendograms provided by hierarchical cluster analysis gave the (Zn, Pb, Mn) and (Cu, Cr, Ni) groups reflecting the mineralization clusters (the latter group representing also, to some extent, the ultramafic association) as well as the (Fe, Al) group standing for clays and other alluvial matter. Application of Principal Component Analysis showed that sampling sites have positive scores for Mn, Zn and Pb. Inter-element correlation coefficients corresponded to values greater than 0,92 for the pair (Zn, Fe), greater than 0,84 for the pairs (Mn, Zn), (Zn, Pb), (Mn, Fe), (Pb, Fe) and (Cr, Al), and greater than 0,68 for the pairs (Al, Fe), (Fe, Cu) and (Cu, Zn). The Simple Kriging geostatistical approach was applied allowing data interpolation [3]. Spatial patterns of Pb, Zn and Cu showed the highest enrichment around the new berth (cited at the eastern part of the harbour), with elevated content around the main harbour area.

Wettability alteration of calcite surface induced by ion exchange

H. SAKUMA[1,2], M.P. ANDERSSON[1] AND S.L.S. STIPP[1]

[1]Nano-Science Center, Department of Chemistry, University of Copenhagen, Copenhagen, Denmark (*correspondence: sakuma.h.aa@m.titech.ac.jp, ma@nano.ku.dk, stipp@nano.ku.dk)

The interaction of water and organic molecules with mineral surfaces controls a range of processes in nature and industry. The thermodynamic property, surface tension, helps describe these interactions. We investigated the change in water affinity for a calcite ($CaCO_3$) {10.4} surface where Ca^{2+} and CO_3^{2-} ions were sequentially replaced with Mg^{2+} and SO_4^{2-}, in the bulk solid and at the surface, which is a system of broad interest, for biomineralisation, oil production, and many others. We used electronic structure calculations based on density functional theory (DFT).

Mg^{2+} substitution for Ca^{2+} is favored but only when SO_4^{2-} ions are present and $MgSO_4$ incorporates preferentially as ion pairs at the fluid-calcite interface. Mg incorporation weakens organic molecule adhesion, while strengthening water adsorption (Fig. 1). Thus, Mg^{2+} substitution renders the calcite surface more water wet, or hydrophilic, making it less favourable for organic compound attachment. We estimated the change in calcite surface tension after ion exchange and determined the resulting change in macroscopic wettability. When only 10% of surface Ca is replaced by Mg, contact angle changes dramatically, i.e. 40 - 70º, converting a hydrophobic surface to a mixed wet surface. Producing magnesium calcite is a simple trick organisms can use for controlling calcite growth and the process helps explain why oil recovery from carbonate reservoirs is enhanced when both Mg^{2+} and SO_4^{2-} are present in the pore water.

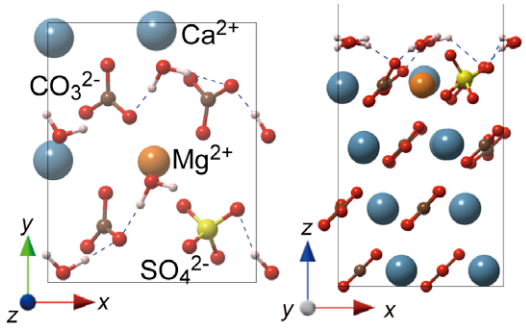

Figure 1: The lowest energy configuration for four water molecules on a calcite {10.4} surface with substitution by a Mg SO_4 ion pair. (Left) Top view. (Right) Side view.

Characterization and Surface Reactivity of Natural and Synthetic Magnetites

C. SALAZAR-CAMACHO[1], M. VILLALOBOS[1]* AND M.D.L.L. RIVAS-SÁNCHEZ

[1]Environmental Bio-Geochemistry Group, Geochemistry Department, Geology Institute (*correspondence: mariov@geologia.unam.mx)

[2]Laboratorio de Paleomagnetismo, Geophysics Institute UNAM, Coyoacan, CU, Mexico 04510, D.F.

Magnetite is an Fe(II/III) oxide mineral that occurs naturally and potentially as small particles with significant surface reactivity, and although much work is reported on synthetic material [1,2], little work exists for natural samples. The goal of the present work was to carefully characterize four natural magnetite samples from an iron ore deposit [3] and two synthetic commercial reference samples, and to compare their surface characteristics and reactivity with the aim of evaluating their geochemical behavior towards adsorption of environmentally relevant ions, as well as their potential for use as environmental remediation sorbents. In addition, their As(V) adsorption behavior was determined at pH 6, and was analyzed as related to the surface characteristics and particle aggregation behavior determined.

The analyses revealed high magnetite purity in the natural samples, and specific surface areas (SSA) ranging from 1 to 8 m^2/g. Small alumino-silicate impurities were found in natural magnetites, apparently occurring at the particle surfaces and significantly lowering the magnetite isoelectric point. All samples are composed of aggregates of 39-52 nm magnetite particle units, but highly aggregated with very large size dispersions. The synthetic sample with the smallest particle size (30 nm in average - 39 m^2/g) showed its entire surface area available for adsorption, despite its highly aggregated state observed, suggesting an open and highly dynamic aggregate framework. The other larger samples showed more complex aggregation behavior, which produced: (1) a widely variable As(V) adsorption behavior with no clear predictable pattern among samples; and (2) a large decrease of the As(V) adsorption maxima with increasing solids concentration (Cs) imposed in the experimental set-up for any one particular sample. Therefore, we recommend high caution in using the BET-SSA and Cs parameters when performing experimental adsorption work with microsized magnetite.

U-Pb age of a syn-collisional lower continental crust anatetic event, Socorro-Guaxupé *Nappe*, SE Brazil

C.A. SALAZAR-MORA[1]* AND M.C. CAMPOS NETO[1]

[1]Geosciences Inst., São Paulo Univ., 05508-080, Brazil. (*correspondance: claudio.mora@usp.br; camposnt@usp.br)

The Southern Brasília Orogen, SE Brazil, accurs along the southern border of the São Francisco Craton and is structured as a pile of Ediacaran syn-metamorphic thicked-skinned nappes that diachronically migrate towards the cratonic margin. The Socorro-Guaxupé Nappe (SGN) is the older and upper allochthon that represents an Andean-type magmatic arc [1]. U-Pb ages in zircon from charnockites, mangerites and Grt-granulites [1] indicate an arc activity around 670 Ma in a subduction-related orogenesis followed by ultra-high-T metamorphism and plutonism lasting until 625 Ma. This age is thought [2] to represent the metamorphic peak of the SGN. In the present study we report on new *in situ* U-Pb and Lu-Hf analysis (both LA-ICP-MS) in zircons from syn-tectonic charnockitic leucosomes that comprise the metatexitic unit of the SGN.

Charnockitic leucosomes were generated under Hbl dehydration melting conditions following the reaction Hbl + Qtz ⇔ Opx + Cpx + Pl ± Melt, which implies minimum temperatures of 850ºC. The leucosomes presented two zircon tipologies. The first comprises bipyramidal-prismatic grains with oscilatory zoning and high luminescence, sometimes preserving low-luminescence cores with 670 Ma. These high luminescene and oscilatory zoning grains show 19 concordant ages at 621 ± 16 Ma. The second tipology of zircons are isometric and *soccer-ball*-type. These grains show sector zoning and a concordia age of 608 ± 4 Ma. Th/U ratios from the *soccer-ball* grains vary from 1.378 to 2.107, whereas prismatic grains vary from 0.118 to 1.774. Some authors also reported high Th/U values from demonstrably syn-metamorphic, high-T melts [3]. ε_{Hf} signatures between -13 and -21 in both tipologies of zircon grains provide evidence of crustal reworking. Despite the 16 Ma error in the age of the prismatic grains, Th/U values clearly sperate the two tipologies of zircon. The older prismatic grains may be related to the onset of the metamorphic peak (~625 Ma), whereas the isometric ones provide evidence of long-lived high-T conditions until ~608 Ma.

Physico-chemical evolution of Fe-Si-rich interfacial layers during olivine carbonation reactions

G. D. SALDI[1]* , H. GUO[1], D. DAVAL[2], J. DAVIS[1] AND K. G. KNAUSS[1]

[1]Earth Sciences Division, Lawrence Berkeley National Laboratory, 1 Cyclotron Road, Berkeley, CA 94720, USA gdsaldi@lbl.gov (*presenting author); hguo@lbl.gov; jadavis@lbl.gov; kgknauss@lbl.gov.

[2]LHyGeS, Université de Strasbourg/EOST-CNRS UMR 7517, 1 rue Blessig, 67084 Strasbourg, France ddaval@unistra.fr.

Several recent investigations of mineral carbonation reactions have shown that the formation of Si-rich protective layers at the interface between olivine and aqueous solution can significantly slow down olivine dissolution, thus limiting the rate of conversion to Mg-carbonates.

The experiments conducted on natural Fe-bearing olivine in flexible Au-bags at 90 and 150 °C and with CO_2-saturated fluids show that the presence of Fe in the mineral+fluid system favors the formation of Fe-Si-rich protective layers. The passivating properties of these coatings originate from the strong interaction between Fe(III) and silica and their action is linked to the permanence of oxidizing conditions in the aqueous fluid.

Transmission electron microscope (TEM) analysis of FIB thin sections of the mineral interfacial region allowed us to study the chemical compositon and the physical properties of Fe-Si-rich layers as a function of the progress of the carbonation reaction. In particular, a series of batch experiments of different duration was performed on a natural olivine powder (150-300 μm) at 150 °C and pCO_2=100 bar to describe the evolution of the olivine/water interface over an overall period of one month. During the initial stage of the reaction, the olivine surface is affected by the incipient precipitation of Fe oxide particles, in association with small amounts of amorphous silica, which cover in a non-uniform fashion the mineral surface and prompts the formation of a Fe^{3+}-Si layer. The oxidation of the Fe(II) released by dissolution gradually consumes the oxygen initially dissolved in the aqueous volume, leading to reducing conditions. The change of redox conditions brings about the breakdown of the Fe-Si-rich layer and re-activates the dissolution of the coated olivine surface. Increased concentrations of Fe^{2+} and Mg^{2+} and $SiO_{(aq)}$ accelerate the rates of the carbonation process by the formation of Mg-Fe carbonate solid solutions which cover the olivine grains on top of a relatively porous (~2μm thick) residual coating, composed of abundant amorphous silica.

SO_2 camera measurements on Stromboli

GIUSEPPE SALERNO[1], GEORGINA SAWYER[2] AND MICHAEL BURTON[3]

[1]INGV Osservatorio Etneo, Italy, salerno@ct.ingv.it
[2]MetOffice, UK, georgina.sawyer@metoffice.gov.uk
[3]INGV Pisa, Italy, burton@pi.ingv.it

The development of the SO_2 camera, an instrument that allows images of SO_2 amounts to be collected, has opened up new possibilities and insights into degassing behaviour at volcanoes. Here we present recent measurements collected on Stromboli volcano, which reveal patterns in the SO_2 flux emitted from the volcano. Our measurements are compared with the automatic network of scanning spectrometers on the Island which monitor SO_2 emissions. Furthermore we demonstrate a fully integrated retrieval system which takes full account of the light dilution effect, allowing much improved quantification of the measured fluxes.

Quantitative analysis with the Cameca SXFIVE FE at high lateral resolution: Applications to geochronology and mineralogy

P. SALIOT[1] C. HOMBOURGER[2] AND M. OUTREQUIN[3]

[1]philippe.saliot@ametek.com
[2]chrystel.hombourger@ametek.com
[3]michel.outrequin@ametek.com

The development of the Schottky emitter and its implementation as electron source in Electron Microprobe has significantly improved the characterization of materials in earth sciences and in metallurgy.

The strength of an Electron Probe Microanalysis (EPMA) is the ability to accurately measure and quantify element in traces at few 10's ppm level. The Field Emission (FE) Source allows trace element analysis with high beam currents thanks to the high brightness of the source

Analysis at low beam voltage is used in order to take full advantage of the small spot sizes achievable with a Field Emission Source. Thus, the analytical resolution is not limited anymore by the beam diameter but only by the diameter of the X-ray emission volume.

This will be illustrated, in a first example, by measuring different areas in a Monazite grain. U, Pb and Th are quantitatively analyzed with high precision in order to characterize age domains.

In a second example, quantification of small refractory phases (hibonite, grossite, perovskite, …) formed by gas condensation in the solar nebula will be presented.

Magmatic Epidote in Calcalkaline tonalite, Dehnow (NW Mashhad, NE Iran)

R. SAMADI[1], S. J. SHEIKH ZAKARIAEE[1] AND N. SHIRDASHTZADEH[3]

[1]Department of Geology, Science and Research Branch, Islamic Azad University, Tehran, Iran
[2]Department of Geology, Facualty of Science, University of Isfahan, Isfahan, Iran

Introduction

The granitoids of Dehnow in NE Iran are part of a calc-alkaline stock (tonalite to granodiorite and diorite) that intruded the remnants of the Paleo-Tethys Ocean in the Triassic [1]. Epidote is commonly known as primary igneous mineral in intermediate plutonic rock [2]. In Dehnow granitoid it occurred as inclusions in the phenocrystic garnet grains or as subhedral grains associated with biotite.

Mineral Chemistry

The major element composition of epidote indicates a Xep (Fe/(Fe+Cr+Al-2)) between 0.43 to 0.65. The average pistacite (Ps) component of the epidote is 0.15 and 0.18 for the inclusions in the garnets and Dehnow granitoid, respectively.

Disscusion and Conclusion

Textural criteria may be used to distinguish magmatic and subsolidus (deuteric) epidotes. [3] and [4] argued that euhedral, weakly pleochroic epidote enclosed within biotite is magmatic. The low TiO_2 contents (<0.17%) of most epidote inclusions and epidote in the groundmass suggest that they are primary according to [5], who ascribe TiO_2<0.2% to primary epidote. Based on [6], the Ps values indicate a low fO_2 condition but suggesting that the epidote inclusions crystallized under relatively lower fO_2 conditions.

Geochemical and isotopic studies of the Hooghly River Estuary, India: Natural vs. anthropogenic sources of organic carbon

SAUMIK SAMANTA[1], TARUN K. DALAI[1]* AND JITEDNRA K. PATTANAIK[1]

[1]Department of Earth Sciences, Indian Institute of Science Education and Research-Kolkata, Mohanpur 741252, INDIA (*correspondence: dalai@iiserkol.ac.in)

Dissolved, suspended and bed loads have been sampled sesonally from the Hooghly River Estuary, the major distributary of the river Ganga. The samples have been analyzed for pH, temperature, TDS, salinity, major ions, $\delta^{18}O$ of water and $\delta^{13}C$ of dissolved inorganic carbon (DIC). The results show clear seasonal variations, wth lower concentrations of major ions during the monsoon period when the water discharge is the highest. Based on salinity- $\delta^{18}O$ variation trends, which are similar to those observed earlier [1], freshwater can be characterized by $\delta^{18}O$ values of ca. -6‰ and ca. -7‰ during the summer and monsoon periods, respectively. This suggests that overall contributions of rainwater to the Hooghly River dominates over those from snow melt in the upper reaches. Calculations made for mixing of seawater and river water suggest that at Gangasagar where the the river drains into the Bay of Bengal, freshwater constitutes ca. 15% and 30% of the water budget during summer and monsoon periods, respectively.

Salinity shows well correlated linear variations with DIC and $\delta^{13}C_{DIC}$ which indicate that mixing exerts the major control on DIC abundances. Based on these trends, it is inferred that $\delta^{13}C_{DIC}$ of freshwater is ca. 1.5‰ lower during monsoon period than in summer. However, $\delta^{13}C_{DIC}$ values are in general lower than those expected due to conservative mixing. Although calcite precpitation may be one of the underlying causes, this seems unlikely in the Hooghly estuary. A more likely explanation is supply of addtional organic carbon to the estuary, oxidation of which could add to DIC pool. The source of such organic carbon is most likely pollution and needs to be assessed. $\delta^{13}C_{DIC}$ data of this study suggest that processes such as outgassing of CO_2 from the waters and biological productivity are insignificant in regulating the DIC variation in the estuary.

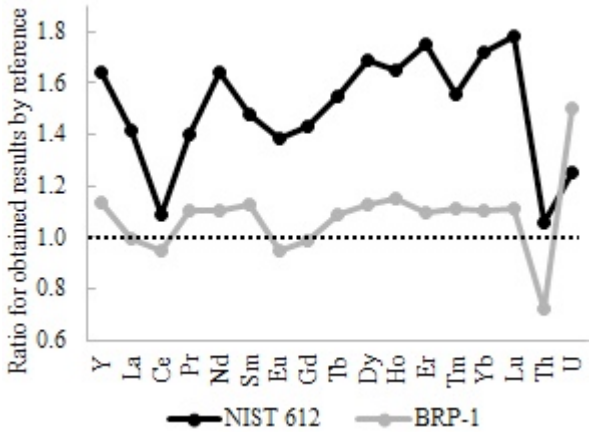
Determination of trace elements in iron formations by LA-ICP-MS

G.M.S. SAMPAIO[1], A.T. DE ABREU[1], H.A. NALINI JR[1]* AND C.C. LANA[1]

[1]Federal University of Ouro Preto, Ouro Preto, MG 35400-000, Brazil (*correspondence: nalini@degeo.ufop.br)

Introduction

Here we present a method to measure trace elements (Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, Th and U) in banded iron formation. The samples (XRF fused beads) were abladed (spot and raster) in a Nd:YAG 213 nm New Wave Laser coupled to an Agilent 7700x ICP-MS. Internal standards ^{29}Si and ^{57}Fe from the certified reference BRP-1 (in fusion beeds) and the glass NIST SRM 612 were used to callibrate the unknows. We discuss our results based on repeated analyses of the reference material IF-G (GIT-IWG, France).



Results and discussion

The internal standards ^{29}Si and ^{57}Fe showed no statistical diference and proved be suitable for the intended use. Although the slight increase in the instrumental error, the raster pattern showed better mean results than the spot. The calibration with the glass SRM 612 showed a significative bias, as demonstrated in the Figure 1. The best results were obtained by calibration with BRP-1 reducing the matrix effect. Figure 1: Ratio between obtained results using NIST 612 and BRP-1 and values from IF-G certificate.

Aknowledgments

Microflora of native biofilm on activated carbon under filtration of fulvic acids

O. SAMSONI-TODOROVA*, N. KLYMENKO AND T. CHEKHOVSKAIA

Institute of Colloid Chemistry and Chemistry of Water, 42 Vernadsky Avenue, Kyiv, 03680, Ukraine (*correspondence: samsoni@online.ua)

Carbon filters long-term exploitation for drinking water treatment causes the inevitable formation of native biofilms on the surface of porous activated carbon (AC). The aim of this paper was to assess the quantitative and qualitative composition of biofilms microflora that formed spontaneously on AC KAU by filtering of fulvic acids (FC) model solutions in the different conditions. Initial composition of these solutions met Dnieper river water. Filtering time was more than 6 months.

Obtained results are shown in the table 1.

Samples	Microorganisms types and quantity, cells/gAC
AC with native biofilm that was formed by passing of FA solutions (pH 2) and hydrogen peroxide	Yeast; $2.0 \cdot 10^2$
AC with native biofilm that was formed by passing of FA solutions (pH 2)	Fungi, yeast; $6.0 \cdot 10^2$
AC with native biofilm that was formed by passing of FA solutions (pH 6) and hydrogen peroxide	Fungi, yeast; $3.5 \cdot 10^4$
AC with native biofilm that was formed by passing of ozonated FA solutions (pH 6)	Fungi, bacteria; $12.1 \cdot 10^4$

Table 1: The qualitative and quantitative composition of native biofilm microorganisms on AC after long-term filtering of FA solutions

Native biofilms were composed from yeast and fungi in the first two cases. This is due to the fact that filtered through charcoal FA solution had low pH, which is more acceptable for the activity of these microorganisms groups. In this case the quantity of microorganisms is lower than by neutral solutions filtering in two orders.

Quantity of live biofilm biomass was about 30% of the total biomass in the biofilm layers near the media and in the outer layers it was about 100%.

Evolution of deep crustal roots of the Arkhangelsk Diamondiferous Province: Evidences from crustal xenoliths and xenocrysts from Devonian kimberlite pipes

A.V. SAMSONOV[1]*, J.G. GRIBAN[1], YU.O. LARIONOVA[1], A.A. NOSOVA[1], V.V. TRETYACHENKO[2], E.N. LEPEKHINA[3] AND A.N. LARIONOV[3]

[1] IGEM RAS, Moscow, Russia (*correspondence: samsonovigem@mail.ru);
[2] NIGP AC "ALROSA", Arkhangelsk, Russia;
[3] VSEGEI, St.-Petersburg, Russia

Juvenile continental crust of the Arkhangelsk diamondiferous province (ADP) crystalline basement consists of ca 2.0 Ga calc-alkaline granodiorites, gabbros, metasediments with minor 1.9-1.7 Ga granites. This crust was formed during evolution of the large Lapland-Kola-Dvina orogenic belt [1]. Investigations of crustal xenoliths and zircon xenocrysts from the Devonian kimberlites allow us to recognize several stages in evolution of deep crustal roots of the ADP.

The 2.0 Ga lower-crustal (8-16 kbar) xenoliths of calc-alkaline mafic and intermediate rocks with T_{DM}(Nd) model ages of 2.0-2.2 Ga possibly represent underplated melts of the subduction stage.

The 1.9-1.7 Ga zircon xenocrysts prevail in a whole zircon population of all kimberlite pipes. The zircons probably grew at collisional and post-collisional stages, because of wide range of geochemical features with distinct high-P garnet-equilibrium population.

The 1.5 Ga zircon xenocrysts occur in all kimberlite pipes and might be captured from deep rapakivi granite plutons that are not recognized on the ADP surface.

The 1.2-1.0 Ga zircon xenocrysts were found in all kimberlite pipes and these zircons might be captured from a lower crust reworked during the Grenville Orogeny event which is not revealed on the ADP surface.

The 0.38 Ga Gar-pyroxenite xenoliths (T_{DM}(Nd) model ages of 0.7-0.8 Ga) are common for the V.Griba pipe and might be regarded as a cumulus of Devonian mantle magmas buried (?) beneath the crust.

[5] Mighty River Power Chile (silke.lohmar@geotermia.cl)

The nature of the interplay between active tectonics and fluid flow is a key feature to better understand the chemical evolution of fluids in geothermal and hydrothermal systems.

The objective of our current research is to assess the nature of the interplay between brittle deformation and chemical evolution of fluids and mineral paragenesis in the geothermal field of Tolhuaca in the Southern Andes volcanic zone. Tol-1 is a vertical 1.080 m deep borehole which could yield relevant information regarding the evolution of the Tolhuaca geothermal system. The methodology includes the structural and geochemical analysis of oriented faults, fault-veins and veins in the core. Fluid inclusions analysis by microthermometry, LA-ICP-MS and Raman spectroscopy will allow a better understanding of the feedback between the fluid flow episodes and the mineralization. More than 120 structural measurements were performed and 47 samples were taken for thin & fluid inclusions sections.

Our preliminary results show that there is a strong correlation between abundance of structures and rock type. Lava intervals exhibit more intense fracturing and veining than tuff and volcaniclastic intervals. In the upper 300 m of the core, structures are primarily steeply dipping with a dominant normal sense of displacement (some dextral component). Below a cataclastic zone at 300 m, structures are more variable in dip and sense of motion, with some reverse faults. Fluid inclusions petrography reveals the periodically feedback between fault-fractures networks activation and mineral mineralization sealing the conduits for fluid flow.

Changes in bacterial diversity and community structure within a geochemically variable uranium-mine water treatment plant

I. SÁNCHEZ-CASTRO[1]*, M. LÓPEZ-FERNÁNDEZ[1], A. AMADOR-GARCÍA[1], V. PHROMMAVANH[2], J. NOS[2], M. DESCOSTES[2] AND M.L. MERROUN[1]

[1]Department of Microbiology, University of Granada, Spain (*correspondence: sanchezcastro@ugr.es)
[2]R&D Department, AREVA Mines, France

Monitoring and treatment of mining waters, containing heavy metals and radionuclides, are essential throughout the uranium mining. In order to meet the increasingly demanding regulatory requirements, optimized treatment and remediation strategies must be developed through the use of comprehensive biogeochemical models. Since biotic factors have been described to play a key role in these processes, an exhaustive analysis of the microbial diversity emerges as an important prerequisite.

Therefore, this work aims to assess the bacterial diversity occurring along the drainage treatment settling ponds of a former uranium mine and to link it to the associated geochemical features. A set of four sediment samples were taken along the treatment facility (before treatment, in the two treatment ponds and after treatment).

Highly diverse bacterial communities were observed in all samples by analyzing a total of 400 clones through a PCR-RFLP approach targeting the 16S rRNA gene. The clone libraries were dominated mainly by sequences closely related to the phyla *Acidobacteria*, *Actinobacteria*, *Bacteroidetes*, *Firmicutes*, *Planctomycetes* and specially *Proteobacteria*. Within this predominant phylum, relative abundance of *Alpha-*, *Beta-*, *Delta-* and *Gammaproteobacteria* varied among the different samples indicating specific distribution of the different bacterial populations according to geochemical variations. Links between the bacterial diversity and the geochemistry of the sediments will be discussed. Moreover, detection of sequences affiliated with metal-reducing bacteria (e.g., *Rhodoferax*, *Ferribacterium*, *Geobacter*, *Geothrix*, *Anaeromyxobacter*) in all four samples, suggests that there is an evident potential for the bioremediation of the studied site.

Raman spectrocopy evidence for the ikaite-calcite/Vaterite transformation

N. SÁNCHEZ-PASTOR[1]*, M. OEHLERICH[2], J.M. ASTILLEROS[13], M. KALIWODA[4], C.C. MAYR[256], W. W. SCHMAHL[245] AND L. FERNÁNDEZ-DÍAZ[13]

Ikaite ($CaCO_3 \cdot 6H_2O$) is a metastable phase that crystallizes from alkaline waters with high phosphate concentrations at temperatures close to 0ºC. Above 4ºC ikaite crystals transform rapidly to produce calcite pseudomorphs which are considered a valuable paleoclimatic indicator. In this work synthetic ikaite crystals were grown at near-freezing temperatures using an experimental setup that involved the diffusion of $CaCl_2$ through a silica gel prepared using natural water from the Argentinian lake "Laguna Potrok Aike". After recovering the crystals from the gel, their transformation was monitored by in situ collecting Raman spectra. The spectra taken in the first stages of the transformation showed the characteristic carbonate vibration modes of ikaite at 1067 cm^{-1} (symmetric CO strech) and 700 cm^{-1} (in plane band). The second most intense band is due to lattice vibrations and found at 200 cm^{-1}, with secondary peaks at 136, 216 and 265 cm^{-1}. Moreover, the ikaite spectra show good resolved OH modes at 3180, 3240 and 3424 cm^{-1} whose intensity changes could be followed. During the transformation new bands at 1081 and 1085 cm^{-1}, characteristic for vaterite and calcite, appeared in the spectra. After a few hours, the Raman spectrum obtained was identical to that of calcite. However, the external shape of ikaite crystals remained unchanged during the replacement. A mechanism involving the coupling of ikaite dissolution and calcite/vaterite crystallization and the generation of a large amount of porosity is propossed for this transformation.

[2]Department of Mineralogy and Petrology and IACT (CSIC-UGR), Faculty of Science, University of Granada, Avda. Fuentenueva s/n 18002, Granada, Spain (nieto@ugr.es)

The Galera Fault zone is a sinistral fault, which is 23 km long and strikes N48ºE [1, 2]. The fault zone is 1.5 km wide with several parallel splays dipping NW between 40º and 60º, although vertical dips have also been noted locally.

During field observations within the area, clastic dikes were identified crosscutting the stratification of the sequence as well as filling spaces in between stratification planes. The clastic dikes are composed of medium sand size grains in a matrix of clay minerals. The mineral species identified through x-ray diffraction include quartz, albite, mica, chlorite and smectite. The SEM study reveals prismatic oriented fragments of diatoms. The muscovite and clinochlore crystals show a larger grain size than smectite which exhibits a flaky morphology and its presence is associated with the diatom fragments.

Injection clastic dikes have been previously described as a form of seismites, and their emplacement corresponds to episodic pulses of increasing hydraulic pressure generated by seismic loading [3]. Given that other co-seismic structures such as globular seismites have been identified in the area [4] and considering the clastic origin of the material we could infer that the sediments were saturated with water as a result of fluid circulation asociated with the fault zone and later injected into fractures during seismic events.

Rio Tinto is considered a good geochemical terrestrial analogue of Mars due to its high content of iron and extreme acidic pH [1]. The occurrence of carbonates in this extreme environment is very local and they are found to occur under certain conditions of pH and iron concentration [2]. To understand its formation we have recovered and generated samples from cores, taken from wells BH10 and BH11 of depths of 340 and 620 meters, respectively, under anaerobic and sterile conditions. These wells were drilled during the field campaign of the Iberian Pyrite Belt Subsurface Life (IPBSL) project. IPBSL is a drilling project, currently under development, specifically designed to characterize the subsurface ecosystems operating in the Iberian Pyrite Belt (IPB), in the area of Peña de Hierro, and responsible of the extreme acidic conditions existing in the Rio Tinto basin [3]. The present study emphasizes the mineralogical, geological-biochemical and microbial implication for carbonate formation in Rio Tinto. Herein, we show that the formation of carbonate minerals in Rio Tinto is closely related to microbial activity and that can occur under both oxic and anoxic conditions. The formation of carbonates in such extreme environment could explain the occurrence of carbonates on Mars. Finally, this environmental and experimental study provides potential mineralogical biosignatures that may be useful to test life on Mars and other extraterrestrial habitats.

Thermodynamics of carbon-bearing fluids and oxidized carbon speciation equilibria in subduction zone fluids

CARMEN SANCHEZ-VALLE[1], DAVIDE MANTEGAZZI[1] AND THOMAS DRIESNER[1]

[1]IGP, ETH Zürich, Switzerland
(correspondence: carmen.sanchez@erdw.ethz.ch)

Subduction zones play an important role in the deep carbon cycle as allow the reintroduction of C into the mantle and the recycling through arc magmatism. The occurrence of diamond-bearing fluid inclusions in HP rocks of oceanic origin suggests that C can be efficiently transfered from the slab to the mantle wedge through dissolution reactions driven by slab-derived aqueous fluids (Frezzotti *et al*., 2011). A better understanding of the role of aqueous fluids on C recycling thus relies on the development of robust thermodynamic models of the properties of C-bearing aqueous species at relevant conditions.

In this contribution, we present first experimental data on the thermodynamic properties of oxydized carbon species at high P-T that have been used to constrain a model of the speciation of oxidized carbon in aqueous fluids at subduction zone conditions. The thermodynamic properties of oxydized C-bearing aqueous fluids were determined up to 650 °C and 4 GPa from acoustic velocity measurements performed on Na_2CO_3 and $NaHCO_3$ aqueous solutions with various concentrations (0.1 to 1 *m*). Experiments were conducted on externally heated diamond anvil cells by Brillouin scattering spectroscopy. Densities of the fluids directly obtained from the measured acoustic velocities were used to calibrate an equation of state (EoS) able to predict the thermodynamic properties of carbonated fluids at high P-T conditions. Further, the derived partial molar volume and compressibility of aqueous CO_3^{2-} and HCO_3^- ions were used to constrain the effect of P on the equilibrium constant controlling the speciation of oxidized carbon in high temperature fluids: $HCO_3^- = H^+ + CO_3^{2-}$ (Eq.1). The calculated volume of reaction $\Delta\overline{V}_r$ for Eq.1 is negative at the investigated P conditions, indicating that aqueous carbonate ions CO_3^{2-} are the dominant C-species in high P oxidized fluid. This observation is consistent with direct investigations of the speciation of fluids in equilibrium with carbonate minerals by Raman spectroscopy. The predicted stability of aqueous CO_3^{2-} in high P fluids and the enhanced solubility of carbonate minerals under P, indicate that CO_3^{2-} ions may be major components in slab-derived fluids and may thus control the mobility of other rock-forming elements in subduction zones.

Branched tetraethers derived temperature reconstruction from northwestern Black Sea: Proposition of correction and associated sensitivity test

L. SANCHI[1]*, G. MENOT[1] AND E. BARD[1]

[1]Aix-Marseille Université, CNRS, IRD, Collège de France, CEREGE UM 34, 13545 Aix-en-Provence, France (*correspondence: sanchi@cerege.fr, menot@cerege.fr, bard@cerege.fr)

Proxies based on branched GDGT (glycerol dialkyl glycerol tetraether) core lipids are promising tools to reconstruct past continental temperatures. However their use is not always straightforward, notably because of the uncertainties on the source of these biomarkers .

Here we study the relative distribution of branched GDGTs (brGDGTs) in lacustrine sediments from a core retrieved in the northwestern Black Sea (from 40 to 9 cal ka BP). We first discuss the origins of the branched GDGTs. Comparisons to geochemical proxies from the same core support a dominant terrestrial origin of the brGDGTs during the last glacial, and a strong decrease of the soil derived brGDGTs relative proportion toward the Holocene. As this lowering of the soil vs. lacustrine derived brGDGTs is prone to bias the temperature signal reconstructed with a soil calibration, we propose a correction of this signal with a binary mixing model. We further test the sensitivity of this model with a Monte Carlo method. The resulting signals are consistent with (discrete) independent temperature reconstructions from the study area. Moreover the temperature relative evolution provides insights into the millennial scale climate variability in central and eastern Europe. Notably, the imprints of Heinrich event cold spells and late glacial climatic oscillations are in line with other regional paleorecords from the northern hemisphere.

Calcite ($CaCO_3$) growth rate has an impact on many natural and industrial processes, ranging from biomineralisation to carbon storage and pipe scaling. Larsen *et al*. [1] noted that Ca^{2+} to CO_3^{2-} activity ratios in natural waters are rarely unity and demonstrated that growth velocities of the calcite acute and the obtuse steps varied with the Ca^{2+} to CO_3^{2-} ratio at constant states of supersaturation. We have extended the work of Larsen *et al*. to quantify the growth rates for acute and obtuse steps as a function of saturation index (SI) and Ca^{2+} to CO_3^{2-} activity ratios. Microscopic analysis of growth spirals show that absolute growth velocities change with SI. We have also observed that, independent of SI, acute step velocities are higher than obtuse velocities at low Ca^{2+} to CO_3^{2-} ratios, whereas obtuse step velocities are higher at higher Ca^{2+} to CO_3^{2-} ratios (Fig .1). This shift is certainly related to the different geometries of the acute and obtuse steps.

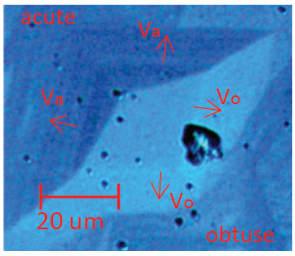

Figure 1. Growth spiral at a Ca^{2+}/CO_3^{2-} = 50. The obtuse step velocities are faster (Vo) and apex shifts toward the acute corner.

These results have implications for current models of calcite growth and reaffirm that calcite growth cannot simply be described using classical crystal growth theory intended for the high order symmetry of cubic atomic lattices. The rhombohedral symmetry of the calcite atomic structure must be considered.

Quantification of organic matter redox states by mediated electrochemical analysis

M. SANDER[1], L. KLÜPFEL[1], A. PIEPENBROCK[2], A. KAPPLER[2] AND M. AESCHBACHER[1]

Electron transfer reactions involving organic matter (OM) play a key role in carbon and element cycling in wetlands. Under anoxic conditions, OM may act as terminal electron acceptor in anaerobic microbial respiration. Reduction of OM may competitively suppress electron transfer to CO_2 and hence methanogenesis. Under oxic conditions, OM is susceptible to enzymatic oxidation, which ultimately leads to OM mineralization and hence CO_2 emissions. Despite the widely recognized importance of OM redox reactions to the biogeochemistry of wetlands, these reactions were difficult to study in past work as direct quantification methods were missing. We recently introduced mediated electrochemical analysis as a novel approach in which water-soluble organic mediator compounds are used to facilitate electron transfer and redox potential equilibration between OM and electrodes. The approach includes two types of measurements: (i) Mediated electrochemical reduction and oxidation directly quantify (changes in) the numbers of electrons that small OM samples accept and donate in electrochemical cells with well defined redox conditions. (ii) Mediated potentiometric redox potential measurements can be used to determine (changes in) the reduction potentials E_h of OM samples and on the thermodynamics of redox reactions involving OM. The unique capabilities of mediated electrochemical analysis for the analysis of OM redox dynamics in wetlands will be highlighted by results of two mechanistic laboratory studies. In the first study, mediated electrochemical analysis was used to quantify changes in the redox states of different OM over successive microbial reduction and O_2-oxidation cycles. The results demonstrate that electron transfer to and from OM was fully reversible, that system thermodynamics controlled the extents of microbial OM reduction, and that OM accepted electrons over wide E_h ranges. In the second case study, OM oxidation during incubation with phenoloxidases (i.e., laccases) was quantified, and fast, extensive and irreversible enzymatic oxidation of phenolic moieties in OM was demonstrated. Implications for OM redox dynamics in wetlands under anoxic and oxic conditions will be discussed.

Measurements of physical and chemical properties at the Mt. Cimone GAW-WMO Global Station (2165 m a.s.l.) allowed the detection of two volcanic transports occurred during the Eyjafjallajökull Icelandic volcano eruption in Spring 2010. Both episodes were characterized by an abrupt increase of fine and especially coarse mode particles number, with a consistent ash mode at an optical diameter of about 2.5 μm and an accumulation mode peaking at 0.2 - 0.3 μm. To figure out whether and to what extent the local aerosol mass was influenced by the transported volcanic ash the chemical composition of filter samples was derived from different analytical techniques (Ionic Chromatography, PIXE-PIGE and ICP-OES) showing a fine fraction dominated by sulphates and a coarse fraction of mainly crustal origin with a composition in good agreement with that of volcanic ash collected at the eruption site. The concentrations of selected elements (Ti, Al, Fe, Mn) allowed to estimate a volcanic plume contribution of about 10 μg m^{-3}, corresponding to about 40% of the total PM10 mass on 18 May, the most intense of the two events. A comparison with contributions observed in other parts of Europe is presented.

Characteristics and genesis of ion-adsorption type REE ores

K. SANEMATSU[12]* AND Y. WATANABE[1]

[1]Geological Survey of Japan, AIST, Tsukuba 305-8567, Japan (*correspondence: k-sanematsu@aist.go.jp)
[2]CODES, University of Tasmania, Private Bag 126, Hobart, Tasmania 7001, Australia

Ion-adsorption type REE deposits are the predominant source of HREE and Y in the world, and they have been economically mined only in South China. In order to elucidate the genesis of the deposits, we review petrochemistry of parent granites of ion-adsorption ores, and geochemical and mineralogical characteristics of the ores.

The REE deposits in China consist of weathered granites called ion-adsorption ores which have over 50 % of ion-exchangeable REY relative to whole-rock REY [1, 2]. The parent granites of the deposits are generally characterized by metaluminous to weakly peraluminous (ASI < ~1.1) compositions and low P_2O_5 contents (< 0.08 %). The granites contain allanite, titanite and REE fluorocarbonates (e.g., synchysite), which are degraded by chemical weathering, and they are poor in insoluble REE phosphates (monazite and xenotime). The HREE-rich granites are particularly fractionated and underwent deuteric alteration associated with mineralization of REE fluorocarbonates. The LREE/HREE ratios of ion-adsorption ores are constrained by nature and occurrences of these REE-bearing minerals in the granites.

The REE-bearing minerals in granites are degraded by low-pH soil water near the surface, and REE are transported downward in a weathering profile. REE are transported by complexing with humic substances and (bi)carbonate ions or as free ions in soil and ground water at low to near-nuetral pH. REE are immobilized by adsorption or incorporation into secondary minerals due to pH increase resulting from the contact of the soil water with rock-forming minerals or higher-pH ground water. Ce is mostly immobilized as CeO_2 by oxidizing from Ce^{3+} to Ce^{4+} near the surface. The other REE^{3+} are most likely to be adsorbed on the surfaces of kaolinite, halloysite and illite because of their points of zero charge and abundances in the ores. As a result, the weathering profile of the deposits is divided into a REE-leached zone of the upper part of the profile with positive Ce anomaly and a REE-accumulation zone (ion-adsorption ores) in the lower part with negative Ce anomaly. The occurrence of ion-adsorption ore is estimated by the negative Ce anomaly which is positively correlated with ion-exchangeable REE [2].

Mantle-crust interactions in the oceanic lithosphere: Constraints from minor and trace elements in olivine

A. SANFILIPPO[1]*, R. TRIBUZIO[1,2] AND M. TIEPOLO[2]

[1]Dipartimento di Scienze della Terra e dell'Ambiente, Università di Pavia, 27100 Pavia, Italy (*correspondence: alessio.sanfilippo@unipv.it)

[2]CNR - Istituto di Geoscienze e Georisorse, U.O. di Pavia, 27100 Pavia, Italy

Minor and trace element compositions of olivines are used as probes into the melt-rock reaction processes occurring at the mantle-crust transitions in the oceanic lithosphere. We considered mantle and lower crustal sections from the Alpine Jurassic ophiolites. In particular, we analyzed olivines from plagioclase-impregnated harzburgites and replacive dunites (Fo 91-90 mol%), and olivines from olivine-rich troctolites, troctolites and olivine-gabbros (Fo 88-82 mol%). The olivines from the hazburgites most likely experienced re- equilibration with the impregnating melts, as indicated by Mn, Ti, Y and HREE variations and the low Na concentrations. The olivines from the dunites have: (i) Mn, Ni, Co and Ca compositions similar to the primitive (Fo 91-89) olivine phenocrysts in MORB [1], and (ii) relatively high Y and HREE contents indicating equilibrium with primitive MORB. We thus reinforce the hypothesis [2] that replacive dunites act as conduits for the extraction of MORB. The involvement of MORB-type melts in the formation of the dunites is substantiated by the spinel compositions (Cr# ~35, TiO_2 ~0.3 wt%). Notably, the concentrations of Mn, Ni and Co in the dunites olivines produce positive correlations, in agreement with a formation through melt-harzburgite reactions. The preservation of this geochemical inheritance indicates that the liquids migrating along the dunites may change their compositions in response to the dunite-forming reactions. The olivine-rich troctolites are considered to be hybrid rocks formed by interaction between an olivine-rich matrix and MORB-type melts. The olivine chemistry in these rocks is controlled by the composition of the infiltrating melts and provides little information about the nature of the olivine matrix. Fractional crystallization rules the compositions of the olivines from the troctolites. Furthermore, the olivines from the troctolites have higher Y and HREE, and lower Co than the olivines in olivine-gabbros. These variations show that the troctolite/olivine gabbro transition is partly constrained by melt-rock reaction processes.

Solid - Liquid Equilibria of K_2SO_4-KBr-H_2O System at 373 K

SHIHUA SANG[1,2]*, TING LI[1] AND YONGXIA HU[1]

[1]College of Materials and Chemistry & Chemical Engineering, Chengdu University of Technology, Chengdu 610059, China. (sangsh@cdut.edu.cn)

[2]State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation (Chengdu University of Technology), Chengdu 610059, P. R. China

Massive high-salinity underground brines are frequently met in the exploitation of oil and gas resources. In particular, the underground gasfield brines in Western Sichuan Basin (China), are very rare liquid mineral resources in the world. The B, K, and Br contents of the brines are far beyond the lower grades of the comprehensive industrial utilization. The ternary system K_2SO_4-KBr-H_2O is a subsystem of the underground gasfield brines. The solid-liquid equilibria for the ternary system at 373 K were measured experimentally using the method of isothermal solution saturation. In the phase diagram of the ternary system K_2SO_4-KBr-H_2O at 373 K(Figure 1), there are one invariant point E and two univariant curves DE and CE. Equilibrium solids were KBr and K_2SO_4 in the studied ternary system. The crystallization area of K_2SO_4 (AED field) in the phase diagram is obviously bigger than that of KBr (BEC field).

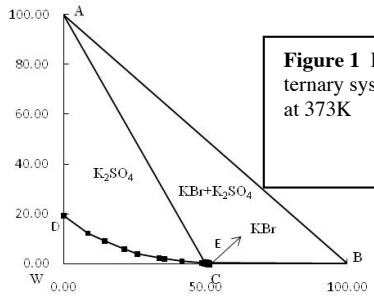

Figure 1 Phase diagram of the ternary system K_2SO_4-KBr-H_2O at 373K

Structural change in molten basalt at deep mantle P-T conditions

C. SANLOUP[1], J.W.E. DREWITT[1], P. DALLADAY-SIMPSON[1], D.M. MORTON[1], N. RAI[2], W. VAN WESTRENEN[2], Z. KONOPKOVA[3] AND W. MORGENROTH[3;4]

In the recent years, structural and density information on silica glass have been obtained up to record pressures of up to 100 GPa[1], a first major step towards obtaining data on the molten state.

In this abstract, the structure of molten basalt is reported up to 60 GPa by means of in situ x-ray diffraction, and structural changes are evidenced. Silicon coordination increases from 4 at ambient conditions to 6 at 35 GPa, similarly to what has been reported in silica glass[1–3]. Compressibility of the melt after completion of Si coordination change is lower than at lower pressure (**P**) conditions, implying that a single equation of state can not accurately describe density evolution of silicate melts over the whole mantle **P**-range. The transition pressure coincides with a marked change in the **P**-evolution of nickel partitioning between molten iron and molten silicates, indicating that melt compressibility controls siderophile element partitioning.

Ion microprobe U-Pb dating and Sr isotope measurement of a proto-conodont

YUJI SANO[1]*, KOSAKU TOYOSHIMA[1], KOTARO SHIRAI[1], NAOTO TAKAHATA[1], AKIZUMI ISHIDA[1] TOMOHIKO SATO[2] AND TSUYOSHI KOMIYA[2]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, Kashiwanoha, Kashiwa, Chiba 277-8564, Japan (ysano@aori.u-tokyo.ac.jp)
[2]Department of Earth Science and Astronomy, The University of Tokyo, Komaba, Meguroku, Tokyo 153-8902, Japan

We report here *in situ* ion microprobe U-Pb dating of a protoconodont micro-fossil using a NanoSIMS [1,2]. Twenty-three spots on the single fragment of the protoconodont (size: approximately 850 μm x 250 μm) derived from a sedimentary layer in the Meishucunian formation, Yunnan Province, South China provide a $^{238}U/^{206}Pb$ isochron age of 547 ± 43 Ma (2σ, MSWD=1.9), which is consistent with the depositional age of the formation, 536.5 ± 2.5 Ma reported by a zircon U-Pb dating [3]. On the other hand, five spots on the small region in the sample yield the isochron age of 416 ± 73 Ma (2σ, MSWD=0.31), apparently younger than the formation age. The younger age may be attributable to the latter metamorphic event, probably Caledonian orogenic activity recorded in the younger zircon with the age of 420 - 440 Ma [4].

We also measured the $^{87}Sr/^{86}Sr$ ratios of the proto-conodont by a NanoSIMS [5]. Nineteen spots on the older age region give the $^{87}Sr/^{86}Sr$ ratio of 0.71032 ± 0.00023 (2σ) on the weighted meab average, while seven spots on the younger area provide that of 0.70862 ± 0.00045 (2σ), significantly smaller than the older part. This is the first finding of U-Pb age and Sr isotope heterogeneity within a single fragment of micro-fossil, even though there is not a large chemical difference measured by a semi-quantitative SEM-EDS analysis.

On the reliability of paired carbon isotope as a pCO_2 proxy in the Ediacarian Araras platform, Brazil

PIERRE SANSJOFRE[1,2,3]*, , MAGALI ADER[1], RICARDO I.F. TRINDADE[2], AFONSO C.R. NOGUEIRA[4]

[1]Institut de Physique du Globe de Paris, France (ader@ipgp.fr)

[4]Universidade Federal do Pará, Belém, Brazil (anogueira@ufpa.br)

The snowball Earth model accounts for many of the typical geological and geochemical features of the Marinoan glaciation deposits (~635Ma) and of their overlying cap carbonate [1]. Melting this snowball Earth would have required a massive increase of the atmospheric carbon dioxide content (pCO_2). Recently however, we proposed instead a low atmospheric pCO_2 in the glaciation aftermath [2]. Our interpretation is based on paired carbon isotope data obtained on cap carbonates from Mirassol d'Oeste section (Ediacarian Araras platform, Brazil), together with previous results from cap carbonates of the Doushantuo Fm. and Zhamoketi Fm [3,4]. All three data sets showed low $\Delta^{13}C_{carb\text{-}org}$ ($=\delta^{13}C_{carb}$-$\delta^{13}C_{org}$). We made the case that these anomalously low values result from a decrease in the photosynthetic fractionation factor (εp), which can be related to pCO_2 lower than 3000 ppmv at the time of cap carbonate deposition.

We performed here a regional study based on 4 other sections sampled along the Araras carbonate platform. This new data set is broadly consistent with a low atmospheric pCO_2 scenario and allow to explore and identify both the local and global carbon isotopic variations of the Araras carbonate platform. In details, some features indicate that the occurrences of the low $\Delta^{13}C_{carb\text{-}org}$ are restricted to shallow depositional environments. In this present contribution, we discuss two alternate hypotheses that can be invoked to explain the low $\Delta^{13}C_{carb\text{-}org}$: (i) a shallow water early diagenetic process inducing a $\delta^{13}C_{org}$ increase and a $\delta^{13}C_{carb}$ decrease or (ii) primary producers presenting lower εp due to other parameter than pCO_2. In both case, the diagenetic event and the primary producers would remain to be constrained.

Magnetic susceptibility and $\delta^{18}O$ characterization of granites related with W, Sn, Mo and Bi (Au) hydrothermal vein deposits

HELENA SANT'OVAIA[1], HELENA C.B. MARTINS[1] AND FERNANDO NORONHA[1]

[1]DGAOT, Centro de Geologia, F.C. Univ. Porto, Portugal, hsantov@fc.up.pt (* presenting author)

The Northern Portugal mainland comprises an important W-Sn metallogenic province characterized by W-(Mo-Bi),W, W-Sn, and Sn hydrothermal vein deposits related with sinorogenic Variscan granites. These granites are usually classified into two main groups: peraluminous and metaluminous. As the granite rocks reflect redox states of their corresponding melts, the presence of magnetite and/or ilmenite as acessory minerals represent oxidized- and reduced-type respectively. The mineralogical features and magnetic susceptibility (K) of the granites were examined in order to deduce the redox conditions of magma systems, using the magnetic susceptibility data from around 644 sampling stations on different massifs of Variscan Portuguese granites. Whole-rock oxygen-isotope ($\delta^{18}O$) values were compilated from bibliography [1,2,3,4]. Despite of different petrographic and geochemical characteristics, K values in the majority of the studied granites vary from 20 to 300 × 10^{-6} SI units corresponding to peraluminous and meta-peraluminous, reduced, ilmenite-type granites. The oxidized or magnetite-type granites are scarce and represented by metaluminous late orogenic with K values ranging from 15 to 20 × 10^{-3} SI units and low $\delta^{18}O$ values ranging from 8.9 to $10.3^0/_{00}$. Major W-Sn ore deposits are related to reduced ilmenite-bearing granites with $\delta^{18}O$ enriched (9.3 to $13.5^0/_{00}$); W- (Mo-Bi- Au) deposits are related with oxidized granite series (i.e. magnetite or titanomagnetite-bearing granites). Magnetic susceptibility measurements, represent a powerful tool on mineral exploration of deposits related with intrusive magmatism.

Microbial communities in terrestrial CO_2 springs: Insights into the long-term biogeochemical effects of geologic carbon storage

EUGENIO-FELIPE U. SANTILLAN[1]*, JONATHAN MAJOR[1] AND PHILIP C. BENNETT[1]

[1]University of Texas Austin, Austin, TX, USA (efu.santillan@utexas.edu * presenting author)

During carbon sequestration, CO_2 is stored in subsurface reservoirs such as sandstone and basalt formations perturbing native microbial communities. Useful and accessible natural analogues to study long term effects of CO_2 on these communities are high CO_2 springs. Laboratory cultures have shown CO_2 to be toxic for microorganisms starting at 1 atm. Here we present data indicating microbes that can survive up to 10 times that pressure.

In this study, 16S rRNA gene sequences were used to characterize microbial communities from 3 sequestration analogues at depths where PCO_2 is at approximately 2 atm: from a basalt formation in Klickitat (KT), WA containing approximately 700 ppm of total dissolved solids (TDS); from a sedimentary formation along the Little Grand Wash Fault (LGW), UT containing 15,000 ppm TDS; and from a saline water in Bravo Dome (BD), NM containing 50,000 ppm TDS. Results show that the springs were dominated by a few major organisms but still contained more diversity than was expected at toxic CO_2 pressures. LGW sequences had no archaea and were dominated (>85%) by the genus *Acinetobacter*. KT sequences were more diverse than that of LGW and contain methanogens and methanotrophs suggesting CH_4 cycling. Candidate phyla were also detected in KT such as those from the OP, WS, and SPAM divisions. Sequencing for BD is currently underway.

Laboratory cultures also show bacteria at LGW performing lactate fermentation at 10 atm PCO_2, demonstrating viability at sequestration conditions. This study confirms the presence and viability of microbial communities in CO_2 rich environments that can continue to affect the geochemistry as well as the long-term storage of CO_2.

Bioremediation and soil formation processes in bauxite residue tailings

T. C. SANTINI[1,2]* AND L. A. WARREN[1,3]

[1]McMaster University, GSB218, Hamilton, ON, L8S4K1, Canada (*correspondence: santini@mcmaster.ca; warrenl@mcmaster.ca)

[2]University of Western Australia, M087, Crawley, WA, 6009, Australia

[3]CSIRO Land and Water, Lucas Heights, NSW, 2234, Australia

Bauxite residue is an alkaline, saline-sodic tailings material generated during the Bayer process, in which alumina is extracted from bauxite. Between 3 and 4 billion tonnes of bauxite residue are estimated to be currently stored in facilities worldwide. *In situ* remediation of bauxite residue by application of inorganic and organic amendments, coupled with natural weathering and soil formation processes, is a cost-effective way to decrease alkalinity and salinity such that the tailings can then support a vegetation cover. Very little information on microbial activity and its potential influence on the geochemistry and mineralogy of bauxite residues currently exists, impeding development of effective remediation strategies. Here, a bauxite residue storage facility was investigated after 15 years of weathering to evaluate the effect of amendments on geochemistry and mineralogy of the bauxite residue, and development of microbial communities.

Tillage, and the addition of compost and gypsum, significantly decreased pH and salinity of the tailings. Highly diverse microbial communities were detected in these tailings, indicating that endemic organisms adapted to these materials occur *in situ*. Further, microbial community species composition varied with applied treatments and depth below surface indicating microbial selection of different conditions based on aeration, pH, salinity, and carbon availability. Experiments indicated that endemic communities were able to degrade oxalate, and reduce Fe^{3+} and SO_4^{2-}, precipitating minerals such as vivianite and siderite; all of which are important steps in the development of soils capable of supporting plant growth. However, the species responsible for carrying out these functions differed between treatments and depths, indicating that knowledge of the specific microbes associated with different conditions is required. Overall, the study demonstrated that microbial communities can influence geochemical cycles and soil formation within bauxite residue deposits, and that the composition and function of microbial communities can be influenced by the application of chemical and physical treatments to bauxite residue.

Acid rock drainage associated with tropical glacier retreat: Nevado Pastoruri, Perú.

E. SANTOFIMIA[1]*, E. LÓPEZ PAMO[1], J. PALOMINO[2] AND A. AGUILERRA[3]

[1]Instituto Geológico y Minero de España, Madrid, Spain (* correspondence: e.santofimia@igme.es)
[2]Facultad de Ciencias del Ambiente, Huaraz, Perú.
[3]Centro de Astrobiología, Torrejón de Ardoz, Madrid, Spain.

An important glacier retreat has been registered in the Nevado Pastoruri (Huascarán National Park) from 1962 to 2001, reducing its surface a 60% [1]. This process is frequent in glaciers located at Cordillera Blanca. Occasionally, glacier retreat exposed pyrite-rich rock outcrops of the Chicama formation, causing its alteration and the generation of acid rock drainages (ARDs) [2].

In the case of Nevado Pastoruri, the glacier retreat has left exposed to atmospheric conditions the sandstones and lutites with coal enriched in pyrite of the Chimú formation [3].

The proglacial zone presents a lot of lakes, scant vegetation, and intense fluvioglacial erosion. On morphologies typically glacier are abundant the ARDs, revealing like springs of underground water, runoff or forming lakes. ARDs are clearly identifiable for the colour and the morphology (terraced iron formations), which is associated with the oxidation of Fe(II).

The water sampling was carried out in the proglacial zone. After cluster analysis using 23 samples, two groups were established. The first group (n=8) gathered the most acidic samples, pH 3, showing also the highest concentrations of elements such as SO_4, Fe, Al, Ca, Mg, Mn and Zn. These samples were directly related to the pyrite alteration (227 mg/L SO_4, 41 mg/L Fe) and aluminosilicate dissolution (10 mg/L Al), showing especially high values. This group is made up by the ARDs. The average concentration of these samples was an order of magnitude higher than the values showed by second group, which showed a scant mineralize (freshwater).

The ARDs geographical distribution is not disperse. These samples are grouped in a band of 600 m length with N-S direction and 250 m wide, between the elevations of 4925 and 5025 m. The mixing of two water types generates the source of River Pachacoto, showing Fe(III) buffer water (pH 3.1, Fe 0.7 mg/L) and several mg/L of dissolved Al (4.5) that confers mineral acidity to water.

Sr and Nd isotope data for arc-related (meta) volcanics (SW Iberia)

J.F. SANTOS[1], J. MATA[2], S. RIBEIRO[1], J. FERNANDES[1], AND J. SILVA[2]

[1]Geobiotec/Dep. Geociências, Un. Aveiro, Portugal, jfsantos@ua.pt
[2]Fac. Ciências Univ. Lisboa/ CeGUL, Portugal

In the southern sector of the Ossa-Morena Zone (Iberian Variscan Chain), along its boundaries with the Beja-Acebuches Ophiolite and the South-Portuguese Zone, Upper Palaeozoic igneous mafic and intermediate rocks, both intrusive and extrusive, are widely represented. The so-called Odivelas Unit (Andrade,1983), include (meta-) basalts and (meta-) andesites, which, according with previous studies, display low-K tholeiitic to calc-alkaline signatures and, therefore, are interpreted as remnants of an active margin volcanic arc. Santos *et al*. (1990) subdivided those volcanics into two groups: in Alfundão-Peroguarda, the tholeiitic nature is dominant; in Odivelas-Penique, the calc-alkaline signature becomes more pronounced. Intercalation of limestone layers provided some age constraints, showing that the subduction-related volcanic activity in the studied area began in the Lower Devonian and continued, at least, through the Middle Devonian (Conde & Andrade, 1974; Machado *et al*., 2010).

In this work, samples previously studied by Santos *et al.* (1990) and Silva *et al.* (2011) were analysed for Sm-Nd and Rb-Sr isotopes. Considering that the volcanics were systematically affected by hydrothermal metamorphism, it is expected that the Sr signatures show significant disturbance. In contrast, Nd isotope ratios probably reflect the primary features. Alfundão-Peroguarda samples show a very limited range of positive initial ε_{Nd}, from +5.1 to +4.3 (assuming 400 Ma), showing no evidence for significant crustal assimilation and, therefore, allowing the attribution of negative Nb and Ta anomalies to arc-related processes On the other hand, $^{87}Sr/^{86}Sr$ varies from 0.7044 to 0.7060 (for 400Ma). These samples rocks define a horizontal trend on the initial ε_{Nd} vs. initial $^{87}Sr/^{86}Sr$ plot, typical of co-genetic rocks that underwent interaction with seawater. On the other hand, Odivelas-Penique volcanics show wide spectra for both initial $^{87}Sr/^{86}Sr$ (from 0.7038 to 0.7066) and ε_{Nd} (from +4.6 to -4.1). Significantly, the highest εNd values for this group are within the narrow range defined by Alfundão-Peroguarda tholeiitic basalts, suggesting a common mantle source (or very similar sources) for the most mafic magmas of both sectors.

The whole set of Nd isotope ratios supports the distinction previously proposed between the two groups of volcanics. In addition, the variation from positive to negative initial ε_{Nd} values in the Odivelas-Penique suite shows that its geochemical features were likely influenced by assimilation of continental crustal material.

Behaviour of rare earth elements (REE) at Funil Reservoir, Southeastern Brazil

J.M.C.O. SANTOS-NEVES[1], M.M. FERREIRA[1], M.S.M. VIDAL[1], A.A. ROCHA[2] AND S.R. PATCHINEELAM*[1]

[1]Department of Geochemistry and [2]Department of Analytical Chemistry. Institute of Chemistry, Universidade Federal Fluminense, Niterói, Rio de Janeiro State, Brazil. *sam_pat_br@yahoo.com

Rare earth elements (REE) have specific biogeochemical characteristics, which allow their use as reliable tracers of natural processes at various spatial and temporal scales in aquatic systems [1-3]. This study aims to evaluate the role of Funil Reservoir on REE behaviour. Considering the objectives, water samples were collected in three sample stations, during dry and rainy seasons: (P-01) upstream the Funil reservoir at Queluz, São Paulo State; (P-02) at the reservoir; and (P-03) downstream the Funil Reservoir, at Itatiaia. REE concentrations were determined by ICP-MS.

REE concentrations area presented in Table 1. Calculed ratios from REE normalized by PAAS indicate that values of Gd/Yb > La/Yb, which suggests that there is an enrichment of heavy REE in all sample points in both seasons.

	Rainy season			*Dry season*		
	P-01	**P-02**	**P-03**	**P-01**	**P-02**	**P-03**
ΣREE (ng/L)	72,91	54,14	102,36	77,97	87,71	83,64
La/Yb	0,19333	0,17172	0,05481	0,216	0,212	0,196
Gd/Yb	0,03696	0,3308	0,17023	0,395	0,378	0,395

Table 1: REE concentrations and ratios at study area.

Our results indicate that REE abundance is controlled by weathering in drainage basin. During dry season REE concentrations increased. And during rainy season, REE concentrations before and after the reservoir were greater than concentrations at Funil reservoir (P-02). The distinct behaviour observed between dry and rainy seasons is the Funil Reservoir act as geochemical barrier modifying fluvial transport of REE. Another factor that probably affect REE behavior is algal bloom, with dominance of cyanobacteria which occurs during rainy season, which influence the behaviour of REE through the incorporation and release of these metals.

Hydromagnesite precipitation in microbial mats from a highly alkaline lake, Central Spain

M. ESTHER SANZ- MONTERO[1]*, ÓSCAR CABESTRERO[1] AND J. PABLO RODRÍGUEZ-ARANDA[1]

[1]Petrology and geochemistry Department. Facultad de Ciencias Geológicas (UCM), Madrid, Spain. mesanz@geo.ucm.es (*presenting author)

Microbialites comprised of up to 45% hydromagnesite and 10% of dolomite have been recognized in Las Eras playa-lake, Central Spain. Las Eras is an evaporitic highly alkaline lake, with pH values ranging from 9.4 to 11, that covers an area of 0.1 km^2 [1]. Mg-enriched groundwater flows into this lake, which is supersatured in hydromagnesite and dolomite. The hydrous Mg-carbonate precipitation occurs in the uppermost layer of benthic microbial mats. This layer is dominated by *Microcoleus* that consists of trichomes in bundles and diatoms embedded in their EPS. Low-vacuum scaning electron microscopy revealed that hydromagnesite nucleation is iniciated on the cells of aerobic heterotrophic bacteria that are responsible for the degradation of the microbial biomass. A progressive mineralization of the heterotroph cells by the deposition of plate-like crystals of hydromagnesite on their surface was observed. This resulting in the entombment of the bacteria and the formation of radiating aggregates of hydromagnesite crystals. The degradation and concomitant Mg-carbonate precipitation, finally, led to the lithification of the microbial mat.

This evolution shows that aerobic heterotrophic bacteria play a crucial role in the formation of microbialites in Lake Las Eras by promoting the Mg-carbonates precipitation. This lake is one of the few modern environments where hydromagnesite is a dominant precipitating mineral in microbialites. Thus, it provides a modern analog to use in the interpretation of saline and/or alkaline environments. In turn, the exceptional preservation of bacteria microfossils clustered into magnesite crystals has been already documented in Miocene saline deposits [2].

The authors greatly appreciate support from MINECO Program (Project CGL2011-26781).

Unravel the role of lake ice cover on the methane budget: A multi-proxy analysis

C.J. SAPART[1], T. BOEREBOOM[2], T. RÖCKMANN[1], H. NIEMANN[3], C. VAN DER VEEN[1], J-L. TISON[2]

[1]Institute for Marine and Atmospheric research Utrecht, Utrecht University, The Netherlands
[2]Laboratoire de Glaciologie, Université Libre de Bruxelles, Belgium
[3]Department of Environmental Sciences, University of Basel, Switzerland

Large uncertainties exist on the evolution of the atmospheric methane (CH_4) budget in the future. Concern about possible feedbacks of natural sources in a changing climate is growing, especially concerning the role of thawing of permafrost areas in the Arctic regions. Subarctic lakes are considered as "hotspots" for CH_4 emissions, but the role of the ice cover during the winter period is not well understood to date. Different types of gas bubbles with high CH_4 mixing ratios have been identified in lake ice cover. A recent study revealed that the gas composition of those bubbles depends on, inter alia, the bubble type, the lake depth and the hydrological status of the lakes.

Analysing mixing and stable isotope ratios of CH_4 and CO_2 on those bubbles is an efficient tool to identify the mechanisms involved in the release, the oxidation and transport of CH_4 in permafrost lakes and to better constrain the potential influence of lake characteristics. Those analyses together with lipid biomarkers distribution analysis on lake ice samples reveal that different bubble types contain different isotopic signatures and that oxidation of dissolved CH_4 is the most important process determining the isotopic composition of CH_4 in bubbles. This shows that the increased exchange time between gases coming from the sediments and the water column, due to the capping effect of the lake ice cover, reduces the amount of CH_4 released and favours its oxidation into carbon dioxide.

Leaching of Zn, Cu and Pb from oxidised sulphidic mine waste as a function of temperature, L/S ratio and leaching reagents

NAEEM SAQIB[1], MATTIAS BÄCKSTRÖM[2]

[1 2] Man-Technology Environment Research Center, Örebro University, SE-701 82, Örebro, Sweden,
[1](naeem.saqib@oru.se) [2](mattias.backstrom@oru.se)

Formation of low pH drainage from sulphidic mine waste enhances trace element mobility and posing a serious threat to the surrounding environment [1]. A sustainable and cost effective remediation method is therefore desired. Utilization of the sulphidic waste as a secondary source for metals might be a viable alternative. In this laboratory scale study chemical extraction has been employed to assess the potential of metal release and possible metal recovery from oxidised sulphidic mine waste. Waste from an old copper and lead mine in Kopparberg, mid Sweden, was used for the experiments. Mine waste was extracted with four leaching agents: (i) distilled water, (ii) sulphuric acid, (iii) sodium hydroxide and (iv) sodium bicarbonate (0.01 M), at three liquid solid ratios (5, 10, 20) and at four temperatures (25, 45, 65, 85 ^{0}C), for a time of 6 hours during intermittent shaking. Generated solutions were analysed with respect to pH, electrical conductivity, acidity and metal concentrations.

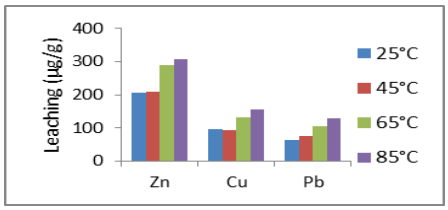

Figure 1. Effect of temperature on metal leaching from sulphidic mine waste using sulphuric acid.

Results indicate that increasing temperature enhances extraction of elements due to increase in reaction rates. Increasing L/S ratio increased extraction only to a certain extent after which it decreased or had no prominent effect. Sulphuric acid proved to be the best extraction media extracting as much as 14 % Zn, 10 % Cu and 3 % Pb of the total content. Leaching of Zn and Pb decreased from acid to neutral pH so it is a very crucial factor governing the extraction. Lead extraction with sulphuric acid is probably limited by anglesite (PbSO4(s)).

Fuzzy Hierarchical Cross-Clustering of Romanian Mineral Waters

C. SÂRBU

[1]Faculty of Chemistry and Chemical Engineering, Babeş-Bolyai University, Arany Janos Str., No 11, RO-400028, Cluj-Napoca, Romania *E-mail address:* csarbu@chem.ubbcluj.ro

Cluster analysis is a large field, both within fuzzy sets and beyond it. The application of Fuzzy sets in a classification function causes the class membership to become a relative one and consequently an object or sample can belong to several classes at the same time but with different degrees. In this investigation, Fuzzy hierarchical cross-clustering algorithm has been applied for simultaneous clustering of different Romanian mineral water samples and their chemical characteristics (ions concentration), and the results obtained have been allowing an objective interpretation of their similarity and differences, respectively. This very informative fuzzy approach allows the qualitative and quantitative identification of the characteristics responsible for the observed similarities and dissimilarities between mineral water samples. In addition, the fuzzy hierarchical characteristics clustering and fuzzy horizontal characteristics clustering procedures revealed a high similarity between some ions concentration and other features.

Surfactants from the gas phase may promote aerosol cloud droplet nucleation

NEHA SAREEN[1], ALLISON SCHWIER[1], TERRY LATHEM[2], ATHANASIOS NENES[2,3] AND V. FAYE MCNEILL[1]

[3]School of Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, GA, USA 30332

The uptake of water-soluble volatile organic compounds (WSVOCs) by wet atmospheric aerosols can lead to the formation of secondary organic aerosol material (SOA). We have performed a series of laboratory studies in order to quantify of the impact of WSVOC uptake and aqueous-phase SOA formation on aerosol cloud condensation nuclei (CCN) activity. Deliquesced, acidified submicron ammonium sulfate aerosols at >60% RH were exposed to ppb levels of gas-phase methylglyoxal, acetaldehyde in a continuous-flow aerosol reaction chamber (residence time = 3-5 h). Aerosol size and CCN activity was monitored at the reactor outlet via scanning mobility particle sizer (SMPS) and continuous-flow streamwise thermal gradient chamber CCN counter (CFSTGC), respectively.

Methylglyoxal and acetaldehyde are known to form SOA and suppress surface tension in bulk aqueous aerosol mimics, but both of these species have relatively low Henry's Law constants. We found evidence that adsorption of these species from the gas phase to the gas-aerosol interface significantly impacts aerosol CCN activity, by directly altering the aerosol surface tension. Up to 15% reduction in critical dry diameter for activation was observed without any detectable particle growth due to bulk uptake of organics (Sareen *et al*., Proc. Natl. Acad. Sci. USA, 2013).

Finally, we have developed a general analytical approach for predicting aerosol surface tension based on gas-phase surfactant loadings, taking into account the effects of both bulk uptake and surface adsorption. These predictions allow calculation of the particle hygroscopicity and predictions of cloud droplet formation. We will present results for atmospheric scenarios and highlight needs for additional experimental work.

[5]Institute for Materials Chemistry and Engineering, Kyushu University, Japan: (keiko@cm.kyushu-u.ac.jp, miyawaki@cm.kyushu-u.ac.jp)

Boric acid is one of the most diffucult species to immobilize in aqueous environments, because it predominantly exists as a molecular form. Boron specific resin is widely used and well known to immobilize with N-methyl-glucamate groups. However, it requies alkaline pHs and is unsuitable to apply to contaminant sites in a large scale like groundwaters. In the present work, permeable reactive barrier column tests were conducted to remove boron (B) in groundwaters in a laboratory scale for 11 months by using combination of MgO agglomerates with woodchips instead of boron specific resin. MgO agglomerates are one of engineering-assisted geomaterials for handling and main reactive materials here, while woodchips are natural and suppremental ones. ^{11}B-NMR and XRD results revealed that boron was mainly immobilized as $^{[3]}$B by co-precipitation with $Mg(OH)_2$ through destructive sorption of MgO and as $^{[4]}$B with woodchips through complexation which is in complementary mechanism and facilitated after alkalization by hydration of MgO. SEM images of solid residues MgO agglomerates after immobilization of B were quite different from without woodchips, suggesting that a variety of organic acids in leachate from woodchips affects to Mg^{2+} species as a precursor for $Mg(OH)_2$ precipitate. This affected also to increase the permeability because of avoiding the formation of bulky and needlelike-shaped precipitates of $Mg(OH)_2$. As a result, boron specific resin can be alternatively replaced with combination of engineering geomimetics with natural materials, which improved the efficiency to immobilize boron in groundwaters.

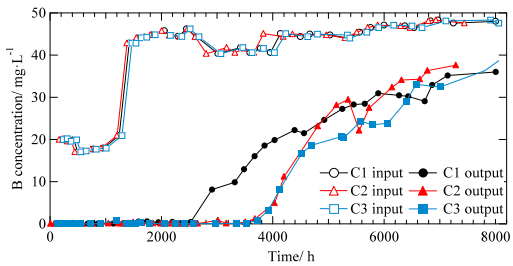

Fig. 1 Changes in B concentrations in input and output solutions with time. C1, MgO; C2, MgO + woodchips; C3, MgO + B specific resin

Investigation of ancient fluid migration in Ordovician carbonates in the Michigan Basin using secondary minerals

J.K. SASO[1], R. CALDAS[2], L. W. DIAMOND[2], A. PARMENTER[3] AND T. A. AL[1]*

[1]Earth Sciences, University of New Brunswick, Canada (*correspondence: TAL@unb.ca)
[2]Institute of Geological Sciences, University of Bern, Switzerland (diamond@geo.unibe.ch)
[3]Nuclear Waste Management Organization, Canada (aparmenter@nwmo.ca)

Investigations of the Upper Ordovician Trenton and Black River group argillaceous limestones in southwest Ontario, Canada, indicate that secondary calcite, dolomite, celestite and anhydrite occur in fracture-filling veins, with dolomite also replacing primary calcite in the limestone. The objectives of this study were to define the paragenetic sequence, identify the source(s) of the fluids, and if possible, place time constraints on the formation of these minerals.

Petrographic studies were conducted by optical and scanning-electron microscopy (SEM). Analyses of $\delta^{18}O$ and $^{87}Sr/^{86}Sr$ were conducted by isotope-ratio and thermal ionization mass spectrometry, respectively. Measurements of $\delta^{18}O$ were also conducted by ion microprobe. Microthermometric data were collected from doubly-polished 150 μm thick sections.

The paragentic sequence, from oldest to youngest, is replacement dolomite, vein dolomite, calcite in veins, and late-stage sulphate minerals. Mass-balance calculations indicate that replacement dolomite in the Trenton Group formed under closed conditions, while replacement dolomite in the Black River Group required an external source of Mg. Depth profiles of $\delta^{18}O$ and $^{87}Sr/^{86}Sr$ in vein carbonates suggest they formed as ^{18}O-depleted and $^{87}Sr/^{86}Sr$-enriched fluid ascended from the underlying shield. The $^{87}Sr/^{86}Sr$ composition of late-stage sulphate minerals suggests they formed from sedimentary basin brine. Fluid-inclusion investigations of the calcite in veins indicate four fluid migration events with homogenization temperatures in the range of 40 to 90 ºC. These temperatures are consistent with predictions of temperature associated with peak burial during the Late Carboniferous.

Osmium isotope evidence for a large impact event in the Late Triassic

H. SATO[1]*, T. ONOUE[2], T. NOZAKI[3] AND K. SUZUKI[3]

[1]Kyushu University, Fukuoka 812-8581, Japan (*correspondence: 3SC12024G@s.kyushu-u.ac.jp)
[2]Kumamoto University, Kumamoto 860-0862, Japan (onoue@sci.kumamoto-u.ac.jp)
[3]Japan Agency for Marine-Earth Science Tecnology (JAMSTEC), Yokosuka 237-0061, Japan (nozaki@jamstec.go.jp, katz@jamstec.go.jp)

Seawater $^{187}Os/^{188}Os$ ratios reflect contributions to the global ocean from riverine ($^{187}Os/^{188}Os \approx 1.4$), and hydrothermal and extraterrestrial inputs ($^{187}Os/^{188}Os \approx 0.12$ - 0.13). Given the distinctive $^{187}Os/^{188}Os$ ratios of these inputs and the relatively short residence time of Os in the ocean, seawater $^{187}Os/^{188}Os$ ratios are highly sensitive to change in these fluxes. Thus, Os isotope has been used to demonstrate the 65 Ma impact event at Chixhulub in Mexico [1, 2], based on an abrupt decline in seawater $^{187}Os/^{188}Os$ ratios during the Cretaceous/Paleogene (K-Pg) boundary.

We report the marine $^{187}Os/^{188}Os$ ratios of the middle Norian bedded chert and claystone succession in Japan to provide new evidence of an extraterrestrial input. These bedded cherts are considered to be deep-sea sediments that accumulated in a pelagic, open ocean setting within the Upper Triassic paleo-Pacific Ocean (Panthalassa).

The initial $^{187}Os/^{188}Os$ ratios exhibit an abrupt and marked negative excursion from 0.477 to unradiogenic values of 0.127 in a claystone layer. The Os concentration of this claystone layer is ca. 3 ppb which is three orders of magtinude higer than those of chert layers. Moreover, a plenty amounts of spherule and Ni-rich spinel granules and extraodrinary PGE-enrichment was reported from the claystone [3]. The amplitude of this negative Os isotope excursion is comparable to those of the late Eocene (0.5 to 0.28) [4] and the K-Pg boundary (0.4 to 0.157) [1]. These geochemical lines of evidence strongly suggest that a large, kilometer-sized impactor is requisite to explain high Os concentration and unradiogenic $^{187}Os/^{188}Os$ ratios of the Upper Triassic claystone layer.

Let's use metastable geomaterials in environmental protection: An intelligent geotechnology learnt from natural processes

T. SATO[1]* AND K. FUKUSHI[2]

[1]Faculty of Engineering, Hokkaido Univ., Kita 13 Nishi 8, Kita-Ku, Sapporo 060-8628 Japan
[2]Institute of Nature and Environmental Technology, Kanazawa Univ., Kakuma, Kanazawa 920-1192 Japan
*Correspondence: tomsato@eng.hokudai.ac.jp

In order to ensure sustainable development, engineering technologies used in environmental protection (e.g. purification, remediation) must utilize safe, cost-effective and environmentally efficient materials. As such, the use of ubiquitous geomaterials, rather than synthetic materials, is envisioned. The use of geomaterials for environmental applications, referred to as "geotechnology", is based on principles learnt from natural processes. Therefore, naturally occurring physical, chemical and biological processes can serve as useful analogs in designing cost-effective and intelligent geotechnologies to address environmental problems.

Geomaterials such as clays, carbonates and iron minerals, which are generally stable under Earth surface conditions, have been used widely for environmental applications. This is due to their cost-effectiveness and stability over a range of conditions. However, metastable materials widely observed in nature have been found to be more environmentally efficient due to their higher reactive surface areas and reactivity to hazardous contaminants compared to more stable materials. For example, iron oxides such as hematite, goethite, ferrihydrite and schwertmannite are seen as important naturally occurring sorbents of arsenate and phosphate. However, poorly crystalline and metastable ferrihydrite and schwertmannite exhibit higher capacities for arsenate and phosphate adsorption compared to crystalline goethite and hematite. Similarly, metastable aragonite and monohydrocalcite show better anion adsorption capabilities compared to calcite. Recently, it has been found that the stability of these materials can be modified by the adsorption of certain ions. Therefore, the long-term stability and efficient performance of metastable materials can be controlled in order to maximize their effectiveness. In this presentation, intelligent geotechnologies learnt from natural processes using metastable geomaterials will be introduced, with natural iron oxides and calcium carbonates as examples.

Analcime alteration of montmorillonite: Growth rates

HISAO SATOH[1,2], KATSUO TSUKAMOTO[2], HITOSHI OWADA[3] AND TOMOKO ISHII[3]

[1]Mitsubishi Materials Co., Naka 311-0102, Japan
[2]Tohoku University, Sendai 980-8578, Japan
[3]RWMC ,Tsukishima, 104-0052, Japan

Analcime is very common zeolite as a low-temperature secondary mineral of alkaline alteration. Growth of analcime was previously studied on precursor Na-clinoptilolite[1] and leucite[2]. Such an alkaline alteration is predicted in the bentonite barrier of radioactive waste repository by cement-leachates in groundwater[3]. Chemical similarity between analcime ($NaAlSi_2O_6 \cdot H_2O$) and montmorillonite ($Na_{0.4}Al_{1.6}Mg_{0.4}Si_4O_{10}(OH)_2 \cdot nH_2O$) may enhance reaction:

Na-mont + 1.2NaOH = 1.6Analcime + $0.8SiO_2$ + nH_2O.

We investigated growth kinetics of analcime to evaluate the behavior of bentonite barrier under hyperalkaline condition.

Direct measurements of analcime growth rate on substrate, analcime at 90-120 °C were conducted using in-situ phase-shift interferometer (PSI)[4]. Supersaturation with respect to analcime was controlled by dissolution of coexisting montmorillonite in the cell with flow of 0.3 M NaOH solution.

The dissolution and growth rates of analcime near equilibrium were observed to be -3.6×10^{-3} and 2.7×10^{-3} nm/s, at ΔG of -11.29 and 8.80 kJ/mol respectively (Fig. 1). Our results agree with previous data[1], which roughly draws a growth rate curve. We conclude that the key of analcime growth is porewater chemistry in montmorillonite. The dissolution of montmorillonite can be affected by porosity (density)[5]. Our results can extend the observed alteration towards a mechanistic model involving porosity change.

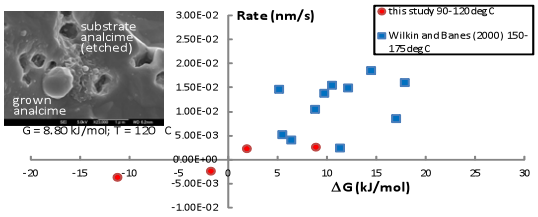

Figure 1: Growth rate curve of analcime and a surface after run showing etch pits and grown grains (FESEM).

Heterogeneity of the uppermost mantle in back-arc settings: Insights from trace-element compositions and water contents in Japanese peridotite xenoliths

TAKAKO SATSUKAWA[1], MARGUERITE GODARD[2], SYLVIE DEMOUCHY[2] AND KATSUYOSHI MICHIBAYASHI[3]

[1]ARC Center of Excellence for Core to Crust Fluid Systems (CCFS) and GEMOC National Key Center, Earth and Planetary Sciences, Macquari University, Sydney, NSW 2109, Australia
[2]Géosciences Montpellier, Université Montpellier 2 and CNRS, Cc 060, Place E. Bataillon, 34095 Montpellier cedex 5, France
[3]Institute of Geosciences, Shizuoka University, Ohya 836, Shizuoka 422-8529, Japan

The uppermost mantle in the back-arc region of a subduction zone is the site of complex interactions between partial melting and fluid migration. To constrain these interactions and reveal the heterogeneity of the uppermost mantle in back-arc setting, we measured geochemical compositions and water contents of spinel peridotite xenoliths obtained from two back-arc volcanoes; Ichinomegata (NE Japan) and Oki-Dogo (SW Japan). The mineral chemistry of Ichinomegata peridotites shows a typical residual peridotite trend, depleted in light rare earth elements (LREE). Some samples of Oki-Dogo peridotites have lower Mg# in olivine (down to 0.88) and are enriched in LREE, indicating that these are affected by melt-rock interactions. Olivine has low water contents in samples from both Ichinomegata and Oki-Dogo. However, the water contents in pyroxenes in Ichinomegata peridotites are significantly higher than in Oki-Dogo. These differences might be due to the different mobility of water during fluid metasomatism versus melt-rock interaction. The water contents of the pyroxenes suggest interactions with water-rich fluids. Hydration incorporation in Ichinomegata peridotite is proposed to be associated with a water-rich metasomatism, which lead to depleted REE patterns in clinopyroxene, and the REE patterns of orthopyroxene are more depleted than for Oki-Dogo samples. However, the chemical composition of Oki-Dogo peridotites shows that they have experienced melt-rock interactions that have lead to the characteristic flat REE pattern of the clinopyroxene. Furthermore, these variations in chemical characteristics between Ichinomegata and Oki-Dogo might be induced by the changes in the subduction system in the Japan Island arc, such as the age and angle of the subducting slab.

Salt Lakes of Western Australia – Emissions of natural volatile organic compounds

T. SATTLER[1], T. KRAUSE[1], H. F. SCHÖLER[1], K. KAMILLI[2], A. HELD[2], C. ZETZSCH[2], J. OFNER[3], W. JUNKERMANN[4] AND E. ATLAS[5]

[3]Vienna University of Technology, Austria;
[4]Inst. for Meteorology and Climate Research, Karlsruhe Inst. of Technology, Garmisch-Partenkirchen, Germany
[5]Rosenstiel School of Marine and Atmos. Sci., Miami, USA

Western Australia is a semi-/arid region that is heavily influenced by global climate change and agricultural land use. The area is known for its many saline lakes with a wide range of hydrogeochemical parameters. This area has been repeatedly investigated since 2006 and consists of ephemeral saline and saline groundwater sourced lakes with a pH reaching from 2.5 to 7.1. The semi-/arid region was originally covered by natural eucalyptus forests, but land-use has changed considerably after large scale deforestation from 1950 to 1970. Today the region is mostly used for growing wheat and live stock. The deforestation led to a rising groundwater table, bringing dissolved salts and minerals to the surface.

In the last decades, a concurrent alteration of rain periods has been observed. A reason could be the regional formation of ultra-fine particles that were measured with car-based and airborne instruments around the salt lakes in several campaigns between 2006 and 2011. These ultra-fine particles emitted from the lakes and acting as cloud condensation nuclei can modify cloud microphysics and thus suppress rain events [1]. New data from a campaign in 2012 accentuates the importance of these hyper saline environments for the local climate.

Ground-based particle measurements around the salt lakes in 2012 were accompanied by novel chamber experiments directly on the lakes. The 1.5 m^3 cubic chamber was constructed from transparent PTFE foil permitting photochemistry within while preventing dilution of the air due to lateral wind transport. This experimental setup allows linking the measured data directly to the chemistry of and above the salt lakes. Another advantage of the PTFE chamber is the enrichment of volatile organic compounds (VOC) that are emitted from salt lakes as possible precursors for the ultra-fine particles.

Chamber air was sampled using stainless steel canisters. Sediment, crust and water samples were taken for investigation of potential VOC emissions in the laboratory using GC-MS technique.

Different VOC and halogenated volatile compounds (VOX), exceeding atmospheric background concentrations, where identified from the sampled chamber air. Their enrichment or depletion over the time in the chamber allows for postulated reaction pathways leading to the formation of ultra-fine particles.

Geochemical and acoustic investigations of hydrocarbon seepage on the continental shelf off northern Norway

S. SAUER[1]*, J. KNIES[1], C. SCHUBERT[2], A. LEPLAND[1] AND S. CHAND[1]

[1]Geological Survey of Norway, Trondheim, Norway (*correspondence: simone.sauer@ngu.no)
[2]Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Kastanienbaum, Switzerland

Active natural hydrocarbon seepage in the Hola area along the continental shelf off northern Norway has recently been found by Chand *et al*. 2008 [1]. We conducted acoustic and geochemical investigations to gain a better understanding of the extent and history of this gas seepage. Seismics and water column acoustic data were used to reveal potential hydrocarbon pathways to the seafloor and to locate active gas seepage. Methane concentrations are determined in the water column and in sediment pore waters and geomicrobiological analyses of the sediments from the seepage sites are used to assess microbial processes involved in the methane cycle.

We use sulfate and methane sediment pore water profiles to estimate the anaerobic oxidation of methane and stable isotopic analyses of methane are applied to identify biogenic or thermogenic methane sources. Concentration profiles of dissolved iron, ammonium and phosphate provide information on biogeochemical activity in the sediments.

The results of the geochemical investigations of seawater and sediment pore waters will ultimately be combined with the investigation of methane-derived carbonate crusts whose presence has recently been documented in the Hola area with an AUV based on photo and synthetic aperture sonar images. U-Th dating of these carbonate crusts will provide insights into past methane release and possible links with climate variations.

Mobility of Au in the mantle

*J. EDWARD SAUNDERS[1], N. J. PEARSON[1], SUZANNE Y. O'REILLY[1], W. L. GRIFFIN[1]

[1]ARC Centre of Excellence for Core to Crust Fluid Systems (CCFS) and GEMOC, Macquarie University, NSW, 2109, Australia, (*Correspondence: james.saunders@mq.edu.au)

Sulfides are the main host for Au in the silicate earth [1,2], but there are few reliable analyses of Au in mantle sulfides. As both a chalcophile and a highly siderophile element, Au is an important tracer of differentiation/ metasomatism in the mantle. Sulfides melt incongruently in the mantle, and are mobile in a range of melts and fluids; thus this component is readily modified during mantle processes. *In-situ* analyses are important for unravelling these processes, because multiple generations of sulfides are commonly present in mantle xenoliths [2, 3, 4].

We have analysed Au in sulfides hosted in peridotite xenoliths from eastern Australia, southeastern China and Spitsbergen (Arctic Norway). These data have been used to assess the average abundance of Au in mantle sulfides, and investigate how mantle processes affect their Au content. The variety of metasomatic characteristics, in terms of style and strength of metasomatism, in the three sample sets makes it ideal for understanding how Au behaves in the mantle.

The Au content in sulfides in mantle peridotites across all datasets is 1.3±4.1 ppm. This is similar to the limited data in the literature (global average Au=1.5±4 ppm). Both this study, and the data in the literature indicate that sulfides in the continental lithospheric mantle contain less Au than would be calculated using whole-rock PUM values (~2.5 ppm). The pyroxenites studied have even lower Au contents (average Au = 0.08±0.10 ppm). This difference has important implications for the ability of mantle melts to transport Au, and as metasomatic agents.

While globally, mantle sulfides hosted in peridotites have a similar average and range of Au concentrations, there are important differences at local scales. This study shows the relationship between mantle metasomatism, as defined by silicate chemistry, and Au concentration in mantle sulfides. A significant amount of metasomatic sulfides can be introduced associated with the modification of the silicates, and these typically have a reduced Au content, similar to the low concentration observed in the pyroxenite melts analysed.

Radiolyis and life in deep subseafloor sediment of the South Pacific Gyre

J. SAUVAGE[1], A.J. SPIVACK[1], A. G. DUNLEA[2], R.W. MURRAY[2], R. POCKALNY[1], S. D'HONDT[1] AND IODP EXPEDITION 329 SHIPBOARD SCIENTIFIC PARTY

[1]Graduate School of Oceanography, University of Rhode Island, Narragansett, RI 02882, USA (*correspondence :justine_sauvage@my.uri.edu)

[2]Department of Earth and Environment, Boston University, Boston, MA 02215, USA.

The nature of the energy yielding mechanisms in the low-energy organic-poor sedimentary environment underlying the South Pacific Gyre (SPG) is not fully constrained. We used the approach of Wang *et al*. (2008) to quantify rates of organic-fuelled metabolic activities at most IODP Expedition 329 Sites (U1365 through U1370). At Site U1366 and U1370 net rates of oxygen-reducing organic oxidation averaged 1.77E-2 and 1.64E-3 fmol O_2 $cell^{-1}$ yr^{-1}, respectively, representing a tremendously low cellular metabolism. At Site U1370, we observe net oxygen reduction throughout the entire sediment column. At Site U1366, statistically significant net oxygen reduction is not detected at depths greater than 11 meters below seafloor. Despite these low rates of organic oxidation, most cell counts are above the minimum detection limit throughout the entire sequence at both sites.

Hydrogen from natural radioactive splitting of water has been hypothesized to be a significant electron donor in organic-poor sediment of the SPG. Becauses water radiolysis produces H_2 and ½ O_2 simultaneously, oxidation of this H_2 does not contribute to net O_2 reduction in the sediment. Our calculation of radiolytic H_2 production, based on radioactive element content and sediment physical properties, indicate that on average 5.63E-1 and 9.79E-2 fmol H_2 yr^{-1} $cell^{-1}$ is available throughout the sequence at Sites U1366 and U1370, respectively. Despite these relatively high production rates, dissolved H_2 abundances are below detection at both sites. These results suggest that H_2 from in situ water radiolysis fuels the predominant energy-yielding pathway for microbes in SPG sediment.

O, Si, Fe isotopes and Ge/Si constraints on the preservation of signatures inherited from the formation of Isua BIFs

LUDIVINE SAUVAGE[1]*, MARC CHAUSSIDON[1], BÉATRICE LUAIS[1] AND CLAIRE ROLLION-BARD[1]

[1]CRPG UMR 7358 CNRS-Univ. Lorraine, BP 20, 54501 Vandoeuvre-lès-Nancy, France (*lsauvage@crpg.cnrs-nancy.fr)

A 5.7 cm long sample, made of 9 alternating magnetite-rich and quartz-rich layers, of the oldest known example of archaean BIF (3.7-3.8 old Isua sample IF-G) was studied by ion microprobe for its O, Si and Fe isotopic compositions, and by laser ICP-MS for its trace element concentrations (Ge/Si ratios). Isotopic profiles across the layers were obtained with a resolution of 50-100µm (spot size 25µm) to look for systematic isotopic variations (total of 580 $\delta^{18}O$ data in quartz and magnetite, 441 $\delta^{30}Si$ in quartz and 641 $\delta^{56}Fe$ in magnetite). Ge contents in quartz were measured in parallel with a spot size of ~120µm.

$\delta^{56}Fe$ values range from -0.1 to +2.4‰ and are quite homogeneous (±0.8‰, 2σ) within a given magnetite layer, with no significant differences between two successive layers, in agreement with previously published values [1, 2, 3]. Up to 3‰ variations in $\delta^{18}O$ values are present in the magnetite and quartz layers (except one showing larger variations) with an average ~8‰ difference in $\delta^{18}O$ between quartz (either in the quartz layers or in the magnetite layers) and magnetite, in agreement with isotopic equilibration under amphibolite facies metamorphism. In contrast to $\delta^{18}O$ and $\delta^{56}Fe$ values, $\delta^{30}Si$ values show systematic "stratigraphic" isotopic variations (from -3.5 to 0‰) with significant differences between quartz in the quartz-rich and the magnetite-rich layers. Ge/Si ratios vary from 0.6 to 1.2×10^{-5} mole/mole (i.e., 7-14 ppm Ge). There are significantly lower than published data on bulk quartz layers from a Isua sample (Ge/Si > 2×10^{-5} mole/mole [4]) due to the occurrence of Ge-rich amphiboles. Ge/Si variations seem to follow those of $\delta^{30}Si$. Because quartz is resistant to Si isotopic exchanges, $\delta^{30}Si$ are likely to reflect variations in the conditions of formation and diagenesis of the Isua BIFs. Ge/Si ratios could trace temperature fluctuations and parent fluids of different origin.

How kimberlites form: Clues from olivine geochemistry

L. SAUZEAT[1], C. CORDIER[1] AND N.T. ARNDT[1]*

[1] ISTerre, Universite de Grenoble, France (*correspondence: Nicholas.Arndt@ujf-grenoble.fr)

The formation of olivine in kimberlites is not well understood. In most kimberlites, olivine occurs as large rounded single or polycrystalline nodules (1-10mm) and as small single crystals in the matrix. It is widely accepted that majority of them are xenocrysts produced by reaction and elimination of minerals from mantle peridotite either within kimberlite melts in transit toward the surface or within the mantle before. The compositions of the cores of olivines in polycrystalline nodules range widely, from about Fo92 to Fo83, whereas the rims have more restricted compositions, usually about Fo88.

In this study, we focus on very well preserved kimberlites from Kangamiut in Greenland. We conducted petrological studies and microprobe analyses along several profiles in one unusual polycrystalline nodule. This nodule is an assemblage of small closely packed fragments, most with the uniform composition Fo92, but some fragments have rims with lower Fo contents. Our results show that the fragment rims are complex and comprise an internal zone with variable forsterite contents (Fo88 to Fo92) but roughly constant minor element contents (e.g. 0.07 wt.% CaO and 0.35 wt.% NiO), and an external zone with near-constant Fo (Fo88) but variable minor element concentrations (0.09-0.41 wt.% CaO and 0.19-0.29% wt. NiO). This external zone is similar to the thin rim surrounding all the polycrystalline nodule. We attribute these compositions to two major processes. The first, which is responsible for the internal zone, occurred before the incorporation of the nodule in the kimberlitic magma and is related to “defertilisation” of peridotite in the lithosphere; i.e. reaction with CO_2-rich fluids that removed pyroxene and garnet to produce a dunitic lithology. The second, which is responsible for the external zone, resulted from crystallization of olivine from the kimberlitic magma.

Ages and deformation of felsic dikes within granulites and gneisses of the Gruf Complex, Central Alps.

J. SAVAGE[1], A. MÖLLER[1], J. OALMANN[1] AND R. BOUSQUET[2]

[1]Department of Geology, University of Kansas, USA, jsav1013@ku.edu, amoller@ku.edu, joalmann@ku.edu
[2]Institute of Geosciences, Christian-Albrechts-Universität zu Kiel, Germany, bousquet@min.uni-kiel.de

Magmatic leucosomes and dikes in metamorphic terranes provide an opportunity to correlate accessory phase crystallization ages with the timing of deformation and metamorphic events as well as larger scale magmatic intrusions.

The Gruf Complex consists of migmatitic gneisses plus scarce charnockites and UHT sapphirine granulites We identified several mineralogically distinct types of leucosomes and dikes: 1) foliation-defining, biotite-bearing leucosomes that are commonly folded; 2) medium-grained hornblende- and/or biotite-bearing granite pods crosscutting these leucosomes; 3) biotite-bearing pegmatite dikes, boudinaged or crosscutting the main foliation; 4) pegmatitic muscovite-, garnet-, beryll-bearing dikes, crosscutting all other rock types. Field observations indicate changing melt composition during and after regional metamorphism and associated deformation. Zircons from these dikes were dated by LA-ICP-MS to constrain deformation and metamorphism.

All analyzed samples contain oscillatory-zoned zircons with ages of 250–300 Ma. A leucosome within a brecciated metaperidotite enclave contains equant, sector-zoned 32.2±0.2 Ma zircons. Most dike sample zircons have rims of 28–30 Ma. An undeformed muscovite-bearing pegmatite dike crystallized at 25.6±0.3 Ma. Another muscovite-bearing pegmatite dike lacks zircon domains <28 Ma, probably due to insufficient Zr in the melt.

Apparent zircon saturation temperatures (T_{Zrs}) for dike and leucosome samples are 680–890°C and uncorrelated with age. We attribute the wide T_{Zrs}-range to inherited zircon that did not dissolve in the melt. The pegmatite without <28 Ma zircon has a T_{Zrs} of 730°C suggesting its parental magma formed by partial melting of material similar to the deformed dikes, but did not exceed 730°C.

Coclusions: partial melting in the migmatites is coeval with the 30–32 Ma Bergell intrusion and main deformation. Dike emplacement and deformation continued until c. 24 Ma, coinciding with intrusion of the Novate granite and cooling of the granulites below the T_c of rutile at c. 500°C. The presence of 32 Ma zircons in all dikes indicates remelting of older leucosomes and dikes as the mechanism to produce the more fractionated pegmatites.

The copper isotope composition of bulk Earth: A new paradox?

PAUL S. SAVAGE[1]*, HENG CHEN[1], GREGORY SHOFNER[2], JAMES BADRO[2] AND FRÉDÉRIC MOYNIER[1]

[1]Washington University in St. Louis, MO 63130, USA (*correspondence: savage@levee.wustl.edu, chenheng@levee.wustl.edu, moynier@levee.wustl.edu)
[2]IPGP, Paris, France (gshofner@gmail.com, badro@ipdp.fr)

It is estimated that two thirds of terrestrial Cu is held in the core [1]; hence, to constrain the bulk Earth Cu isotope composition, δ^{65}Cu estimates for both mantle (BSE) and core are required. By analysing a representative suite (n ~ 50) of basaltic samples and their differentiates, we have investigated the behaviour of Cu isotopes during mantle melting and magmatic differentiation, and established a robust δ^{65}Cu value for BSE. Our results show that, during fractional crystallisation, Cu isotopes can be fractionated to both lighter and heavier compositions, depending on crystallising phase. However, during partial melting, there is no resolvable fractionation. This implies that primitive basaltic melts are a good proxy for the Cu isotope composition of the mantle. Such analyses give an average $\delta^{65}Cu_{BSE}$ value of 0.07 ± 0.12 ‰ (2sd; relative to the standard NIST 976).

To estimate the Cu isotope composition of the Earth's core, we performed a series of piston-cylinder experiments to determine the $Cu_{metal/silicate}$ isotope fractionation factor. These show that metal is preferentially enriched in the heavier Cu isotope, which agrees with emprical data from silicate-bearing iron meteorites [2]. Using these data to estimate a $\delta^{65}Cu_{CORE}$ value, we calculate the Cu isotope composition of bulk Earth to be $\delta^{65}Cu_{BE} \approx 0.16$‰. The "paradox" is as such: bulk Earth has a heavier Cu isotope composition than most (if not all) of the thus-far analysed chondritic meteorite groups [3, 4].

Assuming chondrites = bulk Earth, to explain this "missing ^{63}Cu", we tentatively propose two possibilities:

1) Isotopically light Cu entered the Earth's core as a sulphide phase, or is stored in a thus-far unsampled part of the mantle, again in sulphides.
2) The light Cu isotope was preferentially lost as a result volatile processes during Earth's accretion.

Alternatively, the current δ^{65}Cu chondrite dataset does not represent bulk Earth, and further analyses are required.

[3]School of Ocean and Earth Science, University of Southampton, Southampton SO14 3ZH, UK (eric@noc.soton.ac.uk)

[4]Dept. of Atmospheric Sciences, University of Washington, Seattle, WA 98195-1640, USA (beckya@uw.edu)

Isotopic investigations are instrumental in deciphering sources and processes affecting atmospheric nitrate. Combining the analysis of the ^{17}O-excess ($\Delta^{17}O = \delta^{17}O - 0.52\ \delta^{18}O$) with the nitrogen stable isotope ratio ($^{15}N/^{14}N$) on the same sample is a powerful tool to reveal unexpected processes happening in the air [1].

Despite recent successes in using the isotope composition of nitrate for deciphering atmospheric chemical processes in polar and mid latitude regions [2, 3], the strong oxidative atmosphere of the sub tropical and tropical regions has been largely forgotten [4]. In order to partially fill this gap, we present a full seasonal cycle of the nitrate isotope systematic at the Cap Verde (Lat 16° 85'N, Long. 24° 87' W, Alt. 20m), characteristic of a tropical marine boundary layer (MBL).

While the concentration of nitrate at this MBL do not show any season variations, the oxygen isotopic characteristics display a pronouced seasonal cycle that is compatible with nitrate formation chemistry, which includes the $BrNO_3$ sink at a level of ca. 20 ± 10% of nitrate formation pathways. The results also suggest that the N_2O_5 pathway is a negligible NO_x sink in this environment. Observations further indicate a possible link between the NO_2/NO_x ratio and the nitrogen isotopic content of nitrate in this low NO_x environment, possibly reflecting the seasonal change in the photochemical equilibrium among NO_x species.

Experimental modeling of silicates phosphatization in the hypergenesis zone

A.V. SAVENKO

Moscow M.V. Lomonosov State University, 119991, Moscow, Russia (correspondence: Alla_Savenko@rambler.ru)

Now there was a concept that immobilization of dissolved phosphates on silicate minerals in the hypergenesis zone occurs on the mechanism of superficial adsorption. At the same time it is possible to assume that alongside with it process of silicates phosphatization similar to widespread process of silicates carbonatization proceeds. This hypothesis was verifyed during the longtime experiments.

The phosphatization of two basic clay minerals (kaolin and montmorillonite) was studied after two-year long interaction with 0.25–5.0 mM orthophosphate solutions under acidity conditions ranged pH 1.8–8.8. The results have shown (figure) that variation of dissolved phosphorus and silicon concentrations at pH 3.7–8.8 is close to equivalent: $\Delta[Si] \approx -\Delta[P]$ whereas $\Delta[Si]$ value at pH 1.8 is in 1.5−2 times exceeds decrease in phosphates concentration. Quantity of phosphorus immobilized by clay minerals is in direct proportion of its equilibrium concentration in the solution: $-\Delta[P] = k[P]_{eq}$. The proportionality factor k is identical to all studied samples and decreases from 0.58 till 0.44 at the pH increase with 1.8 up to 8.8. Quantity of silicon passing in the dissolved forms reaches 6–20% of total amount of silica in the solid phase. It specifies phosphatization of clay minerals which products are dissolved silica and poorly soluble basic aluminium phosphates.

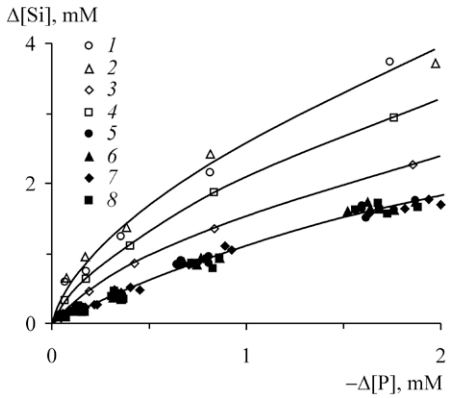

Figure: Relationship between variation of dissolved phosphorus and silicon concentrations at the clay minerals phosphatization. pH 1.8/3.7–8.8: *1*/*5* – kaolin, Glukhoveck; *2*/*6* – ditto, Podolsk; *3*/*7* – montmorillonite, Askanija, sample 1; *4*/*8* – ditto, sample 2.

Multi-proxy investigation of Holocene climate in West Siberia using peat deposits

YU. V. SAVINYKH,[1] N. PEDENTCHOUK,[2] YU.I. PREIS[3] AND E.V.GULAYA[1]

[1]Institute of Petroleum Chemistry SB RAS, Tomsk, Russia, yu-sav2007@yandex.ru

[2]School of Env. Sciences, University of East Anglia, Norwich, UK

[3]Institute of Monitoring of Climatic and Ecological Systems SB RAS, Tomsk, Russia

West Siberia is a vast region that covers a large part of northern Asia and, in spite of its size, is relatively homogenous in terms of topography and climate. It is an ideal target for studying palaeoclimate, because even a relatively limited number of sites would provide representative data for investigating climate changes that affect large areas of this region. This project uses a multi-proxy approach to study Holocene climate change in West Siberia.

A peat core was obtained from an ombrotrophic bog located in the vicity of Tomsk. Bog vegetation is dominated by peat moss, but also comprises a substantial number of vascular plant species. The base of the 6.5-m-long core was dated at 10,500 cal yr BP. Organic matter was subjected to palynological, biomarker, and stable isotopic analyses.

Our preliminary testate amoebae (analyst I.V.Kurina) and *n*-C_{23} alkane (sourced mainly by *Sphagnum* spp.) δD in the upper 260 cm of the core show the following patterns. The percentage of hydrophilic testate amoebae starts to increase from the background level at 140-135 cm, reaches its peak at 125-115 cm, drops to a minimum at 85-65 cm, and then undergoes an increase towards the top of the core. The δD values of *n*-C_{23} decrease from -170‰ at *c*. 200 cm to -225‰ at 105-100 cm, change sharply to -210‰ at 95-85 cm and then reach -190‰ at the top. Because more negative δD values of *Sphagnum* spp. could indicate colder or wetter (or a combination of both) climate, we suggest that these two data sets point to a period of wetter climate during the time interval recorded by the peat sequence between 140 and 100 cm. The integration of our data with palynology from previously published reconstructions of West Siberian climate from 500 and 1700 cal yr BP, corresponding to *c*. 150-50 cm of our core, suggests a period of cold and wet climate. Our ongoing work on biomarker and stable isotopic compositions of various sources of organic matter in this core will allow us to provide more detail with regards to palaeoclimatic changes during this and earlier time intervals in the Holocene.

Boron isotopes in boninites from the Izu-Bonin-Mariana arc system: Insights into subduction initiation

IVAN P. SAVOV[1] AND SAMUELE AGOSTINI[2]

[1] Univ. Leeds, School of Earth & Environment, Leeds LS2-9JT, UK; i.savov@leeds.ac.uk ; [2] Istituto di Geoscienze e Georisorse- CNR, Pisa, Italy s.agostini@igg.cnr.it

The origin of boninites has long been debated and several mechanisms for their formation have been proposed [1]. These rocks have both high MgO contents and somewhat LREE+LILE enrichments, thus their genesis should involve large percentage melting of highly melt-depleted but also highly fluid metasomatized mantle sources. One mechanism to explain boninite generation in the Izu-Bonin-Marianas (IBM) arc-basin system invokes sinking of cold Pacific oceanic slabs, trench retreat and intense backarc spreading [1]- all resulting in anomalous mantle melting conditions and voluminous boninite eruptions close in time and space to the oldest mafic volcanic arc rocks in IBM at ~ 51 Ma [2]. Since the mantle is extremely depleted in B and has very negative $\boldsymbol{\delta}^{11}$B ratios and the slab fluids have very positive $\boldsymbol{\delta}^{11}$B signatures, B and B isotope ratios are able to trace the slab–fluid additions and the resulting boninite generation. We have selected a suite of representative boninites from the the Izu-Bonin (Bonin Ridge) and the Marianas (Guam Island) segments of the IBM. The boninites all have remarkably similar $^{87}Sr/^{86}Sr$ (0.7042-0.7049) and $^{143}Nd/^{144}Nd$ (0.51283-0.51297) isotope signatures. Interestingly the boninites $\boldsymbol{\delta}^{11}$B ranges from +0.9 to +5.1 permil (data always better than ±1 per mil), supporting models for early slab fluid liberation via dehydration of old foundering Pacific slabs. Such fluid additions are necessary for lowering the melting temperature of the depleted mantle wedge and for boninite generation. Based on the isotope (B, Nd, Sr) and trace element similarities we envision the boninite sources to be chemically similar to blueschist-containing serpentinite muds and serpentinized peridotites erupted today via mud volcanoes in the IBM forearc and successfully drilled during ODP Legs 195 and 125 [3]. Links between high Mg arc volcanic rocks and serpentinite-derived fluids are becoming increasingly common [4] and we will discuss possible links between metamorphic petrology of the slab inventory, island arc magma generation and the usefulness of B isotopes as tracer.

Stable C and O isotope ranges of African land snail shells

Y. SAWADA[1]*, D. L. DETTMAN[2] AND M. PICKFORD[3]

[1]Shimane Univ. 402-1 Fukushima, Kurashiki 710-0048, Japan (*correspondence: yoshipikotan4306@sky.megaegg.ne.jp)
[2]Environ. Isotope Lab. Dept. Geosciences, Univ. Arizona, Tucson, AZ85721 (dettman@email.arizona.edu)
[3]Muséum National d'Histoire Naturelle, France (pickford@mnhn.fr)

Cenozoic fossil land snails can be found in many continental sections (Pickford, *J. African Earth Sci*.1995). We show how stable C and O isotope ranges of modern land snail shell from various ecosystems in Africa are related to snail genus, climate, and diet. Sequential powdered samples are drilled following growth lines through multiple years of shell growth to document stable isotope response to seasonal environmental variation. Results are summarized as follows: $\delta^{13}C$: Variation within one specimen is small. Shell $\delta^{13}C$ primarily responds to differences in diet, i.e. C3 plants, C4 plants, and the ingestion of carbonate from detritus, bedrock or soil.

$\delta^{18}O$: (1) Snails of the same genus from same ecosystem have similar values. (2) Oxygen isotope ranges from tropical forest, upland forest, coastal steppe, semi-desert and desert are small, with forest values generally lower than desert or semi-desert. (3) Regions with pronounced dry and wet seasonality (savannah, Mediterranean) can have large seasonal variation in $\delta^{18}O$. Within one climate type, snails of different genus often have similar ranges, although sometimes ranges are different. Habitat/climate has a stronger control on shell chemistry than taxonomy.

The $\delta^{13}C$ and $\delta^{18}O$ ranges of land snail shells reflect ecosystems, diet, and perhaps micro-habitat preference. Land snail fossils are potential targets for paleoenvironmental reconstruction based on a combination of faunal analysis and stable isotope geochemistry. [abbreviation] C: $\delta^{13}C$ VPDB, O: $\delta^{18}O$, VPDB.

Seasonal methane fluxes and sulfate reduction rates in a eutrophied Baltic estuarine system

JOANNA E. SAWICKA*, CAMILLA OLSSON AND VOLKER BRÜCHERT

Department of Geological Sciences, Stockholm University Svante Arrhenius Väg 8, 10691 Stockholm, Sweden (*joanna.sawicka@geo.su.se)

Estuaries and shelves are thought to be the source of 75% of the oceanic CH_4 emissions to the atmosphere, but to date relatively few data are available that report spatial and seasonal variations in production and emission of CH_4 from sediments in eutrophied coastal settings. Himmerfjärden (Baltic Sea, Sweden) is an estuary with a surface area of 174 km^2. The estuary has a well-described eutrophication gradient from the inner part of the estuary to the opening, which is due to a sewage treatment plant (STP) in the inner estuary that has been discharging treated sewage since 1973. The sediments in the bay consist of organic-rich postglacial mud, sand, and glacial clay. CH_4 fluxes at sediment/water interface, pore water concentrations of SO_4^{2-}, CH_4, and H_2S, and ^{35}S-sulfate reduction rates were measured in the spring, summer, autumn, and winter in the estuary at two stations, one close to the STP and one at a reference site outside the estuary. Additionally, sea-air fluxes and CH_4 water column concentrations were measured at the two stations.

Benthic methane fluxes were determined from ex-situ incubations and showed seasonal and spatial variations. The lowest CH_4 flux (0.1 mmol $m^{-2}d^{-1}$) was observed in winter at the reference site and the highest CH_4 flux (8.74 mmol $m^{-2}d^{-1}$) was recorded in the summer in Himmerfjärden sediment. For the other seasons, CH_4 fluxes at both stations were between 1 mmol $m^{-2}d^{-1}$ and 2 mmol $m^{-2}d^{-1}$. Sulfate reduction rates showed spatial variability and were consistently 10-fold higher in Himmerfjärden (~ 0.3 μmol $cm^{-3}d^{-1}$) than at the reference site. There was a distinct zone of organoclastic sulfate reduction in both sediments at 3-7 cm depth. In the contaminated sediments near the STP, the sulphate-methane transition zone (SMT) was observed persistently during the year at depths 12-16 cm, indicating the presence of anaerobic methane oxidation, but was not detected above 40 cm depth at the reference site. Water column CH_4 concentration profiles showed that the sediments are the major source of CH_4 in the water column, as there was a pronounced increase in concentrations towards the bottom. Near-bottom water CH_4 concentrations were between 109 and 131 nmol/l. Concentrations at the surface were generally two-fold lower indicating efficient methane oxidation in the water column. Nevertheless, surface waters at both stations were oversaturated with respect to CH_4 throughout the year indicating that Himmerfjärden is an annual net source of CH_4 to the atmosphere.

Thermodynamics of the C-H-O fluid at extreme conditions

S.K. SAXENA[1]*, R. HRUBIAK[1], V. DROZD[1], A.B. BELONOSHKO[2], P. SHI[3] AND G. ERIKSSON[4]

[1]Department of mechanical and materials engineering, Florida International University, Miami, FL 33199, USA (*correspondence: saxenas@fiu.edu)
[2]Department of Metallurgy, Royal Technical University, Stockholm, Sweden
[3]Thermo-Calc AB, Stockholm, Sweden
[4]GTT-Technologies, Aachen, Germany

The superfluid model [1] for calculation of high pressure-temperature fluid fugacities builds on the combination of experimental data on pure and mixed fluids at temperatures lower than 1000 K over several kilobars and molecular dynamics generated data at extreme conditions (> 5 kbar and up to 100 GPa and 4000 K). The model is found to be generally consistent with post-publication (since 1992) experimental data. The calculated data on water at low pressure differs significantly from the Brodholt-Wood fluid inclusion data [2] but closely reproduces the densities measured by Abramson and Brown [3].The superfluid model and the model of Zhang and Duan [4] are closely similar.

We have used the model to calculate high pressure and temperature phase equilibrium in binary (MgO-CO_2, Al-H_2), ternary (Fe-H_2O-C, wustite-H_2O-C) and multicomponent (carbonaceous chondrite) systems. The results show that while a carbonate may be stable over the entire range of the mantle pressures and temperatures, it is not stable if the mantle is chondritic in composition. Iron carbide (Fe_3C), on the other hand, is stable to extreme pressure and temperatures in the ternary as well as in chondritic composition and may be a good candidate to be assimilated in the core. The conclusions are that a) the carbonate may not be the storage for CO_2 in the deep earth and b) carbon is more likely stored in Earth's core as carbide and as diamond in the mantle.

The authors wish to acknowledge the support and collaboration of the Deep Carbon Observatory.

Effect of magnetite addition on H_2S dynamics in coastal marine sediment

M. SAYAMA

National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba 305-8569, Japan (m.sayama@aist.go.jp)

It has been well known that magnetite is poorly reactive towards dissolved sulfide (H_2S) on a time scale of hours to days (Canfield *et al*., 1992; Raiswell and Canfield, 1996; poulton *et al*., 2004). However, microprofiles of H_2S in experimental sediment cores made wtih coastal marine surficial sediment showed a dramatic change by the addition of magnetite (Fig. 1). The depth of H_2S front at which H_2S concentration starts to increase stayed at the original even after four days incubation in the core with magnetite addition (Fig. 1, right), whereas the H_2S front moved up quickly and reached to the oxic-anoxic interface (OAI) within 24 hours in the control core (without magnetite addition) (Fig. 1, left). Possible mechanism to explain these results might be electrochemical oxidation of H_2S at deep with long distance electron (e^-)-transfer through solid state cycling of structural Fe^{2+} and Fe^{3+} in magnetite (Latta *et al*., 2011).

Variation of trace element partition coefficients

We present the variation of trace element partition coefficients measured at the interface between rapidly cooled clinopyroxene crystals and co-existing melts. Results indicate that, Ds for REE, HFSE and TE increase with increasing cooling rate, in response to clinopyroxene compositional variations. The entry of REE into the M2 site is facilitated by a coupled substitution where either Na substitutes for Ca on M2 site or Al^{iv} substitutes for Si in the tetrahedral site. Due to the lower concentration of Ca in rapidly cooled clinopyroxenes, LILE on M2 decrease at the expense of monovalent cations. Conversely, higher concentrations of HFSE and TE on the M1 site are facilitated as the average charge on this site increases with the replacement of divalent-charged cations by Al^{vi}. At both equilibrium and cooling rate conditions, Ds for isovalent cations define parabola-like curves when plotted against ionic radius, consistent with the lattice strain model.

Implications

Although crystallization kinetics alter clinopyroxene composition, deviations from equilibrium partitioning are insufficient to change the tendency of a trace element to be compatible or incompatible. Consequently, there are regular relationships between ionic radius, valence of the trace element and D. Under both equilibrium and cooling rate conditions, the partitioning of trace elements is driven by charge-balance mechanisms; cation substitution reactions can be treated in terms of the energetics of the various charge-imbalanced configurations.

A Pilot Br Isotopic Study of Arid Playa Lakes and Ordinary Chondrites

BRUCE F SCHAEFER[1]

[1]CCFS, Department of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia (Bruce.Schaefer@mq.edu.au)

Introduction: Bromine possesses a chemistry broadly comparable to that of Cl and F, however its heavier mass and lower abundance results in slightly different behaviours in geochemical cycling. For example it is disproportionately enriched in sea water with respect to Cl. Br can be considered to be a "hydrophile" element, and hence its behaviour is in governed by that of water. It possesses two isotopes ^{79}Br (50.686%) and ^{81}Br (49.314%).

This study has developed new chemical extraction, and most significantly, new mass spectrometric protocols for Br isotopes on silicates, evaporites and waters using N-TIMS methodologies. Existing CF-IRMS methodologies offer internal precision of ~0.3‰ (1SD, [1]), whereas N-TIMS measurements of laboratory HBr and seawater standards produce external reproducibility of <0.07‰ (1SD) over an 18 month period with internal precision typically <0.06‰ (1SD) on single analyses.

This study presents the first high precision, N-TIMS isotopic data on playa lake evaporites and ordinary chondrites, recording a >5‰ variation in solar system $^{81}Br/^{79}Br$.

New data on anisotropy and composition dependence of Na/K-interdiffusion in alkali feldspar

A.-K. SCHAEFFER[1], E. PETRISHCHEVA[1], G. HABLER[1], R. ABART[1] AND D. RHEDE[2]

[1]University of Vienna, Department of Lithospheric Research, Vienna, Austria (anne-kathrin.schaeffer@univie.ac.at)
[2]GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany

Cation exchange experiments have been conducted using crystallographically oriented plates of gem quality sanidine as starting material.

The observed geometry of the diffusion fronts can be explained by a composition dependence of the interdiffusion coefficient. We extracted the composition dependence of the interdiffusion coefficient from our measured data by use of the Boltzmann transformation in the composition interval between X_{Or} 0.5 and 1 for the directions (001) and (010).

At 850°C the interdiffusion coefficient D is nearly constant at 0.3 $x10^{-15}m^2s^{-1}$ over the composition range X_{Or} 0.50 to 0.95 and then rises steeply to values of 2.5 $x10^{-15}m^2s^{-1}$ for profiles normal to (001). Normal to (010) D is nearly constant at 0.03 $x10^{-15}m^2s^{-1}$ over the composition range X_{Or} 0.5 to 0.97 before, too, rising steeply at higher X_{Or}. Thus interdiffusion normal to (001) is faster by a factor of about ten than interdiffusion normal to (010).

Christoffersen *et al*. [1] measured interdiffusion coefficients in the composition range between X_{Or} 0.1 to 0.8 in diffusion couple experiments. They observed a similar anisotropy but they find a composition dependence of D for intermediate compositions which disagrees with our findings. Also, their absolute values for the interdiffusion coefficient at a given composition are smaller by about a factor of ten.

Comparison with theoretical calculations of the interdiffusion coefficient from self-diffusion data found in literature [2, 3] using the Manning relation for interdiffusion in ionic crystals shows a rough fit for interdiffusion normal to (001) while the slower interdiffusion normal to (010) deviates significantly from what would be expected.

The activation energy also shows an anisotropy; normal to (001) it is about 340 kJ/mole while it is 250 kJ/mole normal to (010).

The geochronological signal of a dying magma system

U. SCHALTEGGER[1], C. BRODERICK[1] AND J.F. WOTZLAW[1]

[1]Section of Earth and Environmental Sciences, University of Geneva (urs.schaltegger@unige.ch, joern.wotzlaw@unige.ch, cindy.broderick@unige.ch)

U-Pb dating of zircon is the most commonly used geochronometer for temporal quantification of pluton and batholith forming processes. High-precision zircon $^{206}Pb/^{238}U$ dating repeatedly produces a dispersion of ~50-200 ka between the oldest and youngest zircon of the same sample, and of up to 1 Ma within a plutonic unit, pointing to a prolonged magmatic evolution with non-monotonously varying parameters like melt temperature, crystallinity and melt composition. Combining high-precision U-Pb dates with trace element and Hf isotope analysis on the same dated volume of zircon, we are able to trace different processes acting during the assembly of a pluton and quantify their timing: 1) changing melt composition due to fractional crystallization of zircon and of other accessory minerals (e.g., titanite) over time; 2) quantify the evolution of overall crystallinity of a magmatic body over time; 3) changes in magma temperature by identifying periods of enhanced and suppressed zircon crystallization, and correlate them with periods of mafic magma recharge and thermal rejuvenation of the system; 4) changing sources of incoming melts over time by linking initial Hf isotopes to crystallization age.

Probability density functions of $^{206}Pb/^{238}U$ zircon dates of a pluton usually point to several peaks of enhanced zircon crystallization during a prolonged period of increasing crystallinity of the magma, leading to stalling of the crystal mush and subsequent complete solidification at upper crustal levels. The non-steady decrease of the volume of potentially eruptible crystal-poor liquid leads eventually to the "plutonic death" of a magmatic system.

Labile structures in organic matter under the incfluence of multivalent cations – an issue for dynamic interfaces?

GABRIELE ELLEN SCHAUMANN[1]

[1]University Koblenz-Landau, Insitute for Environmental Sciences, Fortstr. 7, Landau, Germany, schaumann@uni-landau.de

Soil organic matter (SOM) controls large part of the processes occurring at biogeochemical interfaces in soil and may contribute to sequestration of organic chemicals. In this contribution, the idea that sequestration of organic chemicals is driven by physicochemical SOM matrix aging, and its consequences for transport processes will be discussed. In contrast to chemical aging processes, physical matrix aging involves changes in the supramolecular arrangement of SOM molecules and molecule segments. Organic chemicals can be entrapped in nanovoids, which can tranform to a semi-persistent cage. Persistence of entrapment directly depends on the rigidity and stability of the cage. Water molecule bridges (WaMB) and cation bridges (CaB) between segments of soil organic matter (SOM) have been found to stabilize the supramolecular SOM matrix and are therefore suspected to control immobilization of organic chemicals in soil. Contaminants sequestered by WaMB or CaB can be immobilized or released suddenly upon changes in environmental conditions like moisture, temperature or melting. Understanding their dynamics is highly important to model the reaction of soil as well as release and transport of organic chemicals on changes in climatic conditions. While the idea of CaB in solid soil organic matter is more and more accepted, there is increasing evidence that such cross-links are not relevant in all types of soil organic matter, depending on the spatial distribution of charged functional groups in the OM. Only if distances between functional groups are sufficient, CaB can form. Larger distances can be bridged by CaB-WaMB associations. Also interfacial properties are dynamic. Soil wettability can with increasing involvement of functional groups in CaB-WaMB associations. In the extreme case, high concentrations of multivalent cations can hydrophobize surfaces of SOM. Associations of CaB and WaMB evolve slowly and form a supramolecular network in SOM. Those dynamic associations can fix molecular arrangements inducing water repellency and increase kinetic barriers for the release and uptake of water and sorption and transport of organic chemicals in soil.

The role of soil Cu in chelate mediated Fe acquisition by plants

W.D.C. SCHENKEVELD[1]*AND S.M. KRAEMER[1]

[1]University of Vienna. Dept. of Environmental Geosciences, Althanstrasse 14, 1090 Wien, Austria
walter.schenkeveld@univie.ac.at (* presenting author)

Iron is an essential micronutrient to plants. In soils with a neutral to alkaline pH, the solubility of Fe bearing minerals is very low and can become limiting for plant growth. To avoid Fe deficiency in plants grown on such soils, the solubility of Fe needs to be increased. This can be established by means of chelating agents, which strongly bind Fe and form a soluble Fe complex. These chelating agents can either have a natural or an antropogenic origin.

Grasses (including wheat, barley and rice) are very efficient in preventing Fe deficiency, because their Fe acquisition strategy includes the exudation of chelating agents called phytosiderophores (PS). These PS can dissolve soil Fe and the resulting FePS complex can be taken up by a high affinity membrane transporter. In agricultureal practice, plant species that are less efficient in acquiring Fe are commonly supplied with micronutrient fertilizers based ons synthetic chelating agents. For Fe fertilization on calcareous soils, FeEDDHA (iron ethylene diamine bis-N,N'- hydroxyphenyl acetic acid) is among the most effective.

Soils contain several metals that can compete with Fe for binding to chelating agents, thereby compromising the efficiency of the chelate mediated Fe uptake mechanism. Cu is among the stronger competitors and occurs in soil in quantities that could substantially compromise Fe uptake.

It will be shown and discussed that the extent to which Cu effectively competes with Fe for complexation under soil conditions is controlled by both thermodynamic and kinetic factors. These factors include the specific affinity of the chelating agent for Fe and Cu, the Fe and Cu activity in the soil, the extent to which metal complexes adsorb to reactive soil components, the mobilization rate of Fe and Cu, and the displacement rate of Fe from the Fe-chelate by Cu. Both with PS and synthetic Fe chelates, Cu may considerably limit the time-span the chelating agent remains effective as Fe transporter.

New insights into simultaneous determination of mass-dependent isotopic fractionation and radiogenic isotope variations of strontium by multi-collector ICPMS

HOWIE D. SCHER[1], ELIZABETH M. GRIFFITH[2] AND WAYNE P. BUCKLEY JR.[1]

[1]Department of Earth and Ocean Sciences, University of South Carolina, hscher@geol.sc.edu

[2]Department of Earth and Environmental Sciences, University of Texas at Arlington, lgriff@uta.edu

Variability of Sr isotope ratios are due to radioactive decay and mass dependent fractionation through various physiochemical reactions. Radiogenic Sr ratios are used for geochronology and provenance while stable isotope ratios of Sr reveal mechanisms of sample formation and resolve mass balance in geochemical systems.

Accurate and precise measurements of stable Sr isotope ratios (e.g., $^{88}Sr/^{86}Sr$) are possible if the ratio can be corrected for mass-discrimination effects during analysis. Ohno and Hirata (2007) developed a method where Sr solutions were doped with Zr, and measured $^{88}Sr/^{86}Sr$ ratios were normalized to $^{91}Zr/^{90}Zr=0.2181$, while simultaneously measuring $^{87}Sr/^{86}Sr$. Using standard sample bracketing combined with a Zr correction, we tested three variables that influence the mass-discrimination effect on the multi-collector ICPMS. All stable isotope ratios are reported relative to SRM987.

First, solutions of 500 ppb SRM987 with Ba/Sr from 0.002 to 200 were analyzed by bracketing against a SRM987 solution with no Ba. Deviations from $\delta^{88}Sr=0$ ‰ occur above Ba/Sr ratios of 10. Deviations from our long term $^{87}Sr/^{86}Sr$ value also occur above this level of Ba.

Second, seawater was processed through standard microcolumn extraction with SrSpec resin (Eichrom). Eluted Sr was adjusted to 250 ppb and Zr was added so that Sr/Zr was ~1. We repeated the Ba doping experiment using the Zr correction. When Ba/Sr<10 the measured $\delta^{88}Sr$ is 0.37±0.05‰ (2σ, n=28) which is within analytical precision of published values for seawater (0.35 to 0.39). Deviations occur above Ba/Sr = 10.

Lastly we tested the Zr/Sr ratio on the measurements of $\delta^{88}Sr$ in seawater. We determined that the ideal Zr/Sr ratio is slighly lower than unity, and that high Zr/Sr ratios result in inaccurate $\delta^{88}Sr$ determinations.

Dahomeyan Neoproterozoic imprint on Eburnean Palaeoproterozoic rocks in southeast Ghana – Rubust Ar, flimsy Pb

ANDERS SCHERSTÉN[1], LAURENCE PAGE[1], PER KALVIG[2], ANDREAS PETERSSON[1] AND SOLOMON ANUM[3],

[1]Department of Geology, Lund University, Sölvegatan 12, SE-223 62 Lund, Sweden. anders.schersten@geol.lu.se; laurence.page@geol.lu.se; andreas.petersson@geol.lu.se;

[2]Geological Survey of Denmark and Greenland, Øster Voldgade 10 DK-1350, København, Denmark. pka@geus.dk

[3]Geological Survey Department, Ghana, P.O. Box M 80 Accra, Ghana. anumsolo@yahoo.com

The Dahomeyan belt formed during Pan-African suture between juvenile island arcs rocks that were amalgamated to the >2.0 Ga West African craton (WAC). Arc accretion and subsequent continent collision is manifested through eclogites and mafic to felsic granulites. Pre-collisional passive margin sediments were thrust westward over the WAC. A combined zircon U-Pb and hornblende/mica $^{40}Ar/^{39}Ar$ profile across the Eburnean-Dahomeyan orogens was made to constrain Dahomeyan imprint on the Eburnean rocks in the WAC. Hornblende ages are 2.06 Ga, while micas yield 2.0 Ga. Zircon U-Pb ages yield igneous crystallisation ages >2.1 Ga, however som samples display significant Pb-loss with lower intercept ages that are consistent with a 0.6 Ga Dahomeyan imprint. This probably reflect fluid induced variable resetting of the zircon U-Pb system, while mica and hornblende remained below their blocking temperatures and where inert to the fluids that affected the zircon. A granulite and a zoned plagioclase porphyritic metavolcanic rock from within the Dahomeyan belt, yield 0.614 and 0.577 Ga zircon ages respectively. The 0.577 Ga population represent igneous crystallisation as represented by prismatic zoned crystals. The 0.614 Ga population is represented by rounded featureless zircon, and date granulite facies metamorphism. Hornblende from the granulite yield 0.59 Ga $^{40}Ar/^{39}Ar$ plateaux, dating post granulite facies cooling through ~525 °C, correspond to a cooling rate of at least10 °C/Myr.

These result highlights the imprint of the Dahomeyan orogen on the >2 Ga Eburnean rocks of the WAC in southeast Ghana. No resetting of Ar-ages is noted in mica or hornblende in the Eburnean rocks, while zircon is variably reset.

Physical evolution of olivine-hosted melt inclusions during high-*T* homogenization treatments

F. SCHIAVI*, A. PROVOST, P. SCHIANO AND N. CLUZEL

Laboratoire Magmas et Volcans, Univ. Blaise Pascal, CNRS, IRD, 5 rue Kessler, 63038 Clermont-Ferrand, France (*correspondence: f.schiavi@opgc.univ-bpclermont.fr)

Silicate melt inclusions (MIs) form in thermodynamic equilibrium with their host mineral. After entrapment, during the ascent of the host magma and its cooling upon eruption, MIs may undergo physical and chemical changes, part of which are irreversible. Thus, to properly interpret petrological information recorded by MIs, a full understanding of their physico-chemical behaviour when submitted to variations of external temperature (T) and pressure is required. Homogenization temperature (T_h) of the inclusion content (gas + glass ± crystals) is thought to correspond to minimum entrapment temperature (T_e). However, T_h in olivine is observed to increase systematically with time during high-T treatments, thus revealing the occurrence of irreversible physico-chemical changes in the MI-host system.

To figure out what processes are responsible for T_h increase, we performed heating experiments on H_2O-rich (Vulcano Is., Italy) and H_2O-poor (Famous-Zone MORB, East Atlantic) olivine-hosted MIs. Equilibrium between melt and olivine compositions suggests $T_e \approx 1210$°C for Vulcano MIs and $\approx$ 1220°C for Famous-Zone MIs. Each experiment consisted of several heating-cooling cycles performed in a rapid-quench optically-controlled Vernadsky heating stage.

In our experiments large variations of T_h with time were measured, along with high first T_h (1230-1300°C for Vulcano MIs; $T_h \geq 1315$°C, more often $\approx$ 1430°C for Famous-Zone MIs), which are inconsistent with calculated T_e. T_h increase from one cycle to the next is associated with an increase of low-T bubble size and a slower reduction of bubble volume at high T. Images taken during the experiments on Famous-Zone MIs allowed us to measure expansions of MI cavities up to ~30 vol% of the starting volume. Volume expansion occurred quite rapidly (after 10-80 min at $T > 1100$ °C) and increased with time. Its amount, and the associated first T_h as well, seem to be related with MI size, distance of MI walls from olivine faces, and ratio between bubble and MI volumes. T_h increase essentially results from the plastic deformation of host olivine (elastic deformation and dissolution/precipitation interfere but are reversible). Though diffusive water loss may interfere too during the first hours at high T, it cannot explain the observed cavity expansion nor the large and sustained increase in T_h.

Pace of soil formation based on soil structure indices

JASMIN SCHIEFER[1], GEORG J. LAIR[1,2] AND WINFRIED E.H. BLUM[1]

[1]Institute of Soil Research, University of Natural Resources and Life Sciences,Vienna, Austria
[2]Institute of Ecology, University of Innsbruck, Austria.
E-mail: jasmin.schiefer@boku.ac.at, georg.lair@boku.ac.at

Clay sized aggregates play a key role in soil formation as they accumulate and preserve organic matter (OM) by physical protection against microbial decomposition [1]. However, the development of microaggregates during soil formation is not well understood. For our study we collected soils of a chronosequence of approximately 10 to 10000 years in an alluvial plain of the River Danube [2]. A- and AC-horizons of Fluvisols and Chernozems under cropland, grassland and forest were sampled. Microaggregates (< 2μm), gained by ultrasonic dispersion and centrifugation, as well as bulk soil were physically and chemically analysed.

Microaggregates under semi-natural forest showed a steep increase of OM content and a depletion of amorphous Fe-(hydr)oxides in the first years of soil development. In the soils older than about 350 years, OM content in the clay sized aggregates remain more or less constant over time, indicating a possible saturation of the clay sized particles with OM. In contrast, the initally low OM content in the microaggregates under cropland was continuously increasing with soil age. A characterisation of OM in the microaggregtes (e.g. by STA) revealed that with time less degradable compounds are accumulating, especially in the AC-horizon. In the AC-horizon of a 2000 - 3000 year old soil the amount of labile and stable OM in the clay sized aggergates was about the same.

Soil structure build-up was strongly influenced by bioturbation (e.g. earthworms) and plant material inputs (roots, litter). A calculation of the annual soil formation rate, based on the depths of the A-horizons, indicates a very high soil formation rate up to ~4 mm/year at the beginning, decreasing to ~0.1 mm/year after 2000 years.

Using increment cores of eastern cottonwood trees (*Populus deltoides*) to assess the timing of Cd pollution

JOHAN SCHIJF [1]* AND MARY C. GARVIN[2]

[1]Chesapeake Biological Laboratory, P.O. Box 38, Solomons, MD 20688, USA (*correspondence: schijf@umces.edu)
[2]Oberlin College, Department of Biology, 119 Woodland St., Oberlin, OH 44074, USA (Mary.Garvin@oberlin.edu)

We measured the concentrations of 8 trace metals in the trunk wood of ~40 eastern cottonwoods (*P. deltoides*), a fast-growing dioecious angiosperm common throughout much of eastern North America. Large trees were selected more or less at random from an area in northern Ohio (USA) that has a known history of soil pollution with a variety of metals and organic compounds, as well as from an equally sized control area. Two increment cores (L < 40 cm, ∅ 5 mm) were taken from each tree at chest level. To avoid contamination, annual growth rings were marked on one core and the markings were used to guide cutting of the sample core with tungsten carbide surgical tools into eight 5-year sections covering the period 1970–2009. The older and younger rings were not analyzed. All sections were completely microwave-digested (10 min at 200°C) in a mixture of 16 M nitric acid and 30% hydrogen peroxide, along with one blank and one pine wood SRM (NJV 94-5). The cooled digests were then weighed, diluted 100-fold, and analyzed by Octopole Reaction System ICP-MS (Agilent) for As, Cd, Co, Cr, Cu, Ni, Pb, and V.

While some metals (As, V) are always below the method detection limit (DL) and others appear to vary arbitrarily, Cd is the only one showing behavior that may be interpretable in terms of both space and time. Blanks were always below the DL (~15 ng Cd per g dry wood), there was no evidence of sample contamination, and analytical recovery of the SRM was excellent (>98%). The ~40 trees fall into three distinct groups: 1. Trees with low mean Cd concentrations (270 ng/g) and little temporal variability (n = 20); 2. Trees with a clear maximum or temporal trend in the Cd concentration of up to 1300 ng/g (n = 14); 3. Three trees with extremely high Cd concentrations (>2500 ng/g). Replicate cores taken from a single tree as well as from separate trees at a single location yielded satisfactory reproducibility (10–20%). Although the timing of maximum Cd concentrations varies, high amounts are not found in the most recent 10 years of any tree. All trees in group 3 and all but one tree in group 2 are located in the polluted area, whereas all but one tree in the control area are from group 1. A simple statistical test indicates that this distribution has an almost negligible probability of occurring by chance (χ^2 = 8.819, p = 0.003).

Mg isotope evidence for ancient magmatic differentiation on the angrite parent body

M. SCHILLER[1]*, T. MIKOUCHI[2], J. N. CONNELLY[1] AND M. BIZZARRO[1]

[1]Centre for Star and Planet Formation, Natural History Museum of Denmark, University of Copenhagen, Copenhagen, Denmark (*email: schiller@snm.ku.dk)
[2]Department of Earth & Planet. Science, University of Tokyo, Tokyo, Japan

Angrite meteorites are the most alkali-depleted rocks in our solar system and they can be divided into plutonic and volcanic angrites [1]. Of the group of volcanic angrites, NWA 1670 is particularly interesting because it contains significant amounts of olivine xenocrysts of up to 5 mm in size that are chemically distinct from the groundmass [2,3]. The existence of xenocryst olivine not in chemical equilibrium with the groundmass offers the potential for a resolvable temporal difference between both phases. Therefore, considering the old age for this angrite [4], the xenocrysts may reflect an earlier magmatic event.

Here we apply the ^{26}Al to ^{26}Mg ($t_{1/2}$ = 0.7 Myr) chronometer to examine the temporal relationship of olivine xenocrysts and basaltic groundmass in NWA 1670. Mg isotope data for individual olivine grains and groundmass seperates were obtained using the Neptune MC-ICPMS. All olivine xenocrysts have negative μ^{26}Mg* with a mean of –10.7 ± 3.1 ppm. Measured μ^{26}Mg* of the groundmass ranges from –5.3 to +4.3 ppm and are positively correlated with ^{27}Al/^{24}Mg ratios. Both sets of data form an apparent isochron suggesting a similar ^{26}Al/^{27}Al abundance at time of their formation to that of other old angrites. However, the negative intercept of the isochron cannot be reconciled with the low ^{26}Al/^{27}Al abundance and suggests that the correlation is best explained as a two component mixing trend. Model ages for single xenocryst olivine range from 0.36 to 1.18 Myr after CAIs. A model age for the most anomalous groundmass sample yields an age of 3.9 Myr after CAIs, consistent with the Mg isochron ages for other volcanic angrites. These data demonstrate that olivine entrained in NWA 1670 are products of ancient magmatic differentiation on the angrite parent body shortly after solar system formation, which significantly predates the formation of volcanic angrites.

Hydrocarbon gas seeps are surface expressions of petroleum seepage systems, whereby gas is ascending through faults and conduits from pressurized reservoirs that are typically associated with sandstones or limestones. The region around the states of New York and Pennsylvania marks the birthplace of commercial gas production from shales dating back into the 19th century. We sampled two burning seeps in New York and Pennsylvania that had not yet received geochemical scrutiny, including compound-specific stable isotope ratios of hydrogen and carbon. A spectacular "eternal flame" in Chestnut Ridge County Park (Erie County, western New York State) marks a natural gas macroseep of dominantly thermogenic origin emanating directly from deep shale source rocks, which makes this a rare case in contrast to most Petroleum Seepage Systems where gas derives from conventional reservoirs. The main flaming seep releases about 1 kg of methane per day and seems to feature the highest ethane and propane (C_2+C_3) concentration ever reported for a natural gas seep (~35 vol. %). The same gas is also released to the atmosphere through nearby invisible and diffuse seepages from the ground. The synopsis of our chemical and and stable isotope data with available gas-geochemical data of reservoir gases in the region and the stratigraphy of underlying shales suggests that the thermogenic gas originates from Upper Devonian shales without intermediation of a conventional reservoir. A similar investigation on a second "eternal flame" near Clarington in Pennsylvania suggests that gas is migrating from a conventional sandstone pool and that the seep is probably not natural but results from an undocumented and abandoned gas or oil well.

High-precision ^{10}Be-dating and Little Ice Age glacier advances at Steingletscher (Swiss Alps)

The increase in sensitivity of the cosmogenic ^{10}Be technique now provides novel insights into glacier and climate change by giving dates throughout the Holocene and up to present day from moraines around the globe.

We show the first ^{10}Be chronology for Steingletscher in the Central Swiss Alps (47°N, ~2000 m altitude), consisting of 30 boulder ages. The chronology includes early Holocene glacier positions, which most likely reflect glacier responses to abrupt cold spells identified in other Northern Hemisphere paleoclimate records. On the younger inner moraines, fourteen ^{10}Be boulder ages from individual ridges are in stratigraphic order ranging from 170 to 530 years. We relate these boulder ages to glacier advances during the Little Ice Age (LIA, 14th to 19th century in the Swiss Alps). Two samples from moraine ridges inside the LIA limit of Steingletscher yield ages of 170 ± 10 years and 130 ± 10 years. These latter samples potentially allow for quantification of the amount of ^{10}Be inherited during prior periods of exposure, on the order of a thousand atoms per gram.

Our ^{10}Be data from boulders deposited during the last millennium are based on quartz samples as small as 5 g, facilitating routine processing for ^{10}Be dating even on such young samples. Comparing the Steingletscher data with other emerging ^{10}Be chronologies of recent glacier advances, we will discuss the current analytical limits of ^{10}Be dating together with the relevance of cosmogenic nuclide inheritance and other sources of natural uncertainty for the overall sensitivity of ^{10}Be surface exposure dating.

CO_2 fluxes in the submarine hydrothermal system of Panarea

M. SCHIPEK*, R. SIELAND, D. STEINBRÜCKNER, M. PONEPAL, K. BAUER AND B. MERKEL[1]

[1]TU Bergakademie Freiberg, Scientific Diving Center, 09596 Freiberg, Germany
(* correspondence: mandy.schipek@gmail.com)

The measurement of CO_2 fluxes in terrestrial and submarine hydrothermal systems is affected by large uncertainties. Different methodologies were applied by scientific divers to estimate areal gas fluxes and determine massive gas discharges in water depths between 8 and 30 m in the hydrothermal system of Panarea, Italy.

Because several hundreds of hydrothermal vents exist in the submerged caldera of Panarea it is impossible to measure each gas discharge directly. Therefor gas discharges were classified in 5 groups with respect to their amount of gas release. Class A to D (0 to < 40 l/min) discharges were measured by displacement of water in a graduated container according to [1].

By visual counting and classifying discharge points within areas of increased hydrothermal acitivity, a rough estimation of diffuse gas release was realized. Massive gas discharges (class E, 40 – 100 l/min) were determined by means of a device based on impeller and temperature readings [2]. Corrections concerning gas temperature and hydrostatic pressure were performed.

A substantial percentage of the investigated gas discharge points (75 – 95%, n ≈ 700) was classified as weak (class A – D). About 10 fumaroles were identified as very intense gas releases (class E). Small gas discharges had been estimated to release up to 30 ± 14.5 t/d CO_2, while massive outlets account for 5 ± 0.6 t/d CO_2 in the submarine area of the caldera. The total CO_2 flux was calculated by considering the dissolution of CO_2 during the ascent to the sea floor [3]. Assuming 20 – 40% of gas dissolution, the total CO_2 flux in the submarine hydrothermal system of Panarea was estimated to be 47 ± 15.1 t/d CO_2. This is about 26% of the CO_2 emission of the nearby terrestrial volcano Vulcano [4] and <0.47% compared to all Mediterranean hydrothermal emissions [5].

Structure, evolution and function of the root bacterial microbiota of Arabisopsis species

K. SCHLAEPPI[1,2]*, N. DOMBROWSKI[1], E. VER LOREN VAN THEMAAT[1] AND P. SCHULZE-LEFERT[1]

[1]Department of Plant Microbe Interactions, Max Planck Institute for Plant Breeding Research, Cologne, Germany
[2]Swiss Federal Research Institute Agroscope, Reckenholzstrasse 191, 8046 Zurich, Switzerland
(*correspondence: klaus.schlaeppi@agroscope.admin.ch)

Plants touch with their roots soil - one of the richest microbial ecosystems on earth. At this contact zone, the secretion of poorly characterized root exudates fuels the differentiation of a distinct rhizosphere bacterial microbiota compared to the surrounding soil. Rhizobacteria provide microbial services affecting plant growth and health and contribute to ecosystem functioning. We examined the composition and evolution of the bacterial root microbiota within a phylogenetic framework of host species, including *Arabidopsis thaliana* and its sister species *Arabidopsis halleri* and *Arabidopsis lyrata* and evolutionarily ancient *Cardamine hirsuta* with pyrosequencing of 16S rRNA gene amplicon libraries. The composition of rhizobacterial communities varies most as a function of environmental condition and consists of a taxonomically narrow and evolutionarily conserved core microbiota consisting of Actinomycetales, Burkholderiales, and Flavobacteriales. We identified few root microbiota members that provide unique signatures for each host species, possibly reflecting host-specific requirements in a given environment. Most of these host species-dependent microbiota signatures were found for the phylogenetically oldest *C. hirsuta*, indicating that root microbiota diversification is linked to the evolutionary divergence time of the host species. *A. halleri* is the only plant among the tested species that grows on heavy metal (e.g. Cadmium) contaminated soils, tolerating high levels of Cd and accumulating high levels of Cd in leafs. We have initiated the examination of rhizobacterial communities of *A. halleri* grown in soils with elevated heavy metals coupled with community profiling of enrichment cultures and metal uptake measures in leafs. In this context, first insights into microbiota services will be provided.

Continuous soil gas monitoring related to CCS – Lessons learned from a 5-year case study

SCHLOEMER,S.[1], MÖLLER, I.[1] AND FURCHE, M.[1]

[1]Federal Institute for Geosciences and Natural Resources, Hannover, Germany, s.schloemer@bgr.de

The development of adequate monitoring strategies for CO_2 storage sites is one of the most vigorously discussed subjects related to carbon capture and storage (CCS), both in the public and in the scientific community. Public acceptance of CO_2 sequestration will only be achieved if secure and comprehensible monitoring methods for the natural environment are applied in a transparent way. Deep geological monitoring is mostly related to large scale migration of injected carbon dioxide in the storage formations. In contrast, detection and quantification of different gas species in the vadose zone of soil column and/or in the atmospheric boundary layer is a key method in many fields of near-surface environmental research and geohazards as well as CCS. As CO_2 soil gas concentrations vary over broad ranges, reliable statements on CO_2 seepage can only be made by using continuous long-term gas concentration measurements. We describe lessons learned from the first continuous monitoring program applied on a proposed CO_2 storage site in the Altmark area (Germany).

We will focus on our technical experiences, data interpretation and recommendations for further monitoring programs related to CCS. The most important topic is the reliability of a single station's data quality. Each selected site needs a thorough pre-investigation, e.g. regarding the depth of the biologically active zone and potential free water level. Based on our long lasting experience from field studies and including recent monitoring programs, we strongly recommend that baseline monitoring schemes for CO_2 storage sites should start at least 3 years before the gas injection into the reservoir. We will show that vadose zone monitoring can be considerably more sensitive to small seepage rates than surface flux measurements under favourable conditions but will also address pitfalls and limitations of the method.

Sorption of uranium and neptunium onto diorite from Äspö HRL

K. SCHMEIDE*, S. GÜRTLER, K. MÜLLER, R. STEUDTNER, C. JOSEPH, F. BOK AND V. BRENDLER

Helmholtz-Zentrum Dresden-Rossendorf, Institute of Resource Ecology, P.O. Box 510119, 01314 Dresden, Germany (* k.schmeide@hzdr.de)

Granitic subsurface environments are considered as potential host rock formations for the deep underground disposal of radioactive waste. The retention behavior of the crystalline rock diorite from the Äspö Hard Rock Laboratory (HRL, Sweden) towards the redox-sensitive actinides U and Np was studied by means of batch sorption experiments. The influence of various parameters, such as grain size (0.063 – 0.2 mm, 0.5 – 1 mm, 1 – 2 mm), temperature (25 and 10°C), atmosphere and sorption time (5 to 108 days) was studied using a synthetic Äspö groundwater (pH 7.8, $I = 0.178$ M) as background electrolyte. For U(VI), sorption isotherms were recorded (5×10^{-9} M to 7×10^{-5} M). Distribution coefficients, K_d values, were determined. The K_d values decrease with increasing grain size of the diorite and with decreasing temperature. The K_d values determined under oxic conditions are lower than those determined under anoxic conditions.

In the U sorption system, the speciation of U(VI) in solution and thus, its sorption onto diorite is strongly influenced by the groundwater composition. It was found by time-resolved laser-induced fluorescence spectroscopy that $Ca_2UO_2(CO_3)_3(aq)$ is the dominating species in solution. Hence, calcium and carbonate ions leached out of diorite significantly affect U(VI) sorption. Kinetic experiments showed that sorption equilibrium ($K_d = 1.44 \pm 0.30$, 1 – 2 mm fraction) is reached relatively fast (after 10 to 20 days). As predominant surface species on diorite, $UO_2(CO_3)_3^{4-}$ was identified by in situ time-resolved attenuated total reflection Fourier-transform infrared (ATR FT-IR) spectroscopy. About 50% of the sorbed U can be desorbed with Äspö ground water. This part occurs predominantly as U(VI) (94%) as shown by TTA solvent extraction.

In the Np sorption system, the effect of the groundwater composition on speciation and sorption behavior is weak. By ATR FT-IR spectroscopy, NpO_2^+ was detected in solution. During sorption experiments under anoxic conditions (up to 108 days), Np(V) is reduced to Np(IV) by the Fe(II) of the diorite which leads to a very strong Np sorption (95% sorption for $[Np]_0 = 1\times10^{-6}$ M, S/L = 200 g/L). Consequently, only 5-6% of the sorbed Np can be desorbed with Äspö ground water. This small amount was identified as Np(V) by TTA solvent extraction.

Reactivity of nanoscale zero-valent iron particles used for *in situ* groundwater remediation

D. SCHMID, S. LAUMANN, V. MICIĆ AND T. HOFMANN*

Department of Environmental Geosciences, University of Vienna, Vienna, Austria (*correspondence: thilo.hofmann@univie.ac.at)

Nanoscale zero-valent iron (nZVI) is a powerful reducing agent and has therefore been proposed as a tool for *in situ* groundwater remediation [1]. It has a high potential for transformation of a broad range of contaminants, including chlorinated solvents, redox active toxic metals/metalloids and radionuclides, chemical warfare agents, and pharmaceuticals [2,3,4]. The effectiveness of this remediation technique depends on the reactivity of nZVI particles, which is influenced e.g., by particle properties, hydrochemical conditions, and nature of the contaminants.

The aim of this study is to investigate the reactivity of two commercially available nZVI using iopromide in batch and column reactors under pH values typically found in groundwater (pH 7 and 8). Iopromide is a halogenated X-ray contrast media and serves as a model contaminant.

The investigated nZVI included polyelectrolyte-coated nZVI and non-coated nZVI, both in aqueous suspension (NANOIRON s.r.o., Czech Republic). All experiments were carried out under anoxic conditions with the same molar ratio of Fe^0 and iopromide.

First results show that the degradation of iopromide with both nZVI studied follows a pseudo-first order kinetics. Non-coated nZVI appeared to be more reactive. Both types of nZVI were able to fully degrade iopromide in nearly ten minutes under the applied laboratory conditions. The surface area normalized reaction rate constant (K_{SA}) depends on the pH value and the type of nZVI. The non-coated nZVI reacted 2–3 times faster than the polyelectrolyte-coated nZVI. At the pH of 7 the K_{SA} increases from 330 L m^{-2} h^{-1} for coated nZVI to 940 L m^{-2} h^{-1} for non-coated nZVI. At a pH value of 8 the K_{SA} values are 3–4 times lower, varying from 110 L m^{-2} h^{-1} for coated nZVI to 240 L m^{-2} h^{-1} for non-coated nZVI.

Futher experiments will be conducted in column reactors under similar hydrochemical conditions and iopromide concentrations in order to simulate the nZVI-mediated iopromide reduction in groundwater and to compare the reaction rate constants with these obtained in batch reactors.

Alpine metamorphism of the Pan-African gneiss basement in the Menderes/Çine massif, SW Turkey, revealed by garnet Lu-Hf geochronology

ALEXANDER SCHMIDT [1a] AND ROLAND OBERHÄNSLI [1b]

[1]Institute of Earth- & Environmental Sciences, University of Potsdam, Germany
[a]alexander.schmidt@geo.uni-potsdam.de
[b]roob@geo.uni-potsdam.de

The Menderes Massif is one of the large Alpine metamorphic complexes of Turkey. It´s southern part, precisely the Çine submassif, is described as a high-grade gneissic core of Precambrian basement covered by a lower-grade series of Paleozoic schists and Cenozoic-Mesozoic marbles. The geochronology of the gneiss basement in this complex so far highly depends on U-Pb ages of zircons, which yield protolith ages between 560 to 540 Ma. Its metamorphic period has been constrained at Alpine ages between 63 and 25 Ma using Ar/Ar and Rb-Sr geochronology. However garnet, one of the most abundant minerals in schists of this region, has yet to be the focus of geochronological work. Here we present the first Lu-Hf ages of garnet crystals from garnet-biotite schists of the southern margin of the Çine submassif. Lu-Hf analysis have been performed on 4-6 cm sized euhedral garnet crystals by the use of a micro-sampling technique, which permits the analysis of the isotopic composition of cores and rims of garnets, and a set number of intermediate radii. Different zones of these garnet crystals were recognized based on trace element distributions in core to rim profiles. The Lu-Hf results so far reveal at least two events, i.e. the beginning of garnet growth represented by a garnet core age of ca. 60 Ma, and an age of ca. 40 to 38 Ma at an intermediate radius of the garnet crystal (r ~ 50%), which also corresponds to a pronounced change in the distribution of heavy to medium rare earth elements. The Fe, Mg, Mn and Ca as well as the heavy rare earth element distributions in the garnet crystals indicate the preservation of a classical growth zoning pattern, i.e. bell-shaped Mn, constant decrease in Fe/(Fe+Mg), and HREE enrichment in garnet cores. Therefore it is clear that the Lu-Hf analysis yield growth ages rather than retrograde overprinting, hence the evidence for the Alpine metamorphism of the Çine submassif.

Quartz solubility and CO_3^{2-}–HCO_3^- equilibrium in H_2O+Na_2CO_3 and H_2O+$NaHCO_3$ fluids at high *P* and *T*

C. SCHMIDT[1]

[1]Deutsches GeoForschungsZentrum (GFZ), 14473 Potsdam, Germany (Christian.Schmidt@gfz.potsdam.de)

Alkali hydrogencarbonate and carbonate in aqueous fluids may play an important role in the mobilization of the REE and other elements at crustal conditions [1] and in subduction zones [2]. Here, the CO_3^{2-}–HCO_3^- equilibrium and the quartz solubility in aqueous 4.65 molal $NaHCO_3$ and 1.6 molal Na_2CO_3 solutions were studied to 600 °C and 1.53 GPa using a hydrothermal diamond-anvil cell. The recorded spectra were normalized to the temperature dependence of the Stokes-Raman scattering intensity, the frequency and scattering factor, density, and reflection at the diamond-fluid interface [3,4]. The HCO_3^-(aq) and CO_3^{2-}(aq) concentrations were obtained from the integrated intensities of the Raman bands at ~1000 and ~1060 cm^{-1} assuming that the ratio of the relative molar scattering factors J_{1000}/J_{1060}=0.1667/0.2434 [3] is independent of pressure (*P*) and temperature (*T*). In the Na_2CO_3 solution, the fraction of the species CO_3^{2-}(aq) did not show a significant dependence on pressure, but decreased with temperature from ~0.77 at 100 °C to ~0.69 at 200 °C to ~0.41 at 600 °C. Before equilibration at 600 °C, the CO_3^{2-}(aq) fraction at vapor pressure was ~0.99 at 100 °C and ~0.91 at 200 °C. No CO_2 or CH_4 were detected. In the $NaHCO_3$ solution, the CO_3^{2-}(aq) fraction increased with temperature and decreased with pressure along all studied isotherms from 200 to 600 °C, e.g. at 600 °C from 0.16 at 0.63 GPa to 0.1 at 1.5 GPa. Thus, HCO_3^- ions can be stable in lower crustal and upper mantle fluids. The only detectable Raman band from dissolved silica was at ~770 cm^{-1}, which indicates a predominantly monomeric silica speciation. The calibrated integrated intensity of this band was used to determine the SiO_2(aq) molality. The quartz solubility in 1.6 molal Na_2CO_3 increased with *P* and *T*, but was always much higher than the solubility of quartz in water at the same *P-T* condition. The quartz solubility in 4.65 molal $NaHCO_3$ increased with *T*, decreased with *P* along the 500 and 600 °C isotherms to values below the solubility in water, and was approximately constant at 300 and 400 °C. For lower pressure isobars, there was a distinct drop in the solubility between 500 and 400 °C.

Molecular-level comparison of water-soluble sedimentary organic matter extracted by two methods

FRAUKE SCHMIDT[1]*, BORIS P. KOCH[2], MATTHIAS WITT[3] AND KAI-UWE HINRICHS[1]

[1]MARUM – Center for Marine Environmental Sciences, University of Bremen, Leobener Straße, D-28359 Bremen, Germany (*correspondence: frauke.schmidt@uni-bremen.de)

[2]Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Am Handelshafen 12, D-27570 Bremerhaven, Germany

[3]Bruker Daltonik GmbH, Fahrenheitstraße 4, 28359 Bremen, Germany

Organic matter in marine sediments is a complex mixture of numerous individual molecules, which are central reactants in various biogeochemical processes and serve as a substrate for benthic organisms. The fate of organic matter and its bioavailability is largely controlled by composition, size and reactivity of the individual organic molecules. In this study, we aim at a molecular characterization of the easily mobilized and thus accessible fraction of organic matter in marine sediments. We compared the molecular composition of (i) the mobile dissolved organic matter (DOM) pool in interstitial waters, extracted with rhizons, with (ii) the organic matter that was extracted from the associated sediment with water in a Soxhlet apparatus. After solid phase extraction, both DOM fractions were subjected to molecular-level analysis by ultra-high resolution Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR-MS). We selected four different sediment horizons of a core from the Black Sea that represented different ages, depositional and geochemical conditions. FT-ICR mass spectra of the Soxhlet extracted DOM yielded 2- to 3-times higher numbers of molecules compared to the interstitial water DOM, with the former being distributed over a larger mass range and exhibiting higher abundances of heteroatom-bearing molecules. We related the molecular-level differences between both DOM pools to age and sediment geochemistry. The Soxhlet-extractable DOM pool was up to 30-times more concentrated than the DOM pool in the interstitial waters. Soxhlet extraction of sediments in combination with FT-ICR-MS analyses opens a window to studying a so far uncharacterized sedimentary organic matter pool that is potentially the major precursor of “traditional” DOM.

Discrimination scheme for Fe-Mn deposits based on REY, HFSE and Th

KATJA SCHMIDT[1]*, MICHAEL BAU[1] AND ANDREA KOSCHINSKY[1]

[1]School of Engineering and Science, Jacobs University Bremen, 28759 Bremen, Germany, *correspondence: k.schmidt@jacobs-university.de

Marine Fe-Mn deposits can be distinguished based upon the type of aqueous fluid from which they precipitate and their specific setting: While hydrogenetic crusts slowly precipitate from ambient seawater and attain their constituents from this source, diagenetic nodules form within the sediment, with pore water as major source of elements. In the vicinity of hydrothermal vents, hydrothermal crusts precipitate from both hydrothermal fluid and seawater as possible source fluid. Variable concentrations of economically important elements characterize these groups. The individual groups can be separated using discrimination diagrams such as Ce/Ce^*_{SN} vs. Nd, Ce/Ce^*_{SN} vs. Y/Ho_{SN}, Nb vs. Ta, and Ce/Ce^*_{SN} vs. Th, Zr, Hf, Nb, Ta, which combine the effects of redox, growth rate and mineralogy on the trace metal content of Fe-Mn deposits. The redox-sensitive Ce, and HFSE and Th are continuously scavenged during crust growth, while the other REY are controlled by an exchange equilibrium. In contrast to REY, HFSE and Th are mainly scavenged from the Fe oxide phase relative to the Mn oxide phase, and together with the low mobility of these elements during diagenesis, this can be used to separate the individual groups. Hydrogenetic crusts display positive Ce anomalies, negative Y anomalies and high concentrations of REY, HFSE and Th, reflecting slow precipitation from seawater. Diagenetic nodules differ from hydrogenetic crusts and nodules as they display negative Ce anomalies at lower Nd concentrations, related to the low mobility of Ce^{4+} in sub-oxic porewaters. Seawater-dominated hydrothermal crusts differ from hydrogenetic crusts and diagenetic nodules as this is the only group which display positive Y anomalies, together with negative Ce anomalies and low Nd concentrations. This signature reflect the rapid scavening of REY from ambient seawater on hydrothermal oxide particles, without strong fractionation. In contrast to these hydrothermal crusts, hydrothermal Mn crusts which gained significant proportions of their REY content from the mantle via hydrothermal fluids (up to 30%, based on Nd isotopes), often cover the same regions as diagenetic nodules in Ce/Ce^*_{SN} vs. Y/Ho_{SN} and Ce/Ce^*_{SN} vs. Nd diagrams. Both groups can be further be separated in Ce/Ce^*_{SN} vs. Th and Nb vs. Ta diagrams.

Along the Curiosity rover's traverse toward Glenelg (through sol 102) the Alpha Particle X-ray Spectrometer (APXS) analysed four rocks and one soil. Microscopic images and compositions of unbrushed rock surfaces are consistent with 5-20% dust contamination. Nevertheless, the underlying characteristics of these rocks may still be discerned. As a group, they span nearly the entire range in FeO* and MnO of the Martian dataset. In addition, they are particularly enriched in volatile metals (K, Zn, Ge), and these elements do not correlate with Cl or S. One rock, Jake_Matijevic is notably alkaline and evolved; its composition is that of a nepheline-normative mugearite. The other three rocks plot in the basanite field of a TAS diagram, with high K_2O (up to 3.0%) and low SiO_2. These three rocks are otherwise SNC-like (high Fe and low Al). Three out of the four rocks (including Jake_Matijevic) plot along a line in variation diagrams, suggesting mixing of Fe-rich and Al-rich components, likely by sedimentary processes.

With only four rocks analyzed so far and ambiguity as to their geologic context (e.g. outcrop vs. float; igneous vs. sedimentary) additional measurements are needed to fully understand the region. It is nevertheless clear that Curiosity landed in a lithologically diverse, K-rich region of Mars.

The influence of Perchlorate (ClO_4^-) on the sorption behavior of Th(IV) on the Muscovite (001) basal plane

M. SCHMIDT[1], S. S. LEE[2], R. E. WILSON[2], K. E. KNOPE[2], P. FENTER[2] AND L. SODERHOLM[2]

[1]Karlsruhe Institute of Technology (KIT), Institute for Nuclear Waste Disposal, Karlsruhe, Germany
[2]Argonne National Laboratory, Chemical Sciences and Engineering Division, Argonne, IL, U.S.A.

In many sorption as well as other geochemical studies the perchlorate anion (ClO_4^-) is used as a constituent of the background electrolyte for its non-coordinating behavior. It is assumed that by restricting the competitive coordination reaction in solution it is possible to study the unperturbed sorption reaction. The adsorption of tetravalent thorium to the muscovite (001) basal plane gives a cautionary example, where the change from a weakly coordinating anion (Cl^-) to a non-coordinating anion (ClO_4^-) has a drastic and unexpected effect on the sorption behavior of the cation.

Results from surface x-ray diffraction techniques in combination with alpha-spectrometry measurements will be presented. On the basis of these results we will demonstrate that Th(IV) exhibits a straightforward sorption behavior driven by electrostatic attraction and, to a lesser degree solution complexation and hydrolysis, when the reaction is studied in NaCl background electrolyte media (Schmidt *et al*., 2012). Thorium adsorbs up to a slightly higher than charge compensating coverage of 0.4 Th/A_{UC} predominantly as an extended outer sphere complex with two intact hydration spheres.

By the same method and under the same solution conditions – but with $NaClO_4$ instead of NaCl – the adsorption behavior changes drastically: no interaction of Th with the interface can be detected under these conditions. The changes in solution chemistry are comparably minor, and it appears unlikely that changes in the complexation behavior can explain this observation. Potential interfacial reaction mechanisms underlying this unanticipated behavior will be discussed.

[1] Schmidt, M., Lee, S.S., Wilson, R.E., Soderholm, L. and Fenter, P. (2012) Sorption of tetravalent thorium on muscovite. *Geochimica et Cosmochimica Acta*, **88**, 66-76.

Distribution and enrichment processes of lithium and other solutes in the Salar de Uyuni brine

NADJA SCHMIDT*, ROBERT SIELAND AND BRODER MERKEL

TU Bergakademie Freiberg, Department of Hydrogeology, D-09599 Freiberg, Germany (*correspondence: Nadja.Schmidt@geo.tu-freiberg.de)

The world's largest salt pan, the Salar de Uyuni, is located in the Bolivian Altiplano, at 3650 masl between the eastern and western cordilleras of the Andes. Although it hosts one of the world's most promising lithium deposits, accumulation and horizontal distribution of lithium and other solutes in the brine are not satisfactorily understood.

During various drilling and sampling campaigns (2009-2012) numerous brine samples were taken from boreholes down to 12 m all over the salt lake. Further brine samples were gained from one meter deep drilling holes along three transects from the center to the border in the northeastern part of the Salar. All samples were investigated by IC and ICP-MS as well as for stable isotopes.

Li concentrations in the brine vary between 200 and 1500 mg/L, whereby a vertical gradient could not be observed in the upper 12 m. Li is peaking near the northeastern and southeastern shore, with concentration gradients of 100 mg/L/km (own data) and 40 mg/L/km [1], respectively. Li peaks match with the delta areas of former and recent inflowing rivers. Hence, more than one major tributary as a source of lithium exist, which is in contradiction to results of former investigations supposing the Rio Grande to be the only feeder of lithium to the salt lake basin [2].

The surface in areas where increased Li concentrations occur is characterized by muddy sediments interspersed with crystals of halite and other evaporites. Because clay is decreasing in direction from the shore a temporary fixation and release of Li on clay is assumed as controlling factor leading to an effective enrichment in the brine.

Recent studies have shown that Ca isotope ratios have the potential to be important tracers of biological activities in forested ecosystems or more generally in plant physiology and in biogeochemistry.

Field studies performed in forested watersheds point to the importance of Ca isotope fractionations in soil solutions due to biological activity in the surficial soil horizons. Hydroponic experiments, performed on rapid growing bean plants, that allow to have a complete growth cycle, helped to identify the mecanisms responsible for these Ca isotope fractionations (Cobert *et al*., 2011; Schmitt *et al*., 2013). Indeed, the adsorption of Ca by lateral roots, that are enriched in ^{40}Ca compared to the nutritive medium, follows a closed-system equilibrium fractionation with a fractionation factor of 0.9988, suggesting that Ca forms exchangeable bonds with the $RCOO^-$ groups in the cell wall structure of the lateral roots. Two other fractionation levels have been identified within the plant during the Ca transfer from roots to shoots. When the xylem sap goes to the shoots, ^{40}Ca is preferentially bound to the polygalacturonic acids (pectins) of the middle lamella of the xylem cell wall. Finally, a third fractionation occurs in the reproductive organs also caused by cation-exchange processes with pectins. The fractionation mechanisms are the same whatever the Ca content and pH of the nutritive solution. Only the bean plants average signature as well as the amplitude of the Ca isotopic fractionation within plant organs are highly dependent on the composition of the nutritive solution. A comparative field study is installed to examine the Ca isotopic fractionation in trees of a forested watershed.

Atmospheric CF_4 trapped in polar ice – A new proxy for granite weathering

J. SCHMITT [1]*, B. SETH[1], P. KÖHLER[2], J. WILLENBRING[3] AND H. FISCHER[1]

[1]Climate and Environmental Physics & Oeschger Centre for Climate Change Research, University of Bern, CH, (*correspondence: schmitt@climate.unibe.ch)

[3]University of Pennsylvania, Department of Earth & Environmental Sciences, Philadelphia, USA

The reconstruction of continental weathering rates using trace elements and their isotopes measured on marine sediments and crusts is a vigorously growing field. Here, we use a novel approach using the ppt-level trace gas CF_4, tetrafluoromethane, which can be analysed in air trapped in ice cores. CF_4 is a trace impurity in granites and other plutonic rocks, and during weathering this gas escapes into the atmosphere. In preindustrial times, this release from granitic rocks was the only natural source of CF_4. Because CF_4 is inert to destruction processes in the tropo- and stratospheres, its only sink is destruction by UV radiation and radicals in the mesosphere. This chemical inertness is responsible for an exceptionally long atmospheric lifetime which is expected to range between 50 kyr and 400 kyr. Althoug the globally integrated CF_4 emission flux from weathering is only a few tons per year, the exceptionally long lifetime allows to establish a long-term atmospheric concentration of about 33 ppt. We developed a vacuum melt-extraction system for ice core samples coupled to a mass spectrometry detector to precisely measure these trace amounts of CF_4 found in past atmosphere and applied this method to ice over the entire Dome C ice core. During the last 800 kyr, atmospheric CF_4 varied in a narrow band between 31 ppt and 35 ppt, i.e. only 10-15 % variability, providing a first estimate of the long-term weathering rate fluctuations. Our record shows that CF_4 increases during interglacials and falls during the coldest, glacial phases. However, our CF_4 record shows also a pronounced shift toward higher CF_4 levels after 430 kyr (the Mid-Brunhes Event). With the beginning of Marine Isotope stage 11, we find a steep rise in CF_4 that probably relates to intense weathering during the first full interglacial after a series of lukewarm interglacials.

CF_4 and CO_2 - coupling weathering and carbon cycle

J. SCHMITT[1]*, B. SETH[1], P. KÖHLER[2], J. WILLENBRING[3] AND H. FISCHER[1]

[1]Climate and Environmental Physics & Oeschger Centre for Climate Change Research, University of Bern, CH, (*correspondence schmitt@climate.unibe.ch)
[2]Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Bremerhaven, Germany
[3]University of Pennsylvania, Department of Earth & Environmental Sciences, Philadelphia, USA

The analysis of CO_2 and its stable carbon isotopes from ice cores revealed large changes of atmospheric CO_2 related to changes in ocean circulation, marine biological processes and contributions from the terrestrial carbon storage. These processes dominate the glacial/interglacial CO_2 variations. Yet, CO_2 is also modulated by the marine alkalinity balance. The net alkalinity influx to the ocean is driven by silicate weathering drawing down atmospheric CO_2. Conversely, alkalinity is lost when $CaCO_3$ is buried in marine sediments. On orbital time scales, these fluxes are assumed to be almost balanced as atmospheric CO_2 and its climatic effects feedback on the weathering rates providing a negative feedback loop.

Trace elements from marine sediments are widely applied to derive weathering rates or changes in the weathering style for a certain region. Here, we use a novel approach to provide a global weathering estimate using the ppt-level trace gas CF_4 archived in polar ice cores. CF_4 is found as a trace gas in granites, and during weathering it escapes to the atmosphere. Because CF_4 is inert in the lower atmosphere, its only sink is destruction by UV radiation in the mesosphere. This chemical inertness is responsible for an exceptionally long atmospheric lifetime which is expected to range between 50 kyr and 400 kyr. We developed a vacuum melt-extraction system for ice core samples to precisely measure these trace amounts of CF_4 and applied it to ice over the entire Dome C ice core. During the last 800 kyr, atmospheric CF_4 varied in a narrow band between 31 ppt and 35 ppt, i.e. only 10-15 % variability, providing a first estimate of the long-term weathering rate fluctuations. Our record shows that CF_4 increases during interglacials and falls during the coldest, glacial phases. However, our CF_4 record also shows a pronounced shift toward higher CF_4 levels after 430 kyr. With the beginning of MIS 11, we find a rise in CF_4 that probably relates to intense weathering during the first full interglacial after a series of lukewarm interglacials. This dataset lends support to a strong positive coupling of continental weathering and climate.

Multitracer paleoclimate and recharge study of groundwater in the North China Plain

T. SCHNEIDER[1]*, G. CAO[2], C. ZHENG[23] AND W. AESCHBACH-HERTIG[1]

[1]Institute of Environmental Physics, Heidelberg University, Im Neuenheimer Feld 229, 69117 Heidelberg, Germany (*correspondence: Tim.Schneider@iup.uni-heidelberg.de)
[2]Center for Water Research, College of Engineering, Peking University, Beijing 100871, China
[3]Department of Geological Sciences, University of Alabama, Tuscaloosa, Alabama, USA

A multitracer study of groundwater in the North China Plain (NCP) was conducted in the framework of a Chinese-German cooperation project whose main objective is to obtain groundwater ages and recharge rates in order to refine a groundwater flow model of the NCP and to help find ways for sustainable groundwater management [1]. Additionally, the obtained data adds to an existing data set from a previous paleoclimate and groundwater recharge study in the NCP [2][3].

Samples were taken on two sampling campaigns in 2011 and 2012 from 36 wells along a transect in the northern NCP starting at the mountains in the west, passing south of Beijing and leading to the Bohai Sea at Tianjin. In addition, seven wells were sampled on a short transect near Handan, further south in the NCP.

Dating tracers being used are ^3H-^3He, SF_6 and CFCs 11, 12 and 113 for young ages and ^{14}C as well as ^4He for a longer time scale. The climate information is obtained through dissolved noble gases and stable isotopes. The combined use of SF_6 and CFCs allows us to identify and correct for possible SF_6 from natural sources and CFC contamination in the highly industrialized area near Beijing.

Dating results show that the groundwater age mainly increases with depth rather than distance along the transect, with an abrupt rise at a depth of around 100m. Enhanced concentrations of both SF_6 and CFCs are unrelated, indicating different sources. The noble gas temperatures suggest a temperature difference between the Holocene and the last glacial period of about 5°C. Overall, the new data confirm and complement previous results from the NCP [2][3].

^{241}Am supporting ^{210}Pb and ^{137}Cs dating

BERNHARD SCHNETGER[1] KATHARINA HÄUSLER[2] AND OLAF DELLWIG[2]

[1]ICBM, Carl-von-Ossietzky University, 26111 Oldenburg, Germany; b.schnetger@icbm.de
[2]Leibniz Institute for Baltic Sea Research (IOW), Rostock, Germany; katharina.haeusler@io-warnemuende.de; olaf.dellwig@io-warnemuende.de

^{210}Pb dating is usually supported by radioactive ^{137}Cs to verify age models. Atmospheric nuclear bomb testing in the 50th and 60th as well as the Chernobyl accident in 1986 has introduced not only measurable amounts of radioactive Cs but also Pu nuclides into the environment. Due to the relatively short half-life of ^{241}Pu (14.35 a) measureable activities of the daughter ^{241}Am are now present and can directly be analysed by modern gamma-ray detectors (Appleby *et al*. 1991). The advantages of using ^{241}Am over ^{137}Cs are a) its high particle reactivity causing rapid sedimentary burial and b) its immobile behaviour after deposition minimizing redistribution. While the 1963 peak in ^{137}Cs is prone for a large dispersion in the sedimentary environment, ^{241}Am forms sharp peaks in undisturbed sediments. Even the frequency of atmospheric nuclear bomb testing can be identified by high-resolution sampling of geological archives resulting in more trustful age determinations. In sediments where both ^{210}Pb and ^{137}Cs fail to give reliable ages, ^{241}Am can be used for a rough age estimation of sediment intervals. In such cases the following ^{241}Am time markers can be used: increased activities due to the frequency of atmospheric bomb testing in 1951, first maximum in 1958, second maximum in 1962 and a narrow peak in 1986 (Chernobyl) and possibly in the future 2011 (Fukushima). Between these markers, sediment velocities or sedimention rates (if dry bulk density is known) can be calculated spanning at least a half century back in time. The sharp peaks originating from accidents can easily be missed by low-resolution sampling. Due to the much longer half-life of ^{241}Am (432a) compared to ^{137}Cs (30.17a) this tracer can be used when ^{137}Cs cannot be detected in the environment any more. For instance, ^{137}Cs in 1962 sediment layers will be decayed after app. eight half-lifes in 2075. In addition, sediment data from the euxinic Landsort and Gotland Deeps (Baltic Sea) indicate a significant influence on ^{137}Cs and ^{210}Pb burial over time due to the Mn-pump within the redoxkline.

Cr isotopic variations in Neoarchean to Paleoproterozoic near-surface chemical sediments

R. SCHOENBERG[1]*, I.C. KLEINHANNS[1], M. WILLE[1], M. VAN ZUILEN[2], R.B. PEDERSEN[3], V. MELEZHIK[3,4] AND N. BEUKES[5]

[1]Dept. of Geoscience, University of Tuebingen, Germany (*correspondence: schoenberg@ifg.uni-tuebingen.de)

[3]Centre for Geobiology, University of Bergen, Norway
[4]Geological Survey of Norway (NGU), Trondheim, Norway
[5]Dept. of Geology, University of Johannesburg, South Africa

Recent studies explored the potential of stable Cr isotopic variations in oceanic sedimentary archives as tracer for atmospheric oxygen levels through Earth's history [1,2]. Thereby, the stable Cr isotopic variations in up to 2.75 Ga old BIFs were interpreted to indicate oxidative chromium weathering on the continents initiated by an accumulation of small levels of free atmospheric oxygen some 350 Ma before the ca. 2.4 to 2.32 Ga great oxidation event (GOE) [1]. This interpretation, however, was challenged by others [3], who propose that the Cr isotopic variations in these predominantly Algoma type BIFs are due to non-redox isotopic effects caused by rapid precipitation from their deep-water hydrothermal source.

In order to shed light on the applicability of stable Cr isotopes as paleo-redox tracer we investigated carbonates from well-defined supra-, intra- and subtidal depositional environments from the ca. 2.55-2.48 Ga old Malmani Subgroup of the Transvaal Basin in South Africa and 2.06 Ga old lacustrine carbonates, marine stromatolites and near-shore jaspilites from the Pechenga Greenstone Belt, as well as 2.0 Ga organic-rich, siliceous deposits from the Onega Basin, both situated in the NW Fennoscandian Shield. The relatively large variations (ca. +1.4‰ to -1.2‰ in $\delta^{53/52}$Cr) found in post-GOE sedimentary archives from the Fennoscandian Shield support chromium redox-cycling associated with oxidative chromium weathering on the continental surface. Compared to the large Cr isotope variations of these post-GOE deposits, the range in $\delta^{53/52}$Cr values of late Archean sedimentary archives appears to be much smaller. Possible scenarios to explain the observed Cr isotopic variations in these sedimentary archives and their implications to the presence of free atmospheric oxygen will be discussed.

From date to process: Integrating geochemistry and geochronology on very short and very long timescales

BLAIR SCHOENE

219 Guyot Hall, Department of Geosciences, Princeton University, Princeton, NJ, USA. (bschoene@princeton.edu)

How continental crust is created, preserved and recycled, and whether or not these processes have changed through Earth history are important for a) understanding the geochemical and petrological stratification of the crust and b) quantifying long term geochemical and isotopic cycling in the Earth's crust and mantle. Developing models for crustal evolution requires robust geochronology on both the short and long timescales, targeting relatively rapid geologic phenomena (e.g. magma production and differentiation) as well as long term secular change. This contribution highlights recent efforts to better apply high-precision U-Pb geochronology to continental magmatic systems and to develop techniques comparing magmatic systems through Earth history.

Models describing the transfer of mass and heat through the crust during orogenesis demand age constraints with increasing precision and accuracy. While modern ID-TIMS U-Pb geochronology can resolve the timescales of zircon crystallization in single pulses of magma, much work is needed to relate dates to processes such as magma production, transport, differentiation, and emplacement. Our recent work focuses on integrating zircon crysallization ages and geochemistry to both understand the growth history of single zircons on <50 ka timescales and to build a framework for longer timescale geochemical evolution of two Alpine magmatic systems.

To compare differences in magmatic differentiation during crustal magmatism from the Archean to present, we develop statistical methodologies for analyzing large geochemical databases (Earthchem, etc.). Substantial differences in both crustal inputs (basalts) and indicators of differentiation to high-Si compositions suggest either secular changes in magmatic/metamorphic processes during crustal genesis and modification, or preservation bias. These results motivate further detailed investigation of Archean terranes, although robust comparison between any number of orogenic belts, Archean or modern, require geochronology with precision that is relevant to tectonomagmatic processes. Sub-million year precision is now achievable in Archean rocks by ID-TIMS U-Pb geochronology, but necessitates careful integration of field, geochemical, and geochronological data with numerical modelling studies.

Evolution of temperature and precipitation during Marine Isotope Stage 5 recorded in speleothems from the Hüttenbläserschachthöhle, western Germany

[3]CENIEH, Paseo Sierra de Atapuerca s/n, 09002-Burgos, Spain

[4]Institut für Geologie und Paläontologie, Leopold-Franzens-Universität, Innrain 52, 6020 Innsbruck, Austria

[5]Bristol Research Initiative for the Dynamic Global Environment (BRIDGE), School of Geographical Sciences, University of Bristol, University Road, BS8 1SS Bristol, United Kingdom

We present high-resolution $\delta^{18}O$, $\delta^{13}C$ and trace element profiles for two stalagmites from Hüttenbläserschachthöhle, western Germany, which grew during Marine Isotope Stage (MIS) 5.

HBSH-1 provides a climate record with decadal to centennial resolution between 130 and 80 ka, which shows four growth interruptions coinciding with the Greenland Stadials. This shows that stalagmite growth is a very sensitive proxy for cool and dry conditions in the northern hemisphere.

We interpret stalagmite $\delta^{18}O$ as a proxy for past temperature changes, whereas stalagmite $\delta^{13}C$ rather reflects changes in the hydrologic balance. The $\delta^{13}C$ record shows three pronounced negative peaks during MIS 5, and the timing of those is in agreement with MIS 5e, 5c and 5a. This suggests warm and relatively humid climate in western Germany for these phases.

During the Last Interglacial, the evolution of $\delta^{18}O$ and $\delta^{13}C$ is opposite. Whereas the $\delta^{18}O$ signal suggests the warmest conditions around 125 ka followed by a gradual decrease, the $\delta^{13}C$ signal indicates wetter conditions towards the end of the Last Interglacial. This 'decoupling' of temperature and humidity during MIS 5e is also visible in a series of snapshot simulations performed with the general circulation model FAMOUS.

Chemical and isotopic composition of soil solutions from cambisols in Styria (Austria) - Seasonality, evaporation and interstitial distribution

W. SCHÖN[1*], A. LEIS[2] AND M. DIETZEL[1]

[1]Institute of Applied Geosciences, Graz University of Technology, Rechbauerstraße 12, 8010 Graz, Austria, (*correspondence: w.schoen@student.tugraz.at)

[2]Institute of Water, Energy and Sustainability, Joanneum Research, Elisabethstraße 18, 8010 Graz, Austria

In most natural surroundings soil solutions are primary gained from the uptake of meteoric water. Subsequently infiltration, capillary exchange, bioresponse, evaporation etc. result in complex and individual gas-water-solid systems. Knowledge on the isotopic and chemical evolution of soil solutions and its interstitial distribution is highly relevant for environmental and forensic studies, but respective systematic and combined field and experimental studies a rare.

Therefore we investigated the composition of solids and interstitial solutions of individual horizons for three cambisols in Styria (Austria). The solutions were separated from the soils by compaction method at hydraulic pressures of 27.4 and 54.9 MPa, corresponding to respective matric potentials (mp).

The soils consist mainly of quartz, chlorite, muscovite, plagioclase with associated silicates like kaolinite and vermiculite, but without a significant vertical variability. The pH of the separated soil solutions typically increases with depths and elevated mp. Concentrations of dissolved ions such as Ca^{2+} and Mg^{2+} increase at high mp, which correspond to higher δD and $\delta^{18}O$ values. Lab experiments for evaporation and wetting indicate a systematic correlation of the combined isotope data and solution chemistry. The field-related and experimental results are discussed in respect to the impact of seasonality, evaporation, and mp-related interstitial distribution of the (isotope) geochemical composition of the separated soil solutions.

X-ray tomography links macroscopic silicate fabric and AMS fabric

A. SCHÖPA*[1], D. FLOESS[2], M. DE SAINT BLANQUAT[3], P. LAUNEAU[4], C . ANNEN[1] AND L. BAUMGARTNER[2]

[1]School of Earth Sciences, University of Bristol, Wills Memorial Building, BS8 1RJ Bristol, UK (*correspondence: anne.schopa@bristol.ac.uk)

[2]Université de Lausanne, Batiment Geopolis, 1015 Lausanne, Switzerland

[3]Géosciences Environnement Toulouse / Observatoire Midi-Pyrénées, 31400 Toulouse, France

[4]Laboratoire de Planétologie et Géodynamique de Nantes, CNRS/Université de Nantes, 44322 Nantes, France

Anisotropy of magnetic susceptibility (AMS) has been widely applied to gain insight into magnetic fabrics in granitic intrusions, basalt lava flows and dikes. In order to draw this generic link, it is assumed that the AMS fabric reflects the silicate fabric and hence gives information about magma flow, emplacement related strain and/or tectonic strain. However, a detailed analysis of this link between macroscopic magmatic fabric and AMS fabric is still lacking.

We present the first comparison between different fabric datasets to show how the macroscopic silicate fabric is linked to the magnetite-controlled AMS fabric on the grain-size scale. Datasets include 1) macroscopic silicate fabric measured directly in the field; 2) macroscopic silicate fabric derived from image analysis of rock slab pictures and sample pictures [1]; 3) shape preferred orientation (SPO) of mafic silicates from X-ray tomography images; 4) SPO of magnetite grains from X-ray tomography images [2]; 5) calculated distribution of magnetite grains from X-ray tomography images; 6) AMS fabric. The data were collected in the granitic intrusion of the Lago della Vacca Complex, Adamello Batholith, Italy.

Macroscopic mineral fabrics measured in the field and obtained with image analysis agree with each other and with the SPO of mafic silicates calculated from the tomography scans. Furthermore, the tomography results show that the SPO of mafic silicates and of the magnetite grains are consistent with the AMS data whereas the distribution of the magnetites is less compatible with the AMS fabric.

The consistent results obtained from a variety of methods demonstrate that the orientation of the AMS ellipsoid coincides with the macroscopic silicate fabric. This enforces the application of AMS as a robust tool to characterise magmatic fabrics in granitic intrusions.

Controls on the isotope composition of trace metals in calcite - New tools for paleo-reconstructions

J. SCHOTT[1]*, V. MAVROMATIS[1] AND E. H. OELKERS[1]

[1]Université de Toulouse & CNRS, GET, Toulouse, France, (*presenting author jacques.schott@get.obs-mip.fr, mavromat@get.obs-mip.fr, oelkers@get.obs-mip.fr)

Divalent metals including Ba, Mg, Sr, Cd, Co, Cu, Mn, and Zn exhibit contrasting ion size, diffusivity, hydration energy (or rate of exchange of water molecules in their hydration sphere), and affinity to hydrolyze or form inorganic and organic ligands. A large number of past studies have shown that these contrasting properties affect calcite-fluid partition constants, and how these partition coefficients vary with calcite growth rate.

In an effort to extend these observations to isotopic fractionation we have performed a number of related experimentally studies showing how crystal growth rates, and fluid pH and speciation impact the isotopic composition of the divalent metals incorporated into the calcite lattice. For example, the extent of Mg isotope fractionation between calcite and the fluid phase increases considerably with ***decreasing*** calcite growth rate[1]. In contrast, Ba, Sr, and Zn isotope fractionation increases with ***increasing*** calcite growth rate. Equally, Ca and Mg isotope fractionation increase with calcite and magnesite growth rate, respectively[2]. The distinct behavior of Mg stems from the reduced lability of water molecules in its coordination sphere compared to Ca, Ba, Sr, or Zn, and provides new insight on carbonate growth mechanisms. Moreover, Mg kinetic isotope fractionation can be quantified using three isotope diagrams[3] which allow the precise determination of equilibrium fractionation factors and provides a new tool to quantify the growth rates of calcite precipitated in the deep past. Such tools also provide insight into the saturation state of the fluids present when the calcite precipitated. Similarly, the measurement of Zn and Cu concentration and isotope compositions during calcite growth at fixed rates, pH, saturation state, and concentration of selected inorganic and organic ligands, allow quantification of the equilibrium isotope composition of Zn and Cu incorporated in the lattice and its dependence on the aqueous fluid composition. Such observations provide new insight into the metal incorporation mechanisms during calcite growth. Our experimental calibrations, validated by the quantification of Mg, Zn and Cu chemical and isotope fractionation in calcite-precipitating springs, are providing new and powerful tools to reconstruct paleo-environmental conditions from the isotope compositions recorded in carbonate sediments.

Serpentinization, Microbial Activities, and Carbon Flow in the Deep Biosphere

MATTHEW O. SCHRENK[1]

[1]East Carolina University, Greenville, NC, USA

Serpentinizing ultramafic rocks are conduits for the exchange of carbon and energy between the deep Earth and the surface environment and are ubiquitous, occurring on each of the continents and over vast portions of the seafloor. Serpentinization commonly generates high pH (>11), highly reducing conditions rich in hydrogen and methane that can sustain deep subsurface microbial communities which play important roles in controlling the composition and mobility of carbon-bearing compounds. Due to a complex interplay of nutrient sources and sinks and because they are perched near the limits of life, the significance of microbial processes in serpentinites has proven difficult to constrain. Recently, concerted studies of serpentinites in both continental and marine settings have begun to identify the functional potential of serpentinite-associated microbial communities, their energy sources, and their impacts upon carbon speciation. Metagenomic and functional genomic analyses document evidence of both consumption and production of hydrogen and methane in certain environments and in some cases for microbially-mediated sulfur and iron red-ox transformations. These studies also provide evidence for CO and CO_2 assimilation and the potential for the fermentation of organic matter derived from deep Earth materials. These data provide important targets for quantification of subsurface biogeochemical processes and their impact upon the characteristics of circulating fluids and their host rocks. By linking microbiological data with geochemical data, these studies also provide the opportunity to develop new paradigms for understanding microbial adaptations and evolution in the deep subsurface environment.

Intact polar lipids and diagenetic processes in sub-seafloor sediments in the Black Sea

JAN M. SCHRÖDER[1]*, IVANO W. AIELLO[2], TOBIAS GOLDHAMMER[1], VERENA B. HEUER[1], MARCUS ELVERT[1], MATTHIAS ZABEL[1] AND KAI-UWE HINRICHS[1]

[1] MARUM – Center for Marine Environmental Sciences and Dept. of Geosciences, University of Bremen, Germany (*correspondance: jschroeder@marum.de)

[2] Moss Landing Marine Laboratories, Moss Landing, CA, USA

The Black Sea is the world's largest anoxic basin where the water column beneath 100 m depth as well as the underlying sediments are devoid of oxygen. FS Meteor cruise M84/1 (DARCSEAS) [1] investigated site GeoB 15105 in the SW Black Sea and obtained an 8 m-sedimentary record of complex Late Pleistocene environmental change due to the transition from a limnic to a brackish marine system. The resulting diagenetic regime in these sediments is unusual and exhibits signals of overlapping sulfate reduction, methanogenesis, and Fe reduction, coupled with variable concentrations of total organic carbon. This is consistent with evidence for abundant sulfate-reducing bacteria in the methanogenic zone [2]. Using a strongly improved set of methods for extraction, preparation and detection of microbial intact polar lipids (IPL), we examined signals of the sedimentary microbial communities in relation to the complex diagentic regime and sedimentary history as determined by pore-water analysis of electron donors and acceptors and sedimentological examination, respectively.

We found that IPLs were present throughout the whole sediment core with a maximum in a sapropel layer at around four meters. IPL concentrations were highly variable and archaeal glycolipids (e.g., mono- and diglycosidic glyceroldibiphytanyltetraethers) as well as bacterial phospholipids (e.g., diether based phosphatidyl-ethanolamines) were observed down to a depth of eight meters. Furthermore, varying ratios of archaeal to bacterial lipids between 0.1 and 0.6 revealed regional differences of microbial abundance and could also be related to methane oxidation processes. Our study provides new insights into the relationship of microbial communities, diagenetic processes and the sedimentary history in the Black Sea sediments.

More than 10 years of monitoring

Lake Baikal is one of the largest lakes in the world and with a maximum water depth of ~1640 m also the deepest. This makes it unique and comparable to an ocean also since due to efficient vertical mixing oxygen concentrations are high throughout the water column.

We have moored sediment trapes which were recovered and renewed every year since 1999. Up to 18 traps were deployed over the whole water column. Organic carbon and nitrogen concentrations and isotopes as well as chlorin concentrations and chlorin indices were measured to estimate productivity and the composition of the organic material. C/N ratios between 10 and 13 hint to a strong authochthonous together with some allochthonous contribution to the organic material. δ^{13}Corg values around -31 ‰ (rather light for freshwater systems) were described before by Qiu et al [1] and related to diatom blooms. Chlorin measurements showed very strong, i.e., up to 5-fold variations in productivity. Chlorin indices [2] varied from 0.5 to 1.5 indicating differences in organic material freshness over the years.

Rn in water detection by LSC – sample volume optimization

MICHAEL SCHUBERT[1] AND JUERGEN KOPITZ[2]

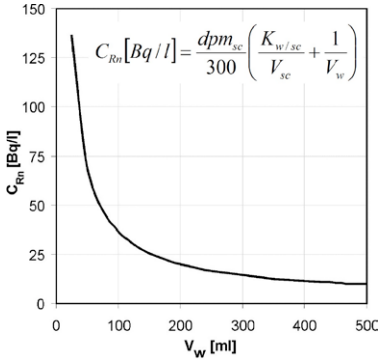
[1]Helmholtz Centre for Environmental Research Leipzig, Germany; (michael.schubert@ufz.de)
[2]Universitätsklinikums Heidelberg, Germany; (Juergen.Kopitz@med.uni-heidelberg.de)

Radon (^{222}Rn) is, amongst the noble gases, of particular interest as tracer in groundwater / surface water interaction studies. In related applications radon-in-water concentrations can be detected either directly in the field by using a mobile radon-in-gas monitor or after a water sampling campaign by liquid scintillation counting (LSC) in the laboratory.

If LSC is applied the radon has to be transferred from the water sample of a certain volume V_w [l] into the scintillation cocktail of the volume V_{sc} [l]. Whereas V_{sc} is preset by the size of the LSC vials (usually 20 ml) V_w is not specified. Aim of the presented study is an optimization of V_w.

The equation given in the figure allows calculating the ^{222}Rn concentration that was originally present in the water sample C_{Rn} [Bq/l] based on V_{sc} and V_w, on the water/cocktail partition coefficient for radon $K_{w/sc}$ and on the dpm value detected in the cocktail dpm_{sc}. The equation is based on the assumption that dpm_{sc} represents the total dpm of ^{222}Rn and its four short-lived progeny (after 3 h equilibration time), i.e. of five radionuclides in decay equilibrium.

Plotting the equation for an exemplary dpm_{sc} value (e.g. 1000), for a $K_{w/sc}$ value of 0.019 (valid for 21°C) and for varying values for V_w and V_{sc} results in a 3D image. Setting V_{sc} to 20 ml (the cocktail volume that is usually applied) results in the 2D plot for C_{Rn}/V_w shown in the diagram. It becomes obvious that the gradient of the function flattens significantly if V_w increases over about 350 ml. That implies that an increase of the water sample volume over about 350 ml does *not* result in significantly higher counting rates (and neither in better counting statistics). On the other hand, a water volume that is significantly smaller than about 250 ml results in a significantly smaller radon concentration in the cocktail and hence in poorer counting statistics. Thus, water sample volumes of about 250 - 350 ml should be chosen if 20 ml vials are applied for radon-in-water detection by LSC.



Transformational faulting in high pressure polymorphs – two case studies in quartz and olivine

ALEXANDRE SCHUBNEL[1] , FABRICE BRUNET [2], NADÈGE HILAIRET [3] , JULIEN GASC [4], YANBIN WANG [4] AND HARRY W. GREEN II [5]

[1]Laboratoire de Géologie, ENS? Paris , France
[2]ISTERRE, Université Joseh Fourier, Grenoble, France

[4]GSECARS, University of Chicago, Argonne, Il., USA
[5]Dept of Earth Sciences, UC at Riverside, CA, USA

Intermediate and deep focus earthquakes (100 -700 km) occur in a pressure and temperature regime where rocks are expected to deform plastically. The idea that they may be triggered by phase transformations in cold subducting lithosphere is appealing. However, the relationship between phase transformation and faulting remains unclear.

Coesite has been recognized as a reliable marker of ultrahigh-pressure (UHP) metamorphic environments in continental collision zones. Recent careful relocation of subduction-zone earthquakes have also shown that at depths of 100–250 km, seismicity occurs in the uppermost part of the slab, where the former oceanic crust has already been converted to eclogite, In the mantle transition zone, olivine undergoes two phase transformations while deep focus earthquakes locate inside the coldest part of slab, where metastable olivine bodies have sometimes been identified.

Here, we provide experimental evidence that, under differential stress at high pressure and temperature conditions ($\Delta\sigma$=2*GPa*, P=2-5*GPa* and T=1150±50*K*), shear fractures nucleate and propagate at the onset of the olivine -> spinel transition in the Mg_2GeO_4 analogue system. Similar observations were performed for quartz -> coesite ($\Delta\sigma$=4*GPa*, P=3-4*GPa* and T=1300±50*K*) in samples of Arkansas novaculite. In both cases, fracture propagation is sufficiently rapid to radiate energy in the form of intense acoustic emissions. These follow the Gutenberg-Richter law over 4 orders of moment magnitudes and like intermediate and deep-focus earthquakes, require no volumetric strain.

Microstructural analysis shows the development of macroscopic faults, filled with a gouge composed exclusively of the HP polymorph (spinel or coesite). Within the gouge, the material is so fine (1-50 nm) that diffusion accommodated grain boundary sliding may have provided a mechanism viable at "coseismic" strain rates (>10^4 s^{-1}). Our results seem to indicate as a rule that HP polymorphic transformations are mechanically unstable under stress, simply because they are exothermic and induce large negative ΔV. This clearly opens the prospects of revisiting a large number of phase transitions to assess their role in the triggering of deep seismicity.

How mass balance affects isotope ratios in the weathering zone

J.A. SCHUESSLER, J. BOUCHEZ AND F. VON BLANCKENBURG

GFZ German Research Centre for Geosciences, Helmholtz Centre Potsdam, Potsdam, Germany (bouchez@gfz-potsdam.de)

The novel stable isotope signatures in the compartments of the weathering zone are controlled not only by isotope fractionation factors that are characteristic of the chemical processes at play in the weathering zone, but are also controlled by the elemental fluxes between the different compartments, *i.e.* by mass balance effects. To deconvolve these two effects, we designed a steady state, batch reactor, mass balance model representing the weathering zone from the soil scale to the large river scale. We assume the main fractionating processes being formation of secondary precipitates, such as clays, and uptake by plants [1]. The model shows that:

$$\delta^X_{diss} - \delta^X_{rock} = -\Delta^X \cdot \frac{E^X_{org+\,sec}}{S^X_{rock+\,prim}} \quad (1)$$

where δ^X_{diss} and δ^X_{rock} are the isotope composition of the metal element X in the dissolved load and in the source rock, respectively, Δ^X the flux-weighted combined isotope fractionation factor, $E^X_{org+\,sec}$ the export flux of X in isotopically fractionated solids (organics and secondary precipitates), $S^X_{rock+\,prim}$ the release flux of X to water through primary mineral dissolution.

The main predictions are: (a) For very "soluble" elements (i.e. those with a low affinity for secondary precipitates and easily redissolved from plant litter), no fractionated δ^X_{diss} solid is exported, and is likely to be close to the source rock, δ^X_{rock}. Therefore, such elements are not viable tracers of weathering processes. (b) Equation (1) predicts that the largest difference in isotope ratios that can be observed between source rock and dissolved species and is equal to the combined isotope fractionation factor of the processes at play in the weathering zone.

The validity of these predictions are verified using an extensive database of measured water and rock isotope compositions and a compilation of experimentally determined isotope fractionation factors for Li, B, Mg, Si and Ca. It is observed that most $\delta^X_{diss} - \delta^X_{rock}$ data fall indeed between 0 (source rocks) and the best estimate of $-\Delta^X$. Moreover, most of the $\delta^{Ca}_{diss} - \delta^{Ca}_{rock}$ values are small compared to estimates of $-\Delta^{Ca}$, due to its high solubility.

Early stage Ostwald ripening of submicrometer calcite

L.N. SCHULTZ*, K. DIDERIKSEN, D. MÜTER, S.S. HAKIM AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*correspondence: lschultz@nano.ku.dk)

Ostwald ripening, also known as grain coarsening, occurs when crystals are at equilibrium with surrounding fluids. Over time, recrystallization favors larger and more thermodynamically stable particles. For calcite ($CaCO_3$), this affects diagenesis, relevant for aquifers and oil reservoirs and plays a role in industrial products where a thin adsorbed water layer covers crystal surfaces. While saturated conditions are common in nature and industry, rates and consequences of recrystallization at equilibrium are much less known and understood than growth and dissolution far from equilibrium.

We exposed submicrometer scale calcite, with a surface area of 11.8 m^2/g, to saturated solutions at 23 °C, 100 °C and 200 °C and we observed grain coarsening for up to 261 days. Scanning electron microscopy (SEM) showed visible calcite crystal coarsening at 100 °C and 200 °C (Figure 1) within one day. BET surface area decreased by an order of magnutide and the average diameter grew to 2 μm or larger. We measured change in particle size distribution and determined that the lognormal shape is indicative of early stage Ostwald ripening, consistent with classical theory.

Coarsening at 23 °C was not observable by BET or SEM, but changes in X-ray diffraction peak widths suggest an evolving surface, characterized by crystallite coarsening and fewer defects. These changes affect surface properties during the early stages of Ostwald ripening and have implications in our understanding of Ostwald ripening theories, behaviour in calcitic reservoirs and commercial calcite powder stability.

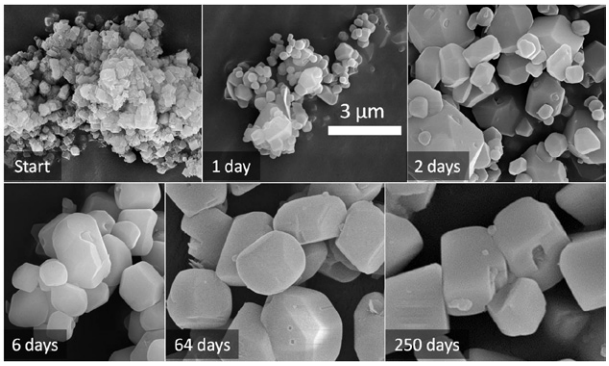

Figure 1. Calcite coarsening at 200 °C in saturated solution. The scale bar applies for all images.

Dehydration of metasomatic rocks along subduction and cold diapiric P-T trajectories

JOHN C. SCHUMACHER[1] AND HORST R. MARSCHALL[2]

[1]School of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's Road, Bristol BS8 1RJ, UK (*correspondence: j.c.schumacher@bristol.ac.uk)

[2]Department of Geology & Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA (hmarschall@whoi.edu)

Material from the subducting slabs is chemically linked to the source region of magmas produced at convergent plate margins. Hydrous fluids and chemical components from (1) subducted altered-oceanic crust and (2) the thin sedimentary veneer are added to (3) depleted mantle-wedge peridotite are invoked as the source of these melts. Exhumed subduction zone mélange show new rock compositions develop through metasomatism and advection during early subduction where metabasic rocks and other rock types are juxtaposed with serpentinites. In large enough amounts in the source, these new (metasomatic) rock compositions may alter or expand the P-T region over which large amounts of fluid or key trace elements are either retained in or released from the source rocks relative to conditions predicted by the widely applied three-component source models.

This study examines the petrologic changes along a subduction P-T trajectory followed by a cold diapiric rise into the mantle wedge; the high-P, metsomatic rock compositions used for the calculations are from the island of Syros, Greece. These following metasomatic assemblages developed under blueschist-facies conditions and were preserved between garnet-epidote-glaucophane schist and serpentinite:

(1)glaucophane+epidote+phengite+chlorite; (2)glaucophane+epidote+chlorite+omphacite; (3)epidote+chlorite+omphacite; (4)chlorite; (5)chlorite+talc.

The calculated phase relations for the metasomatic rocks compositions show that water-rich mineral like chlorite from these rocks could be stable to higher pressures, temperatures, and be more abundant than in hydrated basalt. Chlorite-rich metasomatic compositions produce more garnet than is expected from metabasalts. For example at about 805°C & 21 kbar, metasomatic rock (3) becomes 37 vol% garnet, 19 vol% pyroxene, 37 vol% amphibole; at about 910°C & 20 kbar, metasomatic rock (4) becomes 45 vol% garnet, 15 vol% spinel, 35 vol% olivine.

A decadal lipid biomarker paleohydrological record during the onset of the Younger Dryas from Northeastern Germany

KATHRIN SCHÜTRUMPF[1], ACHIM BRAUER[2], INA NEUGEBAUER [2], OLIVER RACH[1] AND DIRK SACHSE[1]

[1] University of Potsdam, Institute of Earth & Environmental Science, Karl-Liebknecht-Str. 24-25 14476 Potsdam-Golm Germany (correspondence: k.schuetrumpf@googlemail.de)

[2] GeoForschungsZentrum Potsdam Section 5.2, Climate Dynamics and Landscape Evolution, Telegrafenberg C109 14473 Potsdam

Regional expressions of global climatic changes, especially their effect on the hydrological cycle, are difficult to predict. However, their impacts, in the form of droughts or extreme precipitation events can be severe for societies and ecosystems. Therefore, a better understanding of the complex hydrological feedback mechanisms during past abrupt climate changes may ultimately lead to better predictions of regional climate changes.

High-resolution proxy data from well dated lacustrine sedimentary archives are particularly well suited for the reconstruction of regional climate changes in the past. Here we are investigating the hydrological impacts of the abrupt climate change during the onset of the Younger Dryas (YD) cold period between 13.000 and 12.400 years BP from the paleolake Rehwiese in Berlin in Northeastern Germany.

We extracted lipid biomarkers from a 122,10 cm sedimentary sequence covering a period of 600 years during the onset of the YD. We identified abundant mid- and long-chained n-alkanes, usually attributed to aquatic macrophytes and higher terrestrial plants, respectively. In addition, we found hopanes of bacterial origin as well as branched alkanes. Dinosterol, a characteristic biomarker for dinoflagellates, was also detected.

Using these samples we construct a record of hydrological changes in decadal resolution. Therefore, we are analyzing the hydrogen isotope composition of lipid biomarkers (D/H). We will evaluate this palaeohydrological record in conjunction with micro-facies, geochemical and palynological data in order to understand the hydrological evolution of regional climate during the onset of the YD in Northeastern Germany.

The Geobiology of Weathering: The 13th Hypothesis

D.W. SCHWARTZMAN[1]* AND S. BRANTLEY[2]

[1]Department of Biology, Howard Univ., Washington DC 20059, USA (*correspondence: dschwartzman@gmail.com)
[2]Department of Geosciences, Pennsylvania State Univ., University Park, State College, PA 16802, USA (sxb7@psu.edu)

The magnitude of the biotic enhancement of weathering (BEW) has profound implications for the long-term carbon cycle [1, 2]. The BEW ratio is defined as how much faster the silicate weathering carbon sink is under biotic conditions than under abiotic conditions at the same atmospheric pCO_2 level and surface temperature. Thus, a 13th hypothesis could be added to the 12 outlined by Brantley *et al*. [3] regarding the geobiology of weathering: The BEW factor and its evolution over geological time can be inferred from "meta-analysis" of empirical and theoretical weathering studies. We present estimates of the global magnitude of the BEW drawing from lab, field, watershed and models of the long-term carbon cycle, with values ranging from one to two orders of magnitude.

Serpentinization history of the Santa Elena complex peridotites, Costa Rica

ESTHER M. SCHWARZENBACH[1]* AND ESTEBAN GAZEL[2]

Department of Geosciences, Virginia Tech, Blacksburg, VA, United States
([1]*correspondence: esther11@vt.edu; [2]egazel@vt.edu)

Serpentinization is a widespread process where ultramafic rocks react with water or fluids along oceanic ridges or within subduction zones. On the Santa Elena peninsula (Costa Rica) variably serpentinized peridotites outcrop together with layered and pegmatitic gabbros and are intruded by mafic dikes. However, the original tectonic setting of the Santa Elena complex and the origin of the peridotites has not yet conclusively been determined and interpretations range from a supra-subduction zone to an oceanic ridge setting. In this study we identify the alteration history and the sources of the hydrothermal fluids that affected these peridotites by studying the petrology and sulfur geochemistry. Our goal is to contribute to the understanding of the tectonic evolution of Central America.

The Santa Elena ultramafic complex includes lherzolites, cpx-bearing harzburgites and minor dunites. Extent of serpentinization varies between 30 and 100%. Locally clinopyroxene is replaced by amphibole (tremolite, Mg-hornblende, edenite, and pargasite). The peridotites preserve opaque mineral assemblages including pentlandite, awaruite, pyrrhotite, heazlewoodite, magnetite, and locally violarite and smythite. Additionally, most samples contain native Cu and a chemically wide range of Cu-sulfide assemblages including chalcocite, cubanite, bornite chalcopyrite, samaniite $[Cu(Fe,Ni)_8S_8]$, and sugakite $[Cu_2(Fe,Ni)_7S_8]$. Elemental mapping revealed that native copper abundantly forms dendritic rims around pentlandite, while pentlandite is variably replaced by Cu-sulfides.

The mineralogical observations and the opaque mineral assemblages of the peridotites generally reflect i) highly reducing conditions during serpentinization and very low water rock ratios (<< 1), ii) that both formation of amphibole and Cu-alteration occurred subsequent to serpentinization, and iii) that serpentinization occurred at ≤250°C, but that locally fluid temperatures exceeded 300-350°C. Thus, our new data indicates that the peridotites of the Santa Elena complex experienced several stages of hydrothermal alteration and that serpentinization was likely overprinted by a later high temperature hydrothermal event.

Geochemical characterization of thermal springs in the Tete Province, Northern Mozambique

A. SCIARRA*, M. PROCESI, F. QUATTROCCHI AND D. CINTI

Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy (*correspondence: alessandra.sciarra@ingv.it)

A first geochemical survey was carried out in the Northern Mozambique in March-April 2013, with the aim to investigate chemistry and origin of some thermal springs in the Tete Province. The investigated area is located in the East African Rift, adjacent to the marginal sedimentary Mozambique Basin. This area is crossed by the *Rio Zambezi*, one of the main river in Africa and explored during the 19th century by Davi Livingstone.

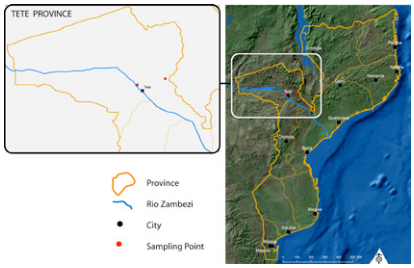

Figure 1: Location of the study area.

Many thermal springs are present in this province due to the proximity with the rift, but considerably little geochemical and geothermal studies have been done, due to the difficulties related both to the site accessibility and social interaction with local tribes. Three thermal springs were sampled close to the *Missao de Boroma,* Tete, crossing the Rio Zambezi by a traditional pirogue. Collected samples are being analysed to determinate major, minor and trace elements, $\delta^{18}O$ and δD, dissolved gas, carbon isotopic ratios of TDIC (Total Dissolved Inorganic Carbon) (expressed as $\delta^{13}C$‰vs. VPDB), the $^{3}He/^{4}He$ and the dissolved Radon. The measured temperature ranges between 66°C to 42°C and the pH from 7.9 to 8. The conductivity is around 2400 µS/cm and the Eh is between -208 to -404 mV. The chemical and isotopical analysis are in progress, anyway this first sampling suggests the need to plan and perform a national geochemical survey of the thermal springs in Mozambique. Data should be organized in organic geodatabase and geographic information systems. This information could have a big relevance not only for the geochemical, hydrogeological and geological knowledge of the Country but also for a potential geothermal exploration and exploitation.

Age of the Bird River Sill (Manitoba, Canada) and the Secular Variation of Layered Intrusion-hosted Stratiform Chromite Mineralization

JAMES S. SCOATES[1], R.F. JON SCOATES[2] AND COREY J. WALL[1]

[1]Pacific Centre for Isotopic and Geochemical Research, EOAS, University of British Columbia, Vancouver, BC, Canada, (jscoates@eos.ubc.ca, cwall@eos.ubc.ca)

[2]2502 Holyrood Drive, Nanaimo, BC, Canada, (jscoates@telus.net)

The Archean Bird River Sill, a 20 km long and up to 800 m thick mafic-ultramafic layered intrusion in the Bird River greenstone belt of southeastern Manitoba, Canada, contains significant resources of chromium and nickel-copper, and locally anomalous concentrations of platinum group elements (PGE). Stratiform chromitite, displaying both remarkable lateral continuity and local irregularities due to synmagmatic disruption, occurs in up to six main intervals over a thickness of ~60 m in the Chromitiferous Zone of the lower ultramafic part of the intrusion. Ni-Cu sulfide mineralization is hosted in ultramafic rocks at the base of, or just below, the sill (e.g., past-producing Maskwa-Dumbarton mines). We report U-Pb zircon ages (chemical abrasion, single grains, ID-TIMS) for cumulates from below and above the Chromitiferous Zone, including (1) a locally pegmatitic, sulfide-bearing, feldspathic peridotite from the PGE Zone beneath the lowermost chromitite horizon (Lower Group) of 2743.72 ± 0.31 Ma (n=6), and (2) a leucogabbro in the Lower Gabbro Zone, approximately 35 m above the uppermost chromitite horizon (Upper Paired Group) of 2743.19 ± 0.31 Ma (n=9; revised from [1]). These ages are interpreted as the age of crystallization of the sill and they define the timing of the associated Cr-Ni-Cu±PGE mineralization. Other Neoarchean mafic-ultramafic intrusions containing economic concentrations of chromite and/or Ni-Cu-(PGE) occur in the northwestern part of the Superior Province in the Canadian Shield (e.g., McFaulds Lake, Big Trout Lake, Puddy Lake, Shebandowan) and share broadly similar geologic relationships. The age of significant intrusion-hosted stratiform chromite mineralization worldwide ranges from Eoarchean (e.g., Akilia, Greenland) to Paleoproterozoic (e.g., Bushveld, South Africa), which is comparable to the range for komatiite-related Ni deposits. This temporal restriction is consistent with both deposit types requiring the involvement of high-MgO, Cr-rich parent magmas produced during large degrees of mantle melting early in Earth history.

Ageing of the Thetyan crust documented by xenoliths from Hyblaean diatremes (Sicily): Implication for crustal assimilation during magma emplacement

VITTORIO SCRIBANO* AND MARCO VICCARO

[1]Dipartimento di Scienze Biol., Geol., Amb., Univ. Catania, Corso Italia 55, 95127 Catania, Italy (Correspondence: scribano@unict.it, m.viccaro@unict.it)

Previous study on xenoliths from Miocenic diatremes from Hyblaean area (Sicily) suggested that the local Meso-Cenozoic sedimentary and volcanic sequence rests upon a fossil oceanic core-complex belonging to the Ionian Thetys lithospheric domain. Hyblaean xenoliths have also suggested that the postulated core-complex hosted long living hydrothermal systems which have produced diverse geochemical and mineralogical modification to the host ultramafic and gabbroic rocks (e.g. hydration, alkalization, sulfidization, carbonation) through time, as well the deposition of hydrothermal brines at different crustal levels. The Upper Miocene volcanic rocks cropping out in the Central-Eastern section of the area were erupted after a 50 Ma non-magmatic period (the Eocene hiatus). The interaction between ascending magmas and the fossil hydrothermal system produced dehydration of the serpentinite wall rock with formation of fluidized eruptive systems (i.e. diatremes). The basalt magma assimilated some hydrous peralkaline anatectit melts thereby attaining a silica-undersaturated, sodic (nephelinitic) character. Magmas that fed the Pleistocene volcanism in the northern margin of the Plateau intersected a section of the fossil hydrothermal system, which was particularly rich in hydrothermal evaporites as testified by the high contents in S, Cl, F, H_2O, Ca, Na, Sr, Ba, relatively high Zr/Hf and occurrence of sodalite series phenocrysts. More in general, we put forward the idea that selective assimilation of hydrothermally altered wall rocks may explain the geochemical paradox of the Hyblaean basaltic lavas, which display Nd-Sr isotope ratios distinctive of MORB-type magmas and distribution of some trace elements more typical of alkaline-series magmas.

Evidence of intergranular melt pools and melt films in lower crustal granite: Products of fluxing by water derived from deformation of nominally anhydrous minerals

S.J. SEAMAN[1]*, M.L WILLIAMS, M.J. JERCINOVIC, G.C. KOTEAS[2] AND L. BROWN

[1]Department of Geosciences, Univerity of Massachusetts, Amherst, MA 01003, USA (*correspondence: sjs@geo.umass.edu)

[2]Department of Geology, Norwich Univerity, Northfield, VT 05663, USA

Water in nominally anhydrous minerals in lower crustal granitoids may move from structural sites and fluid inclusions in nominally anhydrous minerals to grain boundaries during deformation. Along grain boundaries, this water can lower the solidus, facilitating the production of small amounts of partial melt. Outcrops of the 2.6 Ga Stevenson granite, a lower crustal granite in the Athabasca granulite terrane, Saskatchewan, range from K-feldspar megacrystic granite to ribbon mylonite. With increasing deformation, water concentration in quartz and feldspar crystals decreases, and very fine-grained (2-10 micron) brown colored grain boundary films and intergranular pools are progressively developed. The fine-grained multi-phase material on grain boundaries and at grain triple junctions has been interpreted as former melt films and melt pools, respectively. The interpreted melt films have a distinctive pocked texture and a multiphase assemblage with quartz, 2 feldspars and fine (1-2 microns) Fe oxides. Melt films on the grain boundaries of plagioclase, potassium feldspar and quartz are approximately 20 microns wide. Melt pools are up to 100^+ microns in diameter. In some zones of the rock, melt pools are nearly interconnected, possibly beginning to mobilize, approaching a situation in which a melt conduit would be established. Water in nominally anhydrous minerals has the potential to lower the solidus significantly enough to initiate partial melting in lower crustal granitoids at high ambient temperatures. 3000 ppm water in quartz and feldspars that make up large volumes of lower crustal granitoids would lower the dry solidus of granite by 96ºC at 1 GPa, facilitating the production of small volumes of partial melt that wet the grain boundaries along which it is produced.

[3]Département de Biologie, UMR 7138 SAE, Université des Antilles et de la Guyane, 97159 Point à Pitre Cedex, Guadeloupe, France
[4]Observatoire des Sciences de l'Univers de Rennes, UMR Ecobio, Campus Beaulieu, bât. 14. 263 av du Général Leclerc 35042 Rennes Cedex, France.

One of the major challenges of current research on the functioning of the continental ecosphere is to develop integrative approaches allowing scale changes. Isotopic biogeochemistry is an interested integrating tool. The basic idea is that the isotopic composition of a chemical species ($\delta^{15}N$ for nitrogen) at a definite location reflects (i) its various sources and (ii) processes which affect its concentration.
Denitrification generates an isotopic enrichment of ^{15}N and ^{18}O of the residual nitrate in soils or in waters (surface or groundwater).

However, denitrification is intermittent and occurs in hot spots. In order to get insights into this process involved at regional scale, it is important to trace the succession of denitrification in soils and test the hypothesis whether plants could integrate the signal of denitrification occurring in soils.
First results show that for a same type of soil, $\delta^{15}N$ is much higher for agricultural soils than for meadows, forest or mangrove soils. This is mostly likely due to higher gaseous losses processes occurring in agricultural soils such as denitrification.

Moreover, $\delta^{15}N$ of plants increase with increasing of $\delta^{15}N$ of soils. This confirms that the $\delta^{15}N$ of soil organic nitrogen could be an indicator of the intensity of denitrification

Physical and geochemical processes during groundwater replenishment with highly treated wastewater

S. SEIBERT[2], H. PROMMER[1,2,3,*], A. SIADE[1,3] AND O. ATTEIA[4]

[1]University of Western Australia, Crawley, Australia Henning.Prommer@csiro.au (* presenting author)
[2]CSIRO Land and Water, Wembley, Australia
[3]NCGRT, Australia
[4]EGID, Pessac Cedex, France

Decreasing availability of ground and surface water resources in conjunction with increasing water demands has motivated the exploration of unconventional new water sources in Australia and other places. Among possible solutions recycling of municipal wastewater through advanced tertiary treatment techniques presents a promising option to augment existing drinking water supplies. During this treatment process reverse osmosis (RO) plays a critical role in the removal of undesired solutes and results in low ionic strength product water. The purified, desalinated water can be stored underground for protection against evaporation loss and introduce, where required, an additional aquifer treatment step for the removal of trace pollutants (e.g., pharmaceuticals, disinfectant-byproducts). As the recycled low ionic strength water is typically in chemical disequilibrium with the native aquifer conditions, the injection into aquifers often triggers a complex range of coupled physical and geochemical processes that can strongly affect the quality of the groundwater in the recharged aquifer. In this study we present field observations and a model-based interpretation of the data collected during a large-scale groundwater replenishment trial using highly treated waste water in Perth, Western Australia. The trial injection was conducted between November 2010 and December 2012 to clarify the technical feasibility and societal acceptance of a large-scale implementation of this approach. The first phase of the modelling study was dedicated to obtaining an accurate understanding and description of the injectant and temperature propagation within the highly heterogeneous sedimentary aquifer.

The calibrated conservative transport model was then subsequently used to identify and quantify the geochemical reactions that were induced by the injection. In agreement with earlier laboratory results from respirometer tests (e.g., [1,2]) the simulation results show that pyrite oxidation acts as the major driver for reaction-induced concentration changes within the aquifer. Pyrite oxidation showed to cause a rapid removal of oxygen and also the removal of the nitrate contained in the injectant. The acidity produced by the pyrite oxidation showed to be partially buffered by the alkalinity contained in the injected water but also by a range of mineral reactions, including Fe-carbonate and feldspar dissolution. Understanding the nature and longevity of the mineral buffering mechanisms is cruicial for the design of future large-scale implementations of groundwater replenishment.

Competition for sulfide in marine sediments: Electrogenic Filamentous Bacteria versus *Beggiatoa*

DORINA SEITAJ[1]*, SAIRAH Y. MALKIN[2], REGINA SCHAUER[3] AND FILIP J.R. MEYSMAN[1,2]

[3]Aarhus University, Department of Bioscience, Center of Geomicrobiology, Ny Munkegade 116, 8000 Aarhus, Denmark

Recently, a novel mechanism of sulfide oxidation has been described from marine sediments, whereby long filamentous bacteria (ElectroFilaments) couple the reduction of oxygen at the surface to the oxidation of sulfide at centimeters depth via electrical currents. This creates a wide suboxic zone similar to that created by the large sulphur bacteria of the genus *Beggiatoa*. These latter bacteria are motile and capable of intracellular nitrate storage, and in this way, *Beggiatoa* can transport nitrate to deeper sediment layers to oxidize H_2S. In the seasonally hypoxic Lake Grevelingen, The Netherlands, both types of sulfur oxidizing bacteria have recently been observed. This rises the question how these different modes of microbial sulfide oxidation compete?

We conducted a yearlong study of monthly sampling campaigns in Lake Grevelingen. Microsensor profiling of O_2, pH and H_2S revealed the geochemical fingerprint of the dominant microbial process over time (both mechanisms generate a very distinct pH profile). In addition, FISH tagging for Desulphobulbus and microscopic counting of *Beggiatoa* allowed to quantify the abundance of the two competing bacteria. Our results show that both modes of microbial sulfide oxidation follow a predictable seasonal succession, where *Beggiatoa* are dominant in autumn right after summer hypoxia, while Electrofilaments become dominant in spring. Field data and additional mesocosm experiments suggest that bottom water oxygenation, nitrate availability and physical disturbance are the main environmental factors controlling the outcome of this microbial competition. These two competing microbial pathways of sulfur oxidation strongly affect the biogeochemical cycling, but in a very different way, and so, the predominance of either mechanism can have a strong impact on the elemental cycling in coastal sediments.

Tracing the origin of sulphur in Darzila karst cave, NE Iraq

A. SEITHER[1,3]*, K. HEILAND[2,3] AND S. KUMMER[3]

[1]Norges Geologiske Undersøkelse, 7040 Trondheim, Norway (*correspondence: anna.seither@ngu.no)
[2]Ingenieurbüro für Grundwasser GmbH, 04229 Leipzig, Germany (k.heiland@ibgw-leipzig.de)
[3]TU Bergakademie Freiberg, 09596 Freiberg, Germany

Darzila cave, located in the Sangaw district in Northern Iraq, develops by the dissolution of limestone by sulphuric acid through oxidation of H_2S. The hydrogen sulphide may either originate from oil-rich reservoirs, such as the nearby Kirkuk oil field, or from gypsum of the Lower Fars Formation.

Samples from these possible endmembers were subject to isotopic analyses ($\delta^{34}S$, $\delta^{18}O$). The water of three prominent floor feeders inside the cave was analyzed for its content of major ions, trace elements, total organic carbon, as well as for the stable isotopic composition of water (δD, $\delta^{18}O$), dissolved sulphate ($\delta^{34}S$, $\delta^{18}O$) and sulphide ($\delta^{34}S$).

Investigations of water samples pointed towards a potential influence of hydrocarbon-bearing layers at two sites. Indices were significantly elevated SO_4^{2-}/Ca^{2+} ratios, an increased content of total dissolved solids (10-31 g/L) and dissolved organic carbon (14-20 mg/L), and relative enrichments of trace elements such as Cr, Be, Ga, Ni, Co, Mn, and V. The isotopic investigations confirmed the influence of H_2S affluxes from hydrocarbons ($\delta^{34}S \approx -9$ ‰ VCDT) at these sites. Further evidence was given by depleted $\delta^{34}S$ and $\delta^{18}O$ values in sulphate, small differences between the sulphur isotopic signature of sulphate and sulphide, as well as elevated δD values in ambient water.

The third floor feeder had an entirely different isotopic signature, showing distinct signs of bacterial sulphate reduction and therefore pointing towards primary gypsum from the Lower Fars Formation ($\delta^{34}S \approx +22$ ‰ VCDT) as sulphur source. Main indications were a $\delta^{34}S$ value of sulphate above that of gypsum and strongly depleted sulphide. However, it appears that sulphate reduction was superimposed by several secondary transformation processes.

Partial melting of rhyolites in the Chaltén Contact Aureole (Patagonia, Argentina)

S. SEITZ[1]*, B. PUTLITZ[1], L.P.BAUMGARTNER[1], S. LERESCHE[1] AND P. NESCHER[1]

[1]Institute of Earth Sciences, University of Lausanne, 1015 Lausanne, Switzerland (* correspondence: susanne.seitz@unil.ch)

The Chaltén Plutonic Complex (CHPC) consists of mafic and granitic calc-alkaline intrusive rocks emplaced in several successive batches. High-precision U/Pb zircon dating yield ages between 16.9 ± 0.05 Ma and 16.37 ± 0.02 Ma [1]. The host-rocks are formed by a Paleozoic clastic sequence, Jurassic rhyolites and volcanoclastics, and a Cretaceous pelitic sequences. The intrusion of the CHPC post-dates major regional deformation.

Partial melting in the Chaltén contact aureole is limited to small zones at gabbro and tonalite contacts with rhyolites. Partial melting does not occur at the granite-rhyolite contact. The rhyolitic migmatites are characterized by an anastomosing network of veins of quartz, feldspar and almandine-rich garnet. This network is most prominent at 10m to 15m from the contact. Some cm-scale shear zones concentrated partial melt. On a microstructural scale partial melt is segregated along quartz-feldspar grain boundaries. They show typically cuspate grain boundaries with melt penetrating along the edges. Petrologic investigations show that melting is to the result of biotite breakdown to cordierite or garnet.

Thermodynamic calculation for these peralumiumous rhyolites indicate that first melt occurs at 650-700°C and pressures around 3kbar. Simple thermal calculations yield maximum temperatures of about 550°C at the mafic-rhyolite contact, which is 100-150°C lower than the required temperature for partial melting. Melting in the rhyolitic migmatites was intense enough to partially reset U/Pb ages as indicated by the younging of zircon ages (obtained by laser ablation). We are currently studying the mechanism of partial resetting of the zircon ages, as well as the kinetics of oxygen isotope exchange between quartz phenocrysts and the rhyolite matrix. Preliminary modeling suggests, that oxygen isotopes can be re-equilibrated dominantly by diffusion, while zircon most likely recrystallized.

Silicate-natrocarbonate immiscibility in ijolites at Oldoinyo Lengai, Tanzania: Melt inclusion study

V.S. SEKISOVA[1,2], V.V. SHARYGIN[2]* AND A.N. ZAITSEV[3]

[1]Novosibirsk State University, Novosibirsk 630090, Russia
[2]V.S. Sobolev Institute of Geology and Mineralogy SD RAS, Novosibirsk 630090, Russia (*correspondence: sharygin@igm.nsc.ru)
[3]St. Petersburg State University, St. Petersburg 199034, Russia

Xenoliths of plutonic rocks (ijolite, jacupirangite, etc.) in the Oldoinyo Lengai pyroclastics are considered to be cumulates forming in an intermediate chamber from a parental olivine nephelinite magma [1].

Melt inclusions with silicate-carbonate immiscibility were found in nepheline and Ti-magnetite of olivine-mica ijolite. Other minerals (pyroxene, etc.) contains inclusions without immiscibility; fluorapatite bears natrocarbonatite inclusions. Phase composition of inclusions in nepheline (5-100 μm) is silicate glass + vapor-carbonate globule ± daughter/trapped crystals ± sulfide bleb. Vapor-carbonate globule (up to 20 μm) consists of gas bubble (≈60%) and nyerereite-rich carbonate aggregate (≈40%). Some inclusions may also contain numerous submicron carbonate globules in glass. Heating experiments with inclusions indicated the following events: (1) carbonate component melted instantaneusly at 540-560ºC; (2) melting of silicate glass occurred at 580-640ºC; (3) all globules gradually coalesced into one large vapor-carbonate globule at 640-800ºC; (4) homogenization in this globule occurred at 900-920ºC; (5) complete homogenization (miscibility of carbonate and silicate liquids) was not achieved with temperature increase up to 1100ºC.

Our study of inclusions advocates very complex history of the Lengai ijolite and evolution of initial silicate melt in an intermediate chamber. Crystallization of ijolites occurred in conditions of silicate-natrocarbonatite immiscibility in very broad temperature (540-1100ºC). During formation nepheline and other minerals trapped as inclusions at least two immiscible liquids. After entrapment additional carbonate fraction was separated from silicate liquid within inclusion with decreasing temperature. The immiscibility phenomenon was recently recorded in the Oldoinyo nephelinites [2-4].

Ensemble Simulation of the Atmospheric Radionuclides Discharged by the Fukushima Nuclear Accident

T. T. SEKIYAMA*, M. KAJINO AND M. KUNII

Meteorological Research Institute, Tsukuba 305-0052, Japan (*correspondence: tsekiyam@mri-jma.go.jp)

Enormous amounts of radionuclides were discharged into the atmosphere by a nuclear accident at the Fukushima Daiichi nuclear power plant (FDNPP) after the earthquake and tsunami on 11 March 2011. The radionuclides were dispersed from the power plant and deposited mainly over eastern Japan and the North Pacific Ocean. A lot of numerical simulations of the radionuclide dispersion and deposition had been attempted repeatedly since the nuclear accident. However, none of them were able to perfectly simulate the distribution of dose rates observed after the accident over eastern Japan. This was partly due to the error of the wind vectors and precipitations used in the numerical simulations. Unfortunately, their deterministic simulations could not deal with the probability distribution of the simulation errors.

Therefore, an ensemble simulation of the atmospheric radionuclides was performed using the ensemble Kalman filter (EnKF) data assimilation system coupled with the Japan Meteorological Agency (JMA) non-hydrostatic mesoscale model (NHM). The JMA-NHM has been used operationally for weather forecasts by JMA. Through this ensemble data assimilation, twenty members of the meteorological analysis over eastern Japan from 11 to 31 March 2011 were successfully obtained. Using this meteorological analysis, the radionuclide behavior in the atmosphere such as advection, convection, diffusion, dry deposition, and wet deposition was simulated. This ensemble simulation provided the multiple results of the radionuclide dispersion and distribution. Because the large (small) ensemble-spread of the multiple results indicates the low (high) accuracy of the numerical simulation, the probability distribution of the simulation errors is obtainable from the ensemble simulation. These statistics can provide information useful for the probabilistic prediction of atmospheric radionuclides.

Numerical simulations are able to collaborate with field observations in depicting the full picture of the radionuclide contamination in Fukushima.

Imaging the reactivity and transport of ^{99}Tc through Fe-cement/rock barriers

A. F. SELIMAN[1], J. BRIDGE[2], S.A. BANWART[1] AND M.E. ROMERO-GONZÁLEZ[1]*

[1]Cell-Mineral Research Centre. Kroto Research Institute. The University of Sheffield. Sheffield S3 7HQ, UK (*m.e.romero-gonzalez@sheffield.ac.uk)

[2]School of Engineering. University of Liverpool, Liverpool L69 3GH, UK. (j.brigde@liverpool.ac.uk)

Geological disposal of radioactive waste requires a detailed understanding of the critical processes affecting geochemical transformations at laboratory and field scale. The interfaces between storage containers, repository and geological substrata can be viewed as a series of continuous barriers with varying porosity and chemical composition that governs flow and physical-chemical transformation of radionuclides during their long term transport. Using this approach, we have investigated the mobility of ^{99}TcO4$^-$ transport through Fe-cement/sandstone engineered barriers using flow through experiment and gamma imaging of ^{99m}Tc isotope. A flow cell packed with nirex vault reference backfill material (NRVB) containing zero valent iron (ZVI) or magnetite and Sherwood sandstone in a barrier fashion was used. The transport of ^{99m}Tc in synthetic groundwater at pH 10 was imaged using a medical gamma camera at a flow rate of 5.7ml h^{-1}. The Fe-bearing material was prepared to obtain an uniform distrubution of 20% ZVI or 10% magnetite representative of steel materials that may create reactive hotspots in the disposal site. The results showed that the unmodified NRBV/sandstone systems have not capacity to retain ^{99m}Tc. In contrast, ^{99m}Tc was not trasported through the NRBV containing ZVI and it was retained entirely by the modified barrier. The NRBV/sandstone system modified with magnetite showed retardation of ^{99m}Tc that was overcomed over long periods of time, allowing the radionuclide to be eventually transported out of the flow cell. The results showed that ^{99}Tc transport is conservative through cement and sandstone. The implication is that this radionuclide will be transported to the outside natural environment surrounding the geological disposal. However, ammendment with Fe-bearing materials, especially ZVI increases confinement of the radionuclide within the geological disposal reducing the risk of long term environmental contamination.

[4]ETH, Zurich 8006, Switzerland

Gas hydrates (GH) are ice-like solid compounds comprised of gas molecules and water [1]. As it is very difficult to recover natural GH samples due to their fast decomposition under ambient conditions, a lot of open questions are left concerning the microstructure and distribution of hydrates in sediments. This study represents the first direct observation of gas hydrate growth in a sedimentary matrix using time-resolved synchrotron-based tomography leading to first insights on the nucleation and growth of gas hydrates at a high spatial resolution of 740 nm. The time-sequences of the GH formation in the medium reveal that the reaction clearly started at the gas-water interface forming a several μm thick hydrate film (Fig.1). In contradiction to some earlier conjectures a nucleation on the grain surface was not observed. At a later stage the water is replaced by GH of more or less isometric shape with pore space in between. Some of our observations show that water remains as a thin film between grains and hydrate but this needs to be corroborated. Seismic anomalies observed in field studies might be explained by the presence of thin water films in hydrate-bearing sediments. In a next step the full 3D data set will be used as a direct input to model the effective elastic properties.

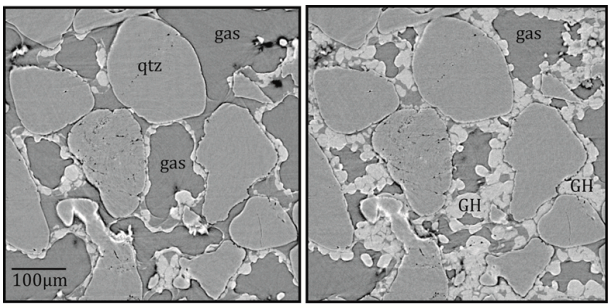

Figure 1: 2D slices depicting the stepwise hydrate growth within the sedimentary matrix.

Application of mineral thermometers and barometers to shoshonitic-ultrapotassic rocks: The Simav Graben (Western Anatolia, Turkey)

B.SEMIZ

Dep of Geological Engineering, Pamukkale University, 20070, Denizli, Turkey (bsemiz@pau.edu.tr)

The study area is located at the intersection of E–W-trending Plio-Quaternary Simav Graben and NE–SW-trending Neogene Selendi and Uşak-Güre basins in the western Anatolia. Due to their morphological, stratigraphical positions and petrographical features in the field, the investigated shoshonitic-ultrapotassic rocks are called Inceğiz, Gediz, Dereköy, Naşa, Kestel basalts, Saphanedağı and Ilıcaksu Lamproites. All the SHO-UK rocks display similar petrographic characteristics.

Fourteen samples, representing the SHO-UK units in the eastern parts of the Simav Graben have been used for mineral chemical studies and for estimation of the temperature and pressure conditions of magmatic crystallization. These samples are porphiritic, hyaloplitic, pilotaksitic in texture and with the following mineral assemblages; clinopyroxene (En_{40-52}, Wo_{39-48}), olivine (Fo_{63-92}), rarely phlogopite (Mg# 65-91), plagioclase (An_{62-88}), and sanidine (Or_{52-84}). Ti-magnetite, ilmenite and chrome-spinel (5-18% MgO, 39-54% Cr_2O_3) are common accessory minerals.

Application of clinopyroxene [1] and olivine-spinel [2] geobarometric studies for the SHO-UK, equilibrium pressure between ~7.6-10.3 and ~16.2-16.8 kbar has been estimated, corresponding to 25-51 km depth, respectively. Oxygen fugasity ranges from -11.9 and -13.8. Olivine [3], Olivine-spinel [4], clinopyroxene [5] and magnetite-ilmenite pairs [6] geothermometers have been applied for estimating the crystallization temperatures of minerals. Calculated crystallization temperatures are 1193-1262°C for olivines, 1086-1191°C for clinopyroxene and 793-851°C for magnetite-ilmenite pairs. The estimates of magmatic parameters indicate that the magmas forming the SHO-UK rocks crystallized at different levels, from mantle depths toward deep-level magma chambers.

Trace element composition of clinopyroxenes from the Kızıldağ ophiolite (S-Turkey): Implication for multi-stage fractionational melting in a SSZ setting

AHMET D. SEN[1], IBRAHİM UYSAL[2], MARGUERİTE GODARD[3], SAMET SAKA[2], RECEP.M. AKMAZ[2], MELANİE KALİWODA[4] AND UTKU BAGCİ[5]

[4]Mineralogical State Collection Munich, LMU, Germany
[5]Mersin University, Mersin, Turkey

Trace-element composition of clinopyroxenes from the mantle peridotites of Kızıldağ ophiolite (Hatay, S-Turkey) were determined by laser ablation ICP-MS to better understand the geochemical processes and the formation of the ophiolite. The peridotite sequence is composed of tectonized harzburgite and ultramafic cumulate rocks representing refractory mantle source and Moho Transition Zone (MTZ), respectively. Harzburgites contain spinel with Cr# 47-70 and Mg# 37-66, indicating that they are residue of high degrees of partial melting. Ultramafic cumulates are mainly dunite and wehrlites. Tectonized harzburgites show two different types of compositions. First type of harzburgites are refractory and have primary pyroxene crystals with ductile deformation signs. Second type of harzburgites are more fertile and have interstitial clinopyroxenes showing similar characteristics with rocks from MTZ. Chondrite-normalized rare earth element (REE) patterns of clinopyroxenes from Kızıldağ ophiolite are clearly depleted in light REE (LREE) ($[Lu/La]_N$>100), and have slightly similar patterns with clinopyroxenes of abyssal peridotites from normal mid-ocean ridges (MOR). Interstitial clinopyroxenes in MTZ dunites have flatter patterns ($[Lu/La]_N$~10) comparable with those from other dunites of all the Tethyan ophiolites (e.g. Oman, Troodos). Clinopyroxenes in tectonized harzburgites having extremely downward REE patterns, characterized by a strong depletion from heavy REE (HREE) to middle REE (MREE), suggest that they are residue of first stage fractional melting in the garnet stability field in a MOR setting. Interstitial clinopyroxene from impregnated harzburgites have more enriched REE patterns than those of depleted harzburgites, indicating spinel field melting in a SSZ setting where melts can percolate within upwelling mantle.

The possible source mantle and magma genesis of basalts from Pitcairn island: Implication from highly siderophile elements and Os isotope ratios

RYOKO SENDA[1]*, TAKESHI HANYU[1], AKIRA ISHIKAWA[1,2], HIROSHI KAWABATA[1,3], TOSHIRO TAKAHASHI[1] AND KATSUHIKO SUZUKI[1]

[1]IFREE, JAMSTEC, Yokosuka 237-0061, Japan (*Correspondence: rsenda@jamstec.go.jp)

It is well known that recycled materials are involved in producing the chemical and isotopic heterogeneities observed in oceanic island basalts (OIB). The type of recycled material present in the Enriched Mantle 1 (EM-1) reservoir has been widely debated. Oceanic crust with pelagic sediment (e.g., Chauvel *et al*., 1992), delaminated subcontinental lithospheric mantle (SCLM) (e.g., Hauri and Hart, 1993), subducted oceanic plateaus (Gasperini *et al*., 2000) and just single melting process involving pristine mantle (Collerson *et al*., 2010) have all been invoked as contributing to EM-1 source. The chemical composition of EM-1 is characterized by radiogenic Sr, unradiogenic Nd, unradiogenic Pb and radiogenic Os isotope compositions compared to the depleted mantle.

We measured Os isotope ratios and highly siderophile elements (HSE) abundances in basalts from Pitcairn Island, south Pacific, which represent strong EM-1 flavor to identify the possible source components of these magmas. The Os isotope ratios (0.138-0.161) have similar to or slightly higher range than, those measured in previous studies on EM-1-type basalts (~0.150). The HSE patterns normalized by chondrites are characterized by fractionation between IPGE (Os, Ir, Ru) and Pd. Among IPGE, Ir abundances of some basalts are depleted compared to Os and Ru. Pt abundances of most basalts also show depleted pattern from Ru and Pd. These characteristics are similar to some picrites from Hawaii (Ireland *et al*., 2009). However the abundances of HSE in Pitcairn basalts are clearly lower than those of Hawaiian picrites with similar range of MgO. The Os isotope ratios of Pitcairn basalts are higher than those of picrites. We will discuss the components of the source mantle of EM-1 and the magma genesis of Pitcairn Island basalts combining our data with previous studies.

Composition and structure of fresh and aged Fe oxidation products

A.-C. SENN*, R. KAEGI, S.J. HUG, J.G. HERING AND A. VOEGELIN

Eawag, Swiss Federal Institute of Aquatic Science and Technology, Überlandstrasse 133, CH-8600 Dübendorf, (*correspondence: anna-caterina.senn@eawag.ch)

The oxidation of dissolved Fe(II) by O_2 leads to the formation of amorphous to poorly crystalline Fe(III)-precipitates. These precipitates control the fate of major and trace elements at redox-interfaces and play an important role in many natural and technical systems. Dissolved phosphate (P), silicate and Ca are major factors controlling composition and structure of fresh Fe(III)-precipitates [1, 2]. In this study, we therefore investigated (i) the effects of silicate and Ca over a wide range of P/Fe ratios on the composition and structure of fresh Fe(III)-precipitates formed by oxidation of 0.5 mM Fe(II) in bicarbonate-buffered solution at pH 7.0 and (ii) changes in precipitate composition and structure during aging for 30 days at 40 °C.

During Fe(II) oxidation, mostly lepidocrocite (Lp) is formed at initial P/Fe ratios below ~0.1. Phosphate was nearly completely co-precipitated with Fe(III) up to an initial molar P/Fe ratio of ~0.55 in the absence of Ca and ~0.75 in the presence of dissolved Ca. Above these P/Fe ratios, only amorphous Fe(III)-phosphate formed and phosphate removal was incomplete. Enhanced co-precipitation of phosphate and Ca with Fe(III) was attributed to electrostatic effects and to the formation of mixed Ca-Fe(III)-phosphates. Silicate did not interfere with the initial phosphate uptake but inhibited lepidocrocite formation at low P/Fe ratios, instead promoting the formation of hydrous ferric oxide (HFO; ferrihydrite-like polymers with limited corner-sharing linkage of Fe(III)-octahedra). Continuing Fe(III) polymerization during aging led to the remobilization of phosphate, especially in the absence of Ca and silicate. Phosphate remobilization was limited in the presence of Ca, which stabilizes mixed Ca-Fe(III)-phosphate, and especially silicate, which inhibits Fe(III) polymerization into crystalline Fe(III)-precipitates.

The results from this study form the basis for an improved mechanistic and quantitative understanding of Fe(III)-precipitate formation and trace element co-sequestration at aquatic redox-interfaces and in technical systems, for example drinking water treatment for As removal.

The occurrence of very high-grade pyrometamorphic xenocrysts/ xenoliths in the plutonic rocks of the Alvand plutonic complex, Hamedan, Iran

ALI A. SEPAHI

Department of Geology, Bu-Ali Sina University, Hamedan, Iran, E-mail: aasepahi@gmail.com, sepahi@basu.ac.ir

The Alvand plutonic complex and a sequence of poly-metamorphic rocks are situated near to Hamedan, Sanandaj-Sirjan zone, Iran. Restites, xenoliths and xenocrysts are abundant in granitoids of the complex but they are rare in gabbroic rocks. Restitic xenocrysts of garnet, sillimanite/andalusite and cordierite which subsequently reacted with granitic magmas are common in granitoids. In gabbroic rocks, especially in a wherlitic olivine gabbro, scarce xenocrysts of andalusitse occur which have been converted to sillimanite and a pelitic xenolith in this rocks has been pyrometamorphosed to a very high grade mineral assemblage (e.g. a spinel, sillimanite, mullite and sanidine-bearing assemblage). Thermometric studies have indicated that this very high grade pyrometamorphic assemblage has been formed at peak temperature of more than 1000 ºC (up to 1300-1400 ºC) when mafic-ultramafic host magma interacted with Al-rich xenoliths.

[5]Steinnman Inst., University of Bonn, 53115, Germany

A thick sequence of the Late Jurassic magmatic rocks in Patagonia (Argentina) extendes over 1x10^6 km^2 from the Atlantic to the Andes [1]. Although bimodal in composition, the Patagonia Province (PP) is one the largest silicic (felsic) LIPs on Earth. It consists of rhyolites and ignimbrites of the Marifil (~187-177Ma) [2,4] and Chon Aike (~168-151Ma) [2,3] Formations (Fm), with a minor andesitic component represented by the Bajo Pobre (BP) (~164-153Ma) [2,3] and Locontrapial Fm. Thus the total duration of magmatism is ~36 Ma. Our new U-Pb ages on zircons for the Marifil Fm confirm that the first felsic pulse coincided with the Karoo-Ferrar magmatic event (~184-178Ma) [4]. However, the main peak activity in the PP is ~10 Ma younger. Basaltic volcanism of the Cañadon Asfalto (CA) Fm fills an extensional basin contemporaneous with the volcanism of the PP. This magmatism was associated with a complex geodynamic evolution during the Gondwana break-up. The setting comprised continental rifts and a subduction zone in the western continental margin, possibly accompanied by back-arc rifting. Andesites from the BP Fm and basalts from CA Fm are Opx rich rocks with occasional anhedral olivine crystals with Cr-spinel inclusions (Mg# 0.48-0.25; Cr# 0.47-0.37). The most primitive Cr-spinel grains from the BP and CA have contrasting compositions in terms of Al_2O_3 (25-28 and 10-12 wt%) and TiO_2 (1.3-1.4 and 0.4-1.3 wt%, respectively). Accordingly, parental melt compositions can be correlated with MORB for BP and island-arc magmas for CA [5]. Compositions of the Late Jurassic volcanic rocks combined with quartz- and pyroxene-hosted melt inclusion and Cr-spinel study will be discussed and applied to understanding the tectono-magmatic environment of this LIP.

Natural and synthetic plagioclases for the interpretation of planetary surfaces

SERVENTI G.[1], CARLI C.[2], ORLANDO A.[3], BORRINI D.[4], PRATESI G.[4], SGAVETTI M.[1] AND CAPACCIONI F.[2]

[1]Department of Physics and Earth Sciences, University of Parma (giovanna.serventi@unipr.it)
[2]Inaf-IAPS Tor Vergata, Roma (cristian.carli@iaps.inaf.it)
[3]Institute of Geosciences and Earth Resources, C.N.R., Firenze (orlando@igg.cnr.it)
[4]Department of Earth Sciences, University of Firenze

Plagioclase, pl, is an important constituent of planetary surfaces, e.g. Moon and Mercury. Spectrometers detected crystalline pl on the lunar surface [1], with composition of ~An90 and variable FeO content. New data from XRS and GRS on the Hermean surface show contents of Na [2] that are compatible with low-An (<90) pl.

Natural and synthetic plagioclase spectroscopy

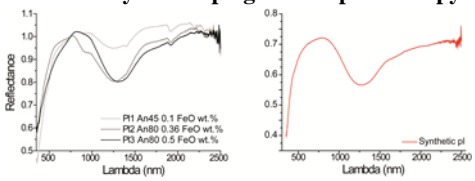

Fig. 1 Natural (left) and synthetic (right) spectra of pl.

Visible and near-infrared reflectance (VNIR) spectroscopy is the most used technique to map the surface of Solar System bodies. Pl, often considered a spectrally neutral phase, shows a clear absorption at ~1.25 μm, even for very low FeO contents (Fig. 1, left); furthermore, an increase of this component, causes an increase of the absorption band depth, while its position moves to the IR region. We synthesized pl with different An and FeO content, in order to investigate how these parameters control the absorption band in the VNIR. A Pl, An90 with 0.5 wt% FeO, was synthesized from oxides and carbonate at logfO_2= -9; the mixture was first heated at 1600 °C for 15 minutes, quenched and then re-heated at 1400 °C for 24 hours. XRD and EPMA confirmed both the presence of a crystalline phase and its compositional homogeneity. The spectrum is reported in Fig. 1, right.

The synthesys of different pl will allow to create a VNIR spectra database wich will be invaluable to better constrain the composition of the crust of Solar System bodies.

Bioaerosols in ECHAM5-HAM

ANA SESARTIC[1], ULRIKE LOHMANN[1], AND TRUDE STORELVMO[2]

[1]ETH Zurich, Institute for Atmospheric and Climate Science, Zurich, Switzerland (ana.sesartic@env.ethz.ch, ulrike.lohmann@env.ethz.ch)

[2]Department of Geology and Geophysics, Yale University, 210 Whitney Ave., USA-06520-8109 New Haven (CT)

Interest in primary biological aerosol particles (bioaerosols) like bacteria and fungal spores is mainly related to their health effects, impacts on agriculture, ice nucleation and cloud droplet activation, as well as atmospheric chemistry [1].

In our study we investigated the impact of bacteria and fungal spores acting as ice nuclei on clouds and precipitation on a global scale. Bacteria [2] and fungal spores [3] as a new aerosol species were introduced into the global climate model ECHAM5-HAM using observational data compiled by [4] for fungal spores and [5] for bacteria.

The addition of bioaerosols into ECHAM lead to only minor changes in cloud formation and precipitation on a global level, however, changes in the liquid water path and ice water path as well as stratiform precipitation in the model were observed in the boreal regions where tundra and forests act as sources bacteria and fungal spores.

This goes hand in hand with a decreased ICNC and increased effective radius of ice crystals. An increase in stratiform precipitation and snowfall can be observed in the model results for those regions as well.

Although bacteria and fungal spores contribute to heterogeneous freezing, their impact in the model was reduced by their low numbers compared to other heterogeneous ice nuclei like mineral dust.

To the best of our knowledge, the influence of bioaerosols on the global climate appears to be small. However, there are still several uncertainties constraining bioaerosol modelling, for example their exact emissions (especially over remote regions and the oceans), the impact of coating and ageing on the bacterial IN-ability, etc. Standardised long-term observations with world-wide coverage of ecosystems, as well as further laboratory data, are therefore necessary for a more precise model evaluation.

N_2O and $\delta^{15}N$-N_2O data in ice cores: atmospheric versus in situ signal

BARBARA SETH, JOCHEN SCHMITT, MICHAEL BOCK AND HUBERTUS FISCHER

Climate and Environmental Physics & Oeschger Centre for Climate Change Research,University of Bern, Switzerland, (*correspondence: seth@climate.unibe.ch)

N_2O is an important greenhouse gas which has several sources in both terrestrial and marine ecosystems. N_2O mixing ratios and stable isotopes measured from air entrapped in ice cores allow to identify different processes driving changes in these sources. We present a new $\delta^{15}N$-N_2O record covering the past 15'000 years and discuss possible explanations for the long-term decrease during the Early Holocene.

However, comparative analyses of different ice cores show offsets in the mixing ratios suggesting that elevated mixing ratios are due to in situ production, especially in glacial ice with higher impurity content.

However, the pathways leading to in situ production of N_2O in ice cores are not yet identified. Sowers [1] observes N_2O isotope anomalies in Vostok ice core samples and supposes that microorganisms might use ammonium (NH_4^+) in ice to produce N_2O. EPICA Dome C (EDC) ice samples suspect to in situ production show fairly heavy $\delta^{15}N$-N_2O values as well, however, the isotope signature of N_2O produced from ammonium is expected to be rather light. Thus, it is unlikely that in situ produced N_2O in the EDC ice core can be related to NH_4^+ oxidation.

Alternatively, we propose that in situ N_2O in the EDC ice is produced from nitrate (NO_3^-). Low accumulation sites like EDC show extremely enriched $\delta^{15}N$-NO_3^- values due to intense post-depositional loss processes [2], while sites with higher accumulation have lighter $\delta^{15}N$-NO_3 values [3] and we found a lighter $\delta^{15}N$-N_2O in situ signature for those samples. More knowledge about in situ N_2O could help to verify hidden in situ production or identify ice cores and time intervals suitable to derive the atmospheric history for both mixing ratios and isotopic signature of N_2O.

Competition between microbial and abiotic Fe(II) oxidation: A kinetic modeling approach

M. SETO[1]* AND P. VAN CAPPELLEN[2]

[1]Dept. of Information and Computer Science, Nara Women's University, Nara 630-8222, Japan, seto@ics.nara-wu.ac.jp (*presenting author)

[2]Ecohydrology Research Group, University of Waterloo, Waterloo, Canada

Neutrophilic Fe(II) oxidising bacteria (FeOB) are ubiquitous in soils and sediments. It has been proposed that under low oxygen conditions they are able to successfully outcompete abiotic Fe(II) oxidation. Not only do FeOB catalyse Fe(II) oxidation, they may also hinder the autocatalytic growth of Fe(III) oxides, possibly through the binding of Fe(II) and Fe(III) to cell surfaces or extracellular polymeric substances. We present a simple kinetic model of neutrophilic Fe(II) oxidation, which explicitly accounts for the inhibitory effect of FeOB on the autocatalytic Fe(II) oxidation pathway. The model comprises kinetic equations for the different forms of Fe in systems with and without FeOB. The microbial Fe(II) oxidation rate is assumed to be a function of the FeOB cell concentration, the O_2 concentration, and the cell-bound Fe(II) concentration. The latter is related to the aqueous Fe(II) by an isotherm. In the proposed model, cell-bound Fe(II) and Fe(III) are intermediates in the transformation of aqueous Fe(II) to Fe(III) oxides. The validity of the model is statistically examined, using data of Fe(II) oxidation batch experiments in the presence of the bacterium *Leptothrix cholodnii* Appels [1]. The observed microbial Fe(II) oxidation kinetics are well described by the model. Compared to the abiotic experiments, the presence of the bacteria increases the initial Fe(II) oxidation rate by nearly a factor of 3, but decreases the subsequent autocatalytic Fe(II) oxidation rate by about 50%. The results suggest that neutrophilic FeOB may broaden their geochemical niche by slowing down the autocatalytic growth of Fe(III) oxides in low O_2 environments.

Sr-Nd isotope geochemistry of the troctolitic-gabbroic Bell Rock Range, Giles Complex, central Australia

R. E. B. SEUBERT[1], R. R. KEAYS[1], S. M. JOWITT[1] AND A. G. TOMKINS[1]

[1]School of Geosciences, Monash University, Clayton, VIC 3800, Australia, roland.seubert@monash.edu

The Mesoproterozoic Giles Complex of the Musgrave Province, central Australia, forms part of the c. 1075 Ma Warakurna Large Igneous Province. Here, we provide new Sr-Nd isotope data for a troctolite-gabbro member (Bell Rock Range) of the Giles Complex and compare them with other members of the Giles Complex; these data provide new insights into the formation and evolution of this under-researched magmatic province.

The most primitive melt within the Bell Rock Range is represented by a sample from the top of the intrusion that has an initial εNd value of +4.8, higher than the main troctolitic body of the range (εNd of -0.3 to +1.3), and εNd values of the gabbroic-ultramafic Wingellina Hills, Ewarara, Kalka and Gosse Pile intrusions range from -5.1 to +0.5 [1]. In comparison, the basal part of the Bell Rock Range has εNd values of -4 to 1.1, identical to later dykes that cross-cut the range, and indicative of formation from magmas that underwent crustal contamination or were derived from an enriched mantle source. Although the troctolites at Bell Rock Range yield a range of εNd and MgO values, they have relatively uniform initial $^{87}Sr/^{86}Sr$ values compared to all other lithologies in our database.

These data shed new light onto the petrogenesis of the Giles Complex, and indicate that it is unlikely that any of the the magmas that formed this complex were derived from a depleted region of the mantle. The magmas that formed this complex must have either been sourced from an enriched region of the mantle or have undergone variable crustal contamination, resulting in the range of isotopic compositions observed within this suite of co-magmatic rocks.

The relatively uniform $^{87}Sr/^{86}Sr$ compositions of the Bell Rock Range troctolites suggests that they represent an uncontaminated end-member style of Giles Complex magmatism, whereas gabbroic-ultramafic cumulates in the same area represent true mixing between mantle-derived melts and crustal rocks indicative of significant crustal contamination. These findings will contribute to an understanding of the tectonic setting of the Giles Complex.

Iodide Ion Hydration in Aqueous Solution to 360°C: Insight from XAS and Ab Initio MD

T.M. SEWARD[1], HENDERSON C.M.B.[2], SULEIMENOV O.M.[1] AND CHARNOCK J.M.[2]

[1]Victoria University of Wellington, Wellington 6140, New Zealand; terry.seward@vuw.ac.nz
[2]University of Manchester, Manchester M13 9PL, UK

The interaction of solute species with solvent molecules is a fundamental aspect of aqueous solutions and changes with increasing temperature and pressure in response to changes in the hydrogen bonding of water solvent. The varying nature of ion hydration in hydrothermal systems plays an important role in many geochemical processes including water stable isotope fractionation, mineral solubility and preciptation, metal complexing and transport reactions.

Anion-solvent interaction is still poorly known at elevated temperatures and pressures and no data exist for iodide solvation above ambient temperatures (Seward and Driesner, 2004). We have therefore studied the first shell hydration of iodide using X-ray absorption spectroscopy from 35 to 350°C at equilibrium vapour pressures. The Exafs of 1.00m RbI as well as 0.10m CsI and SrI_2 was measured using a high temperature X-ray optical cell containing silica glass and/or cvd diamond windows. With increasing temperature from 35 to 350°C, iodide-oxygen(water) distance increased from 3.56 to 3.61Å as the first shell waters are "dragged" away from the iodide ion by expanding bulk water solvent to which they are hydrogen bonded. Over the same temperature range, the number of first solvation shell waters apparently decreases from 7 to 4.

We have also performed ab initio molecular dynamics simulations using the Car-Parinello scheme (Car and Parinello, 1985). The present density functional theory calculations utilised norm-conserving pseudopotentials of Troullier and Martins (1991) to describe the core of all atoms except for hydrogen for which a von Barth-Car analytical pseudopotential was used. The simulation cell was cubic with periodic boundary conditions containing 32 waters and one iodide ion. At 27°C, the iodide-oxygen(water) distance was 3.53Å and increased to 3.59Å at 350°C, in good agreement with our results from XAS.

In most rocks, uranium and thorium are concentrated in favorable crystallographic sites in few minerals such as zircon, monazite, titanite, and rarely uraninite, thorianite, thorite / huttonite, euxenite. These minerals are submitted to intense self-irradiation that can lead to amorphization and also modify their environment by irradiating the host minerals. Here, we focus on accessory minerals in rare-metal-rich pegmatites from southern Norway (Kragerø, Iveland-Evje); some of these minerals are rich in U (e.g. up to 15wt % for euxenite). A complex paragenesis of zircon + monazite + xenotime + euxenite was studied by multiple methods including optical and electron microscopy and U-Pb geochronology (SIMS and LA-ICP-MS). Observations show that complex relationships exist between the different minerals (especially zircon-euxenite) and the various processes (alteration by fluids and radiation effects) which have repercussions on the U-Th-Pb geochronology response. Irradiation (self and out), destroy the crystal lattice (amorphization) promoting the alteration of more or less destroyed parts. Amorphization induces volume increase, leading to the formation of cracks which eventually connected into a network through the rock. This fracturing allows fluid circulation, and promotes alteration of source minerals and dispersion of elements (e.g. Pb and U). Our results demonstrate however that monazite and xenotime crystals, even altered, have a greater potential for U-Th-Pb dating [1].

High-spatial resolution imaging of the distribution and inter-element correlation of metals in modern and ancient stromatolites

M.C. SFORNA[1]*, P. PHILIPPOT[1], M. VAN ZUILEN[1], A. SOMOGYI[2], K. MEDJOUBI[2], P.T. VISSCHER[3] AND C. DUPRAZ[3]

[1] Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Paris, France (*correspondence : sforna@ipgp.fr)
[2] Synchrotron Soleil, Saint-Aubin, Gif-sur-Yvette, France
[3] Department of Marine Sciences, University of Connecticut, Groton, Connecticut, USA

Metals, which are widely used by all microorganisms, could act as indicators in the rock record of past microbial activity if we are able to distinguish between biological uptake and late stage contamination associated with diagenesis. Here we present the results of the study of the distribution, inter-element correlation and speciation of trace metals in modern and ancient stromatolites from Big Pond, a hypersaline lake in the Bahamas and the 2.7 Ga-old Tumbiana formation in Western Australia. Results were obtained using synchrotron-based techniques.

In a cm-scale drill core of an extant stromatolite from the Bahamas, the Fe, Ti, Zn, Cu and As contents in the organic fraction of the stromatolite structure increase with depth. We attributed this to metal uptake during early diagenesis. Both in the Bahamas and in the Tumbiana stromatolites, high-spatial resolution imaging at different scales (from the cm- to the nm-scale) reveals different types of metal distribution and inter-element correlations. Although most of the metal enrichments are of diagenetic origin, the occurrence of specific species in isolated organic structures that are preserved in the core of the stromatolite domes most likely reflects remains of past biological activity.

Insights of the Mt. Etna volcanic activity through multiparametric data recorded by the NEMO-SN1 seafloor observatory

T. SGROI*, M. DE CARO, N. LO BUE AND P. FAVALI

Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy

In the last years the use of seafloor observatories improves the possibility to perform long-term monitoring in abyssal area as far not easily accessible, interested by geophysical processes like volcanism, seismicity or fluid emissions. Presently many programmes to establish permanent underwater networks are launched at global scale (e.g., EMSO in Europe, OOI in USA, NEPTUNE in Canada and DONET in Japan). Recently, a multidisciplinary approach has proven to be a very important tool in the monitoring of volcanic areas. In fact, the different instruments hosted in the seafloor observatory permit to perform multidisciplinary analyses, better focusing on the dynamics of volcanic system.

In the Italian territory, the NEMO-SN1 seafloor cabled observatory is running in the Western Ionian Sea at a depth of 2100 m, about 25 km off-shore Eastern Sicily, as node of EMSO infrastructure (http://www.emso-eu.org). Eastern Sicily is of great scientific interest, due to the proximity to seismogenic structures which originated the most destructive earthquakes of the area and to Mt. Etna. The underwater observatory fills the gap in the off-shore sector of the Mt. Etna, focusing on its deeper feeding system. SN1 was able to record also the low-frequency seismic signals linked to Etna volcanic activity, as the volcanic tremor associated to the 2002-2003 eruptive activity. In this work, the joint analyses of seismological, gravimetric and oceanographic data are used to highlight the dynamics of Mt. Etna. The inferences of background noise from volcanic activity and ocean processes are investigated through the cross-analyses of different kind of geophysical data to improve the confidence of volcanic hazard assessment.

Mantle xenoliths from Bir Ali (Yemen)

SGUALDO P.*, BECCALUVA L., BIANCHINI G. AND SIENA F.

Dip. Fisica e Scienze della Terra, Università di Ferrara (*sglpla@unife.it)

Mantle xenoliths from the Bir Ali diatrema (southern Yemen) consist of spinel peridotites and clinopyroxenites. In this contribution we present bulk rock (XRF, ICP-MS) and mineral (EMPA, LA-ICP-MS) major and trace element analyses carried out on a collection of 62 samples in order to characterize the lithospheric mantle of the area and constrain its relative petrological evolution. Peridotites are mainly equilibrated at 950-1000 °C and include fertile lherzolites and more refractory harzburgites and dunites, suggesting that partial melting processes variably affected the pristine mantle composition. Subsequent metasomatic reactions are evidenced by: a) glassy fims and/or patches; b) interstitial plagioclase; c) rare pargasite amphibole (observed only in one sample). Further evidence of metasomatic interactions is given by anomalously low Fo content (<0.87) of olivine and low Mg# of pyroxene (< 0.88). These metasomatic events are confirmed by the bulk rock trace element budget that reveal enrichments in the most incompatible elements, especially in the most refractory dunites (La_N/Yb_N up to 4.1). Coherently, enrichments in the most incompatible elements are also observed in diopsidic clinopyroxene (La_N/Yb_N up to 3.9) and glasses (La_N/Yb_N up to 9.9). Trace element discrimination ratios [1] suggest that the causative metasomatic agents were mainly represented by alkali-silicate melts. Noteworthy, samples characterized by plagioclase impregnation show unfractionated (flat) bulk-rock and clinopyroxene REE patterns suggesting refertilization by subalkaline metasomatic melts. Therefore, the considered lithospheric section appears to be characterized by remarkable heterogeneity, in contrast with what observed in mantle xenoliths collected from the Ethiopian plateau area that display clear evidence of pervasive refertilization by CFB melts [2]. This suggests that the lithospheric mantle of southern Yemen wasn't affected by the thermochemical effects of the Afar plume.

Pore-scale simulation of calcite dissolution and precipitation using lattice-Boltzmann method

B. SHAFEI[1]*, C. HUBER[2] AND A.PARMIGIANI[3]

[1]*School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta, GA 30332, USA. babak.shafei@eas.gatech.edu
[2]christian.huber@eas.gatech.edu
[3]andrea.parmigiani81@gmail.com

Calcium carbonate dissolution and precipitation plays an important role in the context of CO_2 storage in geologic formation, or as a pH buffer during diagenesis of marine sediments. Using the parallel open-source library palabos (www.palabos.org), we have developed a new multi-species pore-scale model based on the lattice Boltzmann method to investigate the effect of physical and chemical heterogeneities on geochemical behavior of carbonate system in a complex porous media. The model has been successfully applied to study the permeability change of a porous medium associated with a given porosity change during dissolution and precipitation and arsenic sorption on Fe-bearing minerals.

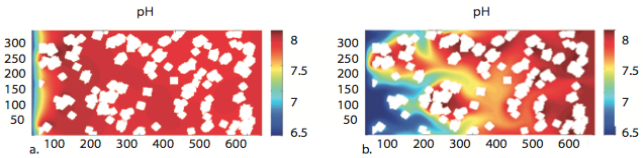

Fig 1. Pore-scale pH distribution at steady-state for a) low Peclet number (Pe=1) and b) high Peclet number (Pe=5).

In this study, we consider standard geochemical pathways for the carbonate system including 7 species (i.e. H^+, OH^-, H_2CO_3, HCO_3^-, CO_3^{2-}, $Ca^{2+}$and $CaHCO_3^+$) and 5 mixed kinetic-equilibrium reactions. The focus of our study is to investigate how spatial distribution of the pH is affected by : 1) the kinetic rates of heterogeneous calcite dissolution and precipitation (i.e. pH-dependent vs. pH-independent rate constants, 2) transport regime (i.e. Peclet numbers) and 3) chemical composition of initial and boundary conditions resulting in spatially variable saturation index with respect to calcite. Results showed that the development of pore-scale concentration gradients is a combined effect of heterogeneous reactions and pore-scale flow within the porous medium. In high Pe simulations (Fig 1.a), both depth of penetration and spatial heterogeneity increase compared to low Peclet scenario (Fig 1.b). Calculated minimum, maximum and average pH values in the computational domain are function of Pe, chemical composition of inflow and initial solution in the domain, and type of rate constants.

Geochemistry and petrogenesis of volcanic rocks in the Lahrud region, of the Ardebil province, Iran

HABIB SHAHBAZI SHIRAN

Department of Archaeology, University of Mohaghegh Ardabili, Ardebil, Iran (Shahbazihabib@yahoo.com)

Compositional analyses of materials from prehistoric contexts have become an important component of most scientifically oriented archaeological projects. Characterizing the elemental signature of materials (obsidian, metals, stones) helps determine provenance and technological production techniques, and therefore is useful for reconstructing trade and interaction between people prehistorically.

Simple petrographic descriptions can provide useful information on raw material provenance, but for some lithic materials more sophisticated techniques are required. Geochemistry can provide this sophisticated tool, trace and interpret the bedrock or the source of the ancient lithic materials. Geochemists have determined the geologic, magmatic and/or tectonic affinities of igneous rocks for decades. This project reports on mineral assemblages and whole-rock geochemistry that mafic rocks used to make lithic artifacts and especially building stones in the Ardebil province, northwestern Iran , have two bedrock sources.

New insights into the isotope exchange reaction between O_3 and CO_2 via $O(^1D)$ from laboratory experiments

ROBINA SHAHEEN[1], THOMAS RÖCKMANN[2], BELA TUZSON[3] AND CHRISTOF JANSSEN[4]

[4]Laboratoire de Physique Moleculaire pour l'Atmosphere et l'Astrophysique, 4 Place Jussieu, 75005 Paris, France, christof.janssen@upmc.fr

Stratospheric CO_2 shows a marked oxygen triple isotope anomaly that is derived from O_3 via $O(^1D)$. So far the precise isotopic composition of the isotope exchange partner of CO_2 has not been identified and it is not clear whether normal mass dependent or anomalous isotope effects contribute during the exchange process. From laboratory experiments using simultaneous mass spectrometric analysis of CO_2 and laser spectroscopy based symmetry selective analysis of O_3 isotopomers, we present experimental evidence that the $O(^1D)$ mediated isotope transfer is coupled to the asymmetric O_3 isotopomers and follows a standard mass dependence. Recently investigated alternative pathways for oxygen isotope exchange between CO_2 and hyperthermal O atoms or O_2 molecules are unlikely to compete significantly with isotope exchange via $O(^1D)$. Existing measurements also indicate unresolved discrepancies for the isotope anomaly of O_3 produced in the laboratory under different photochemical conditions, which may originate from highly energetic oxygen species generated in the photolysis of O_2 and/or O_3. Such variations would be directly transferred to CO_2, and further combined measurements of the isotopic composition of CO_2 and symmetry resolved O_3 are needed to fully unravel all aspects of the isotope exchange.

Symbiont-bearing corals are subjected to internal fluxes of reactive oxygen species (ROS) from their symbiotic algae as well as external fluxes from photochemically generated ROS in overlying waters. Here, combining sensitive methods, kinetic approaches and statistical tools, we characterized the dynamics of the membrane permeable ROS - hydrogen peroxide (H_2O_2) - in the external *milieu* of corals in a laboratory setting and in a natural coral reef. On the organism level, we observed flow-induced release of H_2O_2 and antioxidants from intact corals over 2-4 hour periods. In the absence of flow we found that antioxidants associated with the coral quickly degraded externally applied H_2O_2. Scaling up to the ecosystem level, we observed coral-induced changes in H_2O_2 concentrations and elevated antioxidant activities in the proximity of a coral knoll and in the reef lagoon. This newly described ability of corals to change the chemistry of their surrounding water by releasing both H_2O_2 and antioxidants may bare important implications for coral physiology and interactions with the environment. External antioxidant activity may enable corals to offset exogenous H_2O_2 whereas the flow induced H_2O_2 release may aid corals in discarding internal H_2O_2.

Traffic-associated heavy metal pollution and source discrimination in Jiangxi Province, China

SHAO LI[1,2], XIAO HUAYUN[3]* AND WU DAISHE[1]

[1]Environmental and Chemical Engineering College, Nanchang University, Nanchang, 330031, China

[2]The Key Lab of Poyang Lake Environment and Resource Utilization of Ministry of Education, Nanchang, 330031, China

[3]State Key Laboratory of Environment Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, 550002, China

Road traffic is recognized as an important source of heavy metals. In order to identify the levels and sources of heavy metal contamination on three highways in Jiangxi Province, concentrations of Zn, Cu, Pb, Sb, Cd in different chemical forms in airborne particles, road dusts and soils were analyzed. All of the Zn, Cu, Pb, Sb, Cd concentrations in road dusts and soils exceeded background values. And the heavy metal concentrations in road dusts were higher than those in soils. Heavy metal concentrations in airborne particles, road dusts and soils presented similar rules: Zn > Cu, Pb > Sb, Cd. Zinc, Cu, Pb, Sb, Cd concentrations in airborne particles, road dusts and soils were all significantly correlated with vehicle number, indicating that road traffic was one of the main source of these metals. For all these metals, we also found that the ratios were higher near the toll stations than on normal driving road, indicative of an increased heavy metal emission rates under the conditions of low driving velocity and discontinuous movement of vehicles. The sources of the heavy metals were also identified by comparing chemical forms of the heavy metals in airborne particles, road dusts and soils. Lead in airborne particles was dominated by the acid soluble/exchangeable fractions (67%) while that in road dusts and soils was dominated by the residual fractions (45.3% and 43.8%, respectively), which suggested that Pb in airborne particles was derived from traffic, and that in road dusts and soils resulted mainly from the use of leaded gasoline in the past. In raining days, Zn concentrations in PM10 increased possibly because tire abrasion turned to be weak due to the lubrication of rainwater and so more small particles were emitted from the tyre wear. The difference in chemical forms of the heavy metals in airborne particles, road dusts and soils was associated with concentrations of organic matters. Bioavailability of heavy metals in airborne particles was much higher than that in road dusts and soils..

Redox control on the water column distribution of Ra in a stratified lake - Lake Kinneret, Israel

G. SHARABI[1,2]*, Y. KOLODNY[1], L. HALICZ[1], A. NISHRI[3] AND B. LAZAR[1],

[1] Institute of Earth Sciences, The Hebrew University of Jerusalem, ISRAEL 91904

[2]Gological Survey of Israel, Jerusalem, ISRAEL 95501
[3]Israel Oceanographic and Limnological Research Ltd., P.O. Box 447, Migdal, ISRAEL 14950

The vertical distribution of transition metals in holomictic lakes is controlled by the seasonal mixing/stratification regime that change the redox state in the water column. We studied the control of the Mn redox system on water column distribution of Ra, an element with invariant oxidation state. The study was conducted in Lake Kinneret (The Sea of Galilee), Israel, a warm monomictic lake in northern Jordan valley. Lake Kinneret fluctuates between periods of stratification (spring/summer) and mixing (fall/winter), with full depth mixing (~37 m) in February. The mixed layer (epilimnion) is always well oxygenated while below it (hypolimnion), anoxic conditions prevail.

Vertical profiles of Mn, ^{226}Ra ($T_{1/2}$=1,600 y) and ^{224}Ra ($T_{1/2}$=3.7 d) were measured during October 2012. Practically all the Mn in the well-oxygenated mixed layer (0-15 m) was particulate (10 $\mu g \cdot L^{-1}$). A large peak of dissolved Mn (500 $\mu g \cdot L^{-1}$), appeared at the oxycline ~17.5 m. The reducing hypolimnion, below 20 m, contained ~60 $\mu g \cdot L^{-1}$ of dissolved Mn and was virtually deficient of solid Mn-oxides. The water column profile of ^{226}Ra and ^{224}Ra were remarkably similar.

Mn speciation along the Kinneret water column is redox sensitive: it appears mainly as solid Mn-oxide in the oxygenated epilimnion, and as dissolved Mn(II) in the anoxic hypolimnion. Hence, the particles of Mn-oxide that sink through the water column, dissolve in the epilimnion-hypolimnion interface and form an extremely large and narrow peak of dissolved Mn(II). The Ra water column profile resembled that of Mn, despite being a redox-insensitive element. This is attributed to adsorption of dissolved Ra on solid Mn-oxides in the epilimnion and its desorption in the hypolimnion. We use the ^{224}Ra/^{226}Ra ratios and the large difference in their half-lives to obtain a field estimate of the reduction rate of Mn-oxide.

Magmatic systems of the Paleoproterozoic large igneous provinces: Evidence from the eastern Fennoscandian Shield

E.V. SHARKOV*, M.M. BOGINA AND A.V. CHISTYAKOV

IGEM RAS, Staromonetny per. 35, Moscow, Russia 119017 (sharkov@igem.ru)

It is known that large igneous provinces are usually formed by lava plateaus, dyke swarms and subvolcanic sills, which are united into volcano-plutonic associations. At the same time, rocks within lava plateau were subjected to crystallization differentiation and crustal assimilation, which caused wide variations in their composition. This leaves us with questions where and how this occurred?

For this aim we presented the results of our study of two Paleoproterozoic large igneous provinces in the eastern Fennoscandian Shield: (1) early Paleoproterozoic (2.5-2.35 Ga) province of siliceous high-Mg series, and (2) middle Paleoproterozoic (2.35-1.9 Ga) province composed by high- and low-Ti alkaline and tholeiite basalts. The peculiar feature of these provinces is the presence of layered mafic-ultramafic complexes: dunite-harzburgite-bronzitite-norite-gabbronorite-anorthosite (Monchegorsky, Fedorovo-Pansky, Burakovsky, etc.) and wehrlite-clinopyroxenite-gabbro-alkaline gabbro (Elet'ozero and Gremyakha-Vyrmes), respectively. The formation of these complexes was controlled by replenishment of fresh magmas in solidified intrusive chambers and impregnation of melts into already solidified rocks (multistage formation). Geochemical data indicate that all rocks of these centers are related in different degree, being often close in major and trace-element composition to volcanics in lava plateaus.

So, we suggest that these layered intrusive complexes represent deep-seated long-lived transitional magmatic chambers where melts, derived from magma-generation zones were accumulated and experienced crystallization differentiation, while evolved melts were mixed with fresh magma portions. Cumulates retained in the crust. Correspondingly, the primary magmas partially lost their components and derived evolved magmas continue their ascent to the surface. The evolved magmas arrived at the surface and formed lava piles of different composition. Thus, it is difficult for primary melts to reach surface; as a rule, they are subjected to transformations in such transitional chambers.

Melting phase relations in Udachnaya-East kimberlite and search for parental melt composition

I.S. SHARYGIN[1]*, K.D. LITASOV[1], A. SHATSKIY[1], A.V. GOLOVIN[1], E. OHTANI[2] AND N.P. POKHILENKO[1]

[1]Sobolev Institute Geology and Mineralogy, Novosibirsk 630090, Russia (*igor.sharygin@gmail.com)
[2]Tohoku University, Sendai 980-8578, Japan.

Udachnaya-East kimberlite (UEK) is an unique example of unaltered Group I kimberlites, exhibiting lack of serpentinisation and containing abundant alkaline carbonate and chloride minerals in the groundmass [1]. We studied phase relation in UEK in using multianvil experiments at 3-6.5 GPa and 900-1500 ºC [2]. Super-solidus assemblage consists of olivine (Ol), Ca-rich garnet (Gt), Al-spinel (Sp), perovskite (Pv), $CaCO_3$, and apatite at 3-6.5 GPa with addition of clinopyroxene at 3-4 GPa and Na-Ca carbonate at 6.5 GPa and 900 ºC. The subliquidus phase assemblage (Ol + Gt + Sp + Pv) differs from common mantle lithologies, which may be due to unaccounted CO_2 lost during kimberlite degassing at shallow depth. UEK did not achieve complete melting even at 1500°C and 6.5 GPa. This indicates that kimberlite magma below 90 km depth was a mixture of the melt and xenogenic materials (mainly Ol). In the studied *P-T* range, melt has Ca-carbonatite composition (Ca/(Ca+Mg) = 0.6-0.8) with high alkali and Cl contents (2.8-6.7 wt.% K_2O, 7.3-11.6 wt.% Na_2O, 1.2-3.7 wt.% Cl). The K, Na and Cl contents and Ca/(Ca+Mg) ratio decrease with temperature. The SiO_2 content in the partial melt increases with temperature and decreases with pressure (Fig. 1). Consequently, the ascending melt dissolved increasingly more SiO_2 (Fig. 1) and evolved from essentially carbonatite (<5 wt.% SiO_2) toward carbonate-silicate composition (up to 25 wt.% SiO_2).

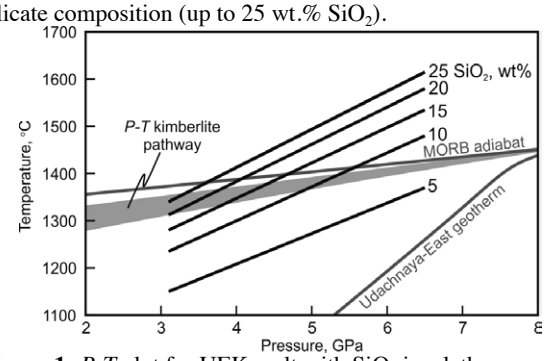

Figure 1: *P-T* plot for UEK melt with SiO_2 isopleths.

Mineralogy of the Chelyabinsk meteorite, Russia

V.V. SHARYGIN[1]*, T.YU.TIMINA[1], N.S. KARMANOV[1], A.A. TOMILENKO[1] AND N.M. PODGORNYKH[1]

[1]V.S. Sobolev Institute of Geology and Mineralogy SD RAS, Novosibirsk 630090, Russia (*correspondence: sharygin@igm.nsc.ru)

The entry in the Earth's atmosphere, further blasting and impact of the Chelyabinsk meteor body have been fixed 15 February 2013. We studied small fragments collected in the area of abundant meteorite shower (nearby towns Emanzhelinsk and Korkino, South Urals).

The Chelyabinsk meteorite was classified as an ordinary LL5 chondrite (S4, W0) [GEOKHI RAS]. It is very similar in mineral composition to other LL5 chondrites such as Salzwedel, Hautes Fagnes and Al Zarnkh [1-3]. All meteorite fragments consist of coarse- to fine-grained matrix, rare submillemetre chondrules and thin fusion crust. Some fragments show brecciated texture.

Olivine ($Fo_{68-72}Fa_{28-31}Ln_{<0.5}$), orthopyroxene ($En_{70-74}Fs_{25-28}Wo_{1-2}$), Fe-Ni-metal, troilite, chromite and Na-plagioclase ($Ab_{77-86}An_{10-20}Or_{3-10}$) are major primary minerals in the inner part. Ilmenite, Cr-diopside ($Wo_{46-48}En_{43-45}Fs_{16-18}$, Cr_2O_3 – 0.6-0.8 wt%), chlorapatite, merrillite and feldspathic glass are minor. Coarse- to meduim-grained matrix mainly contains primary minerals (olivine, pyroxenes, etc.); some areas show fine recrystallization due to melting and further quenching with formation of skeletal crystals of olivine ($Fa_{29-46}Ln_{1-3}$), orthopyroxene, subcalcium pyroxene ($Wo_{22-42}En_{45-65}Fs_{13-22}$) in feldspathic glass (plagioclase). Metal-sulfide assemblage (up to 10 vol%) is represented by kamasite-taenite intergrowths (or their individuals) and troilite; pentlandite and native copper occur rarely. Chondrules are different in mineralogy. Some of them show well-oriented "barred" texture and consist of olivine and Na-plagioclase (feldspathic glass) with minor chromite and chlorapatite. Other chondrules are similar in mineral composition to the matrix and their oriented texture is less pronounced.

Fusion crust (up to 1 mm) contains relics of primary minerals, mafic-ultramafic brown glass, abundant gas bubbles, newly-formed minerals (zoned skeletal crystals of Cr-Ni-rich magnetite, forsterite-fayalite, wüstite, etc.) and Ni-rich metal-sulfide globules (heazlewoodite, awaruite-taenite, godlevskite, rarely Os-Ir-Pt-Ni alloy).

Evidence for formation of alluvial diamonds from North-East of Siberian platform in subduction environment

V.S. SHATSKY[1,2]*, D.A. ZEDGENIZOV[2], A.L. RAGOZIN[2] AND V.V. KALININA[2]

[1]Vinogradov Institute of Geochemistry SB RAS, 1a Favorsky str., Irkutsk, 664033, Russia, (*correspondence: shatsky@igc.irk.ru)

[2]Sobolev Institute of Geology and Mineralogy SB RAS, 3 Koptyuga ave., Novosibirsk, 630090, Russia

Diamonds from placers show large variability in nitrogen content ranging from below detection to 3500 at.ppm. Nitrogen contents in diamonds with eclogitic inclusions are generally high (average of 950 at.ppm) as compared with diamonds of ultramafic suite (average of 513 at.ppm). $\delta^{13}C$ values of the diamonds range from -27 to - 3‰ (n=28) for eclogitic diamonds and from -7.1 to -0.5‰ (n=16) for peridotitic diamonds. The 265 diamonds were polished to expose their mineral inclusions. Inclusions of eclogite suite are predominant (74%). The diamonds of the eclogitic suite contain garnet, omphacitic clinopyroxene, coesite, K-feldspar, rutile, corundum. The peridotitic diamonds contain olivine, Cr-pyrope garnet, ortopyroxene and chromite. Majoritic garnets of both peridotitic and eclogitic parageneses were identified in 4 diamonds. The olivines have Fo contents between 89.7 and 93.8 mol.% (average – 92.4). Eclogitic garnet and Cpx inclusions are within the range of eclogitic inclusions of wordwide. For an assumed pressure of 5 GPa eclogitic garnet and clinopyroxene gave temperatures in the range 1028-1290ºC. The majority of eclogitic diamond show positive Eu-anomalies. High-Ca group garnets are LREE depleted, show strong positive Eu (up to 4.25) and Sr anomalies and have HREE contents that are less than the low- and intermediate-Ca group samples. Eclogitic Cpx inclusions are characterized by convex REE_N patterns with maxima at Nd or Sm. The presence of majorite inclusions indicate that the portion of the diamonds is of sublithospheric origin. Multiple inclusions from diamond and their carbon isotopes composition are consistent with a mixing model in which they result from the interaction of slab-derived melt/fluid with surrounding mantle. The nature of the variations in the carbon isotope composition and the nitrogen contents indicate that the diamonds growth medium have at least two sources (mantle and recycled earth crust via subduction zone). Mantle carbon was involved in the diamond formation process during the final stages of growth.

Telluride-gold-sulfide mineralization in silicification zones of gabbro-dolerite bodyes of hengursk complex (Russia, Pay-Khoy)

R.I. SHAYBEKOV

Institute of Geology Komi SC UB RAS, Syktyvkar, Russia, 54 Pervomayskaya st. (*correspondence: shaybekov@geo.komisc.ru)

According to the previous studies gold-telluride mineralization has been found only in the gabbro-dolerite bodies of Pay-Khoy hengursk complex at the districts "Pervyi" and "Savabeysky" in copper and nickel ores [1]. The studies of sulfide (chalcopyrite highly) mineralization in quartz veins of district "Krutoy" revealed silver-gold-telluride phases with later hydrothermal origin.

Telluride-gold-sulphide mineralization is characterized by a fairly stable composition - chalcopyrite, covellite, wurtzite, gold, silver, coloradoite (found for the first time in Pay-Khoy) and native phase. The composition of coloradoite has minor changes from the classic mineral which could be explained by the specificity of mineral formation or inaccurate analysis due to the small size of the grains. The impurities of silver and lead in insignificant quantities were found, which allowed distinguishing of two kinds - silver-lead and silver. The formation of this type of mineralization occurred in a low-, medium-temperature hydrothermal process in the veins of gold-bearing sulphide mineralization.

The work was made with the support of the program of the presidium RAS №27 (12-П-5-1027) and SC-1310.2012

Use of passive sampling to measure organic chemicals and metabolites in water and soil: Application to human health risk assessment in developing countries

D. SHEA*, T. HONG, X. XIA, X. KONG, K. O'NEAL, AND P. LAZARO

North Carolina State University, Raleigh, NC 27695-7617 USA (*correspondence: d_shea@ncsu.edu)

Measuring chronic exposure to broad chemical mixtures at trace levels is currently not practical because traditional *grab* samples do not capture temporal variations in expsoure and thus provide little information on chronic exposure unless many samples are collected and analyzed. This problem is even greater in developing counties where resources for sampling and chemical analysis can be extremely limited. We will report on the use of passive sampling devices (PSDs) to provide a cost-effective means of estimating chronic exposure and toxic response in water and soil. PSDs sequester and preconcentrate organic chemicals from water and from soil and sediment via desorption to water. Using laboratory-derived and field-verified uptake rates (calibration), PSDs were deployed in the field for a known amount of time (e.g., 1 month), the accumulated chemical residue was measured, and then the average exposure calculated based on the calibration. Extracts of the PSDs also were used in high throughput cell-based assays to measure various toxic endpoints such as genotoxicity and endocrine disruption. We will illustrate the potential utility of PSDs using data from the Red River, Vietnam. In surface waters, we found very good agreement between measured chemicals in the PSDs and synoptically deployed aquatic test organisms, providing strong evidence that PSDs accumulate only the bioavailable fraction of a chemical. In soil, we also found good agreement between PSDs and accumulation in earthworms. In both water and soil, there was generally good agreement between PSD chemical residues and toxic response variables. We will discuss the current utility and limitations for using PSDs for both human and ecological health risk assessments and provide an example of the spatial and temporal variation in human health risk to chemical exposure in the Red River, Vietnam.

Effect of hydrothermal alteration on magnetic susceptibility of Challu Pluton, SE Damghan- Iran

M. SHEIBI[1]*, P. MAJIDI [2] AND M. REZAEI KHKHAYY[3]

[1, 3] Faculty Member, Department of Geology, Shahrood University of Technology, Iran (*correspondence: sheibi@shahroodut.ac.ir, Mehdi.Rezaei@khayam.ut.ac.ir)

[2] MSc. student of Petrology, Department of Geology, Shahrood University of Technology, Iran (parvinmajidi91@gmail.com)

Challu pluton located in the northern part of Central Iran structural zone, SE Damghan. Based on mineralogy and geochemistry, the pluton is I-type granite and compositionaly ranges from monzodiorite and monzonite. The pluton intruded in Eocene volcano-plutonic series of Toroud-Chah Shirin. During the crystallization and cooling, a magmatic-dominated hydrothermal system caused extensive hydrothermal alteration and Fe mineralization.

Challu granitoidic body has been studied using by anisotropy of magnetic susceptibility (AMS). The method carried out by (MFK1-FA) Kappbridge susceptometer (AGICO, Brno) operating at low field (4×10^{-4}T; 920 Hz) at Geomagnetic Lab of Shahrood University of Technology. According to the measurements (32 stations, 96 cores and 384 fragments), the average magnetic susceptibility (Km, in μSI) of monzonites and monzodiorites are 9323 and 28776, respectively. Therefore, the rocks belong to the ferromagnetic granitoids (bulk susceptibility ≥500μSI). Magnetite is the main carrier of the magnetic behavior and pyroxene, biotite and sphene are other carriers. Due to presence of extensive propylitic mineral assemblages (epidote, calcite and chlorite) in the south eastern margin and importance of their effect on AMS, the magnetic susceptibility of some grains of epidotes was determined. The obtained data shows that presence of this mineral has no effect on bulk susceptibility but the grain size of magnetic, it's loss and damage during hydrothermal alteration reduced the amount of magnetic susceptibility.

Microbial communities correlate with Lemon Creek Glacier meltwater discharge

CODY S. SHEIK[1], EMILY I. STEVENSON[1], PAUL DEN UYL[1], SARAH M. ACIEGO[1], AND GREGORY J. DICK[1,2]*

[1]Dept. Earth and Environmental Sciences, [2]Dept. of Ecology and Evolutionary Biology, University of Michigan, Ann Arbor, MI, 48109, USA. (*Correspondence gdick@umich.edu)

Mineral weathering has long been recognized as an important ecological process that is mediated in part by microorganisms. Recently, microorganisms have been implicated in the weathering of rock in the interstitial waters between bedrock and overlying glaciers (1,2), a process which may directly impact carbon cycling in the the northern Atlantic Ocean (3). Here we surveyed microbial communities associated with sub-glacial meltwaters and mixed sediments over the course of four months as they were discharged from the Lemon Creek Glacier located near Juneau Alaska, USA. Utilizing a high throughput small subunit ribosmal RNA gene sequencing approach, the diversity and structure of microbial communities was quantified and correlated to changes in the water geochemistry.

Microbial communities were consistently dominated by *Proteobacteria* classes *Beta, Alpha, Gamma* and *Delta* (in decending order of abundance), which accounted for 40-70% of the total community). Many sequences from uncultured groups often associated with anoxic environments were also recovered, including candidate divisions BD1-5, OD1 and TM7 (1-5%) and novel methanogenic Archaea (<0.1%). Phylogenetic richness was high in most samples (15-85 unique lineages) and resemebled typical sediment community diversity. Community structure was distinct in each sample and was signifcantly correlated with time of discharge and sampling location (*e.g.* lower glacial fed lake, glacial outflow channel, and sub-glacial interstitial waters).

Our results suggest that interstitial microbial weathering supports diverse microbial communities that resemble those from anoxic environments, are highly dynamic with respect to time of discharge, yet retain a consistant phylum level taxonomic structure. Furthermore this work highlights ice-water-sediment interfaces as important microbial habitats that are potential analogs for other low temperature geochemically active environmets such as the deep subsrface.

Causes and consequences of low atmospheric pCO_2 in the Late Mesoproterozoic

NATHAN D. SHELDON[1]

[1] Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI, USA, (nsheldon@umich.edu)

Based upon various proxy, theoretical, and model constraints, Paleoproterozoic atmospheric pCO_2 [1] was much higher than Phanerozoic levels [e.g., 2]. However, relatively little is known about the transition between the two climate states. Here, geochemical mass-balance from ~1.1 Ga old Midcontinent Rift System (USA) paleosols is used to reconstruct atmospheric pCO_2 during the Mesoproterozoic. The calculations robustly indicate low atmospheric pCO_2 (<10 times Preindustrial levels). Results are consistent between seven paleosols at one site, between paleosols at different Midcontinental Rift sites, and between the new results and previously published penecontemporaneous paleosol [3] and microfossil reconstructions [4-5]. In spite of the lower than expected pCO_2 values, climate models driven by the reconstructed pCO_2 levels predict equable conditions [6]. The newly recognized Mesoproterozoic pCO_2 minimum is best explained as the culmination of a long-term C burial event by the biosphere that is also indicated by marine carbonate $\delta^{13}C$ changes during the Mesoproterozoic, and which is consistent with changes in the biosphere including increased stromatolite abundance and diversity, evolution of sulfur-utilizing bacteria, and the spread of microbial mats into continental environments. One potential testable consequence of this hypothesis is that it should be accompanied by a gradual rise in atmospheric pO_2 throughout the "boring billion."

What caused Mongolian Mesozoic magmatism: Was it crustal or mantle driven?

T. SHELDRICK[1]*, T.L BARRY [1] AND A.D. SAUNDERS [1]

[1]University of Leicester, Leicester, LE1 7RH, UK. (*correspondence: thomassheldrick@gmail.com, tlb2@le.ac.uk, ads@le.ac.uk)

Prior to the Himalayan orogeny, the last major phase of continent collision and amalgamation in mainland Asia was the mid-late Mesozoic closure of the Mongol-Okhotsk ocean. Rapidly following on from the collisional event came extensive and widespread basaltic magmatism that infilled extensional basins across parts of eastern and southern Mongolia, and northern China. The production of voluminous basalts soon after an orogenic event has led some to propose that a mantle plume may have interacted with the crust during this period [1]. Opposing this theory are suggestions of slab delamination[2], post-orogenic collapse[3] or lithospheric overthickening and delamination [4]. This study aims to assess the plausibility of these models by constraining the mechanisms of magma genesis for these mildly alkali basalts. Then, using these constraints, we plan to test local and regional tectonic syntheses.

To this end, a large suite of basaltic samples have been collected from the most western limit of the Mesozoic volcanism, from the Gobi, Mongolia. Samples have been analysed for major, trace and REE elements (XRF & ICP-MS) with results showing that the basalts are LREE enriched (high La/Ti) and slightly HREE depleted with variable Mg#'s, Pb & Nb anomalies and Th/Nb ratios. The chemistry and a limited amount of isotope data shows that fractionation and crustal contamination processes were important for melt generation. Further sampling and a more extensive isotope study will help to elucidate some of the processes that produced these enigmatic basalts and thereby test models for melt generation.

The global deposition of cap carbonates after the Marinoan glaciation (635Ma) is key evidence supporting the Snowball Earth hypothesis [1]. The cap carbonate is almost exclusively composed of dolostone with rare occurrences of limestone [2]. Thus, this interval is the only time in the Earth's history when deposition of dolostone occurred globally, suggesting a unique marine geochemistry after the Marinoan glaciation. Here, we report the Mg isotopic composition (δ^{26}Mg) of the Zhamoketi cap carbonates from two sections in the Quruqtagh area, NW China [3], which contain both limestone and dolostone. Our data show an enrichment of heavy Mg in the cap limestone samples, indicating scavenging of light Mg from seawater consistent with global dolostone precipitation. Compared with their Phanerozoic counterparts, the Zhamoketi cap limestones and dolostones have very similar δ^{26}Mg values [4, 5], which may indicate early formation of Marinoan cap dolostone driving seawater to heavier δ^{26}Mg values. This study suggests that the sharp transition from extreme icehouse to extreme greenhouse conditions during the meltdown of Marinoan Snowball Earth might have created a suitable environment for global dolostone formation.

Carbon stable isotope composition in modern snail shell aragonite and it's climatic significance

X. F. SHENG, L. L ZHU AND L. W. LIU

Key Laboratory of Earth Surface Geochemistry, Ministry of Education, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (shenxuer@nju.edu.cn)

Stable isotope signatures recorded in land snail shells have been widely used to characterize the information of paleo-climate and paleo-environment. $\delta^{13}C$ values of the land snail shells can be used to discuss and estimate the compositions of local vegetations, namely the ratio of plants C_3 to plants C_4 in the ecosystem, which can examine the drought degree of ancient ecological system.

Here we explored the relationships between the $\delta^{13}C$ of modern snail shells and associated climatic factors in east part of China in an attempt to develop transfer functions that can be applied to retrieve the climatic information stored in snail shells. Totally 400 $\delta^{13}C$ values of modern land snail shell aragonite from the field collected were measured from 18 localities in a widely spatial scale, with the result shows the $\delta^{13}C$ of modern snail shells are obviously related to precipitation, elevation and weakly related to temperature and latitude. The analysis exhibits that the negative correlations between the $\delta^{13}C$ of shells with the living season precipitation and temperature as the former is robust(R^2=0.47) and the latter is weak(R^2=0.27). However, correlations between the $\delta^{13}C$ of shells with elevation and latitude is positive with the former was robust (R^2=0.48) and the latter was weak(R^2=0.34).

Furthermore, under the condition that the humidity stayed relatively stable, the indoor snail feeding experiment was carried out and the study comes to the conclusion that the food is the dominant factor influencing the $\delta^{13}C$ of snail shells, and the fractionation value between the diet and snail shells is calculated as 14.72‰. The study simultaneously confirmed that the temperature does not affect the $\delta^{13}C$ of snail shell under laboratory conditions. In summary, we discussed that the impact effect from the environmental factors on the $\delta^{13}C$ of snail shells is not a direct action, but through regulating and altering the local vegetation types and compositions in an ecosystem.

The research was financially supported by the NSF of China through Grant 41073065.

A review of radionuclides impact in South Sinai, Egypt: Case study of Sharm El Sheikh area

MAHMOUD I. SHERIF[1], MOHAMED F. GHONEIM[1], MOHAMED TH. S. HEIKAL[1], BOTHINA T. EL DOSUKY[1], MOHAMED M. EL GALY[2]

[1]Geology Department, Faculty of Science, Tanta University, Tanta 31527, Egypt
[2]Nuclear Material Authority, Cairo, Egypt

The area of Sharm El Sheikh consists mainly of granitic rocks of alkaline type. Alkaline granite is the most faourabe host rock for uranium and thorium mineralization. The activity concentration of natural radionuclides (^{238}U, ^{232}Th, ^{226}Ra & ^{40}K) of 100 samples around the studied area, including granites, dikes and stream sediments were investigated using γ-ray spectrometry. The radium equivalent activity (Raeq), gamma activity concentration index (I), external hazard index (Hex) internal hazard index (Hin) and annual effective dose rate (AEDR) have been calculated and compared with the internationally approved values.

The permissible values for each index revealed that all exposures of granite and mafic dikes have values below safety limits of radiation. The stream sediments within the major wadis are also safe. However, the felsic dikes that more or less occur far from the inhibited areas of Sharm El Sheikh town exceed the permissible radiation limits indicating their hazardous effect.

Thereby, it was recommended to restrict land use in a buffer zone adjacent to the felsic dikes of very limited distributions. Moreover, a planned major town extension of Sharm El Sheikh area has to be stopped around and within these dikes sites, but alternative future residential areas could be delineated to the northwest of the town.

Electronic structures of transition metal oxides and sulfides: Applications to the physics and chemistry of the Earth

DAVID M. SHERMAN[1]

[1]School of Earth Sciences, University of Bristol, Bristol BS8 1RJ UNITED KINGDOM (dave.sherman@bris.ac.uk)

A variety of geochemical and geophysical processes result from electronic transitions in minerals and aqueous complexes. In aquatic environments, photochemical excitations on mineral surfaces release dissolved micronutrients and may have played a role in prebiotic synthesis. In the deep Earth, pressure-induced electronic transitions such as spin-pairing, metallization and changes in the band gap/Fermi energies of phases affect the density, transport properties and element partitioning in the core and mantle.

Density functional theory, using approximate exchange-correlation functionals, has enabled us to accurately predict structures and vibrational energies of minerals and aqueous complexes. We can now predict the thermodynamics, phase transitions and seismic properties of minerals in the deep earth and even the thermodynamics of metal complexation in hydrothermal solutions. However, exchange-correlation functionals such as the generalized gradient approximation (GGA) are still based on the local density approximation. Consequently, these functionals still contain an error associated with incorrectly including the electron self-interaction. The self-interaction error yields incorrect electronic structures and band gaps and precludes accurate predictions of electronic transition energies. For the case of a material like FeO, standard GGA functionals incorrectly yield a metallic ground state that becomes Pauli-paramagnetic (rather than a diamagnetic low-spin state) with pressure. Charge-transfer band gaps in Fe_2O_3 are too low. Physicists have addressed this problem using the "Hubbard U" correction to the local density approximation. However the U parameter is an empirical correction. Chemists, however, have recognized that the Hartree-Fock formalism exactly includes the self-interaction correction. A variety of "hybrid" exchange functionals have been developed (e.g., B3LYP) that empirically mix Hartree-Fock exchange with the GGA exchange-correlation functional. Here, I will present several examples to illustrate the application of these functionals to transition metal oxides and sulfides and show how the hybrid functionals predict electronic transitions of importance in geochemistry and geophysics.

Reduced gas flux from Precambrian cratons – Implications for subsurface microbiology

B. SHERWOOD LOLLAR[1]*, G.HOLLAND[2], L. LI[1], G. LACRAMPE-COULOUME[1], G.F. SLATER[3], T.C. ONSTOTT[4] AND C.J. BALLENTINE[5]

Quantification of global H_2 flux has to date been based primarily on thermodynamic and geochemical modelling, or on H_2 measurements at a number of marine systems such as the Rainbow and Logatchev hydrothermal vents, the off-axis Lost City field, and more recently, at diffuse vents. H_2 sources from continental systems are significantly less well constrained. Recent exploration of saline fracture waters more than a km below the Earth's surface in Precambrian continental crust however has identified environments equally as H_2-rich as the hydrothermal vents and spreading centers, and sustaining microbial communities of H_2-utilizing methanogens and sulfate reducers [1]. Here we report on results from > 30 sites and > 250 samples and boreholes in continental Precambrian sites worldwide. Fracture waters accessed via mines and underground research laboratories contain mM concentrations of reduced gases (H_2, CH_4, ethane, propane, butane) as well as high concentrations of noble gases.

First identified in Ne isotope results from the Witwatersrand basin in South Africa [2], novel radiogenic isotope signatures have now been shown to be a consistent feature of these deep waters [3]. Integration of the noble gas signatures with compositional and isotopic information for the reduced gases provide constraints on the residence time of the fracture waters, the degree of interconnectivity of different groundwater systems, and an estimate of the amount of time these waters have been isolated from the surface. This presentation will address the distribution of ancient fluids at selected key reference sites; and the controls of this deep hydrosphere on the biodiversity and distribution of the subsurface microbial biosphere and carbon cycle.

Geodynamic constraints on the recycling of ancient SCLM and genesis of Tibetan diamondiferous ophiolites

R.D. SHI[1,2]*, W.L. GRIFFIN[2], S.Y. O'REILLY[2], X.R. ZHANG[1,3], Q.S. HUANG[1], X.H. GONG[1] AND L. DING[1]

[3] Department of Earth Sciences, The University of Hong Kong, Pokfulam Road, Hong Kong, China

Natural diamonds have been found *in situ* in the chromitites and peridotites of Tibetan ophiolites [1,2]. Whole-rock $^{187}Os/^{188}Os$ values of these diamond-bearing peridotites and chromitites vary from 0.1038 to 0.1266, yielding T_{RD} ages back to 3.4 Ga. This suggests that part of the Tibetan Tethys Ocean (TTO) was underlain by a fragment of ancient subcontinental lithospheric mantle (SCLM), left stranded in the oceanic lithosphere during the opening of TTO [3]. However, there has been little geological evidence to support the geodynamics required to recycle ancient SCLM in the Tibetan ophiolites. Here we present the metamorphic ages (peak age: 191 Ma; retrogression age: 181 Ma) of Amdo HP granulites formed by the subduction of TTO crust, the age (184 Ma) of the Naqu ophiolite representing the initial subduction (SI) of TTO at the south margin of the Amdo micro-terrane, and the age (160 Ma) of the Amdo ophiolite, representing the back-arc basin developed by mantle convection in the supra-subduction zone. These ages indicate that TTO in the Amdo area is older than 191 Ma, consistent with a major PGM Os-isotope T_{RD} age peak (243 Ma) [4]. Fig.1 shows the geodynamic situation of the Tibetan Tethys ophiolites, in which the Amdo micro-terrane was isolated in the TTO during the rifting of Gondwana along listric faults, then subducted to >150 km depth, before exhumation.

Reconstruction of Oil-filling History by Fluid Inclusion Analysis: A Case Study of Tahe Oil Field, Tarim Basin, NW China

WEIJUN SHI, ZHIRONG ZHANG, JOHN K. VOLKMAN, JIANZHONG QIN AND TENGER, BINBIN XI

Sinopec Key Laboratory of Petroleum Accumulation Mechanisms, Wuxi Institute of Petroleum Geology, SINOPEC Research Institute of Petroleum Exploration and Production, 100 Jinxi Road, Binhu District, Wuxi, Jiangsu, China. shiwj.syky@sinopec.com

The Tahe oil field in the Tarim Basin of NW China, has Ordovician carbonates as the main reservoir strata. Core samples from the reservoirs in the eastern Tahe oil field were collected for analysis of fluid inclusions(FIs). FIs occurred mainly in calcite and quartz cements and within calcite veins in the carbonate rock matrix. From the homogenization temperatures, molecular compositions obtained by laser ablation and on-line GC-MS analysis, and simulations for fluid pressures and trapping temperature, we determined that 2 types of oil-bearing inclusions representing the 2 main petroleum charging events in the region were present. The early stage of the petroleum-filling occurred about 245 ~ 255 Ma, during the late Permian to early Triassic (late Hercynian). The late charging occurred in the Pliocene (Himalayan Orogeny).

The dominant FIs have blue fluorescence and relatively high maturity (VR of 0.75% R_o from MPI and 1.22% R_o from MPR aromatic maturity parameters). Homogenization temperatures of the associated aqueous inclusions vary from 74 to 92 ºC. Results from laser ablation GC-MS analysis showed higher proportions of saturated hydrocarbons and gaseous hydrocarbons. The simulated paleo trapping temperature ranged from 150.6 to 156.9 ºC, and fluid pressures ranged from 565.9 to 599.8 bar.

The second type of oil-bearing inclusions displays yellow fluorescence and relatively low maturity (VR of 0.59% R_o from MPI and 1.17% R_o from MPR), and homogenization temperatures from 58 to 113 ºC. The yellow fluorescing inclusions contain much more water-soluble aromatic hydrocarbons than in the blue ones. The simulated paleo trapping temperature range from 79.2 to 83.5 ºC, and fluid pressures range from 221.8 to 245.3 bar.

Iron dissolution kinetics in mineral dust under more realistic aerosol conditions: Re-considering pH scale

ZONGBO SHI

School of Geography, Earth and Environmental Sciences, University of Birmingham, B15 2TT, UK Email: z.shi@bham.ac.uk

Iron (Fe) is a micronutrient that mediates the primary productivity in the global ocean. A significant source of such Fe in the surface ocean is from dust. It is therefore important to quantify the flux of bioavailable Fe from dust, which is strongly dependent on Fe solubility. Fe in dust is mostly insoluble, but such Fe may become soluble after reacting with acidic species during transport. In the last 20 years, many laboratory studies have been conducted to measure the dissolution kinetics of Fe in dust at pH from 1 to 5. It is now known that clouds may actually decrease Fe solubility because of its higher pH, e.g., >4. In contrast, aerosol water can be more acidic but more complicated in composition. However, most of the previous lab studies were conducted under much simplified conditions compared to those in aerosol water. These results, when applied, could lead to large bias in global models. In this work, I measured Fe dissolution kinetics in dust under conditions closer to aerosol water.

The results showed that at the same [H^+] concentration at (1 g dust L^{-1} solution), (i) $(NH_4)_2SO_4$ at 1 mol L^{-1} slows down Fe dissolution; and (ii) NH_4Cl at 1 mol L^{-1} accelerates the Fe dissolution in dust. Based on these results, I propose to use an effective pH scale for simulating Fe dissolution kinetics in aged dust in models. This pH scale considers the activity of H^+ ion and [HSO_4^+], both of which can be predicted by the AIM thermodynamic model (http://www.aim.env.uea.ac.uk/aim/aim.php).

In addition, oxalate (0.03 M $Na_2C_2O_4$) significantly accelerates the dissolution of Fe in dust (1 g dust L^{-1} solution, 0.1 N H_2SO_4 or 0.01 N H_2SO_4, and 1 M $(NH_4)_2SO_4$).

Changes in $^{238}U/^{235}U$ associated with reductive immobilization of uranium in groundwater

ALYSSA E. SHIEL[1]*, CRAIG C. LUNDSTROM[1], THOMAS M. JOHNSON[1], PARKER LAUBACH[1], PHILIP E. LONG[2] AND KENNETH H. WILLIAMS[2]

[1]Dept. of Geology, University of Illinois at Urbana-Champaign, Urbana, IL USA; ashiel@illinois.edu (*presenting author)

[2]Lawrence Berkeley National Laboratory, Berkeley, CA USA

The prevalence of groundwater contamination associated with uranium (U) mining and milling activities has driven the need for the development of effective and economically feasible remediation strategies. U is mobile in its oxidized state, U(VI), but immobile and much less toxic in its reduced state, U(IV). Thus, U(VI) reduction to U(IV) is proposed as a remediation strategy for U contaminated groundwaters. The former U mill site in Rifle, Colorado (USA) hosts experiments that investigate the rates and mechanisms of targeted U immobilization techniques. Our research focuses on the development of $^{238}U/^{235}U$ (discussed as $\delta^{238}U$) as a tool for evaluating immobilization in the subsurface.

U concentrations and $^{238}U/^{235}U$ values have been monitored over the course of three field experiments at the Rifle, CO field site in 2010–11, 2011–12 and 2012–13. These experiments examined changes in U concentrations and $^{238}U/^{235}U$ values associated with biostimulation, desorption and re-oxidation. Large variations accompany acetate-induced biostimulation under both iron reducing and sulfate reducing conditions. In both casees, ^{238}U is preferentialy reduced to U(IV), leaving the remaining groundwater U(VI) relatively isotopically light ($\Delta^{238}U$ = −1.3 and −1.9‰, respectively). Changes in $^{238}U/^{235}U$ accompany changes in the U concentration (dropping from ~150–200 ppb U prior to the acetate injection to ~10 ppb U). During the post-injection phase, as concentrations rebounded, absence of $^{238}U/^{235}U$ greater than pre-injection values implies the primary source of U is advection of U(VI), rather than re-oxidation of U(IV). Bicarbonate-induced desorption, which led to a doubling in the U concentration, has been demonstrated to result in no significant U isotopic fractionation [1].

Our research demonstrates the potential for $^{238}U/^{235}U$ to detect U reductive immobilization in the subsurface and to distinguish between removal by this process and relatively temporary processes such as sorption. U isotopes join the growing number of heavy stable isotopes with demonstrated potential for use in environmental monitoring.

Estimate of residence time of groundwater in Mt. Fuji area, central Japan

N. SHIKAZONO, T.UMEMURA AND T.ARAKAWA

3-14-1,Hiyoshi, Kohoku-ku, Yokohama 223-8522 Japan (sikazono@applc.keio.ac.jp)

Many groundwater samples were collected from Mt. Fuji area, central Japan which is totally composed of basaltic materials. The samples were analyzed for Na^{+}, K^{+}, Ca^{2+}, Mg^{2+}, Si, Al^{3+}, Fe^{2+}, Fe^{3+}, TC (total dissolved carbon), Cl^{-}, NO_3^{-}, SO_4^{2-}. Analytical data plotted against altitude indicate that alkali and alkali earth element and Si concentrations increase with decreasing altitude, indicating that the dissolution of silicates in basaltic materials control the trends. Ca and Mg concentrations positively correlate with each other. This is consistent with CaO/MgO molal ratio of basalt which is 1.47. Therefore, it isi inferred that Ca and Mgi in groundwater were derived mainlyfrom the congruent dissolution of basalt. Ca/Si concentrationratio determined by the dissolution reactions of basalt accompanied by the precipitation of allophane is 0.29 that is lower than 0.48 estimated from the analytical data on groundwater. This lower value could be due to the precipitation of silica mineral (SiO_2). The agreement between theoretical and analytical results indicate that Ca, Mg and Si concentrations of groundwater are governed by dissolution and precipitation reactions. In order to interpret groundwater chemistry and estimate residence time of groundwater the simplified coupled dissolution kinetics-fluid flow model was used. Assuming reasonable values of parameters (reactive surface area, mass of groundwater, temperature etc) and usingr ate constant experimentally determined, residence time of groundwater in southeastern and northern part of Mt.Fuji area was estimated to be several years to 30years. This estimated residence time is consistent with isotope data (herium isotope, tritium concentration and CFCs). The calculation indicate that the reasonable residence time(10-30years) was obtained, if dissolution rate constant of Si for basaltic glass determined by fluid flow experiments but unreasonable one by closed system experiments. It is just conceivable that whether etch pit formed or not and/or heterogeneous dissolution occurred or not has significant impact on dissolution rate of basalt.

Dissolved gallium and gallium/aluminum ratios in the US GEOTRACES North Atlantic zonal section

A.M. SHILLER[1]*, M. HATTA[2] AND C.I. MEASURES[2]

[1]Dept. of Marine Science, Univ. Southern Mississippi, Stennis, MS 39529, USA (*correspondence: alan.shiller@usm.edu)
[2]Dept. of Oceanography, Univ. Hawaii, Honolulu, HI 96822 (mhatta@hawaii.edu, chrism@soest.hawaii.edu)

Gallium has a solution chemistry and geochemical behavior similar to aluminum; however, gallium appears to be less reactive than aluminum. Thus, fractionation of gallium from aluminum has the potential to shed light on aluminum input and removal processes with gallium beaving like a “super-heavy isotope” of aluminum. The 2010/2011 US GEOTRACES North Atlantic zonal section provided an opportunity to create a first detailed ocean section of dissolved gallium. Thirty-two profiles plus ancillary surface water samples were obtained and analyzed for dissolved gallium and aluminum.

In general, this new Ga section is consistent with previous observations: deep and bottom waters ranged between 30 and 35 pmol/kg; a distinct Ga minimum is observed in the Antarctic Intermediate Water; a slight maximum is found in Mediterranean Outflow Water; and, surface waters show a distinct north-westward increase. The surface water trend could be reflective of a residence time effect (i.e., accumulation of dust-derived Ga during North Atlantic gyral circulation) or of greater dust dissolution input. The biggest surprise is the observation of a ~20% increase in Ga in deep waters in the vicinity of the Mid-Atlantic Ridge.

The dissolved Ga/Al ratios are also instructive. Low (i.e., more rock-like) ratios in the Med water and hydrothermally-influenced waters are suggestive of recent inputs of these elements. In contrast, high Ga/Al ratios along the African margin are suggestive of preferential Al scavenging removal. Interestingly, high Ga/Al ratios in Labrador Sea Water along the western margin are actually lower than ratios in the Labrador Sea itself, suggesting accumulation of Al during transit. In surface waters of the eastern part of the section, where there is a significant gradient in chlorophyll fluorescence, the Ga/Al ratio increases with increasing fluorescence. This is consistent with preferential scvanging removal of Al from surface waters.

Spin Transition of Iron in Amorphous Mg-Silicates at Mantle-Related Pressures

S.-H. DAN SHIM [1], C. GU [2], K. CATALLI [3], B. GROCHOLSKI [4], L. GAO [5], E. ALP [5], P. CHOW [6], Y. XIAO [6], H. CYNN [3] AND W. J. EVANS [3]

[6]Cargenie Institute of Washington, USA

A sharp increase in iron partitioning into melt with respect to mineral phases was reported at 70 GPa in an Al-free system [Nomura *et al*. 2011]. Based on the report, it was proposed that melt may be neutrally or negatively buoyant in the deep mantle. Nomura *et al*. [2011] attributed the iron partitioning change to a sharp high-spin to low-spin change in iron, which was found in their measurements on a Fe-diluted (5%) Mg-silicate glass at a similar pressure. However, Andrault *et al*. [2012] found no sharp change in iron partitioning between silicate melt and minerals in an Al-bearing system up to 120 GPa.

We measured the electronic configuration of iron in two differernt iron-rich (20%) Mg-silicate glasses at high pressure and 300 K in the diamond-anvil cell combined with X-ray Emission Spectroscopy (XES) and Nuclear Forward Scattering (NFS): Al-free glass up to 135 GPa and Al-bearing glass up to 93 GPa. We found no sharp changes in the spin state of iron up to our maximum pressure. Instead, the population of low-spin iron increases gradually from 1 bar in both glasses, but significant population of iron still remains high spin (40-50%) even at 90-135 GPa. Our observation is consistent with the expectation of gradual response of disordered systems to compression due to the existence of diverse coordination environments for iron in the glasses and continuous structural adjustment of the disordered system with pressure. If our results on Mg-silicate glasses can provide some insights for iron in mantle melts, the spin transition in iron should be gradual and further smeared out at the high temperatures of mantle melts [Sturhahn *et al*., 2005], and therefore unlikely to induce a sharp change in iron partitioning in the deep mantle.

[1] C. Gu, K. Catalli, B. Grocholski, L. Gao, E. Alp, P. Chow, Y. Xiao, H. Cynn, W. J. Evans, and S.-H. Shim. Electronic structure of iron in magnesium silicate glasses at high pressure. Geophys. Res. Lett., 39:L24304, 2012.

Volatile element content of the mid-ocean ridge mantle

K. SHIMIZU[1]*, A.E. SAAL [1], E.H. HAURI[2], V.S. KAMENETSKY[3] AND R. HÉKINIAN[4]

[1]Dept. of Geological Sciences, Brown University, Providence, RI, 02912, USA
(*correspondence: Kei_Shimizu@brown.edu)
[2]DTM Carnegie Institute of Washington, DC, 20015, USA
[3]CODES, University of Tasmania, Hobart, Australia
[4]Keryunan, 29290 Saint Renan, France

Volatile element (H_2O, CO_2, F, Cl, S) budget of mid-ocean ridge mantle (DMM) is crucial for understanding mantle melting, rheology, and convection. The isotopic composition of MORB demonstrates that the mantle beneath ridges is heterogeneous. MORB from Garrett transform fault and Macquarie Island defines the depleted and enriched end-members respectively. We have analyzed H_2O, CO_2, F, Cl, S contents of Garrett TF and Macquarie Is. MORB to determine the volatile budget of these end-member components.

28 glasses from Garrett TF [1] and 52 glasses from the Macquarie Is. [2] were analyzed for major, trace, and volatile elements by triplicate analyses. Previous works reported the isotopic composition of a subset of our samples from the Garrett TF [3] (minimum $^{87}Sr/^{86}Sr$ = 0.7022) and the Macquarie Is. [2] (maximum $^{87}Sr/^{86}Sr$ = 0.7033), which correlates with the degree of trace element enrichment (e.g. Th/La) indicating a long-lived depletion and enrichment of their mantle sources.

We first considered shallow level processes, such as volatile degassing, sulfide saturation and interaction of melt with hydrothermally altered material. Degassing has affected the CO_2 concentration of the glasses except for a few CO_2 undersaturated samples, but it did not affect H_2O, F, Cl, and S. Samples that were sulfide saturated [4] and contaminated by seawater or hydrothermally altered material (high Cl/K) were filtered out.

The CO_2/Nb of the depleted MORB determined using the CO_2 undersaturated Garrett TF glasses MORB is 250, consistent with Saal *et al*. [5]. We use Cl-Nb-CO_2 correlations to determine a CO_2/Nb of ~ 600 for degassed Macquarie Is. MORB, consistent with the work by Cartigny *et al*. [6]. The H_2O/Ce of the depleted and enriched sources are 120 and 170 respectively. The F/Nd, Cl/K, and S/Dy ratios of our samples expand beyond the range of previous reported values.

Electrochemical Impedance Spectroscopic Study of the Hematite/Water Interface

KENICHI SHIMIZU[1]* AND JEAN-FRANÇOIS BOILY[1]

[1]Department of Chemistry, Umeå University, Sweden, *kenichi.shimizu@chem.umu.se

Hematite is one of the most abundant and stable iron minerals in Earth's upper crust, and thus inevitably plays an important role in various bio-geochemical processes, including mass transport, pollutant migration, and microbial metabolism. This mineral is also a promising material in the search for renewable forms of energy, such as in Li-ion batteries and water splitting. The intrinsic activity of hematite surfaces notably concerns interactions with water and electrolyte ions. Recent cryogenic X-ray photoelectron spectroscopy (XPS) work in our group have addressed such issues by monitoring electrolyte ion loadings and binding mechanisms at nano-sized hematite particle surfaces.[1,2,3]

In an effort to further our understanding of reactions taking place at the hematite/water interface, we used electrochemical impedance spectroscopy (EIS) to extract interfacial properties such as adsorption resistance and electric double layer capacitance using a specially constructed set-up to study surfaces of single body semi-conductive hematite specimens.[4] EIS measurements of crystallographically oriented electrode surfaces contacted with electrolyte solutions (0.1 M NaCl, NaCl/Na_2CO_3, and NH_4Cl) were carried out both in the absence and presence of light in the 4-12 pH range. The resulting spectra were thereafter analyzed using an equivalent electrical circuit model accounting for solution, interface and bulk hematite electrochemical processes. These efforts showed, for instance, that double layer capacitances of the basal (001) plane are insensitive to solution pH and electrolyte type whereas those of the (012) are considerably affected by them. This can be attributed to differences in amphoteric attributes of these two planes. Results revealed that the ammonium ion has a greater influence on charge development than the bicarbonate ion. This finding is consistent with a cryogenic XPS study from our group [3] pointing to hydrogen-bonded interactions between ammonium and hematite surface hydroxo groups.

Photo-irradiation decreased open circuit potentials relative to dark conditions on both (001) and (012) surfaces due to photo-reduction reactions. Impedance spectra show that the (012) is affected more indicating the greater photo-reactivity of this plane. Results also show that the charge transfer resistance within bulk hematite crystal was lower through the (012) plane than on the (001) plane, as can be expected from the anisotropic nature of this mineral.

Volatile behavior in an immature subduction zone inferred from boninitic melt inclusions in Cr-spinel

KENJI SHIMIZU[1 2] AND NOBUMICHI SHIMIZU[2]

[1]Japan Agency for Marine-Earth Science and Technology, Yokosuka, 237-0061, Japan, shimmy@jamstec.go.jp

[2]Woods Hole Oceanographic Institution, Woods Hole, MA, 02543, United States

Recent studies suggest that boninites formed at the immature stage of subduction zone, whereas related arc tholeiites erupted 0-7 Myrs after boninites at Izu-Bonin-Mariana Arc (e.g. Ishizuka *et al*., 2011, EPSL), indicating significant changes in conditions of subduction within this period. We have analysed volatile contents and sulfur isotopic compositions of melt inclusions (MIs) in Cr-spinel from beach sands of fore-arc volcanic islands of boninite (Muko, Chichi) and tholeiite (Mukoo and Guam), using secondary ion mass spectrometry (ims-1280). Major element compositions of MIs fully cover compositional ranges of whole-rocks. Some boninitic MIs have MgO higher than 20 wt%, showing that they are very primitive magmas. H_2O and CO_2 contents of MIs are contrasting between boninites and tholeiites, with boninitic MIs are high (up to 4 wt%) in H_2O and low (< 50 ppm) in CO_2, whereas tholeiitic MIs are lower (H_2O ~1-2 wt%) and higher (CO_2 up to ~1300ppm) than boninitic MIs. Except for H_2O, volatiles of boninitic MIs (Cl <500ppm; S ~150ppm) are considerably lower than those in tholeiite MIs (Cl and S up to 3000ppm). $\delta^{34}S_{VCDT}$ of boninitic MIs are low (-10 to 0 ‰), whereas those of tholeiite MIs ($\delta^{34}S_{VCDT}$ = +2 to +7 ‰) are comparable to reported arc tholeiite data. The results suggest that different sources for S were involved in the formation of boninitic and tholeiitic magmas.

Buried ikaite precipitates in Antarctic sediments: Are they fossil indicators of microbial sulfate reduction or AOM?

MEGUMI SHIMIZU[1]*, MARCOS Y. YOSHINAGA[2], KAI-UWE HINRICHS[2] AND CINDY VAN DOVER[1]

[1]Duke University Marine Laboratory, Nicholas School of Environment, Duke University, Beaufort, NC, USA (*correspondence: megumi.shimizu@duke.edu)
[2]MARUM Center for Marine Environmental Sciences, University of Bremen, 28334 Bremen, Germany

Ikaite is a calcium carbonate hexahydrate ($CaCO_3 \cdot 6H_2O$) formed at low temperature and high concentration of dissolved inorganic carbon (DIC) in organic-rich sediments [1]. Two microbial processes, bacterial sulfate reduction of organic matter and anaerobic methane oxidation (AOM) by archael/bacterial consortia can trigger ikaite precipitation by increasing DIC concentration. To determine which of these processes may contribute to ikaite formation, we studied a 500-cm sediment core from the northern Antarctic Peninsula that contained 4 large ikaite crystals (~50 cm^3 each) at depths > 300 cm. Apolar (fossil) lipids were extracted from six sediment horizons: at the surface, within the modern sulfate-methane transition zone (85 cm), and the four horizons where ikaite was found (304, 454, 480 and 505 cm). Stable carbon isotopic compositions of bacterial fatty acids (FA), and archaeal biphytanes (BP), archaeol (AR), and hydroxy-archaeol (OH-AR) were analyzed. $\delta^{13}C$ values of FA and BP ranged from -30‰ to -20‰ (ave = -23 ±2.3 ‰) from the six sample horizons. AR and OH-AR was extracted from the same horizons, but isotope values were only measurable at the 454 and 500-cm horizons due to low concenetrations. In these two horizons, AR was depleted in ^{13}C (ave = -49‰) as well as OH-AR (ave = -87‰). The ^{13}C-enriched values of $C_{15\text{-}18}$ FA (bacterial markers for AOM) and of BP (archael marker for AOM) suggest they are not derived from AOM beacause lipids derived from AOM are significantly depleted (-110‰ to -60‰) [2,3]. Although the ^{13}C-depleted AR and OH-AR can from AOM realted Archea, they could be also from methanogenic Archaea [4]. $\delta^{13}C$ in ikaite, DIC and methane will provide a scope on ancient carbon flow and help to reavel ancient microbial activities contributed kaite formaiton.

Boron and sulfur isotopic variations during subduction of hydrated lithosphere: The Erro Tobbio case

N. SHIMIZU[1], M. SCAMBELLURI[2], D. SANTIAGO RAMOS[3] AND S. TONARINI[4]

[1]Woods Hole Oceanographic Inst., Woods Hole, MA, USA
[2]University of Genova, Genova, Italy
[3]Amherst College, Amherst, MA, USA
[4]Istituto Geosci. Geores-CNR, Pisa, Italy

Exhumed high-pressure serpentinites provide unique opportunities for advancing our understanding of geochemical changes in hydrated lithosphere during subduction and deep recycling of elements. The Erro Tobbio serpentinized peridotites represent Jurrasic oceanic lithosphere which underwent low-T hydration (T <300°C) followed by high-T serpentinization and recrystallization at ~550°C, 2 – 2.5 GPa during Alpine subduction. Covariations observed for whole-rock δD, $\delta^{18}O$, Sr, and H_2O indicate that hydration continued at high temperatures, placing the Erro Tobbio massif in the mantle wedge. During hydration whole-rock boron concentrations varied from 10 to 32 ppm with $\delta^{11}B$ from +3.8 to +23‰ for low-T serpentinites, and from 12 to 36 ppm with $\delta^{11}B$ from +17 to +24‰ for high-T rocks. In-situ analysis of sulfur isotopic composition of individual sulfide grains (pentlandite with minor heazlewoodite) has revealed that $\delta^{34}S$ varies from -2.5 to +4‰ for low-T rocks, consistent with whole-rock data (Alt *et al*., 2012), while high-T rocks display a much larger range in $\delta^{34}S$ from -2 to +18‰ with significant increases in modal sulphide. B isotopes, S isotopes, and other geochemical variations observed for the Erro Tobbio peridotites suggest that hydration and mass transfer from slab to wedge occurred at relatively shallow level, resulting in the formation of hydrated mantle wedge with high $\delta^{11}B$, high $\delta^{34}S$, enrichment in B, Sr, and other fluid-mobile elements, suitable for the sources for arc magmas and heterogeneous sources for MORB and OIB.

FOZO-HIMU connection: Link to chemical heterogeneity of MORB and variable degree of dehydration

G. SHIMODA*[1] AND T. KOGISO[2]

[1] Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, Tsukuba 305-8567, Japan (*correspondence: h-shimoda@aist.go.jp)
[2] Graduate School of Human and Environmental Studies, Kyoto University, Kyoto, 606-8501, Japan (kogiso@gaia.h.kyoto-u.ac.jp)

It has been considered that source materials of HIMU and FOZO could be recycled oceanic crust. From this perspective, the arising question is what process is responsible for the geochemical difference between HIMU and FOZO. Additionally, coupled production of low Rb/Sr and high U/Pb and Th/Pb ratios of HIMU and FOZO has been controversial. To solve the issue, many studies have been conducted to evaluate the origin of the HIMU source using hydrothermal alteration and/or dehydration reaction. These studies can successfully explain the origin of HIMU and FOZO source. However, they may neglect effect of global chemical trend of MORB composition that should result in variation in isotopic composition of recycled MORB. In addition, variation in condition of subduction process (e.g., amount of dehydrated fluid) should greatly affect the isotopic composition of recycled oceanic crust.

In the present study, geochemical modeling has been conducted to evaluate the origin of HIMU and FOZO reservoirs on the basis of global chemical trend of MORB and variation in subduction processes. For the modeling, MORB compositions from East Pacific rise and Mid-Atlantic ridge are compiled from published data (PetDB: http://www.earthchem.org/petdb). The results suggest that crystal fractionation at a mid-ocean ridge can increase U and Th concentrations relative to Pb content, producing high U/Pb and Th/Pb ratios in evolved MORBs. In addition, high degree of dehydration beneath a subduction zone can increase U/Pb and Th/Pb ratios of subducting oceanic crust compared to less dehydrated oceanic crust, suggesting that strongly dehydrated oceanic crust can be a suitable source for HIMU and less dehydrated MORBs can produce material with FOZO isotopic signature. In this context, magma evolution at mid-ocean ridges and variable degree of dehydration beneath subduction zones play an essential role in producing the isotopic variations between HIMU and FOZO.

Occurrence of >3.9 Ga “Nanok” gneiss from Saglek Block, northern Labrador, Canada

M. SHIMOJO[1]*, S. YAMAMOTO[1], S. AOKI[1], S. SAKATA[2], K. MAKI[2], K. KOSHIDA[1], A. ISHIKAWA[1], T. HIRATA[2], K.D. COLLERSON[3] AND T. KOMIYA[1]

[1]Department of Earth Science and Astronomy, The University of Tokyo, Komaba, Meguro, Tokyo, 153-8902, Japan (*correspondence: shimojo@ea.c.u-tokyo.ac.jp)
[2]Laboratory for Planetary Sciences, Kyoto University, Japan
[3]The University of Queensland, Brisbane Qld 4072, Australia

The Saglek Block is underlain by the Early to Late Archean suites including ca. 3.73 Ga Uivak I Gneiss, ca. 3.62 Ga Uivak II Gneiss, ca. 3.24 Ga Lister Gneiss and ca. 2.5 Ga granite [e.g. 1]. Those rocks underwent high-grade metamorphism, locally reaching granulite facies at 2.8-2.7 Ga [1]. Additionally, presence of over 3.8 Ga, up to 3.91 Ga, zircon cores in the Uivak I Gneiss suggested pre-Uivak I Gneiss rocks [1, 2], named as Nanok Gneiss [2]. However, the origin of the old zircon cores is still unclear: inherited from pre-Uivak I materials or precipitated from an older suite of the Uivak I felsic magma. Thus, we examined the internal structures of zircons using cathodoluminescence (CL) images and conducted laser-ablation ICP-MS U-Pb dating.

The result of the 11 orthogneiss samples from the south of St. John's Harbor is the following. The CL images or microscopic observations clearly display that most of the zircon grains comprise three domains: Zone I to III, respectively. Zone I is located in their central regions, and display clear oscillatory zoning. It is characterized by low U contents and high Th/U ratios. The Zone II lacks obvious oscillatory zoning, and is very dark. It is characterized by high U contents and low Th/U ratio, compared with Zone I. Zone III is a very thin layer in the outermost part of grains or does not exist. The U-Pb ages of Zone I and II shows a peak at 3.96-3.85 Ga and around 2.7 Ga, respectively. Those ages are well-correlated with observations of CL images, U contents and Th/U ratios. The age of the Zone II is in agreement with metamorphic age of previous study. Hence, the age of Zone I can be interpreted lower limit of the magmatic age of the protoliths of the orthogneisses, older than the conventional age of the Uivak Gneiss [1]. We concluded that the granitoid, the precursor of the Nanok Gneiss, were emplaced at 3.96 Ga in the Saglek block, Labrador.

Determination of Boron using Isotope dilution MC-ICP-MS

HYUNG SEON SHIN* , MIN SEOK CHOI, JONG-SIK RYU AND KWAN SOO HONG

Korea Basic Science Institute, Chungbuk, Korea (*correspondence: h2shin@kbsi.re.kr)

A new technology applying to the isotope dilution method was used to estimate the amount of B(boron) in geological samples and was determined to be a viable method to minimize naturally occurring B background signals. The B ratios in geological sample (SDC-1 and SGR-1) were measured using a double-focusing multiple collector inductively coupled plasma mass spectrometer (Neptune). High naturally occurring B background signals and $^{40}Ar^{+4}$ interference were improved using a low RF power technique. A H_3PO_4 in mixed acid (HNO_3 + HF) was used to reduce the loss of B form (BF_3) in the sample dissolution process.

Boron isotopes were measured using a multi-collector, inductively coupled plasma mass spectrometer (Neptune, Thermo-Finnigan, Bremen, Germany).The present study determined an alternative method to minimize B isotope background signals. The B background signal was improved using a low RF power technique. The 800 W setting represents an excellent compromise between lower interference and the reduced matrix effect experienced at 1200 W. The results at 800 W (SGR: 55.246 ± 0.003 and SDC: 13.273 ± 0.003 mg g-1) were equivalent to the reference values (SGR: 54 ± 3 and SDC: 13 mg g-1). However, the values obtained using 1200 W (SGR: 48.600 ± 0.001 and SDC: 11.127 ± 0.004 mg g-1) were slightly lower than the 800 W values. Furthermore, the addition of H_3PO_4 prevented the loss of boron within the sample dissolution process. The SDC-1 and SGR-1 results obtained by the isotope dilution method were within the range of the reference values. Overall, the high performance of our proposed analytical technique (decreased B background signal under low RF power, H_3PO_4, isotope dilution method and MC-ICP-MS) makes it suitable for use in the determination of B in geological samples

Boron and other trace element constraints on the slab-derived component in Miocene volcanic rocks from the Setouchi Volcanic Belt in SW Japan

HIRONAO SHINJOE[1], YUJI ORIHASHI[2] AND TOMOAKI SUMII[3]

[1]Tokyo Keizai University, Tokyo, JAPAN (*correspondence: shinjoe@tku.ac.jp)

[2]Earthquake Reserch Instutiute, Univ. of Tokyo, Tokyo, JAPAN

[3]Geological Surv. Japan, AIST, Tsukuba, JAPAN

We present a dataset for boron and other trace element contents for basalts and high-Mg andesites (HMA) obtained from the middle Miocene Setouchi Volcanic Belt (SVB) in SW Japan. SVB was formed along the SW Japan Arc, immediately after the opening of the Japan Sea and clockwise rotation of SW Japan with the subduction of young hence hot Shikoku Basin of the Philippine Sea plate. Previous studies on HMA and basalt of SVB, laid stress on the contribution of subducting sediment, particularly partial melt of terrigenous sediments to the magma source mainly based on their Sr, Nd, Pb isotopic compositions.

Analyzed samples show a large negative Nb and Ta anomalies, and enrichment of alkaline earth elements and Pb, which are features of typical island arc volcanic rocks. Boron content of basalts and HMA is highly variable (7 – 71 ppm).

Trace element compositions of altered oceanic crust-derived fluid, sediment-derived fluid, and sediment melt are modeled, and resultant fluid mobile/immobile element ratios (B/Nb, Ba/Nb, Pb/Nb, and K/Nb) are used to examine slab-derived component to mantle source. Most of element ratios are explained by <5% contamination of sediment melt to depleted mantle except for some HMAs with rather high B/Na ratios. Mantle source for these HMAs may be enriched with some trace elements including boron before the addition of slab-derived melt.

Mechanism and crystallochemical signature of nano-particle formation by microorganisms

H. SHIOTSU[1], M. JIANG[1], Y. NAKAMATSU[1], T. OHNUKI[2] AND S. UTSUNOMIYA[1]

[1]Department of Chemistry, Kyushu University, Fukuoka 812-8581, Japan (utsunomiya.satoshi.998@m. kyushu-u.ac.jp)
[2]ASRC, Japan Atomic Energy Agency, Tokai, Ibaraki, Japan

Interaction between rare earth elements (REEs) and microorganisms have attracted increasing attention due to the ubiquitous occurrence of microorganisms in the subsurface environment and to implication to the safety assessment of nuclear waste disposal, as REEs are used as a surrogate of trivalent actinides. Post-adsorption nano-mineralization by microorganisms is a key process that can constrain the migration of REEs; however, the mechanisms and factors controlling the process are still unclear. This study demonstrates the REEs (La-Lu) accumulation experiments to understand the effect of pH, coexistent REEs and the functional group of cells surfaces on the crystal chemistry of biogenic nanoparticle formation.

During the exposure of yeast to REE solution at 25 ºC, all REEs were removed from the solution by 24 h at pH 4 and 5, while 50 % of the initial amount remained in the solution at pH 3 after 24 h. Deprotonation of the functional groups on the cell surface merely occurs at pH 3 as evidenced by the other experiments at 4 ºC. In contrast, 10 % of REEs were adsorbed to the cell surfaces at pH 4 and 5. Particles at the size of ~100 nm precipitated on the cell surfaces at pH 3, while ~30 nm-sized nano-particles were observed at pH 4 and 5 at 25 ºC. These nano-particles were characterized as phosphate containing a series of REEs. The nano-particles at pH 3 had monazite structure, while the particles forming at pH 4 and 5 were amorphous, indicating that crystallization took place only at pH 3. REE phosphate inorganically synthesized at room temperature revealed crystalline structure (monazite, xenotime or rhabdophane) depending on the element. Additional inorganic model experiments using the CMC, Ln resin and Cellulose Phosphate, which have the functional groups similar to cell surfaces, demonstrated that the nano-particles precipitated without structure. Based on these data it is suggested that adsorption to the functional groups on the cell surfaces constrain the shape and structure of nanoparticles.

As for the REE pattern, the difference between the distribution coefficient, K_d (ml/g), of LREE and of HREE increased with time increasing. At 24 h, the K_d ratio of Nd to Tm ($K_{d,\ Nd}/K_{d,\ Tm}$) is 1.72, 4.61, and 6.86 at pH 3, 4, and 5, respectively. The K_d rations greater than 1 indicate the preferential uptake of LREE by the microorganisms, which are attributed to the lower solubility products of REE phosphate. As a consequence, the present study underscores the important role of cell surfaces and biological activity on the kinetics, mechanisms and crystal chemistry of nanoparticle formation as well as the physico-chemical properties of nanoparticles.

Sub-daily elemental fluctuation in mussel shell

KOTARO SHIRAI[1]*, TSUZUMI MIYAJI[2], BERND R. SCHÖNE[3] AND KAZUSHIGE TANABE[4]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, Kashiwa 277-8564 Japan (* correspondence: kshirai@aori.u-tokyo.ac.jp)
[2]Department of Natural History of Sicence, Hokkaido University, Sapporo 060-0810 Japan
[3]Institute of Geoscience, University of Mainz 55128 Mainz Germany
[4]The University Museum, The University of Tokyo, Tokyo 133-0033 Japan

Shells of bivalve mollusks such as mytiloids serve as excellent paleoenvironmental archives. They exhibit a broad biogeographic distribution, occur in large numbers in the fossil record and contain a temporally aligned and highly resolved record of past environmental parameters. For example, Mg/Ca ratios of mussel shells have been explored as a temperature proxy. According to several studies, however, the suitability of the Mg/Ca thermometer is limited by vital effects. In order to extract reliable environmental information from the shell through geochemical analyses it is essential to understand the mechanism of elemental incorporation into the shell during calcification and growth.

In the present study, we have analyzed Mg/Ca Sr/Ca and S/Ca ratios of two shells of the Mediterranean mussel *Mytilus galloprovincialis* collected alive from Tokyo Bay, Japan. Environmental parameters were monitored at the sampling site. The elemental distribution was determined in polished cross-sections by means of electron probe micro analysis. Growth patterns were used to place the geochical data in a temporal context.

Growth lines (which formed during low tide) showed higher Mg/Ca ratios compared to adjacent growth increments. S/Ca ratios were also high at the growth line. However, the Mg/Ca and S/Ca do not show linear correlation. Both Mg/Ca and S/Ca ratios showed significant periodic fluctuations at the sub-seasonal scale. These fluctuations likely indicate that the shell Mg/Ca ratios primary reflect biological changes caused by tidal cycle and do not record temperature.

Composition of serpentine after olivine and orthopyroxene: Serpentinized peridotites of Nain ophiolite (Isfahan Province, Iran)

N. SHIRDASHTZADEH[1], G. TORABI[1] AND R. SAMADI[2]

[1]Department of Geology, Facualty of Science, University of Isfahan, Isfahan, Iran

[2]Department of Geology, Science and Research Branch, Islamic Azad University, Tehran, Iran

Introduction

The Naein ophiolite is one of the most complete ophiolitic suits at the East of Central-East Iranian Microcontinent - ophiolitic belt and it comprises a high proportion of serpentinized mantle peridotites [1]. As a possible alteration product of Nain mantle peridotites, serpentine constructed the veinlets and the mesh texture, characterized with a pale green-white chalky feature. The fibrous serpentine filled the cracks and veinlets are crossing the mesh texture and this indicates their former formation.

Raman Spectrometry and Microprobe Data

Raman Spectrometry of the serpentine suggests that the mesh texture is made of lizardite and the rock veinlets are filled by chrysotile. Based on major element data, lizardite is $Mg_{3.00}$ $Fe_{0.31}$ $Ni_{0.01}$ $Si_{1.84}$, with Al_2O_3= 0.00 wt%, Mg#=0.91, Cr#=0.00 in composition and chrysotile is $Mg_{2.14}$ $Fe_{0.10}$ $Al_{0.23}$ $Cr_{0.02}$ $Si_{2.18}$, with Al_2O_3= 2.84-5.97 wt%, Mg#=0.96, Cr#=0.10.

Disccusion of Results

Lizardite is characterized with higher Mg, Fe and Ni in while chrysotile is higher in Al_2O_3 and Cr#. [2] suggested that serpentine after orthopyroxene (bastite) are generally low in MgO (~ 34–37 wt.%), but have silica similar to serpentine after olivine (38–42 wt%). MgO of the studied chrysotile (~ 30-32 wt%), formed after orthopyroxene are generally higher than MgO of lizardite (~ 29 wt%), formed after olivine (i.e. lizardite), but the silica has a similar range (~ 43-54 wt%) in chrysotile and lizardite. The low Mg and high Cr and Al of chrysotile is a consequence of the composition of the original orthopyroxene (e.g., [3]; [4], [2]). Therefore, Al-rich serpentine of chrysotile is found in orthopyroxene bastite with lower MgO and FeO contents, and higher Al_2O_3 and Cr_2O_3 concentrations, while the lizardite is the serpentinization product of olivine.

Water content of inclusions in superdeep diamonds

S.B. SHIREY[1], E.H. HAURI[1], A.R. THOMSON[2], G.P. BULANOVA[2], C.B. SMITH[2], S.C. KOHN[2] AND M.J. WALTER[2]

[1]DTM, Carnegie Institution of Washington, Washington DC 20015, USA (shirey@dtm.ciw.edu, hauri@dtm.ciw.edu)

[2]Dept Earth Sciences, University of Bristol, Queen's Road, Bristol BS8 1RJ, UK (andrew.thomson@bristol.ac.uk)

The water content of the mantle strongly influences mantle convection and partial melting. Previously, direct measurements of mantle water content have been limited to peridotites or inferred from basalts. Superdeep or sublithospheric diamonds from the transition zone and lower mantle carry ultra-high pressure silicate and oxide micro-inclusions that provide an unparalleled opportunity to directly sample the composition, mineralogy and water content of deep mantle minerals.

We measured mineral inclusions in Type II (<20 ppm N) diamonds from the 93 Myr old Collier 4 kimberlite pipe in the Juina field of Brazil for their water content with the DTM NanoSIMS 50L. Studies of these diamonds showed complex growth structures, diverse inclusion assemblages, and heterogeneous C isotopic compositions (-5‰ to -25‰) interpreted as being due to subducted components entrained in the Trinidade plume [1]. Simultaneous scanning ion imaging of ^{12}C, $^{16}O^1H$, ^{18}O, ^{19}F, ^{30}Si and ^{56}Fe was employed and data reduced using the *L'image* (© LR Nittler, DTM) image-processing software. H_2O contents vary from nominally-anhydrous phases such as majorite (30 ppm, J9), walstromite after CaSi-perovskite (74 ppm, J14), and Mg-Al spinel (245 ppm, J2) to more water-rich phases such as Mg-pyroxene (former MgSi-perovskite, 2600 ppm, J2), Fo_{91} olivine (2300 ppm, J20) and K-feldspar (7800 ppm, J2). Mg-silicate phases along an internal fracture (J9) have 2.3 to 3.8 wt% H_2O and may be epigenetic or compromised.

Inferences on the mineralogy and H_2O contents of the inclusions at the time of trapping depend on identification of retrograde phases, final retrograde pressure, and H_2O storage capacity of the retrograde mineral assemblages. Correspondence of lowest measured water with the most anhydrous phases suggests some retention of original water content, however. Forsteritic olivine with 2300 ppm H_2O, and aluminous Mg-pyroxene with 2600 ppm H_2O, are consistent with H_2O saturation at pressures ≥ 7 GPa [2] and represent lower limits on the original H_2O content of these inclusions if their trapping depths were greater than 200 km.

Subcalcic garnets from harzburgites are proxies of the chemical and isotope composition of their bulk rock. The present study and previous work [1,2] on the Sm-Nd and Lu-Hf isotope systematics show that they can be excellent recorders of multiple mantle events. Subcalcic garnets with sinusoidal REE patterns are the results of high degrees of partial melting of their protolith at shallow pressures followed by subduction and reenrichment by (silico-)carbonatitic melts. Metasomatism in a previously depleted mantle (εHf = +16) occurred underneath the crust the East Kaapvaal craton at around 3.2 Ga. Simoultaneously, the crust was affected by widespread activity around that time and Sm-Nd model dates of similar age from pooled peridotitic garnet inclusions in diamonds were interpreted as oldest diamond growth ages. Oceanic lithosphere was created between the West- and East-Kaapvaal around 2.95 Ga [2] and subducted underneath the West-block before the collision around 2.88 Ga. This also caused enrichment process in an overlying, highly depleted mantle wedge 2.9 Ga ago [2] and apparently triggered a major growth period of diamonds as demonstrated by similar Re-Os ages from sulfide inclusions in diamonds from Kimberley and Botswana. Further enrichment in the West-Kaapvaal mantle at 2.62 Ga [1] coincides with the 2.6-2.8 Ga Ventersdoorp magmatism and with a 2.6 Ga Re-Os isochron from E-type sulfide inclusions from Koffiefontein. The attachment of the Kheis-Magondi belt to the Kaapvaal craton caused further metasomatism around 1.90 Ga [2] in the mantle along the Western margin of the Kaapvaal craton. The latest stages of mantle metasomatism lie between 0.9-1.3 Ga, coincident with the Namaqua-Natal belt orogeny. Periods of diamond growth younger than 2.6 Ga cannot be related directly to any mantle or crustal event. Major geotectonic events and plume activity episodically remobilized low melting portions in the mantle keel which lead to episodic (auto) metasomatism of the depleted mantle, episodic diamond growth and destruction of the lithospheric keel.

The differentiation mechanism of W and Sn of Qitianling granite in Hunan province, south China

SHUANG YAN[12] AND XIANG XIAOJUN[12]

[1]Chongqing Key Laboratory of Exogenic Mineralization and Mine Environment, Chongqing Institute of Geology and Mineral Resources, Chongqing 400042, China;
[2]Chongqing Research Center of State Key Laboratory of Coal Resources and Safe Mining, Chongqing 400042, China
E-Mail: shy810124@yahoo.com

Both large-scale tungsten and tin mineralization took place mostly in Nanling Mountains, South China. The two elements are usually related and accompanied with granitic rocks. Hua et al (2010) proposed that the eastern sector of the Nanling Mountains is characterized by strong and dense W mineralization, while Sn mineralization becomes stronger westwards. This study attempts to discuss reasons that cause the two elements differentiation, in the light of the study on the fluid inclusions of Furong Sn deposit and Xintianling W deposit, of which both have genetic relations to the Qitianling granitic rocks in Nanling Mountains, South China.

According to the study on the fluid inclusions of the two deposits, aqueous two-phase inclusions and daughter mineral-bearing inclusions are found in Furong Sn deposit, located in the south of Qitianling granites. The ore forming fluids have the composition of $CaCl_2$-NaCl-H_2O system with high salinity (36.99-42.45 wt% NaCl eq.) and temperature (462-494°C). While in the Xintianling W deposit, the CO_2-riched inclusion has been observed as the major inclusion. The ore forming fluids are characterised with low salinity (below 6%) and high temperature (367-392°C). The first melt temperatures of CO_2 range between -66.6~61.1°C.

These findings suggest that CO_2-enriched hydrothermal fluid differentiated from the Qitianling granites is conducive to the separation of W from the granitic magma system. In the later evolutional tertiary of the magma, the hydrothermal fluid is characterized with high level of Cl^-, which favor Sn enrichment in the ore-forming fluids. Accordingly, the difference of the ore-forming fluids of the two deposit maybe is the major factors responsible for the differentiation of W and Sn.

The speciation of several radionuclide and surrogate metal ions in specific formulations of nuclear waste form glasses has been investigated by synchrotron radiation methods. The primary technique to determine the oxidation state and structural information, and chemical behavior in many of these studies has been hard x-ray absorption fine structure (XAFS) [1]. There has been considerable effort utilizing XAFS to understand the conditions under which surrogates, in large part Re for Tc but also including specific metal ions such as Ce and Hf for Pu, are suitable chemical and structural analogs for the actual radionuclides of interest. Similar approaches have been utilized to validate the reliability of surrogates in glass waste form characteristics under processing and alteration conditions [2].

Recently, studies of glass waste form materials have been initiated using new soft synchrotron radiation tools that include the scanning transmission x-ray microscope (STXM) and ambient pressure x-ray photoelectron spectroscopy (APPES) endstations at the Molecular Environmental Sciences Beamline of the Advanced Light Source at LBNL [3]. Spectromicroscopy studies have been conducted using soft x-ray absorption spectroscopy of light atom constituents and metal ions in glasses with STXM. investigating the early stages of the interaction of water with glass surfaces with PES under more realistic conditions of approximately 10 Torr. New opportunities to address critical issues in nuclear waste form glass science with emerging synchrotron radiation methods will be presented and discussed.

Retention of radiogenic ^{4}He in crystals of most minerals is very low. Helium can escape easily from minerals in a course of their geological history. However, in a group of minerals, namely native metals, the retention of radiogenic helium is anomalously high [1]. Very low solubility of helium in metals leads to formation of atomic clusters of helium atoms, which manifest themselves as nanometer-scale bubbles. Migration of such "bubbles" in the crystal structure requires relatively high temperature close to the metal melting temperature.

The tendency of helium to form stable bubbles in native metals allows to propose a novel method in isotope geochronology for the direct dating of native minerals of platinum that is based on the α-decay of ^{190}Pt isotope [2].

We present nuclear-physical, isotope-geochemical and methodological aspects of the novel ^{190}Pt-^{4}He method. We validate the method on a set of new experimental ^{190}Pt-^{4}He dating measurements of four platinum deposits: (i) the Galmoenan massif, a gabbro-dunite-pyroxenite massif in the Koryak Highlands, Russia; the alkaline-ultramafic massifs of (ii) Kondyor, (iii) Inagli and (iv) Chad in the Aldanian shield, Russia. Our experimental measurements confirm the successful applicability of ^{190}Pt-^{4}He for the direct dating of the native minerals of platinum.

Microbial production and transformation of dissolve organic matter in the hydrothermal system

N.A. SHULGA[1], V.I. PERESYPKIN[1] AND I.I. RUSANOV[2]

[1]P.P.Shirshov Institute of Oceanology of the RAS, Nahimovski prospect 36, Moscow, Russia, 117997, (nash.ocean@gmail.com)

[2]Winogradsky Institute of Microbiology RAS, Prospekt 60-letiya Oktyabrya 7, 117312, Moscow , Russia (rusanov_igor@mail.ru)

This study was inspired by the lack of information on the microbial production of dissolved organic matter in course of chemosynthesis and methane oxidation at hydrothermal fields: most of studies didn't take into account the production of dissolved organic matter (DOM), considering only formed and consumed microbial biomass in the processes of microbial transformation of endogenous gases coming from hydrothermal solutions.

It is well known that the formation of organic compounds in the zones of hydrothermal activity proceeds under the influence of a number of physicochemical and biogeochemical (extremophile consortiums of bacteria and archaea) factors. We present i) radioisotope measurements of the activity of microbial communities in the hydrothermal fields of the Mid-Atlantic Ridge (MAR) and the East Pacific Rise (EPR), ii) investigation of the rates of microbial CO_2 assimilation, sulfate reduction, methane oxidation, lithotrophic and acetoclastic methanogenesis, and assimilation and oxidation of organic carbon, iii) analysis of samples of sulfide, sulfate, and carbonate hydrothermal deposits of various morphological types. Special attention was paid to the measurement of microbial DOM. We show for deep-sea hydrothermal systems, that in the process of microbial methane oxidation and dark assimilation of carbon dioxide at various temperature gradients of microbial production of DOM in most cases significantly higher than biomass production. Intensities of sulfate reduction and methanogenesis have been measured for the first time at different temperatures and dilution of the hydrothermal solution, not only in anaerobic sediments and solutions, but also in water samples of the contact zone and the plume.

The different content of organic compounds in microbiological samples and ore deposits from hydrothermal systems related to basalt volcanism and serpentinization of ultrabasic rocks testifies the different genesis of DOM.

Production and diffusion of cosmogenic noble gases: Using open-system behavior to study surface processes

DAVID L. SHUSTER[12], MARISSA M. TREMBLAY[12] AND GREG BALCO[2]

[1]Dept. of Earth and Planetary Science, University of California, Berkeley, CA 94720 USA

[2]Berkeley Geochronology Center, Berkeley, CA 94709 USA

We present a new geochemical approach to obtaining information about the temperature and surface exposure history of rocks and sediments. The approach is based on the simultaneous production and diffusion of cosmogenic noble gases in minerals at and near Earth's surface, and aims to take advantage of "open-system" behavior that has previously been viewed only as an undesirable obstacle to surface exposure dating. Given knowledge of diffusion kinetics, the relative abundances of cosmogenic ^{3}He, ^{21}Ne and other cosmogenic nuclides in natural samples constrain their temperature histories during surface exposure. When interpreted with a simple theoretical framework, and using laboratory-determined kinetics of He and Ne diffusion [1-3], our preliminary results indicate several pairs of common minerals and easily measureable cosmogenic noble gases that display partial retention at Earth surface temperatures. We focus initially on the minerals quartz and feldspars; these provide sets of nuclide-mineral systems that can be selected and optimized to constrain mean surface temperatures (and changes therein) across a range of climate settings and lithologies over the last few Ma. As an example, we present preliminary results from quartz-bearing Antarctic sandstones that constrain a mean, effective temperature of approximately -15 ºC over 5-10 ka of surface exposure. We present the basic theory and fundamental assumptions of this approach, and discuss potential complexity and limitations to the interpretation of these data.

The Study of Cadmium Accumulation by Floating Macrophytes using Natural Modeling Approach

O.V. SHUVAEVA[1,2]*, L.A. BELCHENKO[2] AND T.E. ROMANOVA[1,2]

[1]Institute of Inorganic Chemistry SB RAS, 3, Ac. Lavrent'ev Pr., 630090, Novosibirsk, Russia, olga@niic.nsc.ru
[2]Novosibirsk State University, 2, Pirogova, 63090, Novosibirsk, Russia, lab305@lab.nsu.ru
[3]Novosibirsk State University, 2, Pirogova, 63090, Novosibirsk, Russia, romanova_toma@mail.ru

It is known that phytoremediation technology became an effective method of environment clearing after it has been found the plant's ability to accumulate the contaminants at high concentration level. The floating macrophytes (*FM*) *Eichhornia crassipes* (*EC*) and *Pistia stratiotes* (*PS*) are applied most often to waste waters purification.

The goal of this investigation was to study the efficiency of the metal's bioaccumulation by *EC and PS* when exposed to cadmium with an emphasis on the mechanism of transport and transformation of pollutant within the plan and its fate during accumulation act.

To estimate hit consequences of pollutant on ecosystem an experiment was carried out in the conditions close to the natural using an approach of natural modeling consisting in a statement of natural experiments with the use of mesocosms, established directly in a reservoir into which one enters the set portion of pollutant and then supervises the dynamics of its concentration.

As a result it was found that the degree of cadmium extraction by *FM* from contaminated natural water while maintaining the viability of the plants depends on the way of pollutant introducing and the maximum is observed in the case of its gradual entry. Herewith at the first stage of cadmium uptake the sorption of the metal on the surface of the roots takes place where cadmium mainly localized in rhizodermis, and then the pollutant penetrates into the tissues of the stem according to its translocation factor

In contrast to the traditional black-box approach, detailed investigations of pollutant transport and distribution in plant tissues have given sound understanding of the phytoremediation phenomenon. Such advancements could provide a basis for future improving the efficacy of the biological remediation processes.

Modelling fluid-mineral equilibria in two-phase fluid systems

YU. V. SHVAROV[1], E. N. BASTRAKOV[2]*, T.P. MERNAGH[2] AND N. N. AKINFIEV[3]

[1]Moscow State University, Moscow 12345, Russia
[2]Geoscience Australia, Canberra, ACT 2601, Australia (*correspondence: Evgeniy.Bastrakov@ga.gov.au)
[3]IGEM RAS, 119017, Moscow 119017, Russia

There is a demand for modeling fluid-rock interaction in geological systems that contain two fluid phases (e.g., liquid + gas) or experience a transition from supercritical to subcritical state of fluids. The relevant problems include CO_2 sequestration into geological formations; exploitation of gas-rich geothermal systems; quantification of metal transport by low-density fluids in porphyry, epithermal, and lode-gold mineral systems. Modelling of geochemical processes in these systems requires software that allows simultaneous prediction of the accurate phase composition of the fluid part of the system and "conventional" water-rock or gas-rock equilibria. Recent experimental and theoretical studies start to provide thermodynamic models to expand these calculations into the realm of metal bearing fluids [1].

To adress these challenges, we employ the HCh software package [2] that uses the Gibbs Free Energy minimization approach for equilibrium calculations. To calculate fluid-fluid equilibria, we have incorporated a customised version of the PRSV equation-of-state [3], where thermodynamic properties of *pure water* at a given temperature and pressure are calculated according to the comprehensive Haar-Gallagher-Kell model [4]. The incorporated algorithms were calibrated and tested against available experimental and theoretical data for the binary H_2O-CO_2 and H_2O-CH_4 systems, and the ternary H_2O-CO_2-CH_4 system.

A practical application of the software to economic geology problems is illustrated by calculation of H_2S concentrations in a supercritical fluid and subcritical gas and liquid phases in equlibrium with mineral assemblages contaning iron sulfides and oxides. An equilibrium between pyrite-pyrrhotite mineral pair and the H_2O-CO_2-CH_4-H_2O-H_2S-H_2 fluid offers a plausible explanation of the H_2S concentrations measured in the vapor-rich inclusions from the Missouri lode gold deposit.

Hg as a proxy for volcanic activity during extreme environmental turnover: the K-T boundary

A. N. SIAL[1]*, L. D. LACERDA[2], V. P. FERREIRA[1], R. FREI[3], R. A. MARQUILLAS[4], J. A. BARBOSA[1], C. GAUCHER[5], C. C. WINDMÖLLER[6] AND N. S. PEREIRA[1]

[1]NEG-LABISE and Dept. Geology, UFPE, Recife, Brazil (*correspondence: sial@ufpe.br)
[2]LABOMAR, UFC, Fortaleza, Brazil
[3]Inst. Geogr./Geol., Univ. of Copenhagen, Denmark, 1350
[4] Univ. Salta, Salta, Argentina
[5] Fac. Ciencias, Univ. de La Republica, Montevideo, Uruguay
[6]Dept. Chem., UFMG, Belo Horizonte, Brazil

Hg tends to concentrate in sediments deposited right after major glacial events as a result from leaching of volcanogenic Hg from land surface and accumulation along argillaceous sediments. Low geological background concentrations of Hg makes it suitable for identifying accumulation pulses during sedimentation that can be tentatively related to weathering processes and thus to climatic changes. Intense volcanism was, perhaps, responsible for climatic changes, decrease in biodiversity and mass extinction in the K-T boundary (KTB).

We have used Hg as a proxy for volcanic activity and atmospheric Hg and CO_2 buildup across the KTB in the Yacoraite Fm., Argentina, where Hg up to 250 ng.g^{-1} has been found. In drill cores across the KTB in the Paraiba Basin, NE Brazil, Hg also increased from late Maastrichtian to early Danian. Hg spikes predating the KTB are, perhaps, the record of volcanic activity very close to this transition. At Stevns Klint, Denmark, Hg contents reached ~ 250 ng.g^{-1} within a clay layer that comprises the KTB, and exhibits marked $^{87}Sr/^{86}Sr$ positive excursion and $^{206}Pb/^{204}Pb$ and $^{187}Os/^{188}Os$ (t = 65Ma) negative ones. Highest Hg values in the Yacoraite Fm. and at Stevns Klint (~250 ng.g^{-1}) are similar to volcanogenic Hg contents in Neoproterozoic cap carbonates (~ 280 ng.g^{-1}), deposited in the aftermath of Snowball glaciation, a comparative extreme environmental turnover, in absence of meteorite impact. Co-variation between Hg and Al_2O_3 is observed in all studied sections suggesting that Hg is adsorbed onto clays. Thermo-desorption experiments in samples from the Yacoraite Fm. showed Hg^{+2} as the major species present, in agreement with a volcanic origin. Combined Hg and C-isotope stratigraphies may become a powerful tool for the eventual assessment of the role of volcanic activity during extreme climatic and biotic events, such as those during the Cretaceous-Tertiary or Permian-Triassic boundaries.

The age of eclogitisation underneath the Kaapvaal craton – A composite xenolith from Roberts Victor

M. SIEBER*, G.P. BREY, H.-M. SEITZ, A. GERDES AND H.E. HOEFER

Institut für Geowissenschaften, Goethe-Universität, Altenhöferallee 1, D-60438 Frankfurt, Germany; *melanie-sieber@stud.uni-frankfurt.de

We have studied a composite, 16x11x5 cm sized, bimineralic eclogite xenolith (texturally Type II) from the Roberts Victor diamond mine (South Africa) with a 1 cm thick layer along its longer side of green, Cr-rich cpx with exsolution lamellae (presumably opx which is now completely replaced by calcite) plus a Cr-rich garnet (up to 6 wt% Cr_2O_3) which gradually change into the dark coloured cpx's (without exsolution lamellae and heavily altered in places) and Cr-free garnets in the major part of the eclogite. Electron microprobe traverses across the xenolith show that the individual mineral grains (~4 mm in size) are homogeneous but that there is a gradient of mineral compositions from the Cr-rich layer into the Cr-free part which appears like a diffusional gradient. For example, Al_2O_3 in garnet increases from 18 to a constant level of 23 wt% over a distance of 3 cm and Cr concomitantly decreases from 6 to practically zero wt%. The Mg-value increases over the same distance from 50 to 57. Clinopyroxenes change in composition complementary to the garnets. This concomitant change also holds for the trace elements which were determined by laser ablation ICP MS. The grt-cpx partitioning of the trace elements is the same throughout the xenolith except for a dependency on the Cr-content of garnet.

The temperature of 915 °C of last equilibration were calculated with the Krogh 1988 grt-cpx thermometer at 4.2 GPa.

We interpret the compositional profile as the reflection of the passage of a basaltic melt through peridotite. A contact zone with Cr-rich cpx and a compositional gradient was formed and the whole package was subsequently metamorphosed to eclogite. The aim is to determine the age of eclogitisation with the Sm-Nd and Lu-Hf isotope systems from garnet separates obtained from rock slices parallel to the Cr-rich layer.

Molybdenum isotope fractionation in the Great Artesian Basin, Australia

C.SIEBERT[1]*, P. POGGE VON STRANDMANN[2] AND K. BURTON[3]

[1] GEOMAR, Helmholtz Center for Ocean Research, Kiel, Germany
[2] Univ. of Oxford, Dept. of Earth Sciences, Oxford, UK
[3] Univ. of Durham, Dept. of Erath Sciences, Durham, UK
* (correspondence: csiebert@geomar.de)

Over the last decade, Molybdenum (Mo) isotopes have become a valuable proxy for redox conditions in marine sediments. More recently, the behavior of Mo and its isotopes during weathering and erosion have been investigated to constrain inputs to the oceans. This study aims to investigate another aspect of terrestrial Mo cycling, namley its behavior in groundwater aquifers. Recent studies suggest that groundwater input could have a significant impact on oceanic elemental and isotopic budgets. Concentrations and isotope compositions of elements in groundwater are ususally controlled by the recharging water (e.g. precipitation) and processes within the aquifer such as chemical weathering. We investigated these processes for Mo in the Australian Great Artesian Basin (GAB), the world's largest confined aquifer underlying ~22% of the Australian continent. The GAB consists of alternating layers of waterbearing sandstone aquifers and non-waterbearing siltstones and mudstones. The thickness of this sequence varies from less than 100 metres at the Basin edges to 3000 metres in the centre. Groundwater in the GAB flows generally west and south with a flow rate between 1 and 5 m/a. Recharge occurs by rainfall into outcropping sandstone along the eastern margins of the Basin. Samples are from the eastern portion of the GAB and range in age from 36 (close to the recharge area) to 700 kyr over a distance of 600 km along the flow of the groundwater.

Molybdenum concentrations and iotopes vary widely throughout the sampled area ([Mo]: 0.4 to 13 ppb and δ^{98}Mo: -0.2 to 1.4 ‰). The isotopes show correlations with [U] and [SO_4], but are not or only weakly correlated with [Mo], [Mn], [Fe] or δ^7Li. The observed patterns point to fractionation of Mo isotopes by a sequestering mineral phase. A systematic change of Mo isotope values with distance from the recharge area indicates that the size as well as the processes within the aquifer could impact the isotope composition of groundwater input to the oceans. The results emphazise the role of groundwater processes for the fractionation of Mo isotopes. However, the quantitative impact of this fractionation on the ocenic budget remains to be determined.

Experimental study of accretion and early differentiation of the Earth

JULIEN SIEBERT[1]*, JAMES BADRO[2], DANIELE ANTONANGELI[1] AND FREDERICK J. RYERSON[3]

[1]Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie, Paris, France (*correspondence: julien.siebert@impmc.upmc.fr)
[2]Institut de Physique du Globe de Paris, Paris, France
[3]Lawrence Livermore National Laboratory, California, USA

The pattern of siderophile (iron-loving) element abundance in the silicate portion of the Earth is a consequence of metal separation during core formation. Thermodynamic expressions used to constrain the metal-silicate partitioning behavior of siderophile elements are mainly established from large volume press experiments that do not cover the full range of potential P-T conditions for core-mantle equilibrium. Using the laser-heated diamond anvil cell technique, we have extended metal-silicate partitioning measurements to 75 GPa and 4400 K, exceeding the liquidus temperatures for both metal and silicate and, therefore, achieving thermodynamic conditions directly equivalent to the full range of P-T conditions relevant to metal-silicate equilibration at the base of a deep magma ocean. Partitioning results obtained for siderophile elements (Ni, Co, V, Cr, Mn, Nb) and light elements (Si, O) are used to constrain a mechanism for terrestrial accretion and core formation reconciling the observed mantle concentrations of V, Cr and geophysical constraints on light elements in the core. The experiments were performed in the P-T ranges of 35-74 GPa and 3100-4400 K. The metal-silicate partition coefficients for nickel and cobalt decrease with increasing pressure and reach the values required to yield present mantle concentrations at ~50 GPa [1]. Enhanced solubility of oxygen in the metal perturbs the metal-silicate partitioning of V and Cr, precluding extrapolation of previous results (Siebert *et al*. 2013). We will present new continuous core formation models for different redox paths showing that terrestrial accretion under highly reduced conditions as proposed by most core formation models [3, 4] could be reconsidered.

Heat producing element enrichment in granitic rocks & zircon Hf isotopic constraints on crustal evolution in NE Queensland, Australia

C.SIEGEL[1,3]*, S.E. BRYAN[1,3], C.M. ALLEN[1], D.J. PURDY[2] AND D.A. GUST[1]

[1]EEBS, Queensland University of Technology, Australia (*correspondence:c.siegel@qut.edu.au)
[2]Geological Survey of Queensland, Australia
[3]QGECE, The University of Queensland, Australia

The primary processes causing enrichment of incompatible Heat Producing Elements (HPE; U, Th & K) in granitic rocks are still poorly understood and are topical in light of increasing interest in engineered geothermal systems. Differentiation of the continental crust, through successive events of granitic magmatism, is expected to lead to a HPE-enriched upper crust and a depleted lower crust. In such a closed system crust model, younger granitic rocks should be more isotopically evolved. Instead, our study of granitic rocks, emplaced within a relatively restricted area (~200x100km), reveals a paradox: isotopic systems become more primitive over time, but HPE concentrations are more elevated. The study area has had ~360 Myr history of granitic magmatism with mainly I- to minor A-type granitic rocks of Carboniferous, Permian, Triassic, Cretaceous & Tertiary age.

Long-term compositional trends are recognised: modal mineralogy and bulk-rock composition record enrichment of K-feldspar and the increase of HPE concentration from the Permo-Carboniferous to the Cretaceous. In contrast, new MC-ICP-MS zircon Hf isotope data indicate secular changes to bulk crustal source compositions. Triassic (εHf: +4.9 to +8.5) and Cretaceous (εHf: +8.3 to +10.8) zircons are generally more isotopically primitive compared to Permo-Carboniferous (εHf: -7.3 to +1.2 & +3.6 to +9.8) and Tertiary (εHf: +0.5 to +5.1) zircons. The restriction of more isotopically primitive zircons in Triassic and Cretaceous rocks does not favor the model of a simple differentiated crust but rather an open crust system and progressive basification of the lower crust. Paradoxically, the isotopically primitive Mesozoic intrusions are also the most compositionally evolved, and have the highest HPE enrichments. To explain this, we interpret that fluid fluxing associated with a subduction-related contractional event in the Late Permian-Triassic was important for fertilising the lower crust and enriching it in HPE. This overcame the effects of basification by underplating during earlier back-arc extensional events. Cretaceous-Tertiary intraplate igneous events then provided important catalysts for more typical crustal differentiation.

Hydraulic and geochemical survey of the lithium-resources in the Salar de Uyuni (Bolivia)

ROBERT SIELAND*, NADJA SCHMIDT AND BRODER MERKEL

TU Bergakademie Freiberg, Department of Hydrogeology, D-09599 Freiberg, Germany (*correspondence: Robert.Sieland@geo.tu-freiberg.de, Nadja.Schmidt@geo.tu-freiberg.de, Broder.Merkel@geo.tu-freiberg.de)

The Salar de Uyuni, located in the southern Altiplano of the Bolivian Andes, is the largest salt flat in the world (10,000 km², 3,653 m a.s.l.). Its alternating sequence of salt, mainly composed of halite, and lacustrine sediments contain a brine which is highly enriched in lithium (up to 4.7 g/L) among other elements [1]. Moreover, it is considered to be the largest lithium-brine deposit in the world.

Between 2009 and 2012 exploration drillings which completely penetrate the upper salt layer (with a maximum thickness of 11 m) as well as brine sampling were conducted at various sites on the salt flat. Porosity measurement of salt cores was realized gravimetrically on dried (70°C, until $\Delta_{weight\ loss} < 1\%$) core samples. Additionally, X-ray tomography on selected core samples was used to verify porosity results. Geochemical analyses on brine samples were conducted using ICP-MS.

Porosity data showed large horizontal differences of the salt crust. While the uppermost two meters of the salt are characterized by total porosities between 25 and 40%, deeper parts of the salt crust showed significantly lower porosities between 5 and 18%. Chemical analyses revealed an inhomogeneous distribution pattern for different elements. Among others, highest lithium concentrations were found close to the main tributary in the south as well as in a small fringe in the north of the salt flat.

Using stratigraphic information from drill cores, porosity data as well as the distribution pattern of lithium concentrations in the brine, a conceptual model was developed in order to estimate the total volume of brine occurring in the salt flat as well as the lithium-resource. The total amount of lithium in the Salar de Uyuni is estimated to around 6.6 million tons. This is in contradiction to previous publications [1, 2] which assume the lithium-resources to be about 35% higher.

Ca, Mo and U isotopes suggest Neoproterozoic-like ocean conditions during the Late Permian Mass Extinction

SILVA-TAMAYO, J.C[1], PAYNE, J.L.[1], WIGNALL P.B.[2], NEWTON R.J.[2], NEUBERT, N.[4], BRUESKE, A.[4], EISENHAUER A.[3], WEYER, S[4], FIETZKE, J.[3] AND MAHER, K[1].

The most catastrophic extinction event in the history of animal life occurred at the end of the Permian Period, ca. 252 Mya. Ocean acidification and global oceanic euxinia have each been proposed as causes of this biotic crisis, but the magnitude and timing of change in global ocean chemistry remains poorly constrained.

Here we use Ca, Mo and U isotopes applied to globally distributed, well dated late Permian- early Triassic sedimentary sections to better constrain the magnitude and timing of change in ocean chemistry through this interval. All the investigated carbonate successions (Turkey, Italy and China) exhibit decreasing $\delta^{44/40}$Ca compositions, paralleling a major decrease in δ^{13}C values. These findings support an episode of ocean acidification coincident with the major biotic crisis. The Mo and U isotope records exhibit significant rapid negative anomalies at the onset of the main extinction interval, suggesting rapid expansion of anoxic and euxinic marine bottom waters during the extinction interval. The rapidity of the isotope excursions in Mo and U suggests substantially reduced residence times of these elements in seawater relative to the modern, consistent with expectations for a time of widespread anoxia. The large C-isotope variability during the early Triassic, which is similar to that of the early-middle Cambrian, suggests imply largely biogenetically controlled perturbations of the oceanic carbon cycle. These findings strengthen the evidence for a global ocean acidification event coupled with rapid expansion of anoxic zones as drivers of end-Permian extinction in the oceans.

Shiveluch volcano: Mineralogical records of geodynamic complexity

SIMAKIN A.[12*], SALOVA T.[2], GORDEYCHIK B.[2] AND CHYURIKOVA T.[3]

[1]Institute Physics Earth, Moscow Russia, simakin@ifz.ru
[2]Institute Experim. Mineral., Chernogolovka, Russia
[3]Inst. Volcanol. Seism., Petropavlovsk-Kamchatskii, Russia

Shiveluch is the most north active andesite volcano on Kamchatka. Several types of magmas mix and interact in Shiveluch magmatic system. There are only two centres of the basaltic eruptions on Shiveluch. Olivine-plagioclase basalts form dyke complex of the NW orientation on the northern edge of caldera. Second centre was found recently on the western slope of volcano. Complex structure of the magma localization in the thick crust of Northern Kamchatka is revealed by the seismic tomography (Lees *et al*., 2007). Contrasted low Vp zones are traced at the depths 5-7, 13-17, 25-30 km with horizontal dimensions up to 100 km larger than typical intervolcano distances. Results of the magmatic amphibole barometry (new barometer-Simakin *et al*.,2012a) also clustered around three observed geophysically levels. Detailed mineralogical study of two types of Shiveluch basalts demonstrates heterogeneity of the whole rock and even individual crystals. Oxygen fugacity estimates with clinopyroxen geo-oxobarometer (Simakin *et al*., 2012b) yield bi-modal distributions with fO_2 around NNO+1(0.5) and NNO+1.6(2.5). Second maximum is close to the high fO_2 estimates (c.a. NNO+2) typical for the high pressure (up to 10-11 kbar) amphiboles.

Compositions of Holocene volcanites around Shiveluch on SiO_2-Ba diagram are separated into several evolutionary series with different initial Ba content. The upper SiO_2-Ba set (Sedanka volcanic centre with several Shiveluch compositions) on the Th/Yb – Nb/Yb diagram adjoins decompressional mantle partial melts array. These magmas presumably originate at the mantle upgoing flow near the subducting plate edge. Low Ba basalts (Baidarnaya centre) belong to the Bezymianny-Klyuchevskoy volcanoes compositions set forming on the Nb/Yb – Th/Yb diagram vertical array between normal IAB and N-MORB compositions. Effective melting of the underpated thick continental crust near the Moho depth produces oxidized siliceous amphibole-bearing magmas of adacite affinities. These three components mix and undergo crystallization differentiation before being erupted on Shiveluch.

Ni sorption at the Particle Edges of Synthetic and Biogenic Birnessite

ANNA A. SIMANOVA[1]*, SHARON E. BONE[2], JOHN R. BARGAR[3], GARRISON SPOSITO[2] AND JASQUELIN PEÑA[1]

[1]University of Lausanne, Switzerland, (*correspondence: anna.simanova@unil.ch, jasquelin.pena@unil.ch)
[2]Lawrence Berkeley National Laboratory, Berkeley, USA sbone@lbl.gov, gsposito@berkeley.edu
[3]Stanford Synchrotron Radiation Lightsource, Menlo Park, USA, bargar@slac.stanford.edu

Biogenically produced manganese oxides play an important role in trace metal scavenging in the environment. The metal sorption capacity of the Mn oxides arises mainly from the presence of negatively charged Mn(IV) vacancy sites in the MnO_2 sheets. For example, recent extended X-ray absorption fine structure (EXAFS) studies showed that Ni binds to vacancy sites in biogenic Mn oxides via two preferential coordination geometries: as a triple-corner-sharing complex (Ni-TCS) at circumneutral pH and a mixture of Ni-TCS and Ni incorporated into the MnO_2 sheet at higher pH [1,2]. However, under-coordinated oxygen atoms at particle edges offer additional sites for metal coordination. Metal sorption by particle edges has been reported for chemically synthesized birnessites, but is poorly understood for biogenic minerals where the admixing of organic and mineral functional groups in these microbe-mineral assembalges may modify the reactivity at the particle edges.

In this work, we used δ-MnO_2 as a synthetic analog of biogenic birnessite to study the reactivity of the birnessite edge since it has fewer vacancies and contains no biomass. We studied adsorption of Ni at the surface of δ-MnO_2 as a function of pH and surface loadings using a combination of wet chemistry methods and Ni K-edge EXAFS spectroscopy and compared these data to Ni adsorption at the surface of the biogenic birnessite produced by *Pseudomonas putida* strain GB-1 [1]. At pH 8 the surface speciation and reactivity of δ-MnO_2 was similar to biogenic birnessite, while at lower pH values we detected an additional surface species that likely formed at the particle edges of δ-MnO_2. The absence of this species in biogenic birnessite suggests that the bacterial cells and extracellular substances decrease the reactivity of the the particle edges of biogenic MnO_2.

Lithium in HED meteorites – Implications for planetary crusts

M.ŠIMČÍKOVÁ[1], T. MAGNA[1] AND F. MOYNIER[2]

[1]Czech Geological Survey, Klárov 3, CZ-11821 Prague, Czech Republic; tomas.magna@geology.cz
[2]Dept. Earth Planetary Sciences, Washington University, St. Louis, MO 63130, USA

The Li contents and isotope compositions are presented for a suite of howardites, eucrites and diogenites (HEDs) thought to originate from asteroid Vesta. The Li contents show notable differences between Li-poor diogenites and Li-rich eucrites whereas howardites have moderate Li contents. Contrary to elemental differences, Li isotope compositions are irresolvable among the individual groups of HEDs, attesting to insignificant Li isotope fractionation during formation of thick basaltic crust by melting of Vesta's mantle.

Several observations are derived. (i) All HEDs span an extremely narrow δ^7Li range (2.2–4.9‰), except for LAP 03569 and Cachari. This asteroidal homogeneity is surprising provided that Vesta experienced core segregation, magma ocean and solidification, and thermal metamorphism some of which could fractionate Li isotopes. The derived bulk mean δ^7Li of Vesta is 3.7 ± 1.1‰ (2σ) which is within the range of the mean δ^7Li values derived for the Earth (~3.3‰), Mars (~4.0‰) and the Moon (~4.1‰). (ii) Ordinary chondrites, considered to represent the bulk composition of Vesta, are on average isotopically ~1‰ lighter than HEDs while δ^7Li values of carbonaceous chondrites fall within the range of HEDs. (iii) Oxygen isotopes in Pasamonte hint to its origin from another parent body than the other HEDs. However, proximity of its δ^7Li provides strong evidence for rapid magmatic evolution and basaltic crust differentiation on other bodies akin to Vesta. This implies the existence of planetary embryos in the infancy of the Solar System that were large enough to sustain large-scale magmatism and yet preserving Li isotope compositions intact during their ephemeral magmatic histories. (iv) Unlike Fe isotopes, δ^7Li of Stannern-trend eucrites do not differ from the main group eucrites implying no particular Li isotope difference of residual enriched melts that were involved in their genesis. (v) No elemental Li depletion is recorded in HEDs relative to chondrites which is contrary to other volatile elements such as Zn or Cd that experienced massive loss. This suggests effective retaining of Li in Vesta despite its later impact history which is compatible with moderately volatile behavior of Li at high temperatures and/or during planetary melting. Thus, the lack of evolved crustal rocks and prevalence of 'juvenile' basaltic lavas at asteroidal levels may be discerned with Li.

The importance of iron mobility in magmatic-hydrothermal systems

ADAM SIMON[1]*, LAURA BILENKER[1] AND AARON BELL[2]

[1]Earth & Environmental Sciences, University of Michigan [*simonac@umich.edu]
[2]Institute of Meteoritics, University of New Mexico

Iron is a ubiquitous component of arc-related magmas and porphyry-, high-sulfidation, iron-oxide-copper-gold (IOCG), and iron-oxide-apatite (IOA) ore deposits. Iron is present as an essential structural constituent in ferromagnesian silicate minerals, magnetite, sulfide crystals, and sulfide liquids, as well as aqueous fluids that exsolve from silicate melt. The observation that the oxidation state for different arc magma systems varies over approximately five orders of magnitude, from approximately one log unit below the FMQ (fayalite-magnetite-quartz) buffer to the HM (hematite-magnetite) buffer, indicates that iron exists in both ferrous and ferric forms in most arc magmas. The valence of iron is proportionally dominanted by Fe2+ in most common ferromagnesian silicate minerals, is 2/3 Fe3+ and 1/3 Fe2+ in magnetite, is Fe2+ in sulfides, and is Fe2+ in Cl-bearing aqueous fluid. Interestingly, there does not appear to be a sliding scale for the oxidation state of iron in aqueous fluids, in contrast to silicate liquids The observation that aqueous fluids contain only a single valence state of Fe across five orders of magnitude of fO2 space is fundamentally different than sulfur, which exists as both H_2S and SO_2 in aqueous fluid and the relative proportion of each is dictated by the fO2 of the system. These observations have critical implications for magmatic systems.

We continue to investigate experimentally the importance of the mass transfer of iron from melt to aqueous fluid, and the many reactions among aqueous fluid, silicate melt, magnetite, and sulfide phases. Our data confirm field-based hypotheses that the transfer of iron from melt to aqueous fluid increases the ratio of Fe3+ / Fe2+ in the degassed melt. This has implications for the composition of ferromagnesian silicates and the stability of sulfide phases during degassing. The mass transfer of iron affects the oxidation state of sulfur in the melt, driving sulfur from sulfide to sulfate, which in turn has implications for the mass transfer of ore metals (Cu, Au) from melt to aqueous fluid. This also may affect the fractionation of iron isotopes, and their ability to serve as geochemical fingerprints for source reservoirs of iron in IOCG and IOA deposits. We will present new data and discuss the incredible role that iron plays in moderating phase equilibria of silicate magmas, and the potential use of iron isotopes to assess the evolving oxidation state and source reservoir characteristics of arc magmas.

Insight to the local melt structures and their influence on the fractionation of rare earth elements (La, Gd, Yb, Y)

S.SIMON[1]*, M. WILKE[1], S. KLEMME[2], W. A. CALIEBE[3], R. CHERNIKOV[3] AND K. O. KVASHNINA[4]

[2] Westfälische Wilhelms-Universität, Münster, Germany
[3] Deutsches Elektronen-Synchrotron, Hamburg, Germany
[4] European Synchrotron Radiation Facility, Grenoble, France

Knowledge of the local structure around rare earth elements (REE) in aluminosilicate melts is of great interest for the geochemistry of magmatic processes, particularly for understanding the partitioning of REE between melt and the coexisting crystals in a more comprehensive way. Several studies already proposed a significant influence of the melt composition on REE fractionation [1 – 4]. In a fundamental study Ponader & Brown [5] showed that the local environment around La, Gd and Yb changes with polymerization of the melt, this was used to explain differences in element partitioning. However, no direct correlation between partitioning data and structural informations was provided.

In this study, melt compositions taken from Prowatke & Klemme [4] and various halpogranitic, -basaltic compositions were doped with La, Gd, Yb or Y and synthesized as glass. EXAFS was used to gather quantitative information on the local environment of Gd, Yb and Y and XANES for qualitative information on the local environment of La in the glasses. Additional high temperature (HT) in situ Y-EXAFS was performed to prove, if the local structure of Y above T_G corresponds to the local structure in the quenched melts. Analysis of the EXAFS data shows that the average bond length, the width and skewness of the REE-O pair distribution function increase with increasing polymerization of the melt for Gd, Yb and Y [6]. XANES spectra confirm a similar trend for La. The HT Y-EXAFS shows no significant change of the local structure above T_G. Finally, correlations of structural parameters and partitioning data from Prowatke & Klemme [4] were obtained.

Oxygen isotope fractionation in formation of CO_2

D. SIMONE[1]*, L.M.T. JOELSSON[2]*, C. JANSSEN[1] AND M.S. JOHNSON[2]

[1]LPMAA, UMR 7092 UPMC/CNRS, Paris, France [daniela.simone@etu.upmc.fr]
[2]Department of Chemistry, University of Copenhagen, Denmark [joelsson@chem.ku.dk]
*DS and LMTJ contributed equally to the work.

The discovery of mass independent isotope fractionation (MIF) of oxygen isotopes [1] opened a new dimension in environmental research. Much subsequent research has focused on isotope effects in ozone formation [2,3]. Despite the apparent similarity to formation of ozone, relatively little attention has been given to the possibility of MIF in the formation of CO_2 through the reaction $CO + O(^3P) + M \rightarrow CO_2 + M$ [4]. A better understanding of the isotope fractionation in CO_2 may give insights into mechanisms of MIF.

The photochemical reactor at the Copenhagen Centre of Atmospheric Research [5] was used to study the reaction $CO + O(^3P) + M \rightarrow CO_2 + M$ experimentally. $O(^3P)$ radicals where obtained from photolysis of O_3 in the visible region. The use of ordinary commercial LED lamps ensured that no $O(^1D)$ and subsequently no OH was formed. An enriched sample of CO (90% $^{13}C^{16}O$, 10% $^{13}C^{18}O$, trace amounts of $^{13}C^{17}O$) was used to distinguish the reaction of interest from possible fluctuations in the background concentrations of ^{12}CO and $^{12}CO_2$ in the reactor. Infrared spectra were recorded with a Bruker IFS 66v/s Fourier Transform Infrared spectrometer. The spectra were analysed using the non-linear least squares algorithm MALT [6]. Experiments were conducted at pressures ranging from 200 to 980 mbar and the isotope chemical kinetics has been modelled using the chemical kinetics software package KPP [7]. Isotope effects were calculated as: $\alpha_n=\{\ln([C^nO]_{t=0}/[C^nO](t)\}/\{\ln([C^{16}O]_{t=0}/[C^{16}O](t)\}$. We present first results, which show unusual ratios of $(\alpha_{17}-1)/(\alpha_{18}-1)$. However, as in earlier experiments [4], unambiguous assignment of this MIF is complicated by the presence of side reactions.

Estimating uncertainties in base cation weathering rates according to mass balance

MAGNUS SIMONSSON[1]*, JOHAN BERGHOLM[2], BENGT OLSSON[2] AND INGRID ÖBORN[3]

[1]Dep. of Soil and Environment, Swedish University of Agricultural Sciences (SLU), P.O. Box 7014, S-750 07 Uppsala, Sweden (*correspondence: magnus.simonsson@slu.se)
[2]Dep. of Ecology, SLU, Uppsala
[3]World Agroforestry Centre, Nairobi, Kenya

Because forestry is often allocated to soils with low weathering capacity, intensive harvesting practices may deteriorate plant nutrition. Reliable estimates of weathering rates are therefore crucial in analyses of sustainability of, e.g., whole-tree and stump harvesting. By the mass balance approach present base cation cycling may be estimated from data on leaching, deposition, and accumulation in biomass and soil. Insight in the uncertainties in the weathering estimates is crucial for the interpretation of the data.

Weathering rate of:	Ca	Mg	K	Na
	(kg ha^{-1} yr^{-1})			
Average	4.0	1.4	3.3	-3.3
Conf. int.	±3.8	±1.6	±4.4	±15

Table 1: Average weathering rates and approximate confidence intervals (ca 95% level) based on spatial variability and uncertainties in allometric functions etc.

Term in balance	Ca	Mg	K	Na
Deposition	8%	43%	2%	26%
ΔK_{exch}	3%	5%	1%	0%
Leaching	4%	28%	0.4%	74%
Biomass accumul	86%	25%	97%	0%

Table 2: Contributions to overall uncertainty in weathering rates according to soil balance.

The present study was carried out in a Norway spruce (*Picea abies* Karst. (L.)) stand on a podzolic soil in SW Sweden. The results pinpoint the difficulty in assessing low weathering rates in general (Table 1), and demonstrates that the influence of the different terms of the balance varies considerably among the different base cations (Table 2). Details of the uncertainty contributions in the different terms of the balance is shown on a poster with the same title.

[6]Civil Engineering Department, Monash University, Clayton, Melbourne, Australia, 3800

Group of thermal and cold springs in Hazaribagh District, Jharkhand with temperatures from 32 to 90 °C and 25 to 27 °C respectively. Three thermal springs and two cold springs are located at Surajkund area, and one thermal spring in Katkamshandi village 15 km from the main town. Theses springs are located in the Archean Chotanagpur Gneissic Complex (CGC) in the eastern part of Peninsular India. pH of the thermal water ranges from 8.3 to 9, which indicates the springs are alkaline in nature. The water types of thermal springs and cold spring are Na-Cl-SO_4 type. Piper diagram suggests that the geothermal waters circulating through the granitic host rocks have their chemistry compatible with that of the host rock. Since the HCO_3 to Cl ratio is less than one suggest that thermal water is believed to be fast ascending without any major mixing with near surface groundwater but for mild to moderate dilution with groundwater. However anion variation shows sifting toward the SO_4 field suggesting addition of SO4 from ancient volcanic rocks of the region (Rajmahal volcanics). Mineral saturation index suggest that thermal water is saturated with silica. Two thermal springs of Surajkund area having similar Na/K ratios indicates that they are fed by the same reservoir. Estimated reservoir temperature based on chemical geothermometers is in the range of 150 to 210 °C.

Dissolved barium distribution and cycling in the Bay of Bengal

SATINDER PAL SINGH[1]* AND SUNIL KUMAR SINGH[2]

[1]Physical Research Laboartory, Ahmedabad, India, satinder@prl.res.in (* presenting author)
[2]Physical Research Laboartory, Ahmedabad, India, sunil@prl.res.in

Eight depth profiles of dissolved barium concentrations have been measured in the Bay of Bengal (BoB) along the 87°E transect (~6°N to ~21°N) to track the dispersion of its large influx from the Ganga–Brahmaputra (G–B) river system and the outflow to the equatorial Indian Ocean. A typical Ba concentration–depth profile shows relatively higher Ba concentrations in surface waters (depth ≤5 m) followed by a minimum in the depth interval ~50–150 m and a further increase with depth. The Ba data in the upper layers (depth <100 m), excluding a very high Ba ~112.8 nmol/kg at salinity 24.5 near mouth of the Hooghly estuary, show a North–South trend with a strong and significant inverse correlation with salinity (R^2 = 0.75; P <0.0001). This indicates the southward flow of dissolved Ba from the G–B river system that also includes its contributions by particle release and SGD. The subsurface Ba minimum is ubiquitous and most probably is a result of Ba uptake on settling particulates. On the other hand, the Ba concentrations in deep waters (depth ≥500 m) is controlled dominantly by water mixing as suggested by a very strong and significant inverse correlation with salinity (R^2 >0.95; P <0.0001). Exceptions to this conservative behavior are the "hot-spots" of dissolved Ba in bottom waters, which are resulted by the dissolution of sediments at and/or below the sediment–water interface.

Attempts were made to budget the Ba abundance in the Bay of Bengal using a two box model approach, surface (top ~100 m) and deep waters (below ~100 m). Under the steady state the annual Ba influx from the Ganga–Brahmaputra river system seems to be balanced through its removal via sinking particulates as a result there is no lateral outflow of dissolved Ba from the G–B to the equatorial Indian Ocean through top ~100 m of the BoB. Most of this sinking particulate Ba (~95 %) is regenerated again in the lower box, preferentially in the intermediate waters ~100–500 m.

Diffusion-driven isotopic fractionations in olivine in laboratory and natural settings

C.K. SIO[1] M. ROSKOSZ[2], M. CHAUSSIDON[3], N. DAUPHAS[1], R. MENDYBAEV[1], F. RICHTER[1], AND F.-Z. TENG[4]

[1]The University of Chicago, (ksio@uchicago.edu)
[2]Université de Lille 1, France
[3]CNRS-CRPG, Nancy, France
[4]University of Washington

Our previous *in situ* measurements of a zoned olivine from Kilauea Iki lava lake revealed large and negatively-coupled Mg-Fe isotopic fractionations [1]. We estimated the relative diffusivities of the isotopes of Mg and Fe in olivine, scaled as $D_1/D_2 = (m_2/m_1)^{\beta}$, with β_{Fe} ~0.25 and β_{Mg} ~0.15 for an olivine zoned from Fo_{80} to $Fo_{83.6}$.

Olivine diffusion experiments were run with the goal to quantify β-values and to compare them with the values estimated from the natural sample. In each experiment, crystallographically oriented Fo_{100} (synthetic) and Fo_0 (Rockport fayalite) crystals were placed in an alumina crucible, held together by gravity, and the rest of the crucible was hand-packed with FeO powder. A total of six crucibles were placed together in the hot spot of a gas-flowing furnace at the Université de Lille 1. Each pair of crucibles were quenched at a time by moving them to a cold spot in the furnace after 10 and 20 days; all crucibles were taken out of the furnace after 30 days. Contacts were made across some Fo_{100}-Fo_0 and all Fo_{100}-FeO interfaces. The Fo_{100}-Fo_0 profiles were fitted using the diffusion equation of [2], while that of Fo_{100}-FeO required slower diffusion coefficients.

The longest profile (Fo_{100}-Fo_0, 30 days, diffusion along c-axis) was analyzed for its Mg isotopic compositions using SIMS (IMS 1280) at CRPG, Nancy. Matrix standards (Fo# 6, 16, 64, 76, 79, 85, 90, and 95) were previously measured by solution for their δ^{26}Mg, and were used to monitor matrix effects. We find that matrix correction is critical in obtaining accurate β-values and that more matrix standards may be required. Our preliminary data shows > 10 ‰ fractionation in δ^{26}Mg, which suggests a β_{Mg} of about 0.1 or less in olivine.

We are currently analyzing more experimental samples and investigating the cause of the apparent discrepancy of the β-value.

[3]Ehime University, Japan (irifune@dpc.ehime-u.ac.jp)

Pyrope-rich garnets of the ultrabasic paragenesis widely abundant as inclusions in diamonds are characterized by significant admixture of the knorringite, $Mg_3Cr_2Si_3O_{12}$, end-member. Such garnets often contain majoritic component, $(Ca,Fe,Mg)SiO_3$, which is an indicator of the sub-lithospheric mantle conditions. Although both components are important for barometry of mantle mineral associations, high-pressure phase relations in the system $MgSiO_3$–$Mg_3Cr_2Si_3O_{12}$ have been not studied yet. In this study we report the first results of experiments on the majorite–knorringite join at 12–25 GPa and 1600 °C aimed on investigation of conditions of the formation, structural peculiarities, and evolution of the composition of Cr-bearing majoritic garnets.

We investigated the full range of starting compositions with steps of 10–20 mol% and 2–3 GPa in multi-anvil experiments, which allowed us to plot the preliminary phase diagram for the system $MgSiO_3$–$Mg_3Cr_2Si_3O_{12}$ and synthesize garnets of a wide compositional range. The phase assemblages for majorite-rich starting materials (<30 mol % knorringite) include garnet, enstatite, and eskolaite (Cr_2O_3). With the increase of knorringite content in the starting composition, garnet + eskolaite association is formed. Typically synthetic garnets contain significant portion of majorite (>15 mol %) even for pure $Mg_3Cr_2Si_3O_{12}$ starting composition. The stability of garnet on the phase diagram is limited by pressure: $MgSiO_3$ ilmenite containing up to 7 wt% Cr_2O_3 appears together with eskolaite at P > 20 GPa. Single-crystal X-ray diffraction studies carried out on the produced garnets demonstrated their cubic symmetry in the studied compositional range and allowed us to study structural peculiarities of garnets. The lattice parameter of garnet (in parentheses) linearly increases with increasing the $Mg_3Cr_2Si_3O_{12}$ component: 11.4725(4) Å ($Mg_{3.88}Cr_{0.24}Si_{3.88}O_{12}$), 11.5187(6) Å ($Mg_{3.58}Cr_{0.84}Si_{3.58}O_{12}$), 11.5445(5) Å ($Mg_{3.38}Cr_{1.24}Si_{3.38}O_{12}$), and 11.5718(1) Å ($Mg_{3.21}Cr_{1.58}Si_{3.21}O_{12}$).

Characterization of indigenous oil field microorganisms for microbially enhanced oil recovery (MEOR)

J.SITTE[1], E. BIEGEL[2], A. HEROLD[2], H. ALKAN[3] AND M. KRÜGER[1]

[1] BGR, Geomicrobiologie, D-30655 Hannover
[2] BASF SE, GVF/H, D-67056 Ludwigshafen
[3] Wintershall Holding GmbH, R&D, D-34119 Kassel

Microbial activities and their resulting metabolites became a focus of attention for enhanced oil recovery (MEOR, microbial enhanced oil recovery) in the recent years. In order to develop a strategy for a MEOR application in a German oil field operated by Wintershall experiments were performed to investigate different sampling strategies and the microbial communities found in these samples. The objectives of this study were (1) to characterize the indigenous microbial communities, (2) to investigate the dependency of microbial activity/diversity on the different sampling strategies, and (3) to study the influence of the *in situ* pressure on bacterial growth and metabolite production. Fluids were sampled at the well head (surface) and *in situ* in approx. 785 m depth to collect uncontaminated production water directly from the reservoir horizon and under the *in situ* pressure of 31 bar (subsurface). In the lab the pressure was either released quickly or slowly to assess the sensitivity of microorganisms to rapid pressure changes. Quantitative PCR resulted in higher microbial cell numbers in the subsurface than in the surface sample. Biogenic CO_2 and CH_4 formation rates were determined under atmospheric and high pressure conditions in the original fluids, with highest rates found in the surface fluid. Interestingly, no methane was formed in the native fluid samples. While nitrate reduction was exclusively detected in the surface samples, sulfide formation also occurred in the subsurface fluids. Increased CO_2 formation was measured after addition of a variety of substrates in the surface fluids, while only fructose and glucose showed a stimulating effect on CO_2 production for the subsurface sample. Stable enrichment cultures were obtained in complex medium inoculated with the subsurface fluid, both under atmospheric and *in situ* pressure. Growth experiments with constant or changing pressure, and subsequent DGGE analysis of bacterial 16S rRNA genes, revealed that the pressure treatment did not affect the bacterial community composition. Our results show that bacteria in the enrichment culture can tolerate pressure changes between atmospheric and *in situ* reservoir pressure, which makes them promising candidates for further MEOR tests. Since substantial differences in microbial activities were observed between the surface and subsurface fluids, the selection of the sampling strategy should also be considered for MEOR research and industrial application.

Uranium accumulation by plants covering piles and dumps in uranium post-mining area in SW Poland

A. SKLODOWSKA[1]*, D. LECH[2] AND D. RUSZKOWSKI [1]

[1]Faculty of Biology, University of Warsaw, Miecznikowa 1, 02-096 Warsaw, Poland; (*correspondence: asklodowska@biol.uw.edu.pl)
[2]Polish Geological Institute, 4, Rakowiecka Street, 00-975 Warsaw, Poland (dariusz.lech@pgi.gov.pl)

The uranium exploration and exploitation in the South-West Poland (Lower Silesia District) had been carried out since 1925 when the first 9 Mg of uranium ore were mined from which 690 mg of radium was extracted and the mining ceased in 1962 (total amount of 704 Mg of U was derived). Nevertheless the old subsurface mines, piles and dumps are still involved in the geochemical cycle of the area. Leaching of uranium and radionuclides may be a serious environmental problem in many countries.

Investigations of the influence of mining activity on the natural environment revealed the local-scale radioactive contamination limited to the dumps and their nearest vicinity at four localities: Kowary-Podgorze, Radoniow, Kopaniec/Kromnow and Grzmiaca. Standard ecological test "MARA" performed on 54 samples of wastes and water taken in 15 localities showed moderate toxicity in 5 waste samples and 1 water sample. Another standard test MicroTox showed minor toxicity in 2 waste samples and did not show ecotoxicity of any water sample.

Accumulation of uranium by plants covering the surface of 5 piles containing the most radioactive wastes (dose 1.94-97μSv/h) was examined. Grasses were found as hyper-accumulator of uranium in all examined places. Maximum uranium concentration 817.15mg/kg d.w. was noted in the roots of fescue (*Festuca* sp.) growing in Kopaniec pile and 178.85 mg/kg d.w. in the roots of meadow grass (*Poa* sp.) growing in Grzmiaca. Aerial parts of these plants contained 10-20 lower concentration of uranium. Dicotyledonous plants accumulate uranium in the roots up to 196.22 mg/kg d.w. and in leaf up to 138.56 mg/kg d.w. (hawkweed in Kopaniec). Hyper accumulation of uranium was noted in mosses (mainly in *Hypnum cupressiforme*) occurring in streams in the nearest vicinity of piles (up to 700mg/kg d.w. in Kowary).

These results clearly show that plants actively participate in uranium geochemical cycling what is important factor in environmental risk assessment and may be valuable indication for planning remediation processes.

New experimental constraints on slab top conditions

S. SKORA[1]*, M. MARTINDALE[1,2], L. CARTER[1,3], J. BLUNDY[1], T. ELLIOTT[1] AND J. PICKLES[1]

[1] Dept of Earth Sciences, University of Bristol, BS8 1RJ (*correspondence: Susanne.Skora@bristol.ac.uk)
[2]Dept of Earth and Ocean Sceinces, University of British Columbia, 6339 Stores Road, Vancouver, BC V6T1Z4
[3] Dept of Earth Sciences, Rice University, 6100 Main Street, Houston Texas, 77005

Subduction zones give rise to arc volcanism because fluids and/or hydrous melts that are released from the slowly heating subducted slab trigger melting in the overlying mantle wedge. The arc geochemical signature points towards a ternary mixture of a melt from subducted sediment, fluid from basaltic oceanic crust and depleted mantle peridotite. The use of the arc geochemical signature in combination with experimental petrology on phase relations, melting and trace element behaviour is therefore key for constraining the P,T,fO_2 conditions in subducted slabs. The aim of this presentation is to place such constrains, using our latest experimental results on subducted sediment and basalt.

A nice example is given by the geochemical signal of the Mariana Arc. Here, the pelagic sediments dominate the incompatible trace element budget over volcaniclastics in the sedimentary column, whereas the volcaniclastics are predominant in the arc geochemical signature. Our study on the melting phase relations of natural volcaniclastic sediments at 3-6 GPa and 800-900°C [1] has revealed that biotite control melting at these conditions in this lithology. The vapour-saturated solidus for volcaniclastic sediments is higher (825-850°C) than in other, phengite bearing marine sediments (700-750°C) at 3 GPa. This trend is reversed at high-pressure conditions (6 GPa) where the biotite melting reaction occurs at lower temperatures (800-850°C) when compared to the phengite melting reaction (900-1000°C). This places tight constraints on slab top temperatures beneath the Mariana Arc at 180 km depth (6 GPa). It must be above the biotite melting reaction (>800°C) but below the phengite melting reaction (<900°C), preventing pelagic sediments from releasing all their incompatible elements into the liquid phase. Another set of experiments using natural altered oceanic crust provide further constrainsts. Here, we find that the elevated Ba/Th ratio characteristic of many (sediment-starved) arc basalts is only generated within a narrow temperature field (800-850°C), above phengite breakdown but below epidote-out.

Micromorphology of diamond resorption at 100 kPa: The role of metal ions

V.L. SKVORTSOVA[1]*, Y.FEDORTCHOUK[2] AND A.A.SHIRYAEV[3]

[1]MSU, Moscow, 119991, Russia (*correspondance: valskvor@yahoo.com)
[2]Dalhousie University, Halifax, B3H 4R2, Canada
[3]IPhCE, RAS, Moscow, 119071, Russia

Natural diamonds show various resorption features produced during ascent in kimberlite magma. Experiments conducted at 100 kPa and 900 °C in KOH melts with constant flow of H_2O vapor or CO_2 gas in the presence of ions of elements common in natural kimberlites (Mg, Ca, Sr, Al, Si, Fe, Cr, Ni, Co, REE) and in mantle minerals (olivine, ilmenite) demonstrated strong catalytic effect of some metal ions on diamond dissolution rate. We report a detailed investigation of micromorphological features induced on diamond surface in these experiments. We examine individually the effects of the oxidizing media, of the catalytic ion, and of the pre-existing defects in diamonds.

The study uses crystals of natural diamonds after loss of 50-80% of the initial weight. Field-Emission SEM and Atomic Force Microscope were used for surface characterisation. It is shown that for the same catalyser ions etching in aqueous fluids leads to smoother surfaces, whereas CO_2-fluids leaves extremely rough surfaces. In presence of the strongest catalysers (Fe, Cr, Ni ions) the {110} faces show rounded steps. Other strong catalysers (Sr,Cr + Si, ilmenite) produce deep positive trigons of various shapes and sizes on {111} faces. The weakest catalysers (Ca, Mg, Si ions, olivine, natural kimberlite) reveal fine details of {110} faces and shallow trigons on {111} even at low H_2O and CO_2 concentrations. In fragmented diamonds severe resorption exhibited internal growth structure and defects. Besides influence of extensive parameters, heterogeneities of internal structure (e.g. growth/resorption features); traces of deformation-related features and other defects play important role in formation of final surface morphology.

Magmatic apatites formed in a composite granitoid pluton usually exhibit distinct zonation patterns caused by changes in trace-element composition, such as REEs and Y. Such compositional variations can be used to describe various petrological and geochemical processes, e.g. mixing of magmas of different composition. Apatites from Karkonosze Massif of Poland were studied using various X-ray-based and spectral analytical methods: FE-EPMA – Field Emission Electron Microprobe (including BSE images), PIXE/PIGE – Particle Induced X-ray/Gamma Emission and CL – Cathodoluminescence. Each method was employed to visualize (mappings) and quantify (spot analyses, line profiles) trace-element distribution patterns in single apatite grains. Slightly different suites of trace elements possessing various detection limits were analyzed with each method, with the largest number of elements measured by EPMA and the lowest detection limits achieved by PIXE. PIGE was proved to be most sensitive for analyzing light elements, such as F and Cl. Cathodoluminescence turned out to be the method best suited for visualizing zonation patterns with subtle, very thin zones not seen either on BSE images or X-ray maps. Because each method has advantages and limitations, their combined application is required to best visualize trace-element variations in apatite, which then can be used for modelling magma- differentiation processes.

Evolution of rhyolite magmas in the Halle Volcanic Complex – A record from Hf and O isotope and Hf concentrations in zircon

SŁODCZYK ELŻBIETA[1]*, PIETRANIK ANNA[1], BREITKREUZ CHRISTOPH[2] AND FANNING MARK[3]

[1]University of Wrocław, Geological Sciences, Poland; elzbieta.slodczyk@ing.uni.wroc.pl (* presenting author) anna.pietranik@ing.uni.wroc.pl
[2]TU Bergakademie Freiberg, Geology and Paleontology, Germany, cbreit@geo.tu-freiberg.de
[3]The Australian National University, Australia, Mark.Fanning@anu.edu.au

The Halle Volcanic Complex (HVC) is located in the northeastern Saale Basin in NE Germany. The region is underlain by the Mid – German Crystalline Zone. The HVC is dominated by rhyolitic rocks (c. 200 km^3), which were mainly emplaced as large laccoliths. The U/Pb age of zircons ranges from 289 to 301 Ma, inherited zircons are scarce [1].

We have chosen four localities within the HVC for detailed isotopic and chemical analyses of magmatic zircon: Spitzberg, Wettin, 1044 and 1390 [1]. εHf, $\delta^{18}O$ and elemental concentrations of Zr, Hf have been measured in previously dated zircons from these localities. On the basis of Hf content we divided zircon in two groups: zoned grains with low Hf core (8 - 9000 ppm) and high Hf rim (10 - 12000 ppm) and unzoned grains with constant low Hf concentration through grains (6 - 9000 ppm). High Hf rims occur also as magmatic overgrowths on inherited cores. Most of high Hf zircon fragments are also characterized by higher εHf compared to low Hf zircon. The diversity in $\delta^{18}O$ (6.3 - 8.1 ‰) does not correlate with Hf concentration and εHf.

Generally, the isotope and chemical characteristic of zircon grains is similar between localities and suggest an input of higher εHf magma towards the late stage of magma evolution, probably shortly prior to the final emplacement. Lack of correlation between εHf and $\delta^{18}O$ implies that at least three sources contributed material [2] to the ca. 300 Ma magmatism contrary to the simple two source contribution observed for the NE German Basin [3].

The role of ultramafic veins in mafic alkaline magmatism: Contrary evidence from continental intra-plate settings

K.A. SMART[1]*, S. TAPPE[1,2], A. STRACKE[3], R. L. ROMER[4] AND D. PRELEVIĆ[5]

[1]University of the Witwatersrand, Johannesburg, South Africa (*katie.smart2@wits.ac.za)
[2]De Beers Group Exploration, Johannesburg, South Africa
[3]Westfälische Wilhelms-Universität, Münster, Germany
[4]GFZ Potsdam, Germany
[5]University of Mainz, Mainz, Germany

Continental and oceanic mafic alkaline magmas have comparable major and trace element compositions that point towards similar P-T and volatile conditions during partial melting of their upper mantle source regions. While it is now widely accepted that OIB source regions must contain small amounts of recycled mafic components that contribute disproportionately to the magmatism, the geochemical and isotopic heterogeneity of equivalent magmas beneath continental interiors are more commonly explained by the contribution of partial melts of ultramafic veins at the base of the lithosphere. Vein-style metasomatism has also been suggested to explain the isotopic heterogeneity observed in OIBs formed on thick oceanic lithosphere, such that recycling of oceanic crust may not be the dominant source of mantle heterogeneity [1].

We analysed a suite of Mesozoic primitive mafic alkaline basalts and Permian alkaline lamprophyres from southern Sweden (Baltic Shield) for their major and trace element, and Sr-Nd-Hf-Pb isotope compositions. Although the Mesozoic alkaline basalts exhibit trace element features typically ascribed to melting of hydrous potassic phases within the mantle lithosphere, relatively homogeneous, moderately depleted radiogenic isotope compositions argue against derivation from old vein-metasomatized lithosphere. Isotopic modelling of hydrous metasomatic veins (represented by the Permian lamprophyres) potentially introduced to the lithospheric mantle beneath the Baltic Shield during Permo-Carboniferous plume magmatism suggests that such vein material, if it persisted to the Mesozoic, did not play a role in later mafic alkaline magmatism. In contrast, our data show that low-volume alkaline basaltic magmas beneath a thick continental lid 'oversampled' recycled oceanic crust from an otherwise highly depleted convecting upper mantle, similar to OIBs and E-MORBs.

Wintertime nitrate isotope dynamics in the Atlantic Sector of the Southern Ocean

S.M. SMART [1]*, D.M. SIGMAN [2], S.E. FAWCETT [2], S.J. THOMALLA [3], M.A. WEIGAND [2] AND C.J.C. REASON [1]

[1]Department of Oceanography, University of Cape Town, Private Bag, Rondebosch, 7700, South Africa (*correspondence: sandimsmart@gmail.com)
[2]Department of Geosciences, Princeton University, Princeton, New Jersey 08544, USA
[3]Ocean Systems and Climate Group, CSIR, P.O. Box 320, Stellenbosch, 7599, South Africa

We provide the first data on the wintertime patterns of seawater nitrate isotopes ($^{15}N/^{14}N$ and $^{18}O/^{16}O$) for the region south of Africa. Water column profile and underway surface samples collected in July 2012 span a range of latitudes from the subtropics to 57.8°S, just beyond the Antarctic winter sea-ice edge (56.7°S). The data are used in the context of simple models of nitrate consumption (including the Rayleigh model) to estimate the isotope effect (the degree of isotope discrimination) associated with the assimilation of nitrate by phytoplankton. Within the Antarctic, application of the Rayleigh model to depth profile N isotope data yields lower isotope effect estimates than are derived from the spatial variations within the mixed layer (the latter yielding isotope effect estimates near the commonly observed value of 5‰). The data from the Subantarctic Zone, both profiles and surface variations, also yield markedly low estimates for the assimilation isotope effect when analysed with the Rayleigh model. Similar behaviour observed in the N and O isotopes of nitrate suggest that the isotope effect is underestimated by the Rayleigh model due to mixing of waters across a wide range of nitrate concentrations in this more northern domain of the Southern Ocean. The nitrate N-to-O isotope relationship (i.e. Δ(15-18), defined as $\delta^{15}N-\delta^{18}O$) is remarkably uniform across the entire sampled Southern Ocean surface; however, there is a measurable Δ(15-18) difference between the surface mixed layer and the underlying deep water. The significance of these observations will be presented.

Unraveling the $CaCO_3$/PSS Mesocrystal Formation Mechanism by *in situ* TEM and *in situ* AFM

P.J.M. SMEETS[1,2], K. R. CHO[1], D. LI[1], M.H. NIELSEN[1], N.A.J.M. SOMMERDIJK[2] AND J.J. DE YOREO[1,3]*

[2]Laboratory of Materials and Interface Chemistry, Eindhoven University of Technology, 5600 MB Eindhoven, Netherlands
[3]Pacific Northwest National Laboratory, Richland, WA 99352, USA (*James.DeYoreo@pnnl.gov)

The interplay between mineral and organic species is central to the control of microbial systems over biomineral formation. Deciphering the underlying mechanisms requires *in vitro* studies in which the physical and chemical parameters can be well controlled.

Using negatively charged polyelectrolyte polystyrene sulfonate (PSS) as aproxy for a bio-organic mediator, we investigate particle-mediated crystallization of $CaCO_3$, one of the most abundant materials for biomineralization. To induce growth, we use a calcium source in combination with the ammonium carbonate diffusion method. Utilizing similar conditions, Wang *et al*. showed that this approach yielded a family of well-defined calcite-PSS mesocrystals – i.e. 3D regular but porous scaffolds composed of easily distinguished and almost perfectly aligned nanocrystals [1]. Although mesocrystal formation was suggested to proceed via assembly of an amorphous precursor, direct proof of this mechanism is lacking. Here we use *in situ* TEM and *in situ* AFM to follow the formation process. For *in situ* TEM a custom designed fluid cell was utilized, containing two Si/Si_3N_4 wafers with electron transparent Si_3N_4 membranes.

We find that the observed mesocrystal morphology can be obtained merely through $CaCO_3$ overgrowth in PSS solution on a single crystal seed, and *in situ* AFM demonstrates that the development of this morphology is due to polymer poisoning of atomic steps during classical layer-by-layer calcite growth. However, both *in situ* TEM and AFM reveal a complex pathway during the initial stages of formation. Ca- PSS particles first adsorb onto the substrate. After about 2h of reaction with ammonium carbonate in the TEM fluid cell, these then appear to transform into larger amorphous aggregates. We are now attempting to detail the structural evolution of these initial particles and draw inferences about their formation mechanism and role in crystallization.

[2]Max-Planck-Institute of Colloids and Interfaces, 14424 Potsdam, Germany
[3]SoftMatter CryoTEM Unit, Eindhoven University of Technology, 5600 MB Eindhoven, Netherlands (*correspondence: N.Sommerdijk@tue.nl)

Calcium carbonate (CaC) is the most abundant biogenic mineral, found in marine organisms and their fossilized deposits. Its crystallization mechanism is heavily debated since recent studies proposed a non-classical crystallization pathway via pre-nucleation clusters [1]. In the present study, we used cryo-TEM in combination with a titration set-up and demonstrated the existence of subnanometer-sized complexes (~0.4-0.6 nm) as prevalent pre-nucleation species in CaC mineralization, even in under-saturated regimes, which persisted after nucleation.

We show that these pre-nucleation species contain only one calcium in the equilibrium structure, which makes them complexes rather than clusters, similar as what was recently shown for calcium phosphate [2]. From a detailed analysis of the titration data we calculated that the average CaC-pre-nucleation complex chemistry represents a Ca/C ratio <<1, contains at least 50 mol% of bicarbonate and has an overall negative charge. This observation is in contrast to the previously proposed neutral $CaCO_3$ clusters that have been reported to exist under similar conditions [1]. We used *ab-initio* calculations to identify the structure of these complexes.

Furthermore, a dense liquid phase [3] of sub-micron sized assemblies of complexes exist already before the nucleation event. We propose a nucleation mechanism in which a calcium carbonate nucleus forms within these assemblies through a transformation of the complexes, after which the bulk phase (vaterite) propagates by ion growth.

Lu-Hf and Sm-Nd garnet geochronology: Closure revisited and new applications in lithosphere studies

MATTHIJS A. SMIT[1,2,3], ERIK E. SCHERER[2], KLAUS MEZGER[4], LOTHAR RATSCHBACHER[5], ELLEN KOOIJMAN[2,6] AND BRADLEY R. HACKER[1]

[1]Department of Earth Sciences, UC Santa Barbara, USA
[2]Institut für Mineralogie, WWU, Münster, Germany
[3]Institute for Geography and Geology, University of Copenhagen, Denmark
[4]Institut für Geologie, Universität Bern, Switzerland
[5]institut für Geologie, TU Bergakademie, Freiberg, Germany
[6]Swedish Museum of Natural History, Stockholm, Sweden

The link between ^{176}Lu-^{176}Hf and ^{147}Sm-^{143}Nd dates and *P-T* information from garnet is still subject to uncertainty because closure systematics are not well constrained. To progress in this field, we performed ^{176}Lu-^{176}Hf and ^{147}Sm-^{143}Nd geochronology on garnet crystals of different size (Ø = 0.90-6.2 mm) from a granulite from the Archean Pikwitonei Granulite Domain, Superior Province, Canada. Metamorphism in this region started at ~2716 ± 4 Ma and peak metamorphism (760 °C [1]) occurred at 2639 ± 2 Ma [2].

The ^{176}Lu-^{176}Hf dates for the larger size fractions (Ø > 2.5 mm) yielded 2714 ± 6 Ma, identical to the age of first garnet growth. Smaller grains exhibit slight younging to ~2680 Ma. In contrast, the ^{147}Sm-^{143}Nd dates are equal to or younger than the age of peak metamorphism. The age trends cannot be explained by inclusion effects or REE zoning, but instead relate to diffusive loss of radiogenic ^{176}Hf and ^{143}Nd.

The data enable the quantitative evaluation of the closure systematics of the ^{176}Lu-^{176}Hf and ^{147}Sm-^{143}Nd chronometers in garnet: ^{176}Lu-^{176}Hf dates for garnet of a typical grain size (Ø > 0.5 mm) represent (re-)crystallization of the phase. The same applies to ^{147}Sm-^{143}Nd, except for UH*T* rocks and cases where *dT*/*dt* is much lower than commonly observed in tectonic settings.

These constraints enable the use of garnet geochronology in unravelling prograde histories of deep-crustal rocks. We used this approach to assess the enigmatic history of the deep crust underlying the Pamir-Tibetan Plateau. We obtained a detailed record of near-isobaric heating between 37.0 and 26.5 Ma and relate this directly to high mantle heat flow induced by roll-back or breakoff of the Indian plate.

Geomicrobiological activity in the Mesoarchean Witwatersrand-Mozaan Succession: Evidence from iron formations and shales

A.J.B. SMITH[1]* N.J. BEUKES[1] AND J. GUTZMER[1,2]

[1]PPM, Department of Geology, University of Johannesburg, Johannesburg, South Africa (*correspondence: bertuss@uj.ac.za)
[2]Helmholtz Insititute Freiberg for Resource Technology, Halsbruecker Str. 34, 09599 Freiberg, Saxony, Germany

The Mesoarchean (~2.96-2.92 Ga) Witwatersrand-Mozaan Succession of southern Africa is one of the oldest, well preserved supracratonic successions in the world. Numerous iron-rich units occur in this succession in the form of iron formations and iron-rich shales. Detailed studies of multiple deep level drill cores have led to the reconstruction of the lateral facies distribution of these iron-rich units. The iron formations are distal deposits, and change from hematite-magnetite, magnetite, mixed magnetite-carbonate to mixed carbonte-silicate facies towards proximal environments [1]. Proximal to the banded iron formations are iron-rich shales with manganese-rich carbonate concretions, grading into iron-poor shales and eventually sandstones [2]. This facies distribution illustrates that iron deposition only took place below wave base, likely below the photic zone. Distribution of iron was likely controlled by ferrous iron- and reduced manganese-rich hydrothermal plumes with a limited vertical extent due to neutral buoyancy [3]. Chemolithoautotrophic iron-oxidizing bacteria are inferred to have caused the precipitation of iron as ferric oxyhydroxides, with hematite preserved where the plume was not in contact with the sediment. Magnetite and isotopically light iron-rich carbonate, in contrast, formed diagenetically through interaction of the hydrothermal plume and organic carbon sourced from biological activity in the sediment [1]. The manganese-rich carbonate concretions in the more proximal iron-rich shale show evidence for dissimilatory manganese reduction of manganese originally precipitated by mangenese-oxidizing bacteria [2]. Microbial oxidation of iron below the photic zone in iron formations and of manganese in shales suggest that free molecular oxygen at micro-oxic conditions were developed at depth in the the Witwatersrand-Mozaan basin since known geomicrobial processes require micro-oxic contitions.

Millennial Scale Holocene Climate Variability: Iberian Precipitation Reconstructed from two Speleothems

A.C. SMITH[1]*, P.M. WYNN[1], P. A. BARKER[1], M.J. LENG[2] AND S. NOBLE[2].

[1] Environment Centre, Lancaster Univ., LA1 4YQ,UK (*correspondence: a.smith8@lancs.ac.uk, p.wynn@lancs.ac.uk, p.barker@lancs.ac.uk)

[2] NERC Isotope Geociences Laboritory, Nottingham, UK (mjl@bgs.ac.uk, srn@bgs.ac.uk)

Palaeoclimate records from the Northern Iberian Peninsula are ideally suited to provide detailed insight into terrestrial climate change and oceanic variability. However, long duration unaltered palaeoclimate records are rare in this region. Two speleothems from a small cave in Matienzo (Cantabria) have been used in conjunction with cave monitoring to develop a continuous, high resolution isotope and trace element palaeoclimate record, which spans the Holocene and Younger Dryas. This speleothem record is interpreted in terms of changing winter precipitation amount, driven by moisture deliverance from the North Atlantic Ocean [1]. Oxygen isotope maxima occur at 1200, 3100, 4500, 5200, 8000 and 9500 years BP, suggesting significant periods of relative winter aridity throughout the Holocene.

Precipitation minima occur in phase with North Atlantic cold periods marked by IRD and identified by Bond *et al*. 1997 [2]. Concurrent alterations in oceanic and atmospheric circulation are known to cause significant reductions in moisture availability, in this case limiting precipitation in Southern Europe. The high correlation between the timing of North Atlantic cold events and speleothem isotope maxima suggests a rapid atmospheric response to changes in oceanic conditions and strong teleconnections between the northern Atlantic Ocean and mid latitudes. This speleothem offers one of the first high resolution, continuous terrestrial records of North Atlantic Ocean cold SST events. These large-scale oceanic processes appear to have dramatically influenced precipitation in northern Iberia and may have played a decisive role in environmental development in the region.

Chemostratigraphy of Pennsylvanian Core Shale Cyclothems, Illinois Basin, Southern Indiana

CHRISTOPHER N. SMITH[1,2]*, CLINTON BROACH[2], HAMED CHOK[1], WILLIAM S. ELLIOTT JR.[3] AND WILLIAM P. GILHOOLY III[2]

[1]Weatherford International Ltd christopher.smith4@weatherford.com*, hamed.chok@weatherford.com

[2]Department of Earth Sciences, Indiana University-Purdue University Indianapolis cbroach@umail.iu.edu, wgilhool@iupui.edu

[3]Department of Geology and Physics, University of Southern Indiana wselliott@usi.edu

Major and trace element data from five Late Middle Pennsylvanian cores (Carbondale Group) were determined to investigate sediement sources and chemical conditions in the water column during organic matter deposition. A series of limestone, gray and black shale (including the Excello Shale), siltstone, sandstone and coals from a coal bed methane exploration well that penetrated the Linton and Petersburg Formations, Vanderburgh County, Southern Indiana were sampled to provide 99 core samples used in this study. These sequences were deposited in a near-shore intracratonic basin flooded by shallow epeiric seas.

Exploratory data analyses including principal component analysis (PCA) and hierarchical clustering analysis (Ward's Linkage HCA) were used to analyze the data for significant groupings of elements by lithology and total organic carbon (TOC) content. Principal component 1 (PC1) accounts for 49% of the toal variance in the data and can be used to distinguish between clastic (Si, Al, K, Na, Ti) and carbonte (Ca, Sr) related elements. Principal component 2 (PC2) accounts for 19% of the total variance and is indicative of the presence or absence of redox sensitive trace element proxies for total organic carbon (Mo, U, V, Cr, Ni, Zn and Hg). Clustering analysis of sandstone and siltstones form a largely homogenous grouping for sequences interpreted as marine and non-marine, wheras there is greater heterogeneity in the groupings of both gray and black shales.

The Excello black shale shows the strongest enrichment in redox sensitive trace metal proxies for TOC. Finally, low TOC gray shales exhibit a relative enrichment in rare earth elements relative to the black shales and the North American Shale Composite (NASC), that may also reflect different sediment sources or diagenetic processes.

Adopting a combined U-Th-Pb strategy to date speleothems >200 ka

CHRISTOPHER J.M. SMITH[1]*, DAVID A. RICHARDS[1], DANIEL J. CONDON[2], MATTHEW S.A. HORSTWOOD[2], RANDALL R. PARRISH[2], JON WOODHEAD[3] AND DEREK C. FORD[4]

[1]School of Geographical Sciences, University of Bristol, UK (*correspondence: chris.smith@bristol.ac.uk)
[2]NERC Isotope Geosciences Laboratory, British Geological Survey, UK
[3]School of Earth Sciences, University of Melbourne, Australia
[4]School of Geography and Earth Sciences, McMaster University, Canada

Speleothems are widely recognised as valuable records of palaeoenvironmental and landscape change with robust and precise chronologies to ~500 ka, principally based on the U-Th decay scheme. However, the practical upper limit for speleothem dating can be extended by the adoption of U-Th-Pb methodologies that account for disequilibrium in the decay chain, see review by Woodhead & Pickering (2012) [1]. While the range of applications is expanding, widespread adoption of these methods is hampered by the need to accurately predict, with high precision, the initial state of U-series disequilibrium (i.e. $(^{234}U/^{238}U)_{initial}$), and also analyse material with a sufficient range of U/Pb to provide high precision isochron age determinations.

For a suite of speleothems spanning the late Pliocene to late Pleistocene exhibiting variable U (1-100 μg g^{-1}) and low non-radiogenic Pb (<50 ng g^{-1}), we have adopted a combined U-Th-Pb dating strategy to take full advantage of the sensitivity and spatial resolution of available techniques. For individual growth layers, we have used: (1) rapid in-situ U-Pb LA-MC-ICPMS (193 nm ArF excimer laser) techniques, which enables fast throughput, high spatial resolution and a wide range in U/Pb for individual spots; (2) conventional U-Pb ID TIMS, for high-precision three-dimensional isochrons at lower spatial lower resolution; (3) U-Th MC-ICPMS static Faraday methods, to obtain high-precision estimates of initial $^{234}U/^{238}U$ for material ⍰500 ka.

We discuss the relative merits of each of the above methods and their combined use, focusing in particular on the compromises that have to be made between spatial resolution and age precision for speleothems with different growth rates and ages.

Diamond inclusions reveal fugitive mantle nitrogen

E.M. SMITH[1]*, M.G. KOPYLOVA[1], M.L. FREZZOTTI[2] AND V.P. AFANASIEV[3]

[1]Department of Earth, Ocean and Atmospheric Sciences, University of British Columbia, 2207 Main Mall, Vancouver, BC V6T 1Z4, Canada (*correspondence: esmith@eos.ubc.ca)
[2]Department of Geological Sciences and Geotechnologies, University of Milano-Bicocca, Piazza della Scienza 4, 20126 Milano, Italy
[3]Sobolev Institute of Geology and Mineralogy, Siberian Branch of the Russian Academy of Sciences, pr. Akademika Koptyuga 3, Novosibirsk, 630090, Russia

Mantle volatiles in mid-ocean ridge basalts and fluid inclusions in mantle xenoliths are dominated by CO_2. Nitrogen generally appears as a trace component. However, we report diamonds from three different localities, the Kaapvaal, Congo, and Siberian cratons, that have N-rich fluid inclusions and melt inclusions.

Nitrogen in the inclusions was analyzed with micro-Raman spectroscopy. Fluid inclusions in the Siberian diamond are CO_2–N_2 mixtures with 40±4 mol% N_2. Melt inclusions in the diamonds from the Kaapvaal and Congo cratons contain exsolved bubbles of volatiles that are nearly pure N_2, with <9 mol% CO_2. At the time of trapping, the silicate melt would have contained ~1 wt% dissolved N_2.

These melt and fluid inclusions are well-preserved samples of mobile, undegassed mantle phases. Such N-rich fluids/melts reveal an unrecognized type of concentrated N flux escaping the convecting mantle. This critical observation casts uncertainty on current flux models, which otherwise suggest considerable net influx to the mantle via subduction that does not return to surface (at mid-ocean ridges, volcanic arcs, back-arc basins, and hotspots).

We propose that the N_2 in our samples was liberated by oxidation from NH_4^+-bearing silicates. The coexistence of N_2 and oxidized carbon species in fluid/melt inclusions supports the idea that oxidizing conditions help to mobilize N and C. This implies redox conditions control mantle nitrogen behaviour, both in terms of storage and geodynamic cycling.

Additionally, the oxidation of NH_4^+ to N_2 could be accompanied by isotopic fractionation. This would allow isotopically light N_2 (low $^{15}N/^{14}N$) to be derived from isotopically heavy subducted or stored NH_4^+ (higher $^{15}N/^{14}N$). This isotopic fractionation may explain the gross mismatch between isotopically heavy N influxed by subduction and the isotopically light N effluxed from the mantle, in diamonds and mid-ocean ridge basalts, for example.

An inert desolvating nebulizer system and rapid washout accessory for tungsten isotope measurements with multicollector ICP-MS

F.G.SMITH[1]*, J. HOLST[2], C.PATON[2] AND M. BIZARRO[2]

[1]CETAC Technologies, Omaha, NE 68144 USA (*correspondence: fsmith@cetac.com)
[2]Center for Star and Planet Formation, Natural History Museum of Denmark, University of Copenhagen, Copenhagen DK-1350, Denmark

Multicollector ICP-MS instruments are specialized devices for high-precision isotope ratio measurements. Prepared liquid samples may be concentrated (100 to 1000 mg/L) in elements of interest; these higher concentrations can cause longer analyte washout times and signal spikes. This poster will describe an inert, low flow (50 to 200 μL/min) desolvating nebulizer system with a rapid washout accessory. This nebulizer system can also be equipped with a dedicated autosampler that features a dual-flowing rinse capability to minimize sample carryover. Wetted parts are composed of fluoropolymers such as PFA (perfluoroalkoxy) for lowest trace metal blanks and maximum chemical resistance. Optimum operating conditions for the nebulizer system with a contemporary multicollector ICP-MS for tungsten measurements will be detailed. Figures of merit will include signal enhancement, isotope ratio measurements and long-term (12 hour) ratio stability, and rinse out characteristics with and without the rapid washout accessory [1].

Biogenic new particle formation and its potential impacts on climate

J. N. SMITH[1,2]*, M. LAWLER[2], P. WINKLER[3], J. ZHAO[4], AND P. MCMURRY[4]

[1]National Center for Atmospheric Research, Boulder, CO 80307 USA (*correspondence: jimsmith@ucar.edu)
[2]University of Eastern Finland, 70211 Kuopio, Finland
[3]University of Vienna, 1090 Vienna, Austria
[4]University of Minnesota, Minneapolis, MN 55455 USA

Observations show that growth rates of freshly nucleated atmospheric nanoparticles are about 5-10 times higher than can be accounted for by sulfuric acid condensation. This additional growth is primarily due to the uptake of organic compounds, often of biogenic orgin, by processes that are not yet understood and that might include condensation of low-volatility vapors or reactions that occur on or within particles. If the growth of freshly nucleated atmospheric aerosols is sufficiently fast, these particles can reach sizes required to serve as cloud condensation nuclei (CCN), and may thereby potentially affect the climate.

We have performed laboratory and field measurements focusing on understanding the role of biogenic organic compounds in the formation and growth of atmospheric aerosols. Measurements were made using the Thermal Desorption Chemical Ionization Mass Spectrometer (TDCIMS), an instrument capable of realtime measurements of the molecular composition of ambient aerosols as small as 10 nm in diameter. In recent laboratory experiments of new particle formation from a-pinene ozonolysis, high molecular weight (m/z 430-560) low volatility gases correlated with initial stages of particle formation [1]. Additional work has focused on identifying particle phase compounds present in nanoparticles of varying size during the earliest stages of growth: in those studies organic acids were observed in the smallest particles formed by nucleation [2].

Our laboratory results are also compared to field observations of nanoparticle composition and gas phase precursors at sites in which biogenic emissions dominate. These include an isoprene-dominated region (Columbia, MO), and several sites with a mixture of terpene emissions (Hyytiala, Finland, Manitou Forest, Colorado). These observations show that atmospheric nanoparticles are often enriched with organic acids and nitrogen-containing compounds. These particles are often quite hygroscopic, and thus may have a far greater effect on cloud formation than previously thought.

Western Oregon as a low-sediment end member of particulate organic carbon export from temperate forested uplands

J.C. SMITH[1]*, A. GALY[1,2], N. HOVIUS[3] AND A. TYE[4]

[1]Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, United Kingdom (*correspondence: jcs74@cam.ac.uk)

[4]British Geological Survey, Keyworth, Nottingham NG12 5GG, United Kingdom (atye@bgs.ac.uk)

The transfer of continental biomass to geological storage has the potential to sequester considerable amounts of carbon dioxide. Despite an initial focus on active mountain belts as prime locations for this erosion, temperate forested uplands might also have a significant role to play.

In some temperate catchments with high connectivity between hillslopes and actively incising channels, clastic yield is high, but soil is preferentially mobilised by overland flow beyond a moderate discharge threshold, resulting in the export of globally significant amounts of biomass [1]. However, these processes are not universal in temperate forested uplands. Using organic carbon and nitrogen elemental and isotopic ratios, we present results revealing contrasting particulate organic carbon dynamics in the headwaters of Western Oregon. Suspended sediment concentrations are typically very low, while organic carbon concentrations frequently reach 30%. A lack of active incision has led to the development of flat, thickly vegetated riparian zones which isolate hillslopes. Nevertheless, considerable amounts of soil and plant material are eroded from the channel and immediately adjacent areas during rain. Such settings export non-fossil organic carbon at rates of ~6 t km^{-2} yr^{-1}, around half the rate from the high-sediment temperate end member. Contrasts between the two systems suggest that ecosystem biology is the principal control on POC export style in temperate forested uplands.

Comparison of our results with studies made downstream of these headwaters at their entry to the Pacific Ocean [2, 3] offers new insights into the fate of biomass mobilised in Oregon's uplands and similar settings.

Helium equilibrium between pore water and quartz: A clever, but limited tool

S.D. SMITH[12]*, G.A. HARRINGTON[1], B.D. SMERDON[1] AND D.K. SOLOMON[2]

[1]CSIRO Water for a Healthy Country Flagship, Urrbrae, SA 5064, Australia
(*correspondence: stan.smith@csiro.au)
(glenn.harrington@csiro.au, brian.smerdon@csiro.au)
[2] Dept. of Geology and Geophysics, Univ. of Utah, Salt Lake City, UT 84112, USA (kip.solomon@utah.edu)

Pore water helium concentrations calculated from quartz helium concentrations [1] offer a unique tool to determine helium distribution in low permeability formations. Analyses have been carried out on shale and sandstone core samples from the San Juan Basin, USA and the Eromanga and Surat basins, Australia.

Comparing quartz-derived helium concentrations to direct pore water concentrations reveal up to an order of magnitude difference between the two. This uncertainty is unacceptable for modelling vertical helium transport to constrain estimates of fluid flux. However, in the San Juan Basin, $^3He/^4He$ ratios agree between methods. In the Eromanga Basin, modelling indicates >90% equilibrium is expected, however, when compared with direct pore water measurements [2], as low as 10% of equilibrium is observed. Regardless of present-day equilibrium, the method could be useful for paleohydrology studies, provided the timing of equilibrium can be constrained.

The method appears more promising in deeper (thus hotter) basins where the equilibrium time between pore water and quartz is reduced significantly. In shallow systems, the equilibrium time may greatly exceed the lifespan of shallow, quasi-steady state hydrological systems. Further testing of the method in additional basins may result in an adequate screening method to find where the method is applicable. The possibility exists that this method will not come to fruition as too much uncertainty remains and equilibrium is found in theory instead of in the samples.

Using tephra layers to provide absolute and relative chronologies for sedimentary archives: An example from the Lake Suigetsu SG06 record from Japan

V.C. SMITH[1], R.A. STAFF[1], D. F. MARK[2], S.P.E. BLOCKLEY[3], C. BRONK RAMSEY[1] AND T. NAKAGAWA[4]

[1] Research Laboratory for Archaeology and the History of Art, University of Oxford, Oxford OX1 3QY, U.K. (victoria.smith@rlaha.ox.ac.uk)
[2] Scottish Universities Environmental Research Centre (SUERC), East Kilbride G75 0QF, U.K.
[3] Centre for Quaternary Research, Royal Holloway University of London, Egham TW20 0EX, U.K.
[4] Department of Geography, University of Newcastle, Newcastle Upon Tyne NE1 7RU, U.K.

The Lake Suigetsu SG06 sedimentary archive from Honshu Island, central Japan, provides a high-resolution palaeoenvironmental record for the last 150 kyrs. The 73 m-long record contains numerous layers tephra (30 visible and numerous cryptotephra) sourced from explosive volcanism from Japan and South Korea. These marker layers can be used for both relative and absolute chronology.

The glass chemistry of these tephras is typically unique, therefore most of the layers can be correlated to those in other archives and to specific eruptions [1]. Since many of these layers are widespread (>600 km from source) these isochrons allow for the assesment of leads and lags in palaeoclimate across the region.

The tephra can also be dated using $^{40}Ar/^{39}Ar$ methods. These $^{40}Ar/^{39}Ar$ ages are crucial for constraining the pre-50 ka SG06 age model. Correlating these distal SG06 tephra layers to proximal deposits is essential as large crystals are required to obtain precise and $^{40}Ar/^{39}Ar$ ages and these are only abundant in the coarser proximal deposits [2].

Precise radiocarbon dates have been obtained for all the post-50 ka visible SG06 tephra layers [1] using the modelled radiocarbon data and varve chronology [3]. These radiocarbon dates and $^{40}Ar/^{39}Ar$ ages of the eruptions can significantly improve the age models of other archives in which the tephra are found.

Molecular simulation of aqueous electrolyte solutions

WILLIAM R. SMITH[1,2],*, FILIP MOUČKA[3] AND IVO NEZBEDA[4]

[1]University of Ontrio Institute of Technology, Faculty of Science;
[2]University of Guelph, Mathematics and Statistics, (william.smith@uoit.ca *presenting author)
[3]J.E. Purkinje University, Physics, (fmoucka@seznam.cz)
[4]J.E. Purkinje University, Chemistry, (inezbeda@icpf.cz)

We employ the Osmotic Ensemble Monte Carlo (OEMC) algorithm [1] to predict the solute and water chemical potentials in aqueous electrolyte solutions. OEMC implements a Semi-Grand Canonical Ensemble simulation of the solution phase, which can be viewed as an application of the Reaction Ensemble Monte Carlo algorithm [2] to the case of an inter-phase chemical reaction, including speciation reactions as appropriate.

Focusing on aqueous NaCl at ambient conditions, we present the following:

1. An improved electrolyte force field based on SPC/E water and a simple charged Lennard-Jones sphere model, determined by fitting the concentration dependence of the density and chemical potential, and the solubility.
2. Calculations of the concentration dependence of the water chemical potential and demonstration of thermodynamic consistency with the electrolyte chemical potential using the Gibbs-Duhem equation.
3. Electrolyte chemical potentials at finite concentrations for polarizable force fields for water and the electrolyte, using the Multi-Particle Move Monte Carlo method [3].
4. Calculations predicting the onset of homogeneous nucleation in supersaturated aqueous electrolyte solutions.

The North Australian Craton: A Palaeoproterozoic accretionary orogen

R.G. SMITS[12]*, W.J.COLLINS[2] AND M.HAND[1]

[1]Centre for Tectonics, Resources and Exploration, University of Adelaide, S.A. 5005, Australia, russell.smits@adelaide.edu.au

[2] School of Environmental and Life Sciences, University of Newcastle, NSW 2308, Australia,

The North Australian Craton (NAC) is 1,830,000Km^2, making up almost one quarter of Australia. The development of this system has a broad spatial and temporal organization such that sedimentation, magmatism and tectonism generally migrated southward over the interval ~2000 to 1700 Ma, and at least in the northern parts of the craton, appears to have a late Achaean substrate. In most regions, within 10-20 Ma, sedimentation was followed by deformation and granite-dominated magmatism associated with high thermal gradient metamorphism, pointing to a systematic pattern of crustal consolidation as the craton developed.

Detrital zircon spectra, maximum depositional of sediments, distribution of mafic intrusives and Hf isotopes over the NAC indicates a southerly migration of depositional activity from the Pine Creek Orogen in the north to the Arunta Orogen in the south, with two main phases of basin formation between 1880-1850 and 1830-1780 Ma. The sediments of these basins share common zircon detritus populations, particularly Neoarchean sources. A general trend toward more primitive Hf values with time is typical for retreating accretionary orogens. The Archean detrital populations recorded in sediments from all regions of the NAC, Hf isotopic data coupled with the systematic spatial and temporal pattern of magmatism and deformation/metamorphism is consistent with an Archean substrate that migrated southwards over a period of ~300 Ma. We can envisage such a migration as being controlled by a long-lived retreating margin, with distinct "pulses" of magmatism related to periods of accelerated extension. This scenario suggests that the NAC developed in an oceanic back arc setting, rather than in an intracratonic setting as has been recently proposed. The model implies that formation of Palaeoproterozoic continental lithosphere can be efficiently achieved in back arc settings, similar to the modern-day western Pacific.

Terrestrial temperature response during Early Eocene hyperthermals

K.E. SNELL[1]*, H.C. FRICKE[2], W.C. CLYDE[3] AND J. M. EILER[1]

[1]Div. of Geological and Plan. Sci., Caltech, Pasadena, CA 91125 (*correspondence: ksnell@caltech.edu)

[2] Geology Dept., Colorado College, Colorado Springs, CO 80903

[3] Dept. of Earth Sciences, Univ. of New Hampshire, Durham, NH 03824

The Early Eocene is marked by a number of rapid global warming events called hyperthermals that are associated with negative carbon isotope excursions (CIE) in both marine and terrestrial records. Each theory to explain the connection of these hyperthermals with the CIEs predicts a different climatic response. Characterizing the timing, duration and magnitude of temperature change will help establish their cause and possibly establish whether or not they are driven by a single process. It is possible that all share a common underlying cause; if so, we might predict that the temperature change during each hyperthermal is proportional to the magnitude of its associated CIE (and perhaps exhibit other similarities, such as the relative amplitudes of marine and terrestrial temperature change). To our knowledge, the only hyperthermal for which we know the terrestrial temperature change is the Paleocene-Eocene Thermal Maximum (PETM).

Here we use carbonate clumped isotope (Δ_{47}) thermometry of paleosol carbonates from the Bighorn Basin (Wyoming, USA) to produce paleotemperature estimates at high temporal resolution for Early Eocene hyperthermals ETM2 and H2. Average baseline temperatures (which likely reflect near-peak summer ground temperatures) before and after the two hyperthermals are ~28°C and increase to ~38°C during the apex of each CIE; temperatures appear to recover close to baseline temperatures between ETM2 and H2. These data (combined with previous constraints on the PETM) suggest that both the absolute temperatures and the magnitudes of temperature change associated with the PETM, ETM2 and H2 are similar (within error); the magnitudes of temperature change (~10°C) also appear similar to/slightly greater than that found in arctic sediments [1]. In addition, our record shows a cooling interval within the peak of ETM2 that is similar in pattern to an event that is present in the arctic record [1]. These results suggest that the temperature change associated with the hyperthermals does not necessarily scale with the magnitude of the local CIEs from paleosol carbonate nodules (~6‰ for the PETM and ~4‰ for ETM2). For ETM2, the CIE appears to precede warming.

Dissolution rates and surface chemistry of calcium aluminosilicate glasses in cementitious systems

R. SNELLINGS[1]* AND K. SCRIVENER[1]

[1]Institute of Materials, EPFL, Lausanne, Switzerland
(*correspondence: ruben.snellings@epfl.ch)

Waste calcium aluminosilicate (CAS) glasses are widely used as supplementary cementitious materials in Portland-cement based construction materials for environmental, economical and technical reasons. The amount of cement that can be replaced by waste CAS is largely depending on their reactivity and composition. Understanding the reactivity or rates of dissolution of these wastes in typical Portland cement pore solutions of high ionic strength and alkalinity (pH ≈ 13) is of great importance to optimise the performance, durability and sustainability of the blended Portland cements.

Water quenched synthetic CAS glasses of selected compositions ranging from pure silica framework to CaO-rich depolymerized glasses were subjected to batch dissolution reactions avoiding hydration product precipitation. The obtained dissolution rates scaled linearly with the Ca/(Al+Si) molar ratio, and showed a large difference in reactivity between framework and partially depolymerised glasses (Fig. 1).

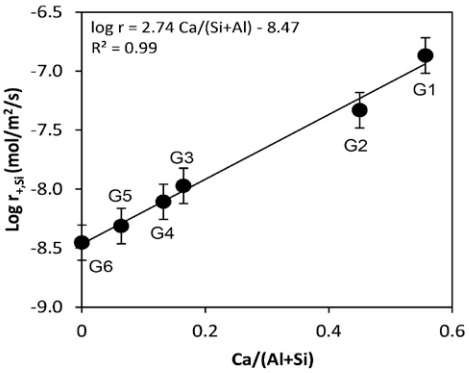

Figure 1: Dependence of glass dissolution rate at pH 13 on the molar Ca(Al+Si) ratio of the glass.

Glass dissolution rates also depended on solution composition. Increasing Al activity decreased dissolution rates of framework glasses, while increasing Ca activity decreased dissolution rates of all glasses. The glass surface chemistry as a function of solution pH and composition was investigated by XPS, zeta potential measurements and surface titrations and lead to a model of CAS glass dissolution for high pH cement type environments.

Isotopic Tomography of Monazite

DAVID R. SNOEYENBOS[1]*, EMILY M. PETERMAN[2], MICHAEL J. JERCINOVIC[3], MICHAEL L. WILLIAMS[3] AND DAVID A REINHARD[4]

[1]Box 513, Chesterfield, MA 01012 USA
*correspondence: kyanite@mac.com
[2]Bowdoin College, Brunswick, ME 04011 USA
[3]University of Massachusetts, Amherst, MA 01002 USA
[4]Cameca Instruments Inc., Madison, WI 53711 USA

In Atom Probe Tomography (APT) a specimen is evaporated atom by atom, and the mass/charge and original position (X,Y, Z to 0.2nm) of each detected atom is recorded to produce a quantitative 3-D reconstruction at the atomic scale. APT can also provide *in situ* atomic scale isotopic tomography of U, Th and radiogenic Pb, allowing access to otherwise cryptic thermochronologic information.

A polymetamorphic monazite grain from the Churchill Province, Canada was selected for analysis by APT. Prior EPMA analysis indicates monazite crystallization at 2.55Ga, overgrowth at 2.37Ga, and fracture-infill and further overgrowth at 1.84Ga. Datasets of up to 200 million atoms were collected, sampling the various domains and their mutual interfaces.

Distinct clusters of Pb atoms <10nm dia. and spaced at 20–30nm were observed in the older, reheated domain. These clusters contain up to 1.7 at.% Pb, 4 at.% Si and 7 at.% Ca in a radial structure. These clusters closely resemble those found by APT in reheated zircon [1. Valley *et al.*]. The presence of 208Pb, 207Pb and 206Pb in the clusters indicates post-crystallization segregation of radiogenic Pb from both the Th and U decay chains. Because Th and U enter the monazite structure via coupled substitution (e.g. Th+Ca, Th+Si and U+Si), Si and Ca in the clusters may represent the unpaired atoms after radionuclide decay. To measure an isotopic age at this scale, precise 207Pb/206Pb determination requires a minor correction for interfering species such as (ThPO3)3+.

Potential temperatures of convecting mantle based on Al partitioning between olivine and spinel

A.V.SOBOLEV[1,2], V.G.BATANOVA[1,2], D.V. KUZMIN[3] AND N.T.ARNDT[1]

[1]ISTerre, University J. Fourier, Grenoble, France, alexander.sobolev@ujf-grenoble.fr
[2]Vernadsky Institute of Geochemistry RAS, Moscow, Russia
[3]Sobolev Inst. of Geol and Min, SBRAS Novosibirsk, Russia

Knowledge of potential temperatures of convecting mantle is required for the understanding the global processes on the Earth [1]. The common way to estimate these is the reconstruction of primary melt compositions and liquidus temperatures based on the Fe-Mg partitioning between olivine and melt. This approach requires knowledge of the compositions of primitive melts in equilibrium with olivine alone as well as composition of olivine equilibrium with primary melts. This information is in most cases unavailable or of questionable quality. Here we report a new approach to obtain crystallization temperatures of primary melts based on the olivine-spinel Al-Cr geothermometer [2]. The advantages of this approach are: (1) common presence of spinel in assemblage with high-Mg olivine and (2) low rate of diffusion of Al in the olivine, which promises to preserve high magmatic temperatures.

We analysed over one thousand spinel inclusions and high-Mg host olivines from different MORB, OIB and Archean komatiites on the JXA-8230 EPMA at ISTerre, Grenoble, France. Concentrations of Al, Ti, Na, P, Zn, Cr, Mn, Ca, Co, Ni were determined with a precision of 10 ppm (2 standard errors) using a newly developed protocol [3]. When available, we also analysed matrix glass and glass inclusions in olivine and found that temperature estimations from olivine-spinel (Al-Cr) and olivine-melt (Fe-Mg)[4] equilibrium match within (+/-30 degree C).

The results show contrasting crystallization temperatures of Mg-rich olivine of the same Fo content from different types of mantle-derived magmas, from the lowest (down to 1220 degree C) for MORB to the highest (up to 1500 degree C) for komatiites. These results match predictions from Fe-Mg olivine-melt equilibrium and confirm the relatively low temperature of the convecting mantle source of MORB and higher temperatures in the mantle plumes that produce the OIB of Iceland, Hawaii, Gorgona, and Archean komatiites.

Crystallization of P-rich minerals from the high phosphorus rare-metal magma of East-Kalguty dyke belt (S.Altay, Russia)

SOKOLOVA E[1,2]* AND SMIRNOV S.Z. [1,2]

[1] V.S. Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia
(*correspondence: ekaterina@igm.nsc.ru)
[2] Novosibirsk State University, Novosibirsk, Russia

High phosphorus content is an important feature of some highly evolved peraluminous Ca-poor granitoids, associated with ore deposits. East-Kalguty dyke belt (South Altai, Russia) is one of the few representatives of rare-metal rich felsic high-phosphorus rocks (avg 0.39 wt % P_2O_5 and ASI=1.23). In this case alkali feldspars (Af) represent significant reservoir of phosphorus, containing 0.14 wt % P_2O_5 in average. Incorporation of P into feldspars involves the substitution $2Si^{4+} = Al^{3+} + P^{5+}$[1].

Average P-content 0.27 wt % of P_2O_5 in the melt equilibrated with Af phenocrysts from dyke rocks was calculated from dependence ASI=0.7273*D[P]Af/melt+0.7818 derived by D.London on the basis of experimental data [1].

Direct measurement of P_2O_5 by EMPA in melt inclusions in quartz phenocrysts showed 0.29 wt %, which is in good agreement with the calculated value. This means that Af crystallized from the same melt with quartz phenocrysts.

Comparison of Ca and P content, and Ca/P ratio in the melt inclusions and rocks shows that apatite crystallized before entrapment of the melt inclusions in quartz. Low Ca content results in excess of phosphorus in the evolved melts, which was later incorporated into feldspars and ambligonite $LiAl[PO_4](OH)$. Main intrusive phase of the Kalguty granite massif, preseding to rare-metal dykes, have P-content close to the clark of felsic rocks [2]. The inrease of P in latest dykes, which reaches a maximum in the rare-metal rich dykes is explained by introduction of phosphorus by external fluids into magmatic system with subsequent its accumulation in the course of magma differentiation.

This study was supported by grants RFBR 12-05-31-290 and 13-05-00471.

Reactive transport modeling of cement/concrete – rock interaction: The Tournemire and Maqarin cases

JOSEP M. SOLER[1]

[1]IDAEA-CSIC, 08034 Barcelona, Catalonia, Spain

In the framework of the GTS-LCS project (JAEA-Japan, NAGRA-Switzerland, NDA-UK, POSIVA-Finland, SKB-Sweden), reactive transport modeling of 2 analogues of cement-rock interaction in a repository is being performed: The DM borehole at Tournemire (France) and the Eastern Springs hyperalkaline system at Maqarin (Jordan). In Tournemire solute transport is dominated by diffusion between concrete and rock (mudstone); in Maqarin there is flow along a fracture zone from a cement-like metamorphic rock body with diffusion between fracture and wall rock (clay-containing limestone). The two cases are examples of diffusion (Tournemire) and fracture-flow (Maqarin) dominated systems. In the modeling presented here, calculations have been performed with the CrunchFlow reactive transport code. Results are compared with observations.

Results for the Tournemire case (concrete-mudstone interaction during 15 years) show sealing of porosity at the rock side of the interface (mm scale) due to the precipitation of C-A-S-H, calcite and ettringite, together with clay dissolution. The location of sealing is influenced by cation exchange. Without exchange, sealing is at the concrete side of the interface.

The hyperalkaline system at Maqarin may have been active for tens or several hundreds of thousands of years. The high-pH solution flows along the full length of the fracture (ca. 80 m), with intense mineral alteration in the wall rock (cm scale). Major secondary minerals include ettringite-thaumasite, C-S-H/C-A-S-H and calcite. C-S-H/C-A-S-H precipitation is controlled by the dissolution of primary silicates. Ettringite precipitation is controlled by diffusion of sulfate and aluminum from the wall rock to the fracture, with aluminum provided by the dissolution of albite. Calcite precipitation is controlled by diffusion of carbonate from the wall rock. Extents of porosity sealing along the fracture and in the fracture-wall rock interface depend on assumptions regarding flow velocity and composition of the high-pH solution. The multiple episodes of fracture sealing and reactivation evidenced in the fracture infills were not included in the simulations.

Financial support from POSIVA and the many discussions with the LCS team are gratefully acknowledged.

Spatial heterogeneity of benthic methane dynamics in the subaquatic canyons of the Rhone River Delta (Lake Geneva)

* *correspondence:* sebastien.sollberger@eawag.ch

Heterogeneous benthic methane (CH_4) dynamics from river deltas, resulting from variable organic matter accumulation, have been recently reported in various aquatic and marine environments. The spatial heterogeneity of CH_4 sediment release from the Rhone delta of Lake Geneva (Switzerland/France) was thus investigated. Methane benthic dynamics were compared (1) between three underwater canyons of different sedimentation regimes, (2) along a longitudinal transect of the canyon most influenced by the Rhone River, and (3) laterally across a canyon. Results indicate higher CH_4 diffusion rates in the canyon, which continuously receives loads from the Rhone River compared to the other canyons, as well as in intermediate sites instead of proximal and distal reaches of the canyon. The lateral canyon survey results were inconclusive due to the shorter length of the cores. The more allochthonous material is found in higher sedimentation rate environments and partially explained the greater CH_4 diffusion rates. The lower river velocity in the intermediate region characterized by a smaller fraction of coarser sediment allowed more organic matter to settle down and be preserved. This induced higher CH_4 diffusion rates than in the proximal region, where the upper layer of sediments were potentially more disturbed by a stronger river inflow. Total CH_4 sediment release was found to range from 0.9 to 1.2 x 10^4 t CH_4 yr^{-1} for the entire delta, although it is most likely oxidized before CH_4 reaches the atmosphere due to the oxic water column. Finally, turbidites were shown to act as sealing layers beneath which CH_4 could accumulate in high amounts and potentially act as source layers for ebullition.

Spatial microbial community structure of a shallow-water hydrothermal system

MIRIAM SOLLICH[1,2]*, IOULIA SANTI[3], PETRA POP RISTOVA[1], THOMAS PICHLER[2], KAI-UWE HINRICHS[1,2] AND SOLVEIG I. BÜHRING[1]

[1]MARUM & [2]Dept. of Geosciences, University of Bremen, Bremen, Germany (*correspondence: msollich@uni-bremen.de)

[3]Max Planck Institute for Marine Microbiology, Bremen, Germany

Marine shallow-water hydrothermal systems are extreme environments, characterized by discharge of hot and often acidic fluids with elevated concentrations of reduced compounds. Steep physico-chemical gradients on small spatial scales lead to the formation of various microniches for microbial communities. In contrast to deep-sea hydrothermal systems, the sun light in shallow systems results in a combination of photoautotrophic and chemoautotrophic primary production. Despite the comparably easy accessability of shallow-water hydrothermal systems, little is known about the spatial microbial community structure and its relationship to physico-chemical conditions.

Here, we present data for the system off Milos island, one of the most hydrothermally active regions in the Mediterranean Sea. A combined approach of gene- and lipid-based techniques (ARISA and intact polar lipids) with porewater geochemistry data was applied along a temperature gradient to investigate the spatial microbial community structure.

Supported by statistical analyses, ARISA data revealed significant changes of the bacterial community structure along the temperature gradient and depth profiles from hydrothermally unaffected areas towards the vent orifices. Intact polar lipid results are consistent with the ARISA data and clearly differentiate samples from close to the vent outlet from those in less affected areas. Changes from phospho- and betaine lipids within the top layer of the unaffected area to glyco- and ornithine lipids in the hydrothermally influenced sediment layers show a change from photoautotrophic algae to a bacteria-dominated community.

Statistical analyses revealed that changes in the microbial community structure were mostly related to spatial heterogeneity in pH and sulfide and less to temperature.

The innovative approach to combine gene- and lipid-based methods proved to be very useful to describe the spatial microbial structure.

Biogeochemical features of the behavior of arsenic in Sherlovogorsk mining district of the Zabaikalsky Krai (Russia)

M.A. SOLODUKHINA AND G.A. YURGENSON

Federal state budget institution of science, Institute of Nature Recourses, Ecology and Cryology, Siberian Branch of Russian Academy of Sciences, Chita, Russia (mabn@ya.ru, yurgga@mail.ru)

As a result of multiyear research (2002-2012 gg.) conducted in Sherlovogorsk mining district of the Zabaikalsky Krai, the peculiarities of biogeochemical behaviour As in the components of the landscape. Shows the sources of his income, concentration, regularities of the spatial distribution of the soil, especially biological capture and accumulation in plants.

The spatial distribution of arsenic (As) on the territory of the region is due to the regularities of the development of the second phase of formation of Sherlovogorsk of ore-magmatic system, which is associated with the formation of tin-polymetallic Deposit.

All of the components of landscapes Sherlovogorsk ore district has considerably enriched with As. It is established, that in natural soils background of the site content As in 6 times exceeds MPC and in 2 times - soil Clark. On the territory of the fields maximum Clark concentration (CC) in the soil (the ratio of the average content in the soil to the soil Clark) is 1183, and the excess of MPC in 1005 times. In техноземе career-dumping landscape respectively QC=340, and the excess of MPC in 289 times. Sherlovogorsk ore area can be identified as arsenic biogeochemical province.

The main form of location As in soils is the residual. In the permafrost meadow-forest, in gravelly low-power soil, Chernozem without carbonates, in the chestnut carbonate soil more than 50% As fixed in a stationary position in the oxidation products arsenopyrite, first of all skorodit and other arsenates.

Capture As different plants varies considerably. Herbaceous plants and shrubs more intensively involve As in biological Cycling, than shrubland. Of wood and shrub of plants Crataegus sanguinea Pallas and Betula pendula Roth do not have гипераккумуляцией As, in contrast to the bushes: Pentaphylloides fruticosa (l.) O. Schwarz, Pentaphylloides parvifolia (Fischer ex Lehm.) Sojak and Artemisia gmelinii Weber ex Stechm. In them, just as in the grassy plants of natural-technogenic landscape detected toxic and critical concentration As (more than 5 mg/kg).

For the majority of the studied plants tend maximum capture As roots and leaves, by the end of the vegetation period is marked its accumulation in these bodies. Minimum contents As found in fruits and seeds.

The obvious hubs, As are herbaceous plants: Potentilla acervata Sojak, Aconogonon angustifolium (Pall.), Gallium verum L. and subshrubs - Artemisia gmelinii Weber ex Stechm.

Melting and breakdown of $MgCO_3$ at high pressures

N.A. SOLOPOVA[1,2,*], A.V. SPIVAK[2], YU.A.LITVIN[2] AND L. S. DUBROVINSKY[1]

[1]Bayerishes Geoinstitut, University of Bayreuth, Bayreuth, Germany, (*correspondes: solopenok@yandex.ru)
[2]Institute of Experimental Mineralogy of the Russian Academy of Sciences, Chernogolovka, Moscow region, Russia

Studies inclusions in ultra-deep diamonds suggest that magnesite can be major stable carbonate in the lower mantle. It can play an importatnt role for the carbon cycle in the Earth's interior. New form of magnesite II was reported at the high-pressure and high-temperature [1]. However, the information about melting of magnesite at high pressure is limited [2].

We study high-pressure high-temperature behavior of magnesite, stability of the melt and its decomposition in static compression experiments between 10 and 60 GPa and temperatures up to 3500 K using diamond anvil cell technique with laser heating. Special methodology was used for determing the melting point. The spherical boron doped diamonds were used as a heat absorber for laser heating.

In accordance with thermodinamic analysis [3] our experimental results showed that magnesite does not decompose to MgO and CO_2 under conditions of the Earth's lower mantle and demonstrate extended field of congruent melting of magnesite. We observed also formation of MgO and diamond or graphite as a result of decomposition of $MgCO_3$ melt. Formation of diamond and graphite may be explained by a two stage reaction: $MgCO_3$=MgO+CO_2; CO_2=C+O_2.

The obtained results allow to determine the phase relations of $MgCO_3$ at high pressures and high temperatures, and important for constraining the conditions of diamond crystallization from the carbonate-bearing parental media in the Earth's lower mantle.

Complex C-O-H-N-S fluids and sulphide-silicate melt immiscibility in the upper mantle

I. SOLOVOVA[1]*, A. BOUIKINE[2], L. KOGARKO[2] AND A.B. VERCHOVSKY[3]

[1]Institute of Geology of Ore Deposits solovova@igem.ru
[2]Vernadsky Institute of Russian Academy of Sciences,
[3]The Open University, Milton Keynes, UK

The minerals (Ol, Opx, Cpx) of metasomatized garnet lherzolite xenoliths from East Antarctica contain diverse microinclusions of melt, fluid, and fluid–silicate–sulphide inclusions with typical liquid immiscibility textures. At room temperature, the fluid inclusions contain one (liquid), two (liquid and gas) or three (H_2O and CO_2 liquids and gas) phases. All the inclusions are CO_2-dominated. The obtained data suggest the existence of two sources of fluids. Fluid of fluid–silicate–sulphide inclusions show homogenization temperatures of up to –64.8°C, and densities of up to 1.17 g/cm^3, which correspond to pressures ≥13 kbar at the moment of fluid entrapment (at 1000°C). Phase transitions at –151°C are close to the critical point of N_2 (–147°C). The Raman spectra of fluid inclusions display lines of CO_2, H_2S and N_2. The high-pressure fluid inclusions have low C/N_2 and N_2/Ar, heavy nitrogen isotope compositions and elevated $^{40}Ar/^{36}Ar$ values (up to 530). Second type inclusions have lower densities (≤0.82 g/cm^3) and, correspondingly, lower entrapment pressures (≤7 kbar). Their Raman spectra exhibit a distinct H_2O line. Their fluid has higher C/N_2 and C/Ar, lower $\delta^{13}C$, and close to atmospheric N_2/Ar and $^{40}Ar/^{36}Ar$ values. It is suggested that the observed fluids are products of mixing between a mantle derived fluid and atmospheric air or/and seawater.

Fe(II) uptake mechanisms on montmorillonite clay minerals: A multidisciplinary approach

D. SOLTERMANN[1,2,*], M. MARQUES FERNANDES[1], B. BAEYENS[1], M.H. BRADBURY[1] AND R. DÄHN[1]

[1]Laboratory for Waste Management, Paul Scherrer Institut, Villigen PSI, Switzerland, (*daniela.soltermann@psi.ch).
[2]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zürich, Zürich, Switzerland

Virtually all radioactive waste repository designs contain large amounts of iron (steel canisters) and reducing conditions will prevail in the long-term. Due to the corrosion of steel canisters, high ferrous iron (Fe^{2+}) concentrations in the interstitial porewaters in the near- and far-fields might be expected, which could have a significant influence on the sorption behaviour of other radionuclides through sorption competition effects. The best suited approach investigating the sorption of Fe^{2+} on clay minerals and the influence of high aqueous Fe^{2+} concentrations on the radionuclide retention by clay minerals is a multi-disciplinary one, consisting of macroscopic sorption experiments, geochemical modelling and advanced spectroscopic techniques, such as X-ray absorption spectroscopy (XAS). Fe^{2+} uptake on an iron-free synthetic montmorillonite in the absence of any competing metal was measured by batch sorption experiments under anoxic conditions (O_2 <0.1 ppm). A two-site protolysis nonelectrostatic surface complexation and cation exchange sorption model[1] was used to quantitatively describe the uptake of Fe^{2+} on montmorillonite. Two types of clay surface binding sites, so-called strong ($\equiv S^SOH$) and weak ($\equiv S^WOH$) edge sites, were required to model the Fe^{2+} sorption isotherms. XAS data showed spectroscopic differences between Fe sorbed at low and medium concentrations, which were chosen to be characteristic for uptake on strong and weak sites, respectively. The XAS data analysis indicated that Fe is located in the continuity of the octahedral sheet.[2]

Sorption competition experiments of divalent metals Fe and Zn were carried out to further elucidate the uptake processes at the clay mineral-water interface. The competition experiments were performed for the combinations of Zn(II)/Fe(II) and Fe(II)/Zn(II) , where the former represents the trace index metal and the latter the blocking metal at high concentration. The results of the wet chemistry and XAS measurements indicate that Fe(II) is competing with Zn(II) if the Fe(II) is present in excess (blocking metal). However, no competition effects between Fe(II) and Zn(II) were observed if Zn(II) is the blocking metal. These results can be explained by a selective uptake of trace Fe on montmorillonite due to Fe(II)/Fe(III) redox processes taking place at the clay surface.[2] The outcome of this study contributes to an improved molecular understanding of the Fe-clay interaction under anoxic conditions in the absence and presence of other divalent metals.

Application of portable XRF analyzers in Au and PGE exploration: An example from the Bushveld Complex, South Africa

ALIREZA SOMARIN

Thermo Fisher Scientific, Tewksbury, MA 01876
alireza.somarin@thermofisher.com

Field portable X-ray florescence (FPXRF) analyzers are used worldwide in exploration and mining of various types of metallic and non-metallic deposits from base metals to REEs, precious metals and even hydrocarbons. FPXRF application in base metal and REE exploration and mining is relatively easy and straight forward due to their high economic threshold combined with low detection limit of these metals by FPXRF. Application in precious metal projects needs good understanding of the limitations of the technique; however, FPXRF can still be utilized in such cases using pathfinder elements. This paper summarizes one of these cases in Au-PGE exploration in the Bushveld Complex, South Africa.

In this study, the pathfinder elements were defined using lab assays of 63 samples that were collected along a stratigraphic section. Elements with highest correlation with the target metals (Au, Pt and Pd) were classified as pathfinder elements. These elements were Ni and Cu in this case study (Figure 1). Analyzes of the samples (both direct shot and pulp samples) by FPXRF indicate that all anomalous zones of Au, Pt and Pd can be easily identified by locating anomalies of Ni and Cu on prepared (pulp) and even un-prepared samples. Such anomalous samples have target elements lower than detection limit of FPXRF and should be analyzed by laboratory techniques.

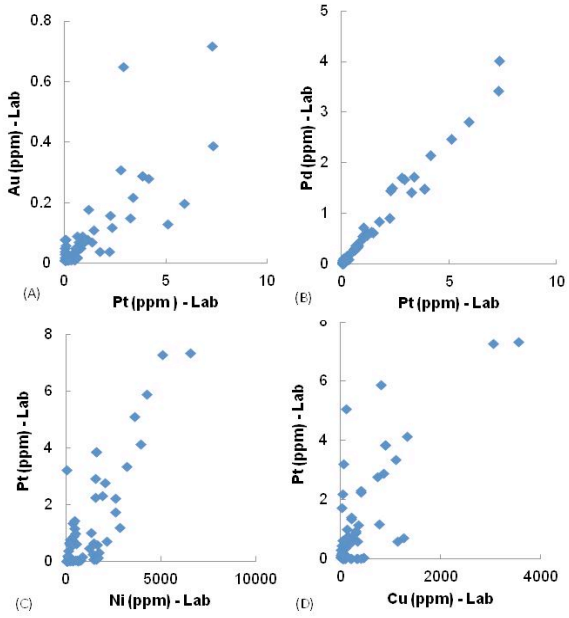

Figure 1: A and B) Correlation between target elements. C and D) Correlation between Pt and pathfinder elements (Ni and Cu).

The Neoproterozoic magmatic evolution in Northern Guangxi, China

SONG HAO[1,2] , XU ZHENGQI [1,2]*, NI SHIJUN[1,2] AND ZHANG CHENGJIANG [1,2]

[1] Department of Geochemistry and Nuclear Resources Engineering, Chengdu University of Technology, Chengdu 610059, China (*Correspondence: xuzhengqi@cdut.cn)

[2] Key Laboratory of Nuclear Techniques in Geosciences of Sichuan Province, Chengdu 610059, China

As a Neoproterozoic giant intrusion, Motianling Pluton in North Guangxi remains a long-standing controversy in the diagenetic age. Based on a series of U-Pb dating in the Motianling Granites, the study of volcanic rocks in the study area mainly aims at retracing the tectono-magmatic evolutionary history in Jinningian epoch of Northern Guangxi. However, the relationship between the Danzhou Group and the Motianling Granites is still in great dispute [1]. This paper attempt to clarify the relationship between Danzhou Group and the Motianling Granites.

With long elongation time in the diagenesis, the Danzhou Group and the Motianling Granites have the time-overlap part and are formed within nearly 100 million years. And the main granite body is formed in the middle-late period of sedimentation of the Danzhou Group, with the later persistent granitic magmatic activity even after the deposition epoch during the formation period of the patched granite body in the Motianling Granites. The severe subsidence of earth surface is resulted from the orogenic extension, which results in the formation of the fine clastic sedimentary of the Danzhou Group (part of Sibao Group can be included). And the partial melting of the crust is resulted from the lithospheric delamination accompanying with the granitic magmatic activity. Through combining the U-Pb dating results with the element geochemistry, the main granite body and the diabase bodies/veins are formed after the Bendong granodiorite, then display the increasing tendency in acidity (SiO_2) and decrease tendency in alkali (Na_2O+K_2O) in the patched granite bodies.

This work is supported financially by the National Natural Scientific Foundation of China (Grants No. 41173059) and the Foundation of China Nuclear Geology (Grants No. 201148 and 200995).

The Triassic Igneous rocks in the Northeastern part of the South Korea

KYO-YOUNG SONG[1]

[1]Korea Institute of Geoscience & Mineral Resources, Daejeon, Korea (kysong@kigam.re.kr)

The Triassic igneous rocks, gabbroic to granite in composition, occur scattered throughout the Yangyang and Gangneung areas in the northeastern part of the South Korea. The total alkali versus silica composition of these igneous rocks shows a series of differentiation well and large variation from gabbro to alkali granite. So these igneous rocks can be classified to the Yangyang suite on the concept of granite suite.

The Yangyang suite is consist of gabbro, two mica granite, biotite granite, the Namhangjin diorite, the Yangyang syenite, the Yangyang granite and the Hajodae granite. The Yangyang suite is divided into two groups by whole-rock geochemistry analysis, alkali and subalkali rocks group. These means the Yangyang suite is consist of two subsuite. The geochemistry and isotopic composition of these two subsuites indicate that these are thought to be derived from the different granitic magma source. Alkali rocks group contains gabbro, the Namhangjin diorite, the Yangyang syenite and the Yangyang granite, subalkali rocks group contains two mica granite, biotite granite and the Hajodae granite.

The SHRIMP zircon U-Pb ages of the Yangyang suite range from 234±2.9 to 226.5±1.8 Ma.

This Yangyang suite is very important to understand and explain the indentation model which the South China Blocks had collided into the North China Blocks in the Korean peninsula as a wedge-shaped.

Water Vapor Interactions with FeOOH Particle Surfaces

XIAOWEI SONG* AND JEAN-FRANÇOIS BOILY

Department of Chemisty, Umeå Univetsity, Sweden *Email: xiaowei.song@chem.umu.se

Iron oxyhydroxide (FeOOH) minerals play important roles in a variety of atmospheric, terrestrial and technological settings. Interactions with water vapor are particularly important given the predominance of water-bearing gases in the environment. In this work, molecular details of water adsorption reactions at FeOOH surfaces were resolved using vibrational spectroscopy, quartz crystal microbalance and molecular dynamics. Acidified and alkalified mineral surfaces were investigated to determine protonation effects on interfacial water loadings and structures. The effects of residual salts on the surfaces were further studied by resolving competitive hydration processes between surface-bound Cl^- ions and hydroxyl groups.

This work reveals the initial mechanisms of formation of thin water films on mineral surfaces under atmospheric conditions [1]. We show that thin films of adsorbed water display liquid water-like attributes. The affinity of surface (hydr)oxo groups for water molecules is strongly dependent on their abilities at forming hydrogen bonds. Coordination number and site accessibility/steric constraints are main factors. These groups have moreover stronger affinities for water than chemisorbed water ($-OH_2$) and Cl-exchanged group (*e.g.* –Cl, μ-Cl). Finally, we identified a *surface memory effect* showing that original surface protonation states can be retrieved by evacuating surfaces from surface-bound waters. This confirms that the original surfaces were at thermodynamic equilibrium prior water uptake reactions and that all reactions are reversible. This reversibility may further hold in mineral particles undergoing several water condensation-evaporation cycles in nature. This work thus opens a path for understanding water structure as well as condensation reactions on these important mineral particles.

A stable isotope perspective on tracing natural and anthropogenic Hg emissions at the global scale.

JEROEN E. SONKE

Observatoire Midi-Pyrénées, 14 avenue E. Belin 31400 Toulouse, sonke@get.obs-mip.fr

A decade of research on the natural variations in mercury (Hg) stable isotope abundances has shown large variations across biogeochemical reservoirs. These variations result from the gradual separation of heavy/light or even/odd Hg isotopes during the numerous physicochemical processes that shuttle Hg across the Earth's surface. As a result, a Hg isotopic measurement gives rise to four useful isotope fingerprints that may characterize its source, or code for the transformations that Hg has undergone in the past.

Tracing the dominant natural and anthropogenic Hg emissions at the global level is a challenge. The further Hg emissions travel from their source, the more likely it is that oxidation/reduction, sorption or (de-)methylation reactions modify the original source Hg isotope signatures. This presentation illustrates an integrated approach to evaluate Hg isotope tracing at the global scale. Similar to modern and historic Hg emission inventories, a parallel Hg isotope library needs to be built per industrial sector and geographical region. Industrial processes include Hg transformations that may change isotope signatures and need to be understood. Monitoring of the isotopic composition of emitted Hg species and associated Hg deposition at different spatiotemporal scales is necessary. Finally, monitoring of critical receptor environments on continents and oceans and on different time scales (modern, geologic) will tell if globally relevant emission sources can be recognized. All of these tasks are compatible with box and process models of the global Hg cyle, so that Hg isotopic information may in the near future be integrated in global models to help understand Hg cycling.

The approach will be illustrated for coal fired power plant (CFPP) emissions: A coal Hg isotope library, containing ~200 coal samples from historically dominant coal burning regions has been made. A study on two large Chinese coal fired power plants suggests that stack emission Hg isotope signatures are slightly modified from feed coal signatures by emission control technologies. Bi-weekly monitoring of gaseous and particulate Hg isotope signatures in Asian urban-industrial environments is compatible with a dominant CFPP source. Finally, a preliminary attempt to integrate an emission isotope library in a global Hg box model will be compared to historical records of Hg deposition and isotopic variation in peat bogs.

(Non-?)Traditional Hg stable isotope geochemistry in the early 1920's

J. E. SONKE[1], N. ESTRADE[2], O.F.X DONARD[3] AND J. CARIGNAN[2]

[1] Observatoire Midi-Pyrénées, CNRS-GET-Université de Toulouse, France, sonke@get.obs-mip.fr
[2] CRPG, UMR 7358, CNRS-Université de Lorraine, Nancy, France
[3]IPREM/LCABIE, UMR 5254, CNRS-Université de Pau et des Pays de l'Adour, Pau, France

In 1919 Sir Francis Aston discovered the multiple stable isotopes of mercury (Hg) using his mass spectrograph. Only one year later Johannes N Brønsted and György de Hevesy used high precision density measurements to prove that liquid Hg distillation into a vacuum fractionates Hg isotopes as a function of isotope mass. In more detailed studies during the 1920's Brønsted and colleagues managed to produce Hg vapors and residual liquids that were heavily fractionated by up to -84‰ and +74‰ on the δ^{202}Hg scale. They derived the kinetic isotope fractionion law, and used Rayleigh equations and diagrams to estimate Hg isotope separation factors. They also explored the natural variations in Hg isotope abundances, by converting cinnabar (HgS) into liquid Hg and measuring its density. By sheer coincidence they did not find any density variations for nine global cinnabar deposits, within their measurement uncertainty of 0.4 - 1.2 ‰ on the δ^{202}Hg scale. Today we know that the δ^{202}Hg of cinnabar may vary by up to 5 ‰ across a single cinnabar deposit.

In 2006 Jean Carignan was interested in the potential isotopic fractionation of volatile metals under natural and industrial conditions. He proposed to examine the distillation of liquid Hg in a vacuum, without knowing that nearly one century before him scientists had looked at the issue. Using MC-ICPMS, we made nearly identical observations as Brønsted and co-workers: a kinetic isotope fractionation factor of 1.0067 for the ^{202}Hg/^{198}Hg pair (Estrade *et al*., 2009). We also performed Hg isotope analysis of Hg vapor that is in equilibrium with liquid Hg. Here we observed deviations from theoretical mass dependency for the two odd Hg isotopes, ^{199}Hg and ^{201}Hg, in what has become the first experimental evidence for nuclear volume fractionation of Hg isotopes. This contribution will look back on both the early and more recent measurements.

A poorly characterized process in warm clouds is the conversion of cloud water to rain water especially with regard to the rate by which this complex process occurs. Using a satellite remote sensing data set, this conversion process is examined in a global sense over oceans to identify regional differences and relationships with relevant environmental parameters [1]. We show that a faster conversion process coincides with conditions of reduced atmospheric stability, higher low-level wind speeds, and low aerosol index values. Aircraft measurements are used in a stratocumulus cloud environment to provide more views on relationships between environmental factors influencing water in clouds [2].

Iron isotope geochemistry of the Balmuccia peridotite massif and the composition of the upper mantle

PAOLO A. SOSSI[1]*, HUGH ST.C. O'NEILL[1] AND MARCO BELTRANDO[2]

[1] Research School of Earth Sciences, Australian National University, Canberra, ACT, 0200
[2]Dipartimento di Scienze della Terra, Università di Torino, Via Valperga Caluso 35, 10125 Torino, Italy

Extensive work on global, unmetasomatised oceanic and lithospheric mantle-derived peridotites reveals a scatter of ±0.1 ‰ δ^{57}Fe around the 0‰ value (vs.IRMM-014) [e.g. 1, 2]. Contrastingly, most primitive basaltic lavas cluster about δ^{57}Fe ≈ 0.1‰ [3]. This disparity has typically been ascribed to iron isotope fractionation during partial melting [4]. However, recent studies place the composition of primitive, undepleted mantle at ≈+0.1‰, obviating the need for such melting-induced fractionation [5]

In order to constrain the relative effects of partial melting and metasomatism on the iron isotope composition of the upper mantle, we present data from the remarkably fresh and well-characterised Balmuccia orogenic peridotite massif of the Ivrea Zone in northern Italy [6]. A spectrum of cogenetic ultramafic samples were analysed, comprising pyroxenites to lherzolites, harzburgites and dunites, faithfully capturing the variation recorded in the massif.

The starting composition of the Balmuccia lherzolite has about 39% MgO, 3.1% Al_2O_3, 2.9% CaO and 8.3% FeO, which could be explained by the extraction of ≈5±0.33% MORB from primitive mantle. This initial composition has a δ^{57}Fe ≈ 0.013‰ ±0.005‰ and defines an anchor point from which trends of pyroxene-addition, melt depletion and Fe-metasomatism are identified. Residual harzburgites extend to lighter δ^{57}Fe and higher Mg#s, while Fe-enriched harzburgites and dunites are typified by heavier iron isotope compositions and near-constant Mg# with respect to the lherzolites.

Lherzolites with lower MgO contents also exhibit heavier δ^{57}Fe values, nearing +0.05‰ at the MgO content of the primitive mantle (36.77%). However, given that MORBs, with δ^{57}Fe ≈ 0.15‰ [3] are derived from depleted mantle, a source of Fe isotope fractionation between partial melting and their eruption onto the ocean floor seems to be required.

Hf isotope systematics of Archean anorthosites: The Manfred Complex, Yilgarn Craton, Western Australia

A.K. SOUDERS[1] *, P.J. SYLVESTER[1], J.L. CROWLEY[2] AND J.S. MYERS[3]

[1]Department of Earth Sciences, Memorial University, St. John's, NL A1B 3X5, Canada (*kate.souders@mun.ca)
[2]Department of Geosciences, Boise State University, 1910 University Drive, Boise, Idaho 83725-1535 USA
[3]Department of Applied Geology, Curtin University, Perth, WA 6845, Australia

Archean anorthosite complexes represent a minor, yet distinct rock type found within many Archean terranes. These mantle-derived melts are commonly found in layers with associated leucogabbro, gabbro, and ultramafic units of similar origin. Most Archean anorthosites are intensely deformed and metamorphosed yet preserved igneous minerals have been identified within several complexes. It has become obvious that Archean anorthosites contain zircon crystals, which can be used to establish robust crystallization ages for anorthosite complexes. These minerals are also ideal targets for in situ Lu-Hf isotopic analysis to further characterize the source of Archean anorthosites and provide insight into the formation and evolution of the continental crust during the Archean.

The ca. 3.7 Ga Manfred Complex is exposed northeast of Mount Narryer within the Narryer Gneiss Terrane, Yilgarn Craton, Western Australia. The layered anorthosite-gabbro-ultramafic intrusion outcrops in pods and lenses, engulfed by granitic gneisses [1, 2, 3]. We have sampled anorthosites, leucogabbros and gabbros from the Manfred Complex and determined their age by LA-ICPMS U-Pb zircon geochronology. Zircons separated from these rocks give ages of 3.63 Ga to 3.73 Ga. LA-MC-ICPMS Lu-Hf isotope analyses were performed by focusing the laser spot directly on top of the U-Pb analysis location for each zircon grain. Initial Hf isotope compositions of zircon grains from the Manfred complex range from ca. εHf +2 to -3. This range suggests contributions from both depleted mantle and ancient crustal sources to the parent magma of the Manfred Complex.

Secondary Organic Aerosols in the coupled climate aerosol model ECHAM-HAM: Insights into production dependencies and climate impacts

G.SOUSA SANTOS[1]*, T. STANELLE[1], I. BEY[1] AND U. LOHMANN[1]

[1]Institute for Atmospheric and Climate Science, ETH Zurich, Universitaetstrasse 16, 8092 Zurich (*correspondence: gabriela.sousa-santos@env.ethz.ch)

Aerosols are an integral part of the climate system, because they play essential roles in the atmosphere's radiation budget and in the hydrological cycle. An important fraction of the aerosols in the troposphere are organic. So far, most models only considered Primary Organic Aerosol (POA) emissions into the atmosphere. However, Secondary Organic Aerosols (SOA) are a non negligible fraction of the total organic.

We aim to investigate SOA processing and impacts on the climate system using two sets of simulations with ECHAM-HAM: two equilibrium simulations for 2000 conditions without SOA and with interactive computation of SOA, and a 50-year hindcast (1960-2010).

The hindcast simulation shows a general increase in SOA burdens in the Northern Hemisphere from 1960 to 2010. SOA production increases from 25 to 30Tg/yr globally and 0.75 to 1.3Tg/yr in Europe. This translates in a increase in SOA surface concentrations of roughly 30% globally and 40% in Europe. In Europe, the reported changes mainly resulted from an increase in biogenic precursor emissions, which are, in turn, most likely connected to changes in anthropogenic land cover and in a lower degree to changes in surface radiation. In other regions of the world other factors like anthropogenic precursor emissions and temperature changes have higher importance. According to the model, SOA has impact on the Earth radiation budget, with a direct radiative effect at the top-of-the-atmosphere (TOA) of -0.35W/m^2. We will present details of the effect on other climate variables, especially on cloud properties at the conference.

Best practices for reducing energy poverty and (as a result) emissions of methane, carbon dioxide, and black carbon/aerosols

BENJAMIN K. SOVACOOL

Institute for Energy and the Environment, Vermont Law School, bsovacool@vermontlaw.edu

This presentation demonstrates how small-scale renewable energy technologies such as solar panels, cookstoves, biogas digesters, microhydro units, and wind turbines are helping Asia eradicate energy poverty and (as a result) reduce greenhouse gas emissions. Through an in-depth exploration of case studies in Bangladesh, China, India, Laos, Indonesia, Malaysia, Mongolia, Nepal, Papua New Guinea, and Sri Lanka, the presentation highlights the applicability of different approaches to the promotion of renewable energy in developing countries. It also illuminates how household and commercial innovations occur (or fail to occur) within particular energy governance regimes. It lastly, and uniquely, explores successful case studies alongside failures or "worst practice" examples that are often just as revealing as those that met their targets. Based on these successes and failures, the presentation concludes by presenting twelve salient lessons for policymakers and practitioners wishing to expand energy access and raise standards of living in some of the world's poorest communities.

Benthic fluxes and early diagenesis processes in Adriatic Sea

F. SPAGNOLI[1]*, G.BARTHOLINI[2] AND P.GIORDANO[3]

[1]CNR-ISMAR, Largo Fiera della Pesca, 60125, Ancona, Italy
[2]Università di Bologna, Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Piazza di Porta S. Donato, 1, Bologna
[3]CNR-ISMAR, Via Gobetti, 101, 40120, Bologna, Italy

During the last decades various researches in the Adriatic and Ionian Sea allowed the individuation of different area characterized by various early diagenesis environments that generate dissolved fluxes at the sediment-water interface with different intensity.

North of the Po River a thin and discontinuous band of terrigenous fine carbonate sediment and with different reactivity of organic matter produces benthic flues extremely variable in functions of the fresh organic matter entered by the main rivers

In front of the Po River a limited area, with high sedimentation rate and high continental and autochthonous organic matter inputs, generates high nutrient benthic fluxes.

In the western Adriatic sediments are characterised by progressive southward decrease of sedimentation rate and reactive organic matter that generate decreasing benthic fluxes. The central Adriatic Sea bottom sediment area is characterized by prevalently carbonate sediments and low fluxes of nutrients due to little organic and inorganic inputs and to precipitation of authigenic mineral.

In the Meso-Adriatic and South Adriatic Depression low sedimentation rates and strongly reworked organic and inorganic matter produce very low benthic nutrient fluxes.

In Ionian Sea slope sediments are carachterized by very lo particulate imputs and by negative fluxes of DIC acting in this way as CO2 traps while basin sedimts show higher benthic fluxes due to increses of organic matter inputs.

AMERIGO: A new benthic lander for dissolved flux measurements at sediment-water-interface

F. SPAGNOLI[1]*, G. CICERI[2], G. GIULIANI[1], V. MARTINOTTI[2] AND P. PENNA[1]

[1]CNR-ISMAR, Largo Fiera della Pesca, 60125, Ancona, Italy
[2]RSE SpA, Via Rubattino 54, 20134, Italy

Amerigo is a new autonomous and automatic benthic lander for the measurements of dissolved benthic fluxes at the sediment-water interface. The lander is able to measure fluxes of nutrients such as ammonium, nitrites, nitrates, phosphates and silica, gases such as oxygen, carbon dioxide and methane, trace elements such as heavy metals, and also other dissolved pollutants resulting from human activity. AMERIGO is able to operate from transitional environments to continental shelf and abyssal plain. The Lander can include various components, at present it is equipped with 3 benthic chambers for measuring the fluxes at the water-sediment interface and is prepared to host a microprofiler and other benthic instruments (mini-penetrometer, gravimeter, etc.). The 3 benthic chambers are equipped with a water sampler, which also allows injection of tracers, a system for the refilling of the consumed oxygen (Oxystat) and sensors for pH and dissolved gas monitoring (oxygen, methane and in future CO2). Outside the benthic chambers a CTD probe for measuring the chemical-physical parameters (temperature, conductivity and pressure) and a niskin bottle for the sampling of the water column are present. The lander is equipped with all mechanisms for the dipping (ballast weights), positioning on the bed, raising (a timed release mechanism (burn-wire type) for the release of the ballast and glass spheres for the flotation) and recovery (radio transmitter, GPS position system and flasher) on board. A useful property of AMERIGO is the modularity and flexibility, that is different components, which can be assembled and programmed on the basis of needs and of the environmental conditions in which it will operate.

After the two first testing cruises early results of the AMERIGO functioning will be presented.

Hydrogeochemical radiation burden in the ambiance of natural radioaktivity in the hills of Vršac

[1]V. SPASIĆ-JOKIĆ, [2] V. GORDANIĆ, [2] M. VIDOVIĆ AND [3] D. JOVANOVIĆ

[1]Faculty of Technical Sciences, University of Novi Sad, svesna@uns.ac.rs
[2]IHTM, University of Belgrade gordanicv@gmail.com, mivibgd@yahoo.com
[3]Geologocal Survey, Belgrade, dragan.jovanovic@gzs.gov.rs

During regional hydrogeochemical prospection (500 km2) samples were collected from surface flows, springs, wells andborings. In water, contents of uranium, radium and radon weredetermined. Three anomaly zones of radionuclides in water were identified, and their values vary within the interval: 0.1-166 ppb for U, up to 7 Bq for Ra and 2.8-36 Bq. Risk for cancer incidence was calculated using Monte Carlo techniques. Anomalies of radioactive elements are located in the area which is built of granites, gneiss and crystalline schists. According to the available data it is considered that the granites have intruded in the crystalline schists during hercynian orogeny which is of significance for uranium deposits formation. In the purpose of defining coditions of uranium migration and depositing at favorable geochemical barriers, beside contents of U, Ra and Rn in water, some other parameters (Eh, pH, Ep, content of microelements,etc) were determined. Identification of the areas of hydrogeochemical radiation burden caused by presence of radionuclides (U, Ra, Rn) in water is of special relevance for determination of geopathogene zones of the influence of natural radioactivity. By applying conversation factorsthe radiation burden was calculated for each radionuclide. Research results are shown on maps and charts. That results are representing the influence of natural radionuclides in water, which are ingested in the ambient of living environment of rural settlements.

Keywords:hydrogeochemistry,radioactivity, cancer incidence, uranium, radium, radon.

This work has been financed by the Ministry of Science and Technological Development of the Republic of Serbia (project No. 45006).

Mineral Physics in the Terapascal Regime: Dynamic Studies of Planetary Interiors

DYLAN K. SPAULDING

Origins Initiative, Harvard University, dylanspaulding@fas.harvard.edu

Laser-driven shock wave techniques extend the reach of mineral physics to the terapascal regime, permitting unprecedented studies of planetary compositions. Such experiments probe extreme states of matter characteristic of late-stage giant impacts (such as that believed to have formed the moon) as well as the present-day interiors of several Earth-mass exoplanets. Here, I present a suite of recent results on the physical and transport properties of fundamental mineral phases in the Earth's mantle: SiO_2, MgO and $MgSiO_3$. Experiments on molten $MgSiO_3$ show the first evidence of a liquid-liquid phase transition with a 6% volume reduction over a wide temperature range, suggesting the potential for unexpectedly complex behavior in silicate liquids at ultra-high pressure. Results on MgO resolve controversial predictions for high-pressure melting and the B1-B2 transition. In addition, data for all three materials reveal thermal and electrical conductivities enhanced by one to two orders of magnitude in the fluid state relative to estimates for the present-day terrestrial mantle. These results underscore the potentially significant role of conductive liquid silicates and oxides in governing the early thermal-chemical evolution of the Earth and other extra-solar 'rocky' planets.

Evidence from fluid inclusions extends the record of seawater chemistry by ~300 million years, from ~544 Ma to ~830 Ma

NATALIE SPEAR[1]*, H.D. HOLLAND[1], JAVIER GARCIA-VEIGAS[2], T.K. LOWENSTEIN[3] AND ROBERT GIEGENGACK[1]

[1]Earth and Environmental Science, Univ. of Pennsylvania, Phila., PA 19014, USA (*correspondence: nahilln@sas.upenn.edu)
[2]Univ. of Barcelona, Barcelona 08028, Spain
[3]Department of Geological Sciences, State Univ. of New York at Binghamton, Binghamton, NY 13902, USA

We analyzed primary fluid inclusions in halite from marine evaporites in the ~830-Ma Browne Formation of the Officer Basin in Western Australia by the Cryo-SEM-EDS technique. The parent seawater, calculated from the concentrations measured in those inclusions, contained ~565 mmolal Cl^-, ~456 mmolal Na^+, ~50 mmolal Mg^{2+}, 9-12 mmolal Ca^{2+}, ≥ 3 mmolal SO_4^{2-}, and ~1 mmolal K^+. The concentrations of the major ions, except K^+ and possibly SO_4^{2-}, fall within the known range of Phanerozoic seawater composition. Ours is the first direct measurement of the composition of Mid-Neoproterozoic seawater, and extends direct documentation of seawater chemistry by ~300 Ma.

We sampled the Browne Formation from two cores (Empress 1A and Lancer 1), both from the western Officer Basin, a large intracratonic basin that covers an area of ~525,000 km^2 in Western and South Australia. In spite of the distance between the two studied wells (~264 km), the lithology and thicknesses throughout the sedimentary succession of the encountered Browne Formation are remarkably similar.

The amount of sulfate in the Mid-Neoproterozoic ocean was closely linked to the amount of oxygen in the atmosphere and deep ocean. Our estimates suggest that Mid-Neoproterozoic marine-sulfate concentrations were considerably lower (≥ 10%) than modern values. By terminal Neoproterozoic time, the composition of fluid inclusions in halite and the mineralogy of evaporite rocks indicate that seawater-sulfate levels rose significantly, to 50 to 80% of modern concentrations, a trend that parallels a similar increase in atmospheric and oceanic oxygen. By imposing a tighter constraint on the sulfate levels of Neoproterozoic seawater, we can define more accurately the circumstances and timing of the oxygenation of the Earth's atmosphere and oceans.

Geochemical evolution of prehistoric magma sources beneath Mt. Etna

E.A. SPENCE[1], H. DOWNES[1]*, J. BLICHERT-TOFT[2], J.G. BRYCE[3] AND E. HEGNER[4]

[1]Dept of Earth and Planetary Sciences, Birkbeck University of London, UK (*correspondence: h.downes@ucl.ac.uk)
[2]Ecole Normale Supérieure de Lyon, Lyon, France.
[3]UNH Earth Sciences, Durham, New Hampshire, USA.
[4]Dept of Earth and Environmental Sciences, Ludwig-Maximilians Universität, Munich, Germany.

Prehistoric alkalic lavas of Mount Etna representing a ~70 ka time span, sampled from four vertical sections in the southern wall of the Valle del Bove (VdB), exhibit geochemical and isotopic variations distinguishing them as six separate lithostratigraphic and volcanic units within the newly defined framework of Etna [1]. Intersecting geochemical correlations between lavas highlight their stratigraphic relationships, and new isotopic data such as $^{87}Sr/^{86}Sr$ (0.7033-0.7036) and $^{206}Pb/^{204}Pb$ (19.76-20.02), indicate subtle changes in evolution of the magma sources beneath Etna. The alkalic centres of the VdB and modern Etna no longer tap the source(s) of ancient Iblean magmatism (2.6-1.4 Ma) [2]. Isotopic variations indicate that the oldest unit Salfizio-1 (>85 ka) tapped a mantle source similar to present-day Etna ($^{87}Sr/^{86}Sr$ >0.7035), while four other units relate more closely to the source of historic Etna magmatism ($^{87}Sr/^{86}Sr$ <0.7035) [3]. The sixth group, part of Piano Provenzana formation (~42-30 ka) of Ellittico, has the most chemically evolved lavas (58-62 wt% SiO_2) and exhibits lower Hf and Nd isotopic ratios and less radiogenic $^{206}Pb/^{204}Pb$ and $^{87}Sr/^{86}Sr$ than the oldest unit, implying that the temporal trend generally observed in the evolution of Nd-Sr isotope systematics breaks down over a ~70 ka period. Mt. Etna's unique position on an accretionary wedge related to the Calabrian Arc, formed during convergence of the African and Eurasian plates and close to the extensional Malta Escarpment [4], presents a complicated tectonic evolution model for Etna magmatism. Subduction processes, slab rollback of Ionian oceanic lithosphere and upwelling asthenospheric mantle are all likely to introduce chemical and isotopic heterogeneities into the convecting mantle.

The isotopic artifacts of enhanced crustal preservation in collisional orogenesis

CHRISTOPHER J. SPENCER[1]*, PETER A. CAWOOD[1], CHRIS HAWKESWORTH[1] AND NICK M.W. ROBERTS[2]

[1]Department of Earth and Environmental Sciences, University of St Andrews, North Street, St Andrews KY169AL
[2]NERC Isotopes Geosciences Laboratory, British Geological Survey, Keyworth, Nottingham, NG12 5GG, UK
*cs207@st-andrews.ac.uk

The generation of felsic crust at accretionary/collisional tectonic boundaries is considered globally to be in steady-state, although the rate of crustal production can vary locally.

U-Pb, Hf, and O isotopic analyses in detrital zircon are widely used to assess the timing and isotopic composition of crustal growth. The age distribution of global detrital zircon record is comprised of “peaks” and “troughs”.

This episodic temporal distribution of zircon crystallization ages has been argued to represent periods of global collisional orogenesis that isolated continental crust formed within accretionary settings within the interior of newly formed supercontinents. This is shown by comparing U-Pb, O, and Hf isotopes in detrital zircons dervied from the accretionary, collisional, and post-rift stages of the assembly of the supercontinent of Rodinia based on data from Laurentia nd Baltica.

Our results show that continental crust with highly negative εHf and high $\partial^{18}O$ values that formed during the accretionary stage is largely removed from the record preserved in collisional and post-rift stages, probably via sediment subduction, subduction erosion or tectonic delamination. These relations support the hypothesis that detrital zircon age peaks do not represent non-steady state felsic crust formation, but are an artifact of selective preservation during collisional orogenesis.

SCLM super-Si garnet traces the Archaean

DIRK SPENGLER

Institute of Earth and Environmental Science, Potsdam University, 14476 Potsdam, Germany (spengler@geo.uni-potsdam.de)

Sub-continental lithospheric mantle (SCLM) garnet that hosts oriented pyroxene lamellae, that exsolved from former super-Si garnet, have been reported only from the oldest parts of cratons including the Kalahari, Laurentia and Siberia composite cratons [1-5]. Direct implications are: the exsolution microstructure has (1) an Archaean affinity and (2) a global distribution. This study reviews reconstructed and normal garnet chemistries to evaluate proposed garnet origins and exsolution scenarios.

Proportions of pyroxene lamellae in garnet that were quantified using standard techniques range with 0.5-9.6vol.%. Re-integrated garnets have Si+Ti in the range of 2.992-3.086 (median 3.034) cations per 12 oxygen. Maximum values correspond to 7.9 GPa (median 6.4 GPa) [6] that favour a lithospheric origin of all garnet prior to exsolution. Garnet Si isopleths have negative slopes in P-T space [6] suggesting that the above P estimates are overestimated if pre-exsolved garnet formed at high T.

Ti-Na systematics shows a bimodal distribution. The larger fraction of pre-exsolved garnet (G1, G4, G5, G12) has TiO_2 >0.4 wt.% and has a positive correlation between TiO_2 and Na_2O with TiO_2/Na_2O >10. These features overlap those of lamellae-free garnet megacrysts [7], consistent with an origin from re-fertilising melts. The other, minor fraction of pre-exsolved garnet (G4, G5) has TiO_2 <0.4 wt.% that correlates negatively with Na_2O at dominantly TiO_2/Na_2O <2. Major elements suggest these pre-exsolved garnets to have a pyroxenite/websterite origin. Non-eclogitic lithospheric garnet diamond inclusions from the Siberia, Kaapvaal and Slave cratons include the negative, but not the positive correlation defined by the pre-exsolved garnet chemistry. Thus, low TiO_2/Na_2O garnet (pyroxenitic/websteritic) formed part of Archaean SCLM prior to local lithospheric diamond formation.

In summary, (1) lamellae type pyroxene exsolution in garnet occurred at SCLM depth most likely by cooling and (2) appears to be a tracer of Archaean provinces, (3) high TiO_2/Na_2O pre-exsolved garnet may have formed by infiltrating melts, (4) low TiO_2/Na_2O pre-exsolved garnet is related to the origin of websterite/pyroxenite. Additional REE systematics will be presented to provide constraints on the latter.

Tracking environmental changes over the past 3000 years in the Region of Ria do Mamanguá, Rio de Janeiro, Southeastern Brazil using molecular organic markers

A. M. SPERA[1]*, S. TANIGUCHI[1], J. LEONEL[1] AND M. C. BICEGO[1]

[1] Praça do Oceanográfico, 191, Cidade Universitária, São Paulo – SP, Brazil. 05508-120
(*correspondence: amandaspera@usp.br)

Molecular organic markers (terrestrial *n*-alkanes and alkenones) and other geochemical tracers ($\delta^{13}C$, $\delta^{15}N$ and % Terr) were used to assess changes in rainfall patterns and in the sea surface temperature over the past 3000 years in the Region of Ria do Mamanguá, located on the southern coast of Rio de Janeiro, Brazil. It was possible to identify periods with distinctive contribution from terrestrial organic matter in the sediments cores. The wetter periods between 2733 and 2000 cal years BP and between 1100 and 200 cal years BP presented a higher contribution of terrestrial organic matter to the area. While the dryer period between 2000 and 1100 cal years BP showed a lower input. Furthermore, it was possible to identify the presence of the Little Ice Age event, that was characterized as a period of wetter conditions and with relatively low SST in the Region of Ria do Mamanguá, corroborating with other paleoclimate records in South America. A possible reduction in the termohaline circulation during these cold events may have contributed to the increase in the latitudinal temperature gradient. A lower sea surface temperature in the North Atlantic could have contributed to a displacement in the atmospheric system of the South Hemisphere through a change in the latitudinal position of the Intertropical Convergence Zone (ITCZ). The ITCZ acts as the main source of moisture to the region where the South American Summer Monsoon is formed and consequently the South Atlantic Convergence Zone (SACZ). The SACZ is one of the main features responsible for most of the rain in the Region of Ria do Mamanguá.

The global record of local iron geochemical data from Proterozoic through Paleozoic basins

E.A. SPERLING[1], C. WOLOCK[2], A.H. KNOLL[1,2] AND D.T. JOHNSTON[1]

[1]Dept. of Earth and Planetary Sciences, Harvard University, Cambridge, MA, USA
(*correspondence: sperling@fas.harvard.edu)
[2]Dept. of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA, USA

Iron-based redox proxies represent one of the most mature tools available to sedimentary geochemists. These techniques, which benefit from decades of refinement, are based on the fact that rocks deposited under anoxic conditions tend to be enriched in highly-reactive iron. However, there are myriad local controls on the development of anoxia, and no local section is an exemplar for the global ocean. The global signal must thus be determined using techniques like those developed to solve an analogous problem in paleobiology: the inference of global diversity patterns through time from faunas seen in local stratigraphic sections. Here we analyze a dataset of over 4000 iron speciation measurements (including over 600 de novo analyses) to better understand redox changes from the Proterozoic through the Paleozoic Era. As with paleobiological diversity curves, it is expected that a number of biases affect such a dataset, including both spatial and temporal sampling bias and stochastic error.

Preliminary database analyses yield interesting observations. We find that although anoxic water columns in the middle Proterozoic were dominantly ferruginous, there was a statistical tendency towards euxinia not seen in early Neoproterozoic or Ediacaran data. Also, we find that in the Neoproterozoic oceans, oxic depositional environments–the likely home for early animals-have exceptionally low pyrite contents, and by inference low levels of porewater sulfide. This runs contrary to notions of sulfide stress on early metazoans. Finally, the current database of iron speciation data does not support an Ediacaran or Cambrian oxygenation event. This conclusion is of course only as sharp as the ability of the Fe-proxy database to track dissolved oxygen and does not rule out the possibility of a small-magnitude change in oxygen. It does suggest, however, that if changing pO_2 facilitated animal diversification it did so by a limited rise past critical ecological thresholds, such as seen in the modern Oxygen Minimum Zones benthos. Oxygen increase to modern levels thus becomes a Paleozoic problem, and one in need of better sampling if a database approach is to be employed.

Viscosity and structure of fayalite liquid at high pressure up to 9GPa

H. SPICE[1]*, C. SANLOUP[1], J. DREWITT[1], C. DE GROUCHY[1], C. CRÈPISSON[2], Y. KONO[3], C. PARK[3], AND C. MCCAMMON[4]

[4]Bayerisches GeoInstitut, Universitaet Bayreuth, Germany

Viscosity of magma is a crucial transport property of melts that influences a variety of important igneous processes, both during the evolution of the early Earth and in the present day mantle[1]. Previous experimental work on polymerized silicate melts e.g.[2] show a decrease in viscosity with increasing pressure. Viscosities of depolymerized silcate melts are poorly documented at mantle P-T due to experimental difficulties.

Here we present the results of *in situ* experiments on the viscosity and structure of pure fayalite melt at high pressure. Fayalite consists of isolated silica tetrahedra, so is as depolymerized as possible for a silicate melt. Viscosity measurements were carried out using the falling sphere viscometry technique e.g. [3]. Viscosity was found to decrease along the fayalite liquidus up to ~9GPa.

The structure and compressiblity of fayalite melt was studied up to 7.5GPa. The coordination of the Fe-O bond was found to increase gradually from ambeint pressure to 7.5GPa.[4]. Higher coordination numbers allow for a more densely packed structure, resulting in a longer and hence weaker Fe-O bond, causing a decrease in viscosity [5]. The results suggest that deep Fe-rich melts will have a high density, but will be very mobile due to their low viscosity. Compressibility of the melt is derived from extrapolation of the structure factor to q=0 A^{-1}. This enables the determination of density as a function of P with an unprecedented P resolution. This is a promising method to extract the equation of state of non-crystalline materials at mantle P.

Origin of curved CSDs: Heterogeneous nucleation of crystals in crystallizing magmas

VÁCLAV ŠPILLAR* AND DAVID DOLEJŠ

Institute of Petrology and Structural Geology, Charles University, Albertov 6, 128 43 Praha 2, Czech Republic (*correspondence: vaclav.spillar@seznam.cz)

Crystal size distributions (CSDs) are becoming a routine method to quantitatively describe textures of plutonic and volcanic rocks. Simple batch or open system crystallization models involving homogeneous nucleation and crystal growth predict linear trends in the logarithmic population density *vs*. crystal size space. Since numerous magmatic rocks show concave-up curves, their origin was interpreted as due to multiple crystallization stages or population mixing. Many crystal populations in magmatic rocks also have a non-random, clustered, spatial distribution whose origin remains unclear. We show that both curved CSDs and clustering of crystals can be self-consistently explained by crystallization involving heterogeneous nucleation on crystal surfaces.

We performed three-dimensional numerical simulations of melt crystallization by homogeneous and heterogeneous nucleation and crystal growth. The rates of heterogeneous and homogeneous nucleation were coupled in order to simulate texture with a characteristic ratio of heterogeneous to homogeneous nuclei (H). Quantitative parameters describing sizes, contact, and spatial relationships of crystals were evaluated as functions of the H-ratio.

As H increases above ~2, the CSD evolves from straight to progressively curved, the number of neighbors around a crystal increases, and the clustering index, R, decreases below unity. At $H > 10$, the resulting texture gains porphyritic appearance, and for $H > 200$, the crystallization proceeds as radial growth of heterogeneous nuclei on isolated centers and a spherulitic texture develops. Numerical simulations with variable nucleation and growth rate functions indicate that these results are general and robust, thus solely depend on the H-ratio. This approach allows meaningful determination of the role of the heterogeneous nucleation in natural samples without of a detailed knowledge of the underlying kinetics of crystallization.

Our simulations are consistent with the number of heterogeneous nuclei being about an order of magnitude predominant over the number of homogeneous nuclei in ordinary magmatic rocks with curved CSDs, without involvement of mechanical mineral-melt interactions or late magmatic coarsening.

The climate impacts of natural aerosol

DOMINICK VINCENT SPRACKLEN, CATHERINE SCOTT AND ALEX RAP,

School of Earth and Environment, University of Leeds, Leeds, UK; dominick@env.leeds.ac.uk

Natural aerosol plays a significant role in the Earth system because climate controls many natural aerosol sources and because natural aerosol alters the radiative balance of the Earth. Here we explore a wide range of interactions and feedbacks between natural aerosol, anthropogenic aerosol and climate.

Firstly, we quantify the direct and first aerosol indirect effect of different natural aerosol sources. We explain the magnitude of these different radiative effects in terms of atmospheric chemistry and aerosol microphysics. Secondly, we quantify the impact of the natural aerosol background on the anthropogenic aerosol indirect effect. We find that a higher natural aerosol background tends to reduce the first aerosol indirect effect attributed to anthropogenic aerosol. Next, we explore the impact of anthropogenic aerosol on natural aerosol – climate feedbacks. We demonstrate that anthropogenic pollution aerosol in the Northern Hemisphere has reduced the climate feedback that occurs due to changes in natural aerosol emissions. Finally, we explore the impact of natural aerosol on diffiuse radiation and the impact on the terrestrial biosphere.

Age calibration of geomagnetic polarity reversals around the Cretaceous-Paleogene boundary

COURTNEY SPRAIN[1]*, PAUL J., RENNE[1,2] AND GREGORY P.R. WILSON[3]

[1]Dept. Earth and Planetary Science, Univ. California, Berkeley, CA 94720, USA (*correspondence: spra0111@berkeley.edu)

[2]Berkeley Geochronology Center, 2455 Ridge Rd., Berkeley, CA 94709, USA

[3]Dept. Biology, Univ. Washington, Seattle, WA 98195, USA

Improved understanding of the timing of events attending the end-Cretaceous mass extinction is limited by difficulty in correlating marine and terrestrial records. The Geomagnetic Polarity Time Scale (GPTS), if well-calibrated, offers an important means to address this problem. Terrestrial sections in the Hell Creek region of Montana, interbedded with abundant sanidine-bearing tuffs, provide an opportunity to refine the ages of polarity reversals near the Cretaceous-Paleogene boundary (KPB), ultimately providing a test on the accuracy of orbital tuning chronologies e.g. [Ogg, 2012] for these reversals. Variable sedimentation rates often render terrestrial sequences unsuitable for such purposes, but in this case close stratigraphic proximity between reversals and tuffs allows very small fractional interpolations, ranging from 0.01 to 0.25 of the distance between bounding dated tuffs.

Preliminary new $^{40}Ar/^{39}Ar$ ages for 3 tuffs were combined with existing magnetostratigraphic data from two sections [Swisher *et al.,* 1993] to evaluate the potential of these records for time-scale calibration. Magnetic data gaps as large as several meters were used as conservative proxies for the uncertainty in reversal placement. Ages and uncertainties (+/- systematic sources) based on the optimization calibration of the $^{40}Ar/^{39}Ar$ system [Renne *et al.,* 2011] were determined by linear interpolation for the following three polarity reversals immediately following the KPB, and are shown compared with the GTS 2012 values [Ogg, 2012].

Chron boundary		Age (Ma)	±σ (Ma)	GTS 2012
C28r	top	64.755	0.028/0.050	64.667
C28r	base	64.900	0.044/0.061	64.958
C29r	top	65.605	0.080/0.092	65.688

The uncertainties in our ages are dominated by the coarse spacing of samples defining the Chron boundaries. Our modelling indicates that with sampling at the decimeter scale and with age precision demonstrably attainable from these tuffs [Renne *et al.,* 2013], these reversals can be dated with a resolution of ±10 ka, and an absolute accuracy of ±40 ka.

Initial $^{176}Hf/^{177}Hf$ of the Earth and early silicate differentiation

P. SPRUNG[1,2], T. KLEINE[1] AND E.E. SCHERER[3]

[1]Institut für Planetologie, University of Münster, 48149 Münster, Germany (sprungp@uni-muenster.de)
[2]Institute of Geochemistry and Petrology, ETH Zürich, 8092 Zürich, Switzerland
[3]Institut für Mineralogie, University of Münster, 48149 Münster, Germany

Investigating silicate differentiation on Earth using the ^{176}Lu-^{176}Hf system requires knowledge of the $^{176}Hf/^{177}Hf$ evolution of the bulk silicate Earth (BSE). The starting point of this evolution is commonly determined by back-calculating the present-day $^{176}Hf/^{177}Hf$ of chondrites to the age of the solar system [1]. Relative to this $^{176}Hf/^{177}Hf$ evolution, most Hadean zircons exhibit less radiogenic $^{176}Hf/^{177}Hf$ and were interpreted in terms of crust extraction from a primordial mantle at 4.4-4.5 Ga [e.g., 2]. However, Bizzarro *et al*. [3] argued that the initial $^{176}Hf/^{177}Hf$ of the angrite Sahara 99555, which is ~4 ε-units below the back-calculated chondrite initial [1], provides a more appropriate initial $^{176}Hf/^{177}Hf$ of the BSE. Relative to such a revised $^{176}Hf/^{177}Hf$ evolution of the BSE [3], Hadean zircon populations show both enriched and depleted signatures, which was inferred to imply continuous crustal growth throughout the Hadean [3].

To better constrain the initial $^{176}Hf/^{177}Hf$ of the BSE we have initiated a Lu-Hf study on primitive meteorites, complemented by investigations of KREEP-rich lunar rocks, which provide the signature of a strongly enriched reservoir that formed at *ca*. 4.4 Ga [4]. Our data for low-Lu/Hf phases in primitive meteorites, which should directly provide the initial $^{176}Hf/^{177}Hf$ of the solar system, overlap with the back-calculated chondrite initial [1]. Moreover, we show that the $^{176}Hf/^{177}Hf$ of KREEP at ~3.9 Ga is ~5.5 ε-units below the contemporaneous $^{176}Hf/^{177}Hf$ of chondrites, yielding a two-stage model age of *ca*. 4.4 Ga, assuming a chondritic Lu-Hf isotopic evolution for the bulk Moon. This Lu-Hf model age of KREEP is fully consistent with other, independent estimates for the age of KREEP. In contrast, the two-stage model age of our KREEP-rich lunar rocks relative to the revised BSE evolution of [3] is *ca*. 4.0 Ga and thus *ca*. 400 Myr too young. Thus, our new data do not support the revised initial $^{176}Hf/^{177}Hf$ of the BSE based on Sahara 99555 [3], but rather indicate that the back-calculated chondrite composition [1] is a reliable estimate for the initial $^{176}Hf/^{177}Hf$ of the BSE.

The structural role of iron in pantelleritic glasses

P. STABILE[1]*, M.R. CICCONI[1], G. GIULI[1], H. BEHRENS[2], J. KNIPPING[2] AND E. PARIS[1]

[1]School of Science and Technology, Geology Division, University of Camerino, Via Gentile III da Varano, 62032 Camerino, Italy (paola.stabile@unicam.it)
[2]Institute of Mineralogy, Leibniz University Hannover, Callinstr.3, D-30167, Hannover, Germany

The main objects of this work are to determine the effect of oxygen fugacity and composition on the structural role of Fe in silicate glasses representative of pantelleritic magmas. Since many studies have investigated melts using glasses as a structural analogue [1, 2, 3], we have focused on the structural environments of Fe and S in synthetic glasses to relate their behaviour to natural magma with the same composition.

Several glasses have been synthesized under controlled oxygen fugacity conditions (from air to iron-wustite buffer) and with different (Na+K)/Al ratios. In fact, alkali content is known to affect strongly the Fe oxidation state in silicate glasses [4], but it is still controversial to which extent alkali can modify Fe structural role in glasses/melts. Hydrothermal syntheses have been carried out at 1.5 kbar and temperatures between 800°C and 1000°C. Additionally, glasses were produced by melting in a Ar/H_2 gas mixing furnace at ambient pressure and at 1250°C.

Water incorporation in the glasses has been characterized by Karl-Fischer titration (KFT) and IR spectroscopy. Additionaly, the redox state of iron in the glasses has been determined by colorimetric wet-chemical analyses. Preliminary Fe K-edge X-ray Absorption Spectroscopy data allowed to study the kinetic of Fe reduction under anhydrous conditions. Here we present preliminary results on Fe oxidation state, coordination number and geometry [5]. The results will be useful for understanding the role of Fe in the polymerization of the silicate melt and the interaction Fe-S.

karki@csc.lsu.edu

The rate of loss of heat from Earth's core is controlled by the thermal conductivity of the minerals that comprise the overlying mantle. The heat-flux at the core-mantle boundary has implications for the thermal evolution of both the core and mantle, the size and stability of plumes, and magnetic field generation. As insulators, conduction in lower mantle phases is expected to be dominated by phonon transport. Estimates of the thermal conductivity of $MgSiO_3$ perovskite, the most abundant phase, at core-mantle boundary conditions, vary significantly, with the phonon contribution reported to lie between 1.6 and 17 $Wm^{-1}K^{-1}$. In view of this, we have performed ab initio non-equilibrium molecular dynamics simulations to determine the lattice thermal conductivity of $MgSiO_3$ perovskite at lower mantle conditions, calculating it to be 6.5 ± 0.8 Wm^{-1} K^{-1}, a value consistent with geophysical constraints on the thermal state at the base of the mantle. Our results suggest that the conductivity depends strongly on pressure, helping to explain the dynamical stability of super-plumes, and weakly on temperature and composition, so that lateral variations in thermal conductivity at the base of the mantle are small.

Origin of methane to n-butane in marine sediments of the New Jersey shallow shelf

S. STADLER[1], R. VAN GELDERN[2] AND S. SCHLÖMER[1]

[1]Federal Institute for Geosciences and Natural Resources (BGR), Stilleweg 2, 30655 Hanover, Germany, susanne.stadler@bgr.de, stefan.schloemer@bgr.de
[2]GeoZentrum Nordbayern, Schlossgarten 5, FAU Erlangen–Nürnberg, 91054 Erlangen, Germany, robert.van.geldern@fau.de

Concentrations and stable carbon isotope compositions of C_1 to C_4 in pore fluids were measured in three cores (M0027A, M0028A and M0029A) of IODP Expedition 313 that targeted Mioscene sedimentary sequences up to 67 km off the coast of New Jersey, USA (Mountain *et al*. 2010), to understand processes related to gas geochemistry and carbon cycling in the investigated shallow shelf. Stable carbon isotope data and $C_1/(C_2+C_3)$ ratios suggest a biogenic origin of methane. If methane is produced by a biogenic process this could in principle also be the case for C_{2+} gases as suggested by Hinrichs *et al*. (2006). An alternative explanation could be low-temperature kerogen cracking (Rowe & Muehlenbachs 1999). Showing first data we discuss gas formation mechanisms including the potential source of the organic material, secondary alteration processes and the role of mixing of gases of different origin (biogenic versus thermal) at the investigated site.

High-pressure stability of synthetic $Al_{63}Cu_{24}Fe_{13}$ icosahedral quasicrystal

V. STAGNO[1], L. BINDI[2]*, C. MURPHY[1], Y. FEI[1], AND P.J. STEINHARDT[3]

[1]Carnegie Institution of Washington, USA (vstagno@ciw.edu; cmurphy@ciw.edu; yfei@ciw.edu)
[2]Università di Firenze, Italy (luca.bindi@unifi.it).
[3]Princeton University, USA (steinh@princeton.edu).

Quasiperiodic crystals are solids characterized by quasiperiodic translational order and a discrete point group impossible for ordinary periodic crystals [1]. Among synthetic quasicrystalline solids, icosahedral-$Al_{63}Cu_{24}Fe_{13}$ is of particular interest since it is representative of icosahedrite, the first quasicrystal found in nature [2, 3]. Although an extraterrestrial origin has been recently established for icosahedrite [4], pressure and temperature conditions at which the mineral would be stable are still not clear. Previous studies showed that synthetic AlCuFe quasicrystals do not undergo any phase transitions over pressures up to 35 GPa (at room temperature) [5] and over a temperature range of 500-870 °C at ambient pressure. However, no data are available for $Al_{63}Cu_{24}Fe_{13}$ quasicrystal at high temperatures and pressures.

We have performed *in situ* high-pressure synchrotron X-ray diffraction experiments under quasi-hydrostatic conditions (neon pressure medium) using diamond anvil cell technique up to 51.5 GPa (in both compression and decompression) to investigate the possible structural evolution of the synthetic analogue of icosahedrite. We also performed a series of quenched experiments with multi anvil to determine the thermal stability of $Al_{63}Cu_{24}Fe_{13}$ at different isobars (between 3 and 20 GPa) and employing different capsule materials to intrinsically buffer the oxygen fugacity.

Preliminary results from *in situ* X-ray diffraction data collected at ambient temperature confirm that the high degree of translational order for the $Al_{63}Cu_{24}Fe_{13}$ icosahedral quasicrystal is retained at much higher pressures than previously reported.

Results from this study will improve our knowledge regarding the origin of icosahedrite in nature and provide constraints on the pressure and temperature conditions for its formation.

Impact of anthropogenic land cover changes (ALCC) on dust particle emissions and associated impact on radiation

TANJA STANELLE[1], ISABELLE BEY[1], CHRISTIAN REICK[2], THOMAS RADDATZ[2] AND INA TEGEN[3]

[1]Institue for Atmospheric and Climate Science & Center for Climate Systems Modeling, ETH Zurich, Switzerland, tanja.stanelle@env.ethz.ch
[2]Max Planck Institute for Meteorology, Hamburg, Germany
[3]Leibniz Institute for Tropospheric Research, Leipzig, Germany

Mineral dust particles are usually considered as 'natural' aerosols. Human activities can however affect emission of dust particles by altering land properties or through an increase in desertification associated with climate change. Changes in wind speed due to climate change also alter the amount of dust particles emitted in the atmosphere. The goal of this work is to estimate the extent to which human activities contribute to dust emissions and how this has changed since the pre-industrial time taking into account both climate change and ALCC.

For this purpose, we use the global aerosol-climate model ECHAM6-HAM2.1, in which a new method to calculate potential dust source areas was implemented. This allows us to quantify emissions from agricultural sources and to account for past and future land cover changes. The results from the simulation using the new method compare relatively well to measurements and data available in the literature, indicating that the new approaches allows a reasonable representation of today's dust load and providing confidence into the new method.

In a 'best guess' simulation, where we consider the attempts of farmers to prevent ground erosion, we find that nearly 10 % of today's dust particles are emitted globally from agricultural sources. But agricultural dust sources are not necessarily new dust sources. Often natural grass or shrub land, where emissions of dust particles can take place, were converted into agricultural land. We then account for ALCC between 1850s and 2000s in the model system and simulate emissions under different climate conditions. The contribution of ALCC on changes in dust emissions between pre-industrial times and today is estimated. Further an estimate of the changes in radiative fluxes due to dust particles emitted from agricultural sources including both the direct and indirect aerosol effect is provided.

Geochemical and isotopic monitoring of dissolved carbon dynamic in a karst aquifer, located above the Rousse site test for CO_2 geological storage

Y. STANISZEWSKI[1], A.GROLEAU[1], D.JEZEQUEL[1] AND P.AGRINIER[1]

[1]IPGP-Paris 7, Institut de Physique du Globe de Paris & Univ. Paris Diderot, Sorbonne Paris Cité, UMR 7154 CNRS, 75005 Paris, France (stanis@ipgp.fr)

A new method for monitoring CO_2 sequestration.

A near surface perched karst aquifer is considered as an integrative system of putative CO_2 leaks above the Rousse site test of CO_2 storage (operated by Total near Pau - France). We develop a low cost and long term geochemical monitoring of spring waters in order to describe the natural forcings that drive the dynamics of the dissolved carbon. Such procedure is mandatory in order to determine dissolved carbon thresholds above which excursions can be anomalies.

The chemical composition of the groundwater is ultra-dominated by calcium and bicarbonate ions. Dataset of 4 main springs is obtained with:

(*1*) high frequency measurements (15') of conductivity (C_{25}), pH & hydrodynamics (C_{25} and pH are used to determine the dissolved carbonate system: pH, pCO_2, DIC & alkalinity .

(*2*) bi-monthly geochemical and isotopic samples which give another appreciation of the dissolved carbon dynamics.

We show that the C_{25} is a very robust proxy of the alkalinity because a strong linear relation has been established between C_{25} and carbonate composition in all meteorological conditions. At present, after three years of monitoring, we note that the dominant natural forcing of dissolved carbon is the hydrodynamic which is linked to pluviometry.

Modelisation of the geochemical impact induced by an input of CO_2 in the aquifer is in progress, using thermoddem database [1] with the software PHREEQC [2].

Other aquifers will be tested like a typical carbonate karst: "Parc des Grands Causses".

Formation mechanism of hematite-rutile pseudomorphs from Mwinilunga (Zambia)

N. STANKOVIĆ*, N. DANEU AND A. REČNIK[1]

[1]Department for Nanostructured Materials, Jožef Stefan Institute, Jamova 39, 1000 Ljubljana, Slovenia nadezda.stankovic@ijs.si

In geologic environments we often find minerals which formed by replacement reactions from a parent mineral as a consequence of solid-liquid interactions [1]. The newly formed mineral or mineral assemblages retain some characteristics of the parent minerals like their euhedral shape, whereas the chemical composition and texture of the products may be different. The changes are readily used for the interpretation of geological history of the samples.

In our work we studied rutile-hematite intergrowths from the Mwinilunga locality in Zambia. Samples can be described as euhedral hematite crystals intergrown with oriented rutile crystals. The general relationship between rutile and hematite can be determined already by macroscopic observation of hematite crystals and larger rutile crystals on their surface as ‹010› $(101)_{RUT}$ II ‹001› $(110)_{HEM}$. Besides single rutiles, also rutile twins on (101) and (301) planes are found on the surface of the samples [2].

In order to determine the mechanism of ilmenite replacement by hematite and rutile, we analyzed the sample with different methods of electron microscopy. Detailed structural analysis of the sample interior along the $[001]_{HEM}$ confirmed the macroscopically observed orientation relationship and all six possible orientations of rutile crystals within the single-crystal hematite ma trix were found. The stable hematite-rutile interface was determined from the HRTEM images. In the perpendicular orientation, i.e. along the $[100]_{HEM}$ zone axis, we found nano-sized relicts of parent ilmenite and we observed the diffusion paths of Ti-ions towards the rutile lamellae. The results of our analyses suggest that re-crystallization of ilmenite to hematite and rutile is structurally controlled. The transformation is possible since all three minerals (ilmenite, rutile and hematite) have a common oxygen sublattice which is controlling the re-crystallization to rutile and hematite [3].

Mg-aenigmatite from the Tazheran massif (East Siberia, Russia)

STARIKOVA A.E.[1] SKLYAROV AND E.V.[2] KANAKIN S.V.[3]

[1]IGM SB RAS, Novosibirsk, Russia, a_sklr@mail.ru
[2]IEC SB RAS, Irkutsk, Russia, skl@crust.irk.ru
[3]Institute of geology SB RAS, Ulan-Ude, Russia, skan_61@mail.ru

Aenigmatite ($NaFe^{2+}_5TiSi_6O_{20}$) occurs usually in high-Na magmatic rocks in association with nepheline, aegirine or augite, arfedsonite or riebeeckite, K-feldspar, sometimes fayalite. Variations of its composition are related mostly to the presence of Fe^{3+} whereas content of MnO and MgO is low (usually < 1 wt%). The Tazheran Massif of alkaline and nepheline syenites (East Siberia, Russia) [2] is the second occurrence of high-Mg aenigmatite (up to 10 wt% MgO, Mg/(Fe+Mg) – 0.3-0.4). The only high-Mg variety have been described before in Ne-syenite on Mount Kenia [1]. In the Tazheran massif both high-Mg and typical aenigmatites occur separately at the marginal part of the Ne-syenite veins with Mll-Wo-Cpx-Grt-Ne metasomatic rocks. Both aenigmatite varieties associate with aegirine-augite, nepheline, K-feldspar, sometimes with ilmenite, Fe-olivine and richterite (only with high-Mg aenigmatite) and have low content of CaO (less than 2 wt%) and Al_2O_3 (up to 5 wt%). In Mg-aenigmatite content of MgO varies from 8.5 to 10 wt%, whereas in aenigmatite – from 1 to 2 wt% There are no transition on composition between the minerals. In most cases aenigmatites as well as Cpx and Amp occur as symplectite with nepheline. According to composition high-Mg aenigmatite does not belong to aenigmatite-rhonite ($Ca_2(Mg,Fe^{2+},Fe^{3+})_5TiO_2[(Si,Al)_6O_{18}$) series, but is transitional veriety of series $Na_2Fe^{2+}_5TiO_2[Si_6O_{18}]$ (aenigmatite) - $Na_2Mg_5TiO_2[Si_6O_{18}]$ (unknown).

The work was supported by RFBR (№ 12-05-31253, 12-05-00229) and special grant of OPTEC LLC.

Fe isotopic composition of sequentially extracted reactive Fe from marine sediments

MICHAEL STAUBWASSER[1]*, SUSANN HENKEL[1], SABINE KASTEN[2] AND SIMON W. POULTON[3]

[1]Institute of Geology and Mineralogy, Uni. of Cologne, GER
*correspondence: m.staubwasser@uni-koeln.de
[2]Alfred Wegener Institute, Bremerhaven, GER
[3]School of Earth & Env., Uni. of Leeds, Leeds LS2 9JT, UK

The partitioning of Fe in sediments and soils has traditionally been studied by applying sequential leaching methods. These are based on reductive dissolution and exploit differences in dissolution rates between different reactive Fe (oxyhydr)oxide minerals. We used lab-made ferrihydrite, goethite, hematite and magnetite spiked with ^{58}Fe and leached two-mineral mixtures with both phases abundant in excess of the methods dissolution capacity. Leaching was performed with 1) hydroxylamine-HCl and 2) Na-dithionite as the reactive agent. Following Poulton & Canfield (2005) [1], the first dissolution is designed to selectively leach the most reactive Fe-phases, ferrihydrite and lepidocrocite, whereas the second dissolution is designed to leach goethite and hematite. Magnetite would then be dissolved in a third dissolution step with oxalic acid.

First results show that the hydroxylamine-HCl method for ferrihydrite dissolves only insignificant amounts of goethite and hematite. However, magnetite-Fe constitutes about 10% of the total dissolved Fe. The Na-dithionite dissolved Fe from goethite-magnetite and hematite-magnetite mixtures contain about 30% of magnetite-Fe.

We applied selective sequential leaching and Fe isotope analysis to fine-grained marine sediments from a depocenter in the North Sea, which contain abundant reactive Fe (oxyhydr)oxides and show evidence for Fe sulfide formation within the upper 10 cm. Fe isotopes of the hydroxylamine-HCl leach targeting ferrihydrite shows a downcore increase of $\delta^{56}Fe$ typical for sediments undergoing microbial reductive Fe dissolution, whereas Fe isotopes of the Na-dithionite leach (goethite and hematite) and oxalic acid leach (magnetite) are identical and show no downcore variation in $\delta^{56}Fe$. This means, that only the most reactive Fe phases participate in the Fe redox cycle in this location. The similar isotopic composition of goethite + hematite and magnetite suggests a detrital source, which is not utilized possibly due to the abundant ferrihydrite and lepidocrocite present.

The Connection Between Life and Oceanic Volcanism: Biosphere Meets Lithosphere

HUBERT STAUDIGEL[1]

[1]Scripps Institution of Oceanography, UCSD-0225, La Jolla CA 92093-0225, USA; hstaudigel@ucsd.edu

Life and volcanoes have been intimately connected since the beginning of life on Planet Earth. Microbial trace fossils in volcanic glass are amongst the earliest well preserved physical fossils on earth and we can trace the association of microbes with volcanic features throughout the geological record. Interactions between volcanoes and life may occur in diverse settings, in the deep biosphere and hydrothermal systems, in the hydrosphere and at the earth's surface and atmosphere. The total biomass associated directly or indirectly with oceanic volcanoes may comprise a substantial fraction of the total biomass on Earth. Volcanoes are known to impact life, as volcanic aerosols disrupt air traffic, change the earth's radiation budget and cause tsunamis (e.g. Thera and Krakatoa). Consequenes for civilization may be substantial, with well documented changes in climate, crop failures and major loss of life and property, including the destruction of an entire culture. Oceanic volcanoes are particularly relevant as the most common and voluminous volcano type and for their immediate interaction with the oceanic/atmospheric systems that control many key global geochemical cycles.

Feedbacks between life and volcanoes are best studied using combined geo- and biological investigations. There is a clear relationship between microbial activity and many types of mineralization. Distinct microbial communitites are known to preferentially colonize particular substrates. Their activity may accelerate substrate dissolution processes and distinct microbial dissolution fabrics. There are remarkable similarities in sub-sea basalt-hosted microbial communities with the ones in terrestrial soils, in terms of diversity as well as the relevance of *eukarya*, *prokarya* and *archea* . We are beginning to understand specific microbial consortia associated with volcanic rock and their main functions such as their capabilities to gain energy from chemolithotrophic reactions and their mechanisms for carbon fixation. We are beginning to explore many details of the genetic underpinnings of microbial function specializing in volcano/ hydrothermal interactions. However, there remains much room for illuminating the geological/ geochemical controls of extremely slow-growing microbial communities, microbial evolution in the geological record and the biological controls of global geochemical cycles, amongst many other issues.

Inert nano-reactors or dynamic micelle intrefaces? $CaCO_3$ precipitation from microemulsions

TOMASZ M. STAWSKI[1] AND LIANE G. BENNING[1]

[1]Cohen Geochemistry Group, School of Earth and Environment, LS29JT, University of Leeds, Leeds, United Kingdom, (t.m.stawski@leeds.ac.uk and l.g.benning@leeds.ac.uk)

Reverse microemulsions are, thermodynamically stable suspensions of water droplets in oil i.e. micelles that are stabilised by an interface surfactant. Water droplets are typically 1-50 nm in diameters and can carry dissolved salt ions and exchange their content upon collisions, which lead to mineral precipitation. These droplets are believed to act as "nano-reactors" because precipitation occurs in the water pools shielded by the surfactants from the oil phase

Here we show how we can use microemulsions to elucidate the formation of $CaCO_3$ phases and stabilise initial amorphous stages. Micelles are used to confine volume in which nucleation and growth occurs. Mixing of two distinct microemulsions containing Ca^{2+} and CO_3^{2-} ions leads to a reproducible method to make nano-sized, monodisperse particles. However, there is no correlation between the initial droplet size and the size of solid $CaCO_3$ particles, which are considerably larger than the original micelles. Therefore, the notion of a "nano-reactor" may in this case be inaccurate, because it implies the formation of an inert, impenetrable water-surfactant-oil interface that limits the growth to a single droplet.

By using time-resolved and *in situ* small and wide-angle X-ray scattering and high-resolution imaging we demonstrated that $CaCO_3$ grows through a continuous but progressive and slow disintegration of the micelles, rather than precipitation inside of individual droplets. Upon destabilisation of the original salt-ion carrying micelles, new water-mineral-surfactant interfaces are created. These constitute a nucleus and they direct further growth. The formation of this interface is crucial in stabilising amorphous $CaCO_3$ in the form of nanoparticles (30-100 nm) and this also slows down or prevents further growth and crystallization.

We believe that these findings are relevant for understanding of the $CaCO_3$ growth mechanisms occurring at water-nonpolar liquid interfaces in natural and industrial environments (e.g. preventing scale formation). Microemulsions could also be a good analogue model system for mineralization of coccolith plates formed within the cell vesicles produced in the Golgi apparatuses of coccolithophores.

The fall of the Tissint meteorite has provided a unique opportunity to study a minimally contaminated piece of Mars. Martian organic carbon has been detected previously in igneous basalts and the carbonates of ALH 84001. Analysis of sealed maskelynite inclusions using *in situ* techniques including Raman, NanoSIMS, ToFSIMS, STXM and TEM, coupled with whole rock analysis by stepped combustion, GCMS and evolved gas analysis has revealed an inventory of organic compounds containing –CH, -CN, -CNO, -COOH, -CO and aromatic complexes. These are spatially resolved to known inorganic catalysts, i.e. magnetite, pyrite, nickel containing pyrrhotite and clays. Furthermore there is a release of nitrogen containing organics above 600ºC, at which temperature $\delta^{15}N$ is ~ +40 ‰. These results show that Mars has an inventory of organic carbon and nitrogen containing molecules that are probably produced through abiological hydrothermal activity.

PTX properties of $FeCl_2$-bearing fluids at elevated *PT* conditions

MATTHEW STEELE-MACINNIS[1]*, PILAR LECUMBERRI-SANCHEZ[1] AND ROBERT J. BODNAR[1]

[1]Department of Geosciences, Virginia Tech, Blacksburg VA 24061, USA (*correspondence: mjmaci@vt.edu)

Iron chloride is a significant component of saline aqueous fluids in many ore-forming environments, commonly occuring at concentrations of up to several mass percent [1]. Thus the effect of $FeCl_2$ on the phase equilibria of aqueous fluids is a significant factor in interpreting fluid evolution in iron-rich systems such as tin-tungsten deposits and some porphyry copper deposits. However, there are few available experimental data on the phase equilibria and thermometric properties of iron-bearing aqueous fluids [2].

We have used the synthetic fluid inclusion technique to investigate the pressure-temperature conditions along the locus of critical points in the system H_2O-$FeCl_2$, from 0 to 35 wt% $FeCl_2$. Our results show that the effect of $FeCl_2$ on the phase equilibria of aqueous fluids is unlike that of other divalent cation chlorides such as $CaCl_2$ or $MgCl_2$. Specifically, the locus of critical points for H_2O-$FeCl_2$ fluids occurs at significantly lower pressure (at a given temperature) compared to the critical curve of the system H_2O-NaCl. For example, at 500 °C the critical point for H_2O-$FeCl_2$ fluids occurs at 480 bar, compared to about 560 bar for H_2O-NaCl. The low pressure along the H_2O-$FeCl_2$ locus of critical points implies that immiscibility (boiling) of $FeCl_2$-rich fluids can occur only at relatively low pressures, or relatively shallow levels in the crust. These results allow us to reinterpret the conditions of mineralization at boiling, Fe-rich hydrothermal systems.

IR specroscopic and quantum chemical study of metal bicarbonate and carbonate intreaction in aqeuous solutions

ANDRI STEFÁNSSON[1], KONO LEMKE[2], PASCALE PÉNÉZETH[2] AND JACQUES SCHOTT[3]

[1] University of Iceland, Sturlugata 7, 101 Reykajvík, Iceland (e-mail: as@hi.is)
[2] University of Hong Kong, Pokfulam Road, Hong Kong
[3] GET, CNRS/UMR 5563-Université Paul Sabatier, 14 rue Edouard Belin, 31400 Toulouse, France

Carbonate speciation are among the most important in aqueous systems. Carbonic acid deprotonates to form HCO_3^- and CO_3^{2-}, which further may complex with dissolved cations in solution. In this study, potentiometric and IR spectroscopic measurements were conducted as well as molecular simulation calculations to gain insight into the aqueous speciation of H_2O-CO_2-NaCl±$MgCl_2$ solutions. In H_2O-CO_2-NaCl solutions CO_2(aq), HCO_3^- and CO_3^{2-} predominates, with addition to the $NaHCO_3$(aq) and $NaCO_3^-$ ion-pairs. These ion-pairs are weak at low-temperatures but become increasingly important with increasing temperature under neutral to alkaline conditions in moderately dilute to concentrated NaCl solutions. With addition of $MgCl_2$, $MgHCO_3^-$ and $MgCO_3$(aq) ion-pairs form, these accounting for significant part of the carbonate species concentrations. The combined potentiometric and IR measurements demonstrate that these ion-pairs truly exist in solution and cannot solely be explained by non-ideal ion-ion interaction. Moreover, the coordination number of Mg^{2+} is reduces upon substitution of HCO_3^- and CO_3^{2-} to the hydration shell from six to a maximum number of five. These changes may have profound effects on further reactions of $[MgCO_3 \bullet nH_2O]^0$ and $[MgHCO_3 \bullet nH_2O]^+$ to from Mg-carbonate and bicarbonate clusters and minerals. No such coordination changes were observed associated with Na^+ HCO_3^- and CO_3^{2-} ion pairing. Based on the experimental results the equilibrium ionization and ion-pair formation constants were retrieved that can be used to calculate aqueous speciation in H_2O-CO_2-NaCl+$MgCl_2$ containing solutions.

δ^{30}Si in early Archean cherts and implications for the silica cycle

E. J. T. STEFURAK*[1], W. W. FISCHER[2] AND D. R. LOWE[1]

[1]Stanford University, Stanford, CA 94305, USA (*correspondence: ltrower@stanford.edu)
[2]California Institute of Technology, Pasadena, CA 91125, USA

Si isotopes in Archean cherts offer insight into mass fluxes and mechanisms associated with silica concentration, precipitation, diagenesis and metamorphism. Previous studies have used Archean chert δ^{30}Si to estimate seawater δ^{30}Si [1-4], assuming a simple mass balance model with silica inputs from crustal weathering balanced by outputs of hydrothermal silicification and amorphous silica precipitation from seawater. This model relies on reservoir analogies, even though silicon reservoirs often have broad δ^{30}Si ranges resulting from low temperature dissolution and precipitation reactions. We propose that process analogies are more appropriate for the early Archean system.

To connect isotope composition to process, we used secondary ion mass spectrometry (SIMS) to compare δ^{30}Si and δ^{18}O in distinct silica phases present in cherts, including carbonaceous bands, pure chert bands and grains, early cavity-filling cements and later quartz-filled veins. Our results indicate that low temperature processes fractionated silicon isotopes in early Archean marine basins—behavior that probably precludes the application of chert δ^{30}Si as a paleothermometer. Relationships between δ^{18}O and petrographic textures are consistent with setting during early burial and diagenesis [5]. The average value we observe for petrographic textures we infer to be primary silica precipitates from seawater, δ^{30}Si +0.6‰, is heavier than expected for bulk silicate Earth (δ^{30}Si -0.4‰). This constraint is consistent with an isotope mass balance wherein contemporaneous iron formation deposits have negative δ^{30}Si composition and form a notable fraction of the mass balance of Si leaving seawater. Precipitation of authigenic clay minerals may have also comprised a large part of the required ^{30}Si-depleted sink, in addition to playing a role as an important non-carbonate alkalinity sink consuming cations released by silicate weathering. We present a new model for the Archean silica cycle based on process analogies and existing data sets.

[4]Duke University, Durham, NC 27708

Engineered silver nanoparticles (Ag NPs), often partially or fully sulfidized, enter the environment. There, sulfidation of Ag NPs greatly decreases the rate of oxidation of Ag^0 and the release of Ag^+. We hypothesized that sulfidation of Ag^0 NPs added to an emergent freshwater wetland mesocosm would greatly decrease silver bioavailability. We dosed a 1.2x1x3m freshwater wetland mesocosm with 30nm PVP-coated Ag NPs (25 mg/L Ag) and then determined the distribution and speciation of Ag NPs after 18 months. A sediment diagenetic model was developed and used to predict the distribution and speciation of Ag in the mesocosms.

Ag^0 NPs in sediments sulfidized over 18 months. Ag speciation was approximately 50% Ag_2S, 30% Ag-S-R (likely organic matter complexed) and 20% Ag^0 as determined by X-ray absorption spectroscopy. Sulfidation decreased dissolved Ag concentration in the water column to below method detection (2 μg/L). The sediment diagenetic model could predict Ag distribution and speciation well using parameter values (e.g. bioturbation) and partition coefficients (e.g. Ag-organic matter) in the range expected for freshwater sediment and demonstrated seasonal fluctuations. There was measurable uptake of Ag into several sediment dwelling organisms, suggesting that Ag_2S or Ag-S-R species remained bioavailable. The uptake of Ag2S in duckweed roots was confirmed with synchrotron based micro-X-ray fluorescence (μ-XRF) and μ-XANES indicates that the silver within the root cortex was predominantly Ag^0.

Cavity ring-down spectroscopy for the high-precision analysis of the triple oxygen isotope composition of water and water vapor

E. J. STEIG[1], V. GKINIS[2], A.J. SCHAUER[1], J. HOFFNAGLE[2], S. TAN[2] JAND S.W. SCHOENEMANN[1]

[1]Earth and Space Sciences, University of Washington, Seattle, WA 98195, USA, steig@uw.edu
[2]Institute for Arctic and Alpine Research, University of Colorado, Boulder, CO 80309, v.gkinis@nbi.ku.dk
[3] Picarro Inc., 3105 Patrick Henry Drive, Santa Clara, CA 95054, jhoffnagle@picarro.com

High precision analysis of the $^{17}O/^{16}O$ isotope ratio is an important new tool in water isotope analysis. The ^{17}O-excess (= $\ln(\delta^{17}O+1)-0.528\ \ln(\delta^{18}O+1)$) is sensitive to kinetic fractionation processes and nearly invariant with temperature [1]. For most applications, measurements of ^{17}O-excess must have a precision of ~5 per meg. This precision is normally obtained by flourination of H_2O to O_2 and analyzed by dual-inlet isotope ratio mass spectrometry (IRMS).

Cavity ring-down spectroscopy (CRDS), commonly used for measurements of $\delta^{18}O$ or δD in water [2, 3], provides several advantages over IRMS, including streamlined sample handling and the ability to measure ambient water vapor in the field. Use of CRDS for ^{17}O-excess poses unique challenges not addressed by existing commercial instruments. While a $H_2{}^{17}O$ absorption region is present in some instruments, the absorbance is influenced by the tail of the $H_2{}^{16}O$ spectrum; resulting precision is inadequate for distinguishing samples from the meteoric water line.

We describe a new CRDS system for high precision ^{17}O-excess measurements. Innovations include i) use of two lasers that measure absorption in different IR regions; ii) sample introduction system for continuous introduction of water vapor over long time periods (similar to [3]); iii) novel improvements to the spectroscopy. Samples can be analyzed with ~5 per meg precision in 60 min. Calibration with respect to VSMOW is achieved using working laboratory standards previously calibrated with IRMS [4]. The results show that both the precision and the accuracy of the new CDRS are competitive with IRMS methods. An additional benefit is improved precision of $\delta^{18}O$ and δD (0.02 ‰, 0.08 ‰).

Eocene hydrocarbon migration, Green River Formation, Utah

HOLLY STEIN[1,2], JUDITH HANNAH[1,2], GANG YANG[1], HELGE LØSETH[3], LARS WENSAAS[3] AND PETER COBBOLD[4]

[1]AIRIE Program, Colorado State University, Fort Collins, CO 80523-1482 USA; holly.stein@colostate.edu
[2]CEED Centre of Excellence, University of Oslo, Norway
[3]Statoil ASA, Research Centre Rotvoll, Trondheim, Norway
[4]Géosciences, Université de Rennes, France

The renowned Eocene Green River Formation presents a spectacular field setting to study both source rock and migration of hydrocarbon. From the Uinta basin, we combine field observations with Re-Os data from pristine outcrop and drill core samples to interpret hydrocarbon migration history.

To build a meaningful Re-Os data set, we employ our sampling strategy to capture just a few mm of stratigraphic section for each analysis. Larger bulk samples risk homogenization of real variations in the initial Os ratio and any time occupied by non-depositional or erosional intervals. Re-Os data for the Mahogony Bed and the petroliferous Mahogony Zone in Hells Canyon (Utah) are combined with Re-Os data from drill core from the Parachute Creek and Douglas Creek members to provide a compelling story for hydrocarbon migration. Samples from high-TOC "Rich Zones" (local stratigraphic nomenclature; the Mahogany Zone is "Rich Zone 7") show a narrow range of Re and Os concentrations and a narrow range in $^{187}Re/^{188}Os$ ratios relative to low-TOC "Lean Zones"; this combination can lead to easily misinterpreted Model 1 isochron ages with low MSWDs and large age uncertainties. Such data sets do not provide accurate depositional ages. Rather, these data sets may characterize Re-Os behavior on initiation of hydrocarbon migration. In effect, we may be looking at source rock with incipient migration of its own oil (i.e., unconventional hydrocarbon), with local homogenization of organic matter and the Re and Os it carries. Samples from designated Lean Zones have nearly an order of magnitude lower Re and Os and yield Re-Os scatterchrons of 47-49 Ma. Scatterchrons and variable $^{187}Os/^{188}Os$ ratios are attributed to local migration of oil still mixed with original kerogen.

Our Re-Os data and an interpretation that accommodates the full data set bring new understanding to hydrocarbon systems in lacustrine rocks. In some cases, Re-Os results inform us not just about the shale, but about hydrocarbon generation and incomplete expulsion. Field relationships are used to support this interpretation.

Project initiated and funded by Statoil ASA, including joint field work; additional core samples from USGS library.

Dust transport over the late Quaternary Red Sea - Dead Sea regions from Nd-Sr isotopes in deep-sea cores and lake sediments

M. STEIN[1]*, D. PALCHAN[1,2], A. ALMOGI-LABIN[1], Y. EREL[2] AND SL GOLDSTEIN[3]

[1]Gological Survay of Israel, 30 Malkhe Israel St. Jerusalem, 95501 ISRAEL (motistein@gsi.gov.il)
[2]Institute of Earth Science, The Hebrew University of Jerusalem, ISRAEL 91904
[3]Lamont -Doherty Eath Observatory, Columbia University, Palisades NY 10964, USA

The Red and Dead Seas situated along the African – Syrian Rift valley between the Sahara and Arabia deserts and the subtropical Mediterranean received during the late Quaternary dust particles that were transported from the Sahara-Arabia deserts, Ethiopian Highlands and the Nile delta. Nd and Sr isotope ratios, chemical and mineralogical compositions of fine-detritus particles, that were recovered from the deep-sea cores: KL15, KL11 and KL23 and from Dead Sea and east Mediterranean sedimentary archives were used to determine the particle sources and reconstruct the synoptic conditions responsible for their transport.

The data indicate that during glacials dust was blown to the northern Red Sea and the east Mediterranean- Dead Sea area from the Sahara deserts by winds associated with the strong-glacial Mediterranean winter cyclones. At the same time dust was blown from Sahelian sources by southern winds associated with monsoonal circulation. During the last interglacial and the African Humid Period, monsoonal rains caused erosion and flooding at the ANS margins of the Red Sea, increasing the contribution of granitic ANS material to the Red Sea floor. During the Heinrich events (e.g. H11 and 1), mixed basaltic-granitic dust was blown from all sources reflecting severe regional aridity, when both monsoonal and Mediterranean cyclone activity were weak.

Enhanced ice nucleation activity of soil dust particles

I. STEINKE[1], R. FUNK[2], A. DANIELCZOK[3], K. HÖHLER[1], N. HIRANUMA[1], N. HOFFMANN[1], M. HUMMEL[1], S. KIRCHEN[4], A. KISELEV[1], M. LEUE[2], O. MÖHLER[1], H. SAATHOFF[1], M. SCHNAITER[1], T. SCHWARTZ[4], B. SIERAU[5], O. STETZER[5], E. TOPRAK[1], A. ULRICH[2], C. HOOSE[1] AND T. LEISNER[1,6]

[6]Institute of Environmental Physics, Heidelberg University, Germany

Primary biological particles have been identified as very efficient ice nuclei at high sub-zero temperatures. Soil dust particles emitted from agricultural areas contain large amounts of organic material such as fungi, bacteria and plant debris. Thus, soil dust particles may act as a carrier for highly ice-active biological particles. In this work, we present ice nucleation experiments conducted in the AIDA cloud chamber where we investigated the ice nucleation efficiency of three types of soil dust from different regions of the world. Results are presented for the immersion freezing and the deposition nucleation mode of these soil dust samples: all soil dusts show higher ice nucleation efficiencies than desert dusts, especially at high temperatures. In addition, inertially separated ice crystal residuals from these AIDA experiments have been analyzed in order to elucidate the ice nucleation process in more detail. The organic content of the soil dusts is investigated with regard to morphology and composition, hydrophilicity, as well as the diversity and viability of species. These characteristics are then related to the ice nucleation efficiencies of the individual dusts.

Oceanographic control on microbial methane oxidation in the water column offshore Svalbard

LEA I. STEINLE*[1,2], CAROLYN GRAVES[3,4], CHRISTIAN BERNDT[2], TOMAS FESEKER[5], MORITZ F. LEHMANN[1], TINA TREUDE[2] AND HELGE NIEMANN[1]

[1]University of Basel, Dept. of Env. Geosciences, CH (*correspondence: lea.steinle@unibas.ch)
[2]Helmholtz Centre for Ocean Research (GEOMAR), DE
[3]National Oceanography Centre Southampton, UK
[4]University of Southampton, UK
[5]University of Bremen, DE

A large number of gas flares were recently discovered at the landward termination of the methane gas hydrate stability zone off Svalbard. The gas ebullition is most probably caused by seasonal bottom water temperature fluctuations of 1-2°C, causing periodic methane hydrate formation and dissociation. During summer time, methane concentrations were consistently elevated in bottom waters (up to 825 nM), providing abundant substrate for aerobic methanotrophs. Our investigations on the spatio-temporal variation of aerobic methane oxidation (MOx) rates revealed highest rates (up to 3.1 nM/day) at ~50 m above the sea floor. Despite constant supply of methane, MOx rates displayed a high temporal variability. Comparison of MOx rates and water temperature revealed consistent spatio-temporal patterns that suggest an oceanographic control on the magnitude of MOx: Cool Arctic bottom water contains a comparably large standing stock of methanotrophic bacteria. This water mass is episodically displaced by the warmer W-Spitsbergen current, which is depleted in methanotrophic biomass. CARD-FISH analyses confirmed that high MOx rates are associated with the presence of methanotrophic cell aggregates. Our data thus imply that MOx fluctuations offshore Svalbard are indirectly controlled by ocean circulation patterns rather than methane substrate availability.

Absorption and fractionation of Rare Earth Elements (REE) by plants

M. STEINMANN[1]*, L. BRIOSCHI[1], E. LUCOT[1], MC. PIERRET[2], P. STILLE[2], J. PRUNIER[2,3], PM. BADOT[1]

[1] Chrono-Environnement, Univ. Franche-Comté/CNRS, F-25030 Besançon, France (*correspondence : marc.steinmann@univ-fcomte.fr)
[2] LHyGeS-EOST, Univ. Strasbourg/CNRS, F-67084 Strasbourg, France
[3] GET, Univ. P. Sabatier/CNRS, F-31400 Toulouse, France

Rare Earth Elements (REE) are increasingly used by man (electronics industry, medicine, agriculture) and therefore considered as emerging pollutants. The present study documents REE mobility in non-polluted natural soil-plant systems in order to characterize their environmental availability for future anthropogenic pollution.

The study is based on a field approach in non-polluted natural sites with contrasting geological environments (limestone, granite and carbonatite) and highly variable REE contents. The data show that REE uptake by plants is not primarily controlled by the plant itself, but depends on the concentration and the speciation in the soil and the adsorbed soil water pool. REE uptake by plant roots are linked with those of Fe. Roots absorb preferentially the light REE (Fig. 1). Before translocation, REE are retained by the Casparian strip leading to much lower concentrations in the aerial parts. The transport of the REE within the xylem is associated with the general nutrient flux.

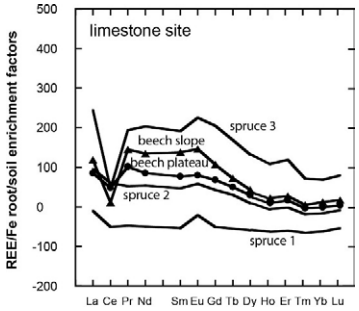

Figure 1: Soil-normalized REE/Fe ratios of plant roots ($[REE/Fe]_{root}/[REE/Fe]_{soil}*100$) showing that roots absorb the LREE preferentially with respect to Fe. Figure from [1].

Late Devonian "Kellwasser-Event" A global mass-extinction equivalent to the Precambrian-Cambrian boundary interval?

YANNIK STEINMANN[1]*, ULRICH STRUCK[1] AND ANTONIA GAMPER[1]

[1]Museum für Naturkunde, Invalidenstr. 43, D-10115 Berlin, (*yannik.steinmann@fu-berlin.de)

The Late Devonian Kellwasser Event characterizes a significant epoch in the evolution of the Palaeozoic ecosphere and hosts one of the five major global mass-extinction events in Earth history. During this period massive continental renovations forced seawater level changes and climate instabilities thus provoking biogeochemical perturbations of the oceans likely comparable to the Precambrian-Cambrian evolution events. Culminating in the extinction of up to 60% of the pelagic biosphere the Kellwasser period is characterized by the deposition of two black shale successions, the so-called Kellwasser horizons (e.g. Germany, France, USA). Well preserved Devonian strata crop out in sections around the Kellwassertal in the central German Harz Mountains. However, geochemical data especially sedimentary bulk nitrogen isotope values from these rock sections are rare.

We determined $\delta^{13}C_{carb}$, $\delta^{13}C_{org}$ and $\delta^{15}N$ isotope values from an outcrop near Goslar including the basal cephalopod limestone, the lower and upper Kellwasser horizons and the overlying lower Famennian limestones. The section represents a carbonate-siliciclastic setting in a submarine rise environment permanently connected to the ocean but influenced by multiple trans- and regression events. $\delta^{15}N$ isotope data from the Kellwasser horizons reveal two major negative excursions, one shift down to -1.2‰, the latter -1.7‰. Two positive co-occuring $\delta^{13}C_{carb}$ and $\delta^{13}C_{org}$ excursions represent the global Kellwasser carbon isotope signal as already reported in other upper Devonian sections worldwide.

Our data represent trustful markers for the marine palaeo-oxygenation state and nutrient availability suggesting that biogeochemical events during the Frasnian-Famennian interval can roughly be compared to the Precambrian-Cambrian boundary interval and may record phases of photic zone anoxia. Scenarios like the stepwise upper Devonian mass-extinction of biota associated with marine transgressive events and negative $\delta^{15}N$ excursions can be paralleled to the Precambrian-Cambrian event recorded in sections e.g. of South China and Kazakhstan thus enabling new approaches of interpretation.

Mineralogical characterization and crystallization kinetics of fibrous and acicular volcanic orthopyroxenes from Mt. Etna, Sicily, Italy

I. STELLUTI[1]*, C. VITI[2], A. GIANFAGNA[1]

[1] Dipartimento di Scienze della Terra, Sapienza Università di Roma, Italy (*correspondence: igor.stelluti@uniroma1.it)
[2] Dipartimento di Scienze Fisiche, della Terra e dell'Ambiente, Università di Siena, Italy (cecilia.viti@unisi.it)

The present study reports mineralogical characterization of unusual acicular and fibrous orthopyroxenes occurred in the autoclastic volcanic products from Santa Maria di Licodia, belonging to "Mt. Calvario Formation", Etna Volcano. The orthopyroxene is associated to Na-feldspar, augitic clinopyroxene, apatite and Fe-Ti oxides and shows variable morphology from prismatic to fibrous, with composition enstatite to ferroan-enstatite. Prismatic and acicular morphologies highlight a composition with high Fe contents (FeO 18-20 wt%) and moderate Ca enrichments (~1 wt %), whereas the fibers present enrichment in Mg contents (FeO < 11%). Fibrous orthopyroxene has been investigated by Trasmission Electron Microscopy (TEM), revealing fibers less than 1 μm in diameter, with perfectly euhedral habit, high crystallinity and crystal order. Selected Area Electron Diffraction (SAED) patterns show sharp and intense reflections, with limited streaking effects, probably corresponding to polytypic disorder and twinning. Corresponding HRTEM images confirm the occurrence of rare packing defects and twinning, giving rise to lamellar nanostructures in both parallel and orthogonal orientations with respect to c fiber axis. A remarking feature is represented by the systematic occurrence of a very thin amorphous film that envelops the entire fiber. Focused-beam EDS microanalyses highlighted reverse zoning, with Fe-enriched cores and Mg-enriched rims.
Orthopyroxenes with fibrous morphology are rare [1, 2] and there is no evidence in literature about their presence in volcanic environment. The occurrence of the fibrous orthopyroxene in the volcanic area studied [3] allowed to undertake this detailed mineralogical investigation. The data obtained provide some preliminary constrains on crystallization kinetics pointing to conditions of high temperature crystallization and very fast cooling.

Magmatic evolution at Yellowstone: The role of isotopically juvenile magma inferred from zircon age, trace-element and Hf isotope data

MARK STELTEN[1]*, KARI COOPER[1], JORGE VAZQUEZ[2], JOSH WIMPENNY[1], QING-ZHU YIN[1]

[1]University of California – Davis, Davis, CA, USA (*correspondance: mestelten@ucdavis.edu)
[2]U.S. Geological Survey, Menlo Park, CA, USA

Yellowstone caldera (USA) is a prime example of a long-lived, large-volume silicic magma system that has produced numerous eruptions of rhyolite and basalt during Quaternary time, including caldera-forming eruptions at ca. 2.1 Ma, ca. 1.3 Ma and ca. 0.640 Ma [1]. The most recent post-caldera eruptive episode at Yellowstone produced the Central Plateau Member (CPM) of the Plateau Rhyolite, which erupted between ca. 170-70 ka. Previous research (e.g., [2]) has documented that the Nd isotopic compositions of the CPM rhyolites lie between that of the local crust and Yellowstone basalts, leading to the hypothesis that both local crust and isotopically juvenile material are required to explain the genesis of the CPM rhyolites. Additionally, it is clear from oxygen isotopic studies that the low $\delta^{18}O$ values of the CPM rhyolites (~4 to 4.5‰) require some contributions from remelted, hydrothermally altered crustal rocks [3, 4]. Here we use zircon age, trace-element and Hf isotopic compositions to explore the role of isotopically juvenile magma in the generation of the CPM rhyolites.

New Hf isotope data from CPM zircons demonstrate the presence of zircons with juvenile Hf isotope compositions (-4 to 0 ε_{Hf}) relative to their host CPM glasses (-5.7 to -6.2 ε_{Hf}), which requires that isotopically juvenile silicic magmas contributed mass to the CPM magma reservoir. Local crustal sources and older Yellowstone rhyolites have ε_{Hf} values lower than the CPM rhyolites (<-6.5 ε_{Hf}) and therefore cannot represent the sources responsible for contributing the high-ε_{Hf} zircons observed in the CPM rhyolites. Instead, new Hf isotope data show that the Yellowstone basalts (-0.1 to 5.5 ε_{Hf}) are the only source identified to date with an appropriate isotopic composition to account for the Hf isotopic heterogeneity observed in CPM zircons. Thus, these data suggest that 1) the high ε_{Hf} CPM zircons crystallized from isotopically juvenile silicic magma that is a hybrid of silicic liquids derived from Yellowstone basalts and local crust and 2) this isotopically juvenile hybrid magma is then added to the CPM reservoir periodically thorough time. In turn, these data provide direct evidence supporting the concept that both crustal-derived and mantle-derived (i.e., juvenile) components are required to generate Yellowstone rhyolites.

Biotite is an important host for Nb in the lower crust

STEPANOV A.S.[1,2], HERMANN J.[1]

[1]RSES, Australian National Univeristy, Canberra, Australia
[2]CODES, University of Tasmania, Hobart, Australia
(sasha.stepanov@utas.edu.au)

The trace element-enriched continental crust is a result of partial melting of the mantle, which displays a complementary depleted composition. Nb and Ta are elements regarded as geochemical twins showing very similar properties and they display a strong affinity to Ti minerals. Therefore it is surprising that significant fractionation of Nb and Ta are observed at global scale. The subchondritic Nb/Ta ratio of both the continental crust and the depleted mantle is known as the "missing Nb paradox".

We present partitioning data between biotite and granitic melt for experimental and natural samples that provide evidence that Nb is compatible in biotite. Nb can thus be enriched in the residue during partial melting of crustal rocks. Additionally, biotite preferentially incorporates Nb over Ta (Stepanov and Hermann, 2013). Hence, incipient partial melting in the lower crust with biotite as residual mineral can result in restites with high Nb contents and super chondritic Nb/Ta.

Data from two key localities of crustal anatexis provide additional evidence for intracrustal Nb and Ta fractionation during partial melting of biotite-bearing rocks. Crustal, granulite facies metapelite encalves from the El Hoyazo (EH) dacite, Spain, contain melt inclusions that have significantly lower Nb and Nb/Ta than the bulk rock composition. In contrast, residual biotite is an abundant phase in the enclaves and has high Nb contents and Nb/Ta significantly higher than the bulk rock. In the classic lower crustal section in the Ivrea Verbano zone, northern Italy, metasedimentary amphibolite grade rocks have typical crustal Nb/Ta ratios, whereas granulite grade restites have higher and partial melts lower ratios. Therefore we suggest that intra-crustal differentiation might be an important process to produce Nb-rich rocks with superchondritic Nb/Ta that represent one of the missing reservoirs to balance the subchondritic Nb/Ta of the upper crust and the depleted mantle.

The Paleoproterozoic MORB-type tholeiitic dykes as indicators of early continents breakup

A.V. STEPANOVA[1]*, A.V. SAMSONOV[2], E.B. SALNIKOVA[3], YU.O. LARIONIVA[2], A.N. LARIONOV[4], V.S. STEPANOV[1]

[1]Institute of Geology, Karelian Research Centre, Russian Academy of Sciences, Petrozavodsk, Russia (*correspondence: stepanov@krc.karelia.ru)
[2]IGEM Russian Academy of Sciences, Moscow, Russia
[3] IPGG, Russian Academy of Sciences, St. Petersburg, Russia
[4]CIR VSEGEI, St. Petersburg, Russia

The time and circumstances of the Precambrian continents fragmentation is usually highly controversial issue because of deep erosion and absence of clear evidences of breakup events. Relics of various igneous provinces occur in Precambrian Shields, but it is difficult to decide which of them is indicator of final continent breakup.

In the Karelian Craton, Eastern Fennoscandian Shield there are a lot of Paleoproterozoic (2.5 -1.97 Ga) mafic dykes that vary in composition from high-Mg to high-Fe-Ti tholeiites [1]. Among them we recognize very specific dykes of age 2.13-2.14 Ga. In spite of intracontinental tectonic setting these dykes are MORB-type tholeiites with flat REE patterns, HFSE enrichment, Nb/Nb*=0.7-1.6 and εNd_t range from +3.0 to +1.4. Geochemical modelling indicates that chemical and isotopic compositions of the dykes are best explained by derivation of their parental magmas from partial melting of depleted mantle sources in the spinel peridotite stability field, followed by fractional crystallization and low (< 6%) extent assimilation of continental crustal material. The latter suggests a rapid rise of mafic melts, accompanied by rapid crust extension, which follows from the morphology of the dykes.

Widespread MORB-type tholeiitic dykes on the Karelian Craton suggest substantial lithosphere thinning accompanied by asthenosphere rising. This allows us to consider MORB-type tholeiitic dykes as indicators of final breakup of the Achaean continent and Lapland-Kola and Svecofennian oceans opening. This statement is supported by strong compositional similarity between studied dykes and syn-breakup basalts in North Atlantic Igneous Province [2], [3] and Afar [4], [5].

Formation of Se(0) nanoparticles by *Azospirillum brasilense*

R. STEUDTNER[1]*, A. MAFFERT[1], M. VOGEL[1], C. FRANZEN[1] AND A.C. SCHEINOST[1]

[1] Helmholtz-Zentrum Dresden-Rossendorf e.V., Institute of Resource Ecology, P.O. Box 510119, D-01314 Dresden, Germany (*correspondence: r.steudtner@hzdr.de)

We investigated the reduction of SeO_3^{2-} by *Azospirillum brasilense*. The formation of fairly soluble Se(0) nanoparticles during this process is of interest for both bioremediation of Se-contaminated sites and for nanobiotechnology.

A. brasilense was cultured in 30 mL medium at 30 C in a shaking (100 rpm) incubator for 3 days in the presence of 1 mM Se(IV). The cellular material was then separated from the red Se precipitate by using a modified procedure of Oremland *et al*. [1]. The cleaned precipitate was resuspended in deionized water. For selective Se(IV) quantification in the culture media we used hybrid generation atomic absorption spectrometry (HG-AAS) [2]. The formed Se precipitate was characterized by scanning electron microscopy with energy-dispersive X-ray spectrometry (SEM-EDX), photon correlation spectroscopy (PCS) and zeta potential measurements.

After exposing *A.brasilense* to Se(IV), the bacterial growth continued after an extended lag-phase. After a cultivation time of 3 days, a reddish staining of the sample was observed, indicating the formation of Se(0). SEM coupled to EDX confirmed the formation of nanoparticulate, red Se(0). Only 10 % of the initial Se(IV) concentration could be recovered from the culture media by HG-AAS. The separated Se(0) suspension was stable for several hours, sufficient for the PCS and the zeta potential measurements. In contrast, Se(0) chemically formed by reduction with hydroxylamine solution produced amorphous aggregates with rapidly settled down. PCS and SEM imaging showed that the Se(0) particles had a particle size distribution between 100 and 300 nm with an averaged particle diameter of 200 nm. The isoelectric point of Se(0) particles was at pH 2.8 ± 0.2. The preference of forming Se(0) particles with a negative charge agree very well with the literature [3].

Stable and Radiogenic Strontium isotope behaviour in the subglacial environment

E. I. STEVENSON[1]*, S. M. ACIEGO[1], , I. J. PARKINSON[2] K.W. BURTON[3], C. ARENDT[1]

[1] Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI 48109 USA, (*correspondence: emisstev@umich.edu)

[2] Bristol Isotope Group, School of Earth Sciences, University of Bristol, Wills Memorial Building, BS8 1RJ, UK

[3] Department of Earth Sciences, Durham University, Science Labs, Durham DH1 3LE, UK

Subglacial hydrology plays a key role in determining the nutrient fluxes from glaciated terrains. Differences in the chemical and isotopic composition of the glacial outflow are controlled by variations in initial inputs, mineralogy, mineral dissolution and residence time. We present geochemical data from the glacial discharge of two geographically, geologically and climatologically distinct glaciers over two field seasons: the Athabasa Glacier, Canada (AG, Precambrian sedimentary bedrock) and the Lemon Creek Glacier, USA (LCG, Southeast Alaska metamorphic belt).

Strontium isotopes are widely utilized in studies of weathering and hydrology. Radiogenic Sr ($^{87}Sr/^{86}Sr$) is a good proxy for varying hydrological inputs and weathering reactions, however Sr *stable* isotopes ($\delta^{88/86}Sr$) can be fractionated by both precipitation and dissolution reactions. A combination of the two strontium systems should therefore provide improved constraints on the weathering environment.

Radiogenic Sr results indicate differences in glacial outflow composition with $^{87}Sr/^{86}Sr$ ~0.7142 and ~0.7106 for AG and LCG respectivly. Radiogenic Sr data from the AG show clear resolvable seasonal excursions, varying from 0.716 in May to 0.712 in July. By contrast, the meltwater from the Lemon Creek shows little variability in radiogenic strontium with time. The $^{87}Sr/^{86}Sr$ in suspended sediments from the LCG are consistently less radiogenic than their water counterparts and show a similar trend toward more radiogenic values as the season progresses.

The $\delta^{88/86}Sr$ data, however clearly show the difference in the underlying bedrock geology with mean $\delta^{88/86}Sr$ ~0.19 and ~0.33 for AG and LCG respectivly. Analysis of $\delta^{88/86}Sr$ from suspended sediments from LCG show consistently lighter compositions than the corresponding water sample.

Variations in both $^{87}Sr/^{86}Sr$ and $\delta^{88/86}Sr$ in the meltwater will be analyzed using principle component analysis to reveal relationships with water mass source and elemental fluxes.

Determining the pre-eruptive magmatic conditions and sulfur release of the AD1280 Quilotoa eruption, Ecuador

A-M. STEWART; J. CASTRO

Johannes Gutenberg Universität, 55099 Mainz, Germany (*stewara@uni-mainz.de, castroj@uni-mainz.de)

Pre-eruptive conditions in the magma storage zone prior to the AD1280 eruption of Quilotoa volcano in Ecuador have been constrained using geothermobarometry; values of 240 MPa average magma pressure and fO_2 NNO+1.63 were calculated; a relatively oxidized, shallow magma of 800°C.

Using FTIR and EMPA on glass melt inclusions in quartz phenocrysts, total water dissolved in the melt was determined to be ~6.65 wt% (XH_2O 0.21), of which 5.05wt% exists as H_2Om while 1.6wt% is OH. CO_2 in the melt is variable. The average, 141ppm, corresponds to XCO_2 $1.8e^{-4}CO_2$.

Using CO_2-H_2O solubility models, a melt XH_2O 0.2 was computed – equal to the value measured in the melt, indicating water saturation at the time of trapping.

A dominance of H_2O over CO_2 is revealed in the vapor phase: 0.98 and 0.02 respectively.

Melt sulfur concentrations are 47-92ppm. Petrologic methods, magma volume-SO_2 degassing correlations and ice core records were combined to estimate values of 969 Mt H_2O and 2.25 Mt SO_2 degassed from the melt during the eruption, from which ≤3.4 Mt H_2SO_4 could have been produced (assuming 100% SO_2-to-H_2SO_4 conversion) and a total of 35-75Mt SO_2 (melt + excess S vapor phase), producing ~52-115 Mt H_2SO_4.

Origin of dissolved solids in Marcellus shale produced water

BRIAN W. STEWART[1]*, ELIZABETH C. CHAPMAN[2], ROSEMARY C. CAPO[1], JOSEPH R. GRANEY[3] AND JASON D. JOHNSON[3]

[1]Department of Geology and Planetary Science, University of Pittsburgh, Pittsburgh, PA 15217, USA (*correspondence: bstewart@pitt.edu)

[2]Echelon Applied Geoscience Consulting, 1229 Twlve Oaks Ct. Murrysville, PA 15668, USA

[3]Department of Geological Sciences, Binghamton University, Binghamton, NY 13902, USA

Hydraulic fracturing of black shales for natural gas production results in large volumes of flowback and produced water, which rapidly (within days to weeks) achieves high levels of total dissolved solids (TDS), sometimes >$2x10^5$ ppm. This highly saline water continues to be produced, albeit at much diminished rates, over the lifetime of the well. This brine could originate from (1) interaction of injected water with salts in the formation, (2) extraction of brine trapped in pores within the shale and /or (3) formation water previously held in fractures, sandy lenses, or adjacent strata. To evaluate the origin of these dissolved solids, we carried out sequential leaching experiments on dry-drilled cuttings from the Middle Devonian Marcellus shale and adjacent units in Tioga County, New York, USA. The samples were treated with ultrapure water to dissolve soluble salts and sulfates, 1N ammonium acetate buffered to pH 8 to extract exchangeable cations, 8% acetic acid to dissolve carbonate minerals and 0.1N HCl to target other acid-soluble phases.

The water leachates had consistently higher Na/Cl and lower Ca/SO_4, Na/Ca and Sr/Ca ratios compared to produced water [1, 2]. Ba/Ca ratios were highly variable (as in the produced water) and >90% of the Ba extracted was in the ammonium acetate fraction, suggesting it is bound in exchangeable sites within the shale. $^{87}Sr/^{86}Sr$ ratios of water-soluble and exchangeable Sr range from 0.7093 to 0.7112, mostly within the range of $^{87}Sr/^{86}Sr$ values measured in produced waters [1], but well above Devonian seawater and well below bulk-shale values (>0.731). Based on the significant differences between the chemistry of the leachates and that of Marcellus produced waters, we suggest that most solutes in the latter are inherited from highly saline formation waters in fractures or adjacent strata. Long-term interaction of these waters with the shale imprinted similar Sr isotope ratios on the water-soluble and exchangeable portions.

Improved boron isotope pH proxy calibration for the deep sea coral *Desmophyllum dianthus* through sub-sampling of fibrous aragonite

J.A. STEWART *[1], E. ANAGNOSTOU [1] AND G. L. FOSTER[1]

[1] Ocean and Earth Science, National Oceanography Centre, University of Southampton, Southampton, UK, (*Joseph.Stewart@noc.soton.ac.uk)

The isotopic composition of boron ($\delta^{11}B$) in marine carbonates is well established as a proxy for past ocean pH [1,2]; however, its robust application to palaeo-environments relies on the generation of species-specific calibrations. Existing calibrations utilising the deep sea coral *Desmophyllum dianthus* highlight the potential application of $\delta^{11}B$ measurements of this species to pH reconstructions of intermediate depth waters [3,4]. However considerable uncertainty remains regarding the estimation of seawater pH from these bulk $\delta^{11}B$ measurements, resulting from sub-structural heterogeneities in $\delta^{11}B$ of *D. dianthus*. To circumvent this problem, thus improving the reliability of the *D. dianthus* $\delta^{11}B$ calibration, we present a new $\delta^{11}B$ calibration of micro-sampled fibrous aragonite from *D. dianthus*. Modern coral specimens recovered from the Atlantic, Pacific and Southern Oceans (depth range of 274-1470 m) were micro-sampled using a MicroMill (New Wave), analysed using multi-collector ICP-MS (Neptune) and the measured $\delta^{11}B$ was regressed against ambient pH taken from hydrographic data sets (pH range 7.4 to 8.0). $\delta^{11}B$ values from this new fibre calibration are generally lower than bulk septal measurements [e.g. 3] and suggest a stronger and better-defined dependence on ambient seawater pH. This study confirms the utility of *D. dianthus* as an archive of palaeo-pH, provided suitable sampling strategies are applied.

Dual sources for early Taranaki magmas: The Sr isotope story

R.B. STEWART[1]*, R.C. PRICE[2], I. E.M. SMITH[3] AND A. ZERNACK[4]

[1]Volcanic Risk Solutions, IAE, Massey University, Palmerston North 4442, New Zealand (*correspondence: r.b.stewart@massey.ac.nz)

[2]Faculty of Science and Engineering, University of Waikato, Hamilton, New Zealand (rprice@waikato.ac.nz)

[3]School of Environment, University of Auckland, Auckland 1142, New Zealand (ie.smith@auckland.ac.nz)

[4]Tanenuiarangi Manawatu Inc., PO Box 1341, Palmerston North, New Zealand (a.zernack@massey.ac.nz)

Mount Taranaki, located 140 km west of the Taupo Volcanic Zone (TVZ), lies 180 km above the Wadati-Benioff Zone and is the most westerly subduction-related volcanism in New Zealand. Compositions are basaltic andesite to andesite with minor dacite and basalt. Taranaki has erupted episodically for more than 130 ka, generating debris avalanche deposits by catastrophic failure of the edifice. These deposits provide a record of the early magmatic evolution of the Taranaki volcanic system. K_2O and LILE are enriched with time, culminating in Holocene high-K andesites [1]. Pre-100 ka magmas include primitive basalts and basaltic andesites with higher silica compositions in progressively younger units and the appearance of late-stage low pressure mineral phases (high-Ti hornblende, biotite and Fe-rich orthopyroxene) confirms a gradual shift to more evolved magmas with time.

Sr isotope compostions have been constant at around 0.7046; similar to the least radiogenic compositions at Ruapehu, a long-lived active andesite volcano in the TVZ, suggesting a common mantle wedge composition for both Taranaki and the TVZ. However, the Taranaki isotope data set contains evidence for the presence prior to 100 ka of an even less radiogenic source with $^{87}Sr/^{86}Sr$ compositions of < 0.7040, mostly in primitive basalts with < 50% SiO_2. Trace element data for these samples have only weak arc signatures. A similar dual Sr isotope source is evident in the older Pouakai volcano in Taranaki. We suggest that in the early Taranaki magma systems a component of relatively unmodified mantle was present that was eclipsed after c. 100 ka by subduction-modified material.The slab under Taranaki is near-vertical and this slab configuration might allow edge flow to contribute to the Taranaki magma source.

Rare Earth Elements origin and dynamic in contaminated river basins: Nd isotopic evidence

STILLE P.[1], HISSLER C.[2] AND CHABAUX F.[1]

[1] LHyGeS - UMR 7517 CNRS - EOST/UdS, 1 rue Blessig F-67084 Strasbourg cedex (pstille@unistra.fr, fchabaux@unistra.fr)

[2] GEOSAT/EVA/CRP –GL, 41 rue du Brill L-4422 Belvaux (hissler@lippmann.lu)

Uncertainties in identifying the origin of pollutants in river systems and in quantifying their impact particularly exist for ecosystems in strongly contaminated river basins. The difficulty of such estimations is based on the relative significance of both anthropogenic and natural sources of trace metals in the environment. The natural geochemical background is characterized by important variations at global, regional or local scales. Moreover, elements currently considered to be undisturbed by human activities and used as tracers of continental crust derived material have become more and more involved in industrial or agricultural processes. The global production of lanthanides (REE), used in industry, medicine and agriculture, for instance, has increased exponentially from a few tons in 1950 to about 150 kt in 2012. Consequently, these contributions interfere in the estimation of natural REE sources.

The application of Nd isotope ratios has very recently been successfully used for the first time for tracing the anthropogenic contribution of atmospheric deposition in urban and industrial areas (Lahd Geagea *et al*., 2008; Hissler *et al*., 2008; Guéguen *et al*., 2012). However, at our knowledge, no study focused on the fractionation of the Nd isotopic ratio due to anthropogenic activity in river systems. For this reason, this work is dedicated to the understanding of processes that control the Nd isotopic fractionation in river waters heavily contaminated by anthropogenic activities.

The upper Alzette River basin, in Luxembourg, suffers from substantial historical and current contamination principally due to the presence of the steel industry, which has been active from 1875 until now. The particulate and dissolved fractions of river waters were monitored using a multitracer approach (including REE and Nd isotopes) during two hydrological cycles (bi-weekly and flood event based sampling). This extensive sampling design allowed to understand the seasonal dynamics of the waters Nd isotopic compositions according to the REE composition of the particulate fraction of the water. Combining REE concentrations and the Nd isotopic information allowed us to quantify the annual anthropogenic fluxes of REE.

A review of CO_2 and O_2 gas dynamics within the sub-surface Critical Zone and implications for early-atmosphere studies using paleosols

G. E. STINCHCOMB[1]*, S. L. BRANTLEY[1]

[1]Department of Geosciences, Pennsylvania State University, University Park, PA 16802

([1]*Correspondence: ges130@psu.edu, [1]sxb7@psu.edu)

The pCO_2 concentrations of early Earth's atmosphere are a key component for resolving the faint young Sun paradox and have been intensely debated for some time. Regolith models that use mass-balance geochemical arguments, based on the consumption of CO_2 through the neutralization of soil, saprolite and rock, prove to be one of the more reliable methods for estimating atmospheric pCO_2 [1, 2, 3]. Yet, many of the assumptions used to estimate the early atmosphere are difficult to test in the modern biotic Earth. This study serves as a review of modern regolith gas research and explores the potential use of deep weathering profiles for refining paleoatmosphere reconstructions. We compiled 248 soil CO_2 and O_2 assays from 29 regolith studies spanning a range of environments that includes deep (>3 m) profiles. Soil CO_2 values (n=174) range from 0.01 to 15.5% by vol., whereas soil O_2 values (n=74) range from 0.2 to 22.85% by vol. The compilation of regolith gas data shows that only 30% of the assays were collected from a depth >3 m; and few of these studies include both gas and bulk geochemical data. The data that do extend to depths >3 m show O_2:CO_2 ratios that exponentially decline with increasing depth. This deep portion of the modern sub-surface Critical Zone has lower O_2:CO_2 ratios and presumed lower biomass concentrations than the modern surface. These observations suggest that the highly acidic, low-oxidizing soil atmosphere *deep* in modern regolith may be a suitable analogue for Precambrian abiotic *near-surface* weathering. Contemporary deep (> 3 m) regolith studies that include both bulk geochemical and gaseous phase data are not only lacking but could provide a much-needed empirical dataset for refining Precambrian atmosphere estimates using paleosols. Environmental parameters that determine distribution coefficients of radionuclides for repositories

M. STOCKMANN[1]*, V. BRENDLER[1], J. FLÜGGE[2], S. BRITZ[2] AND U. NOSECK[2]

[1]Helmholtz-Zentrum Dresden-Rossendorf, D-01314 Dresden, Germany (*correspondence: m.stockmann@hzdr.de)
[2]GRS Braunschweig, D-38122 Braunschweig, Germany

In order to treat radionuclide sorption processes in natural systems more realistically, temporally and spatially variable distribution coefficients (smart K_d-values) are calculated as a function of important environmental parameters such as pH, ionic strength (IS), concentration of dissolved inorganic carbon [DIC], calcium [Ca] and radionuclides [RN]. This smart K_d-concept is implemented into the transport code r³t [1].

As a test of the modified code r³t and the sensitivity analysis of radionuclide sorption regarding the mentioned environmental parameters, a possible future climate transition (seawater transgression) at Gorleben site / Germany was modelled [2]. Seawater inundation drastically influences the distribution and values of all environmental parameters. Chemical changes cause dissolution or precipitation of calcite and these in turn affect the pH, DIC and Ca concentration. In consequence the K_d-values and therewith the transport of radionuclides is impacted.

The results of the calculations are plausible: environmental parameters follow expected trends and major dependencies. As a consequence of the low Ca and DIC concentration in seawater, calcite dissolves in the aquifer and causes an increase of the pH. The K_d-values change according to the changes in environmental parameters. The pH has the most dominant impact on the smart K_d-values for most of the considered RNs, except for Pu and Th, for which the DIC concentration has the strongest impact. Under the assessed conditions for seawater transgressions the smart K_d-values of Cs, Ni, Am and Np(V) increase, those of Se(VI) and U(VI) decrease with increasing pH. The smart K_d-value particularly of Pu and Th decreases with increasing DIC concentration.

This project is funded by the German Federal Ministry of Economics and Technology (BMWi) under contract no. 02 E 11072A and 02 E 11072B.

Detrital zircon U/Pb ages on sedimentary rocks from the South Carpathians, Romania and implications for regional tectonic provenance

A. STOICA[1]*, M. N. DUCEA[1,2], D. JIANU[1]

[1] Faculty of Geology and Geophysics, University of Bucharest, Bucharest, 010041, Romania
[2] Department of Geosciences, University of Arizona, Tucson, AZ, 85721, USA
(*stoica.mala@gmail.com)

We present new detrital U/Pb zircon ages on six sands and sandstones collected from the South Carpathians, Romania. The Southern Carpathians have a nappe structure assembled during Middle to Late Cretaceous Alpine continental collision, consisting of several thrust nappes: the Getic-Supragetic nappe system, the underlying Severin complex and the lowermost Danubian nappe system, each composed of several amalgamated blocks of different affinities [1]. The analyzed rocks are: 3 mid-Cretaceous sanstones from Bucegi Mountains, one latest Cretaceous from Cozia Mountains, one Quaternary sandstone and one modern sand from Pianu Valley, north from Sebes Mountains. Our LA-MC-ICPMS U/Pb ages on detrital zircons confirm periods of magmatism in the Neoproterozoic and Cambro-Ordovician, as well as an episode of metamorphism in Late Devonian to Carboniferous documented by high U/Th ratio zircons.

The three early Cretaceous sedimentary rocks, collected from Bucegi Mountains, contain detrital zircons of different crystallisation ages ranging from 2.7 Ga to 340 Ma, but mostly clustering around 500 Ma. The predominant Neoproterzoic (550–850Ma) and Cambro-Ordovician (450-520 Ma) zircons indicate subaerian exposure of Leaota metamorphic unit in Aptian. Precambrian tectonics is documented by inherited zircons (cca. 900-1200 Ma, 1800-2200 Ma, 2600-2800 Ma), most likely recycled from Cumpana metasedimentary rocks due to their similarity in age distribution.

In the other samples, the most prominent population occurs between 450 and 500 Ma, followed by less abundant age group between 550 and 800 Ma. Older ages are also present but less frquent frequencies than in the early Cretaceous samples.

Age distribution patterns from all samples are consistent with derivation from basement rocks of the Getic-Supragetic thrust sheets and no contirbutions from Danubianunits.

A coordinated in situ NanoSIMS, HR-SEM and TEM search for presolar grains in an ALHA77307 chondrule rim

A.N. STOJIC[1]*, F. E. BRENKER[1], J. LEITNER[2] AND P. HOPPE[2]

[1]Institute of Geosciences, Mineralogy, Goethe University, Altenhoeferallee 1, 60438 Frankfurt/M., Germany (*correspondence: stojic@em.uni-frankfurt.de)
[2]Max-Planck Institute for Chemistry, Hahn-Meitner Weg 1, 55128 Mainz, Germany

Only recently, fine-grained rims around chondrules (FGRs) have been reported to contain presolar grains [e.g.,1, 2]. Competing hypotheses explaining formation history of FGRs are namely formation in the solar nebula or as a result of meteorite parent-body alteration processes [3]. FGRs and interchondrule matrix material do not differ chemically or mineralogically except for the grain size of the respective constituent minerals [4]. From the primitive CO3.0 chondrite ALHA 77307 containing a 390 μm x 300 μm large porphyritic chondrule surrounded by a FGR of 30 μm - 75 μm thickness, a transparent thin film suitable for TEM studies was prepared with a new preparation technique, ArIS [5]. Subsequently, 2,200 μm^2 of the FGR part of the thin film was analyzed with the NanoSIMS 50 ion probe in Mainz to search for O-rich presolar grains. Obtained isotope images, HR SEM images and TEM images of the same area were superimposed to unambiguously relocate the presolar grains among the surrounding solar material in the TEM. We detected 4 oxygen anomalous grains (3 silicates and one oxide), showing excesses in their $^{17}O/^{16}O$ ratio relative to the solar value. These grains represent relative abundances of ~ 70ppm and ~ 33ppm for the silicates and oxides, respectively. All grains are Group I which to date constitute the bulk of identified presolar O-rich species forming around low mass RGB/AGB stars. One presolar silicate is a crystalline fayalitic olivine, 180 nm x 40 nm in size. The grain is embedded in a groundmass comprising fine-grained Fe-rich silicates, refractory silicates, sulfides and Fe-Ni metal. There is no microscopically observable evidence of equilibration and this absence more likely favours the solar nebula accretion hypothesis rather than parent body alteration, a conclusion previously obtained only by SEM and NanoSIMS studies in the case of ALHA 77307 [e.g., 6].

High-precision LA-ICP-MS analysis of microanalytical reference materials for environmental research

B. STOLL[1]*, K.P. JOCHUM[1], U. WEIS[1] AND M.O. ANDREAE[1]

[1]Max Planck Institute for Chemistry, Mainz, Germany (*correspondence: brigitte.stoll@mpic.de)

The high spatial resolution available with LA-ICP-MS microanalysis of speleothems, biogenic calcium carbonates, bones and teeth holds the promise to improve the understanding of past climate conditions and environmental change. However, there are analytical problems with this method, such as interferences, elemental fractionation and matrix-dependent mass load effects using non-matrix-matched microanalytical reference materials (MRM) [1]. We therefore have investigated new carbonate MACS-1, MACS-3 and phosphate MAPS-4, MAPS-5, STDP5, Durango apatite MRM by a sector-field ICP-MS coupled either with 213 nm or 193 nm Nd:YAG nanosecond (ns) lasers, or a 200 nm Ti-sapphire based femtosecond (fs) laser.

Our studies show that many masses are affected by interferences, such as $^{24}Mg^{++}$ by $^{48}Ca^{++}$ in the carbonate and $^{47}Ti^{+}$ by $^{31}P^{16}O^{+}$ in the phosphate matrix. Elemental fractionation and mass-load-dependent matrix effects have been detected for the ns laser systems. They are small for refractory lithophile elements, such as Ba and Sr (< 5 – 10%). For chalcophile/siderophile trace elements with low boiling points (e.g., Pb, Zn) these effects are high (up to 20 - 40%) and different for the NIST silicate glasses, commonly used for calibration and the carbonate and phosphate MRM. Experiments with the femtosecond laser demonstrate that these matrix-related effects are negligibly small with this system [2]. This means that NIST glasses are suitable as calibration material [3] for carbonate and phosphate LA-ICP-MS microanalyses when using fs-UV lasers. They are also appropriate for the determination of lithophile element concentrations in environmental samples when using UV-ns lasers. However, when using ns lasers, matrix-matched calibration is still preferred for an accurate analysis of chalcophile/siderophile and volatile elements.

To further characterize the few available carbonate and phosphate MRM, we have analyzed them using the different laser ablation systems. Overall analytical uncertainties at the 95 % confidence level are about 5 – 10% for most elements. Our fs-UV laser results agree well with available reference values.

Combined ^{13}C-D and D-D clumping in CH_4: Preliminary results

D.A. STOLPER[1]*, S.S. SHUSTA[2], D.L. VALENTINE[2], A.L. SESSIONS[1], A. FERREIRA[3], E.V. SANTOS NETO[3] AND J.M. EILER[1]

[1]Caltech, Pasadena, CA, USA (*dstolper@caltech.edu, eiler@gps.caltech.edu, als@gps.caltech.edu)
[2]University of California, Santa Barbara, CA, USA (sshusta@umail.ucsb.edu, valentine@geol.ucsb.edu)
[3]Petrobras, Brazil (alexandreaf@petrobras.com.br, eugenioneto@petrobras.com.br)

Methane is a key component of natural gas reservoirs, biogeochemical cycles and greenhouse gas emissions. Its cycle is often studied with stable isotopes (e.g., δD and $\delta^{13}C$), which help to distinguish between various environmental sources (e.g., thermogenic vs biogenic) and sinks [1]. However, as many of these processes generate methane with similar isotopic compositions, new measurements can aid in understanding various aspects of the methane cycle.

We present a new mass spectrometric technique that allows for the measurement of isotopologues of methane with more than one rare isotope ('clumped' isotopologues) at natural abundances. Specifically, we simultaneously measure $^{13}CH_3D$ and $^{12}CH_2D_2$ without interferences from water [2] and with external errors of 0.25-0.3‰ (in the Δ_{18} notation [3]).

Clumped isotopologues can serve as geothermometers for equilibrated systems, quantify kinetic processes and fingerprint different sources and sinks. To better understand the information recorded by the clumped isotopes of methane, we experimentally generated a high-temperature (200-500°C) calibration of equilibrium clumping, including approaches to equilibrium from multiple starting points. Application of this calibration to thermogenic methane samples from natural gas fields generally yields high temperatures (~190 ± 65 °C), which span the range of nominal natural gas formation temperatures, though with one high temperature outlier. The same calibration applied to biogenic gases gives lower temperatures (~45-60°C) that are consistent with their inferred or known formation temperature.

Preliminary results indicate that the temperatures derived from combined $^{13}CH_3D$ and $^{12}CH_2D_2$ clumping are, in most cases, reasonable formation or storage temperatures. This suggests that methane may achieve internal isotopic equilibrium in both high and low temperature processes and retain that signature during storage. If so, then measurements of methane clumped isotopes will serve as a straightforward way to distinguish sources of methane in nature and give insight into the physics and chemistry of how methane forms.

The petrochemistry of Jake_M: A martian mugearite

E.M. STOLPER[1]*, M.B. BAKER[1], A. COUSIN[2,3], M. FISK[4], R. GELLERT[5], P.L. KING[6], S. MAURICE[3], S.M. MCLENNAN[7], M.E. MINITTI[8], M. NEWCOMBE[1], V. SAUTTER[9], M.E. SCHMIDT[10], A.H. TREIMAN[11], R.C. WIENS[2] AND THE MSL SCIENCE TEAM

[1]Caltech, Pasadena, CA 91125, *correspondence: ems@caltech.edu; [2]LANL, Los Alamos: [3]Institut de Recherches Astrophys. Planétol., Toulouse, France; [4]Oregon State Univ.; [5]Univ. Guelph; [6]Res. School Earth Sci., ANU; [7]SUNY, Stony Brook; [8]APL, Johns Hopkins Univ.; [9]LMCM, Paris, France;[10]Brock Univ.; [11]Lunar & Planet. Inst.

Jake_M (JM), the first rock analyzed by the APXS instrument on the Curiosity rover, is an alkaline igneous rock (~13% normative nepheline). It differs significantly in composition from other known martian rocks and it is fractionated relative to typical martian igneous rocks (MgO ~3.5 wt%; Mg# ~0.37; Ni < 50 ppm; normative oligoclase and orthoclase [~13%]). JM is compositionally similar to terrestrial mugearites, a magma type typically found on ocean islands and in continental rift zones; indeed, were JM found on earth, we would be hard pressed to tell from its composition that it is a martian rock.

The discovery of this rock type on Mars likely indicates an origin by significant fractional crystallization of a primary alkaline or transitional magma generated by melting a region of the martian mantle compositionally distinct from the sources of other known martian basalts. JM's chemical composition (especially its high Al_2O_3 and low FeO contents) suggest that this fractional crystallization occurred under conditions that suppressed plagioclase crystallization relative to crystallization at 1 atm. Although non-unique, MELTS calculations indicate that a reasonable match to JM's composition can be achieved at 2 kbar (~15 km depth on Mars) after ~50% fractional crystallization of an estimated parental composition from St. Helena island containing 1.5 wt% H_2O. This result suggests a possible role for elevated pressure and/or water content in JM's petrogenesis.

The discovery of JM has implications for magmatic and eruptive processes on Mars, for the possibility of primary hydrous minerals in martian igneous rocks and for encountering even more fractionated alkaline magmas such as phonolites and trachytes. JM is also distinctly richer in potassium than other martian basalts, consistent with a metasomatized mantle source, perhaps characteristic of the mantle beneath the Gale Crater region.

A novel approach for determining the rate of organic carbon remineralization in bioturbated marine sediments at the global scale

K. STOLPOVSKY[1]*, A. W. DALE[1] AND K. WALLMANN [1]

[1]Helmholtz-Zentrum für Ozeanforschung Kiel (GEOMAR), Wischhofstr. 1-3,24148 Kiel, Germany,
* kstolpovsky@geomar.de

The spatial variability in benthic particulate organic carbon (POC) mineralization kinetics throughout the ocean is currently unknown. This creates considerable uncertainties when diagenetic models are used to couple benthic and pelagic biogeochemical cycles in global models. The aim of this study is to derive a predictive algorithm to calculate the depth-dependent rate of POC degradation in bioturbated surface marine sediments.

Our approach first uses measured fluxes of oxygen and nitrate across the sediment-water interface to calculate the total depth-integrated rate of POC degradation [1]. Next, a diagenetic reaction-transport model is used to simulate these fluxes to within a defined tolerance range by optimizing the parameters of a depth-dependent POC decay function. The model describes POC mineralization using oxygen, nitrite and nitrate as electron acceptors and also their transport into and out of the sediments by molecular diffusion, sediment burial and bioirrigation.

We applied this approach to published data from 151 stations around the globe to simulate the fluxes of oxygen and nitrate in the uppermost 50 cm of the sediment including the bioturbated layer. Where published data were available, the modelled and measured oxygen and nitrate concentration profiles were compared. Ongoing work attempts to search for spatial trends in the parameters of the optimized POC degradation model and relate these trends to master variables such as the rain rate of POC to the seafloor (RRPOC). Our over-arching goal is to use these results to better predict the benthic exchange fluxes between marine sediments and the overlying water column in global models. This is especially for the main ocean basins where field data is currently limited.

Soil organic matter and microbial activity in critical zones of tropical soils from Luquillo, Puerto Rico

M.M. STONE[1] AND A.F. PLANTE[1]*

[1]Department of Earth & Environmental Science, University of Pennsylvania, Philadelphia, PA 19104-6316, USA (*correspondance: aplante@sas.upenn.edu)

The Luquillo Critical Zone Observatory (LCZO) is located in northeastern Puerto Rico in the El Yunque National Forest (18.33 °N, 65.73 °W) and seeks to understand the evolution of landscapes over time due to varying critizal zone processes occuring in areas with similar climates, land use and geologic history. The critical zone is generally defined as the zone "where rock meets life" [1]. From this perspective, it is interesting to examine how microbial activity declines with depth into the critical zone as energy and substrate supplies decline and how this decline might be affected by various landscape properties.

The LCZO Soil Network consists of 216 quantitative soil pits, stratified across two parent materials (volcaniclastic and granodiorite), three forest types (Tabonuco, Palm and Colorado) and three hillslope positions (ridgetops, slopes, valleys). The current study used a subset of soils sampled to a depth of 140 cm and analyzed for organic C, total N and extractable organic P concentrations. Soil microbial biomass was determined using phospholipid fatty acid (PLFA) total lipid analysis [2] and enzyme activities were assayed according to German *et al*. [3].

All enzyme activities declined exponentially with depth, tracking exponential declines in total organic and microbial carbon. However, these trends differed when normalized by substrate or microbial C (i.e., specific activity). Soil parent material did not significantly affect microbial biomass or enzyme activity, though there were several significant depth × forest type interactions. Taken together, the results indicate that soil depth (as a surrogate for substrate availability) is the main driver of microbial activity in the critical zone of these tropical soils, rather than differences in landscape-scale variables.

Eliminate the organic nitrogen fraction to perform $\delta^{15}N_{tot}$-$\delta^{15}N_{bnd}$ analyses in bulk rocks: Application for Iguanodon-bearing Wealden facies of Bernissart (Belgium)

J.-Y. STORME[1], P. IACUMIN[2], G. ROCHEZ[1] AND J. YANS[1]*

[1]University of Namur, Department of Geology, 61 rue de Bruxelles, 5000 Namur, Belgium. (*correspondence: johan.yans@fundp.ac.be, jean-yves.storme@fundp.ac.be, gaetan.rochez@fundp.ac.be)

[2]Earth Sciences, Parma University, Viale G.P. Usberti 157/A, 43100 Parma, Italy (paola.iacumin@unipr.it)

$\delta^{15}N_{org}$ on bulk could be a useful proxy for reconstructing paleoclimatic and paleohydrologic conditions of the pre-Quaternary Past [1]. Total nitrogen (N_{tot}) and inorganic nitrogen bound (N_{bnd}) concentrations are automatically determined for each sample, to provide nitrogen isotopes on organics ($\delta^{15}N_{org}$) using of a mass balance equation. The inorganic nitrogen bound is deciphered by treating decalcified subsample with KOBr–KOH solution to eliminate the organic nitrogen fraction [2,3,4]. Here we experienced this procedure on samples from a borehole cutting the lacustrine succession of the Iguanodon-bearing Wealden facies of Bernissart, middle Barremian to earliest Aptian in age [5,6,7]. $\delta^{15}N_{org}$ data show positive trend upwards whereas $\delta^{13}C_{org}$ show negative trend, suggesting variations in paleoclimatic and paleohydrologic conditions. However samples with relatively high TOC contents, after boiling with KOH-KOBr solution by ~5 minutes, show chaotic $\delta^{15}N_{org}$ values, maybe due to uncomplete extraction of organic nitrogen. Similar analyses are required to understand the extraction of organic nitrogen during preparations. Many tests have to be performed such as: use of HCl or other acid, analysis of the type of organic matter in the sediments, limits of TOC contents, KOH-KOBr treatment before or after HCl treatment, etc. Matching this with other proxies in other successions will improve our knowledge of $\delta^{15}N_{org}$ variations in geological Pre-Quaternary successions.

[4]Geology, Univ. of Vermont, Burlington, VT, USA

Exhumed magmatic arcs are critical for understanding subduction processes and the growth and deformation of continents. The duration and rates of tectonic shortening and the transition from over-thickened arc crust to thinned crust and ocean floor spreading are poorly understood. This transition may be related to buoyancy changes and delamination of dense lower crust. The Cretaceous rocks of New Zealand's Median Batholith provide a natural laboratory for understanding these processes because the rocks show evidence for eclogite facies metamorphism, magmatism and granulite-facies metamorphism with local loading during metamorphism. Garnet Sm-Nd ages indicate pulses of metamorphism that closely follow magmatic pulses in the Western Fiordland Orthogneiss suite (WFO). Eclogite facies rocks (Breaksea Orthogneiss) SW of the extensional Resolution Island shear zone (RISZ) juxtaposed these ca. 1.8 Gpa rocks against one (Malaspina Pluton) of three large granulite-facies WFO plutons. Rocks on both sides of the RISZ experienced granulite facies conditions, but those on the NE were metamorphosed at a lower P of 1.2 – 1.4 Gpa. Garnet Sm-Nd ages for peritectic garnet indicate that Malaspina rocks in the hanging wall of the RISZ underwent 116-112 Ma granulite-facies metamorphism shortly after pluton emplacement. Preliminary garnet Sm-Nd ages for eclogite-facies metamorphism SW of the RISZ indicate initial high P at ca. 123 Ma, then high T granulite facies metamorphism that lasted until ca. 108 Ma, following initial extension and collapse of the magmatic arc. Granulite facies metamorphism in the Malaspina and Breaksea postdates similar metamorphism in N Fiordland (Pembroke Granulite) by 10 Ma. Compilation of igneous and metamorphic ages along the lower crust exposed in Fiordland indicates temporal pulses of high-temperature metamorphism which may have progressed from north to south over ca. 15 Ma. preceding extension and continuing during initial extensional collapse of the over-thickened arc crust.

Insights in the methanogenic degradation of BTEX and PAH in different geological systems

N. STRAATEN[1]*, N. JIMENEZ-GARCIA[2], F. GRÜNDGER[1], H. H. RICHNOW[2], T. LÜDERS[3] AND M. KRÜGER[1]

[1]BGR, Stilleweg 2, 30655 Hannover, Germany (*Correspondence: Nontje.Straaten@bgr.de)

[3]GSF, Ingolstädter Landstr. 1, D-85764 Neuherberg, Germany

Biodegraded oil is found in many reservoirs worldwide. The more complex hydrocarbons belonging to the PAH and BTEX groups are harder to degrade by prokaryotes than e.g. alkanes. To understand the degradation processes of these hydrocarbons into simpler components, it is very important to get insight in the microbial communities and metabolic processes involved.

The lack of alternative electron acceptors in many habitats limits the possible anaerobic degradation pathways to methanogenesis, which has been shown to be the most important process in different hydrocarbon reservoirs. The composition of the microbial communities in enrichments from habitats with differing geochemical settings, e.g. shallow and deep subsurface terrestrial and marine systems showed a relatively similar composition, independent of the sampling site. Especially methanogenic Archaea, members of the *Syntrophaceae* and sulfate-reducing Prokaryotes contributed to the community in most enrichments. Moreover, in samples from a Chinese oilfield, the crucial process, the conversion of alcanoic, aromatic and polyarmoatic hydrocarbons to methane, was proven in incubations via 13C-labeling [1]. The further molecular biological analysis of this habitat confirmed the presence of methanogenic Archaea as well as of different Bacteria capable of hydrocarbon degradation. In the ongoing work 13C-labeled substrates combined with SIP of proteins and DNA is used to identify the actively involved microorganisms. Preliminary analyses revealed labeled proteins belonging to methanogens, SRB and *Syntrophus* species thus confirming the 16S results. In addition the results from these enrichments are compared with data from environmental samples of gas, shale and oil reservoirs, to determine the *in situ* importance of the enriched hydrocarbon degraders.

Observed large- and meso-scale oxygen changes in the ocean

L. STRAMMA[1]*, R.A. WELLER[2], R. CZESCHEL[1], S. BIGORRE[2], S. SCHMIDTKO[3] AND A. OSCHLIES[1]

[1]GEOMAR Helmholtz Centre for Ocean Research Kiel, 24105 Kiel, Germany (*correspondance: lstramma@geomar.de)

[3]School of Environmental Sciences, University of East Anglia, Norwich, NR4 7TJ, UK

Model results predict a decline in ocean oxygen and observations confirmed declines at different locations [1]. Within the research initiative 'Climate – Biogeochemistry Interactions in the tropical Ocean' the temporal-spatial scales of oxygen changes were investigated. Large scale oxygen changes for the world ocean were derived at 300 dbar for the last 50 years and in the South Atlantic Ocean even for a 70 year period [2]. Declining upper-ocean oxygen levels in many regions, especially in the tropical oceans, are dominant, whereas areas with increasing trends are found in subtropical and in a few polar regions. A comparison to a numerical biogeochemical Earth system model reveals that the magnitude of the observed change is consistent with CO_2-induced climate change, however there is a large mismatch between observed and modeled oxygen trends.

In the equatorial Pacific the zonal current bands are important in resupplying oxygen to the oxygen minimum zone in the eastern Pacific. In the Pacific strong oxygen changes are related to the Pacific Decadal Oscillation while oscillations on shorter time scales like an El Nino signal in the upper 350 m are superimposed upon this signal [3].

Meso-scale related oxygen changes are expected to be important on the poleward side of the tropical oxygen minimum zones. Recent measurements of the oxygen distribution of eddies near the Peruvian shelf as well as mooring observations at the Stratus mooring at ~20°S, 85°W show a large expanded low oxygen layer in anticyclonic eddies while in cyclonic eddies the low oxygen layer decreased.

The derived results indicate the importance of a large range of temporal-spatial scales which needs to be investigated further.

Photochemistry of arsenite and chromate on iron oxyhydroxide

NARAYAN BHANDARI[1], ELIZABETH CERKEZ[1], RICHARD J. REEDER[2] AND DANIEL R. STRONGIN[1,*]

[1]Department of Chemistry, Temple University, Philadelphia, PA 19122, USA (dstrongi@temple.edu)
[2]Department of Geosciences, Stony Brook University, Stony Brook, NY 11794, USA

The (photo)chemistry of arsenite [As(III)] and chromate [Cr(VI)] in the presence of ferrihydrite and goethite was investigated. A variety of techniques, including infrared spectroscopy, X-ray absorption near edge structure (XANES) and solution phase analysis were used to characterize the surface bound and aqueous phase species. The exposure of the iron oxyhydroxides to As(III) in the dark resulted in a adsorbed layer of As(III). Irradiation of the As(III)/ferrihydrite or As(III)/goethite system to simulated solar radiation resulted in the conversion of As(III) to adsorbed and aqueous phase As(V). The relative amounts of adsorbed and aqueous phase As(V) product varied whether ferrihydrite or goethite was present in solution due to differences in the rate of the heterogeneous oxidation of surface Fe(II) on the surfaces by dissolved oxygen. This particular reaction resulted in the formation of reactive oxygen species. Redox reactions of mixtures of As(III) and Cr(VI) in the presence of the two iron oxyhydroxides also were investigated. In this circumstance even in the absence of light, As(III) was oxidized to As(V) (~ 92% conversion) and Cr(VI) was reduced to Cr(III) if one of the small band gap semiconductor iron oxyhydroxide materials was present. As a comparison nanophase aluminum oxyhydroxide (an insulator) was exposed to As(III) and Cr(VI) under dark conditions. Under these experimental conditions far less As(III) oxidation and Cr(VI) reduction occurred (~ 50% conversion of As(III) to As(V)) compared to when iron oxyhydroxide was present. Furthermore, the exposure of the As(III)/Cr(VI)/ferrihydrite system to simulated solar light led to additional As(III) oxidation and Cr(VI) reduction (compared to dark conditions) while light had no effect on the As(III)/Cr(VI)/aluminum oxyhydroxide system. In general the results suggested that the semiconducting materials were able to drive the redox chemistry more efficiently due to facile surface mediated electron transfer from As(III) to Cr(VI).

Water mass mixing in the Drake Passage during the last 40 kyrs

T. STRUVE[1]*, T. VAN DE FLIERDT[1], L. F. ROBINSON[2], A. BURKE[3], K. C. CROCKET[4], M. LAMBELET[1] AND M.E. AURO[5].

The modern Southern Ocean is a key area for the global ocean circulation as wind-driven mixing, upwelling and redistribution of water masses in the Antarctic Circumpolar Current (ACC) all have a significant impact on the properties and flowpatterns of global water masses. It has been suggested that the Southern Ocean plays a central role in oceanographic and climatic changes observed on glacial-interglacial timescales, in particular with respect to carbon sequestration between the deep ocean and the atmosphere.

For the purpose of unravelling Southern Ocean water mass mixing over the past ~40,000 years, the aragonitic skeletons of solitary deep-sea corals collected from two cruises on the Nathaniel B. Palmer to the Drake Passage are used as archives for seawater Nd isotopes. These corals were collected from water depths between 300 and 1750 m and have previously been directly dated by U-Th and analysed for their radiocarbon content.[1]

Neodymium was extracted from the wash solution of the U-series anion-exchange chemistry using a two-stage ion chromatography (RE-spec and Ln-spec resins). Subsequent analyses of Nd were performed as NdO^+ on a Triton TIMS using a TaF_5 activator on W filaments. This method yields within run uncertainties around 10 ppm (2σ SE) and external uncertainties around 20 ppm (2 σ SD) for sample loads as small as a few ng of Nd.

Preliminary Nd isotope results on *D. dianthus, F. curvatum and B. malouinensis* specimen growing during the last 40 kyrs show significant variability at intermediate water depths (εNd of ~-5 to -8) and a more stable Nd isotopic composition in the lower water column (>1000m; εNd ~-8).

We will interpret our unique data set in the context of published glacial-interglacial radiocarbon results and inferred Southern Ocean water mass variability and ventilation rates.

Emerging understanding of anthropogenic interferences in the ecosystem silica filter

ERIC STRUYF[1]* AND DANIEL J. CONLEY[2]

[1] University of Antwerp, Department of Biology, Universiteitsplein 1C, 2610 Wilrijk, Belgium, eric.struyf@ua.ac.be

[2] Lund University, Dept. Geology, Sölvegatan 12, 22362 Lund, Sweden

The annual fixation of DSi into terrestrial vegetation is 60 to 200 Tmole, 10–40 times more than the yearly export of DSi from the terrestrial geobiosphere to the coastal zone and 3-6 times more than annual weathering of silicates. Ecosystems form a large filter between mobilization of DSi by silicate weathering and mobilization to rivers. A large reservoir of biogenic amorphous Si (mostly plant phytoliths) and pedogenically reworked amorphous Si (ASi) accumulates in soils. ASi is substantially more soluble than mineral Si. Still, ASi persistence and reactivity in soils, the dependence of the ASi turnover on ecological processes and ultimately the global relevance in Si budgets are poorly constrained [1]. A major challenge is presented by the difficulty to separate pedogenic and biogenic amorphous Si phases in the soil. This hampers quantification of the silicate weathering-related C-sink and accurate modelling of transport of Si to rivers and estuaries, where Si plays a crucial in phytoplankton productivity.

Human land management can cause abrupt shifts to the biogeochemical cycle in terrestrial ecosystems and their ability to sequester Si. Our results from a novel technique that allows for separation of biogenic and pedogenic ASi phases, shows that turnover rates of ASi in temperate cultivated soils are strongly reduced compared to forests and stocks of pedogenic ASi are depleted. Newly acquired analysis of Si isotopes in soil water also show this. This results in timescale dependent, 2-4 fold shifts in terrestrial Si mobilisation [2]. Human harvest of crop ASi has created a parallel anthropogenic Si cycle, which has received virtually no quantification so far [3]. Our observations show that intense domestic reindeer and cattle grazing alters physical and chemical reactivity of biogenic ASi (Si is a defense mechanism against herbivory) and can causes abrupt shifts in ecosystem ASi storage and cycling. The combination of experimental, field and modelling studies shows that land use has strongly altered mineral-soil-plant interactions.

[3] Faculty of Humanities and Social Sciences, Latrobe University, Melbourne, 3086, Australia (colin.smith@latrobe.edu.au)

South-east Australian seamounts and their associated deep-sea ecosystems, are located in an oceanographically complex and climatically sensitive region. Across this region, Bamboo Corals inhabit a tremendous depth range (600-4000m) archiving surface processes by incorporating raining particulates into their banded skeletons. Bulk organic ^{15}N has previously been used to substantiate the region's shifting surface regimes in response to current climate change, but trophic enrichment was necessarily approximated, obscuring the ^{15}N-signal of the producers at the base of the foodweb [1].

In this study, we revisit the ^{15}N archive, instead using invididual amino acids (AA) to reconstruct ecosystem dynamics. We are able to capture and decouple, a centenary of trophic interactions from the ^{15}N-signal of primary production. Furthermore, as specimens were collected between 1000-3000m, we are able to explore deep-sea particle transformations and microbial heterotrophy that connects surface and deepwater ecosystems. By exploiting previously validated ^{15}N-AA patterns [2] and considering those in the ^{13}C-AA record, we propose likely mechanisms that could support the inexplicably high biomass that has been reported within the local bathyl zone [3].

Our preliminary results indicate that clear distinctions seen between depths in the bulk record naturally reflect the isotopic signature of the most abundant AA, glycine, as well as trophic complexity. Furthermore we find evidence of differing particulate processing histories, provenance and species effects that all have important implications for the future interpretation of records from deep-sea coral organics.

Constraints on the source of mantle plumes from the first picrites erupted Ethiopian flood basalt province

F. M. STUART[1]* AND N. ROGERS[2]

[1]Isotope Geosciences, SUERC, East Kilbride G75 0QF, UK (*fin.stuart@glasgow.ac.uk)
[2]Department of Earth & Environmental Sciences, Open University, Milton Keynes MK7 6AA, UK

The earliest basalts erupted by largest mantle plumes are typically 200-300°C hotter than those derived from convecting upper mantle at mid-ocean ridges. They originate from a thermal boundary layer deep in Earth that is assumed to be the core-mantle boundary. Consequently the first plume-derived basalts provide constraints on Earth structure and differentiation history. The first picrites erupted by the Iceland plume have a high proportion of primordial He (^{3}He/^{4}He ~ 50 R_a) yet a range in radiogenic isotope and incompatible trace element ratios that overlap the global mid-ocean ridge basalt range [1]. This is difficult to reconcile with pristine mantle dominating the plume head. The simplest interpretation is that the convecting mantle has been polluted by primordial He either at the core-mantle boundary or during ascent, thus still requires the existence of primordial volatile-rich reservoir.

In an attempt to provide better constraints on the deep mantle source of plumes we have analysed the He-Sr-Nd-Pb isotopic composition of the earliest high-Ti picrites (HT2) from the Dilb section of the ~30 Ma Ethiopian flood basalt province. The basalts are characterized by high Fe and Ti contents for MgO = 14-15% that implies the parent magma was derived from a high temperature small melt fraction, likely the plume head. The basalts are characterized by a narrow range of ^{87}Sr/^{86}Sr (0.70396–0.70412) and ^{206}Pb/^{204}Pb (18.82-19.01). ^{3}He/^{4}He of olivine never exceeds 21 R_a. The Afar plume was sourced in a discrete mantle reservoir that is less degassed and more enriched than the convecting upper mantle. The source region is significantly more degassed than the mantle sampled by the proto-Iceland plume and more homogenous. Clearly the largest mantle plumes are not initiated in a single deep mantle domain with the same depletion/enrichment history and they do not mix with convecting mantle to the same extent.

Oxidative corrosion of uraninite (UO_2) surfaces

JOANNE E. STUBBS[1]*, PETER J.ENG[1], CRAIG A. BIWER[2], ANNE M. CHAKA[3], GLENN A. WAYCHUNAS[4] AND JOHN R. BARGAR[5]

[1]Center for Advanced Radiation Sources, University of Chicago, Chicago, IL, USA, stubbs@cars.uchicago.edu (* presenting author)

[3] Physical Measurement Laboratory, National Institute of Standards and Technology, Gaithersburg, MD, USA
[4] Lawrence Berkeley National Laboratory, Berkeley, CA, USA
[5] Stanford Synchrotron Radiation Lightsource, Menlo Park, CA, USA

Uraninite (UO_2) is the most abundant uranium ore mineral, the product of proposed bioremediation strategies for uranium-contaminated soils and aquifers and its synthetic analog is the primary constituent of most nuclear fuels. It incorporates interstitial oxygen up to a stoichiometry of $UO_{2.25}$ without disruption of the uranium lattice, but the structural details of the process are the subject of ongoing study and debate. Because the solubility and dissolution kinetics of uraninite depend heavily on the oxidation state of uranium, understanding the mechanims of UO_2 surface oxidation and corrosion is essential to predicting its stability in the environment throughout the nuclear fuel cycle. To date, however, no study has addressed this process at the molecular scale at atmospheric pressure and room temperature.

We present crystal truncation rod (CTR) x-ray diffraction studies of pristine and oxidized UO_2 (111) and (100) surfaces. The clean (111) surface shows minimal contraction of the uppermost atomic layers and a layer of oxygen or hydroxyl group adatoms above the vacuum-terminated surface. Upon exposure to oxygen, an oxidation front proceeds into the crystal, intersitial oxygen atoms penetrate to depths of 30 Å or more, surface-normal layer distances contract (consistent with bulk uraninite oxidation) and an ordered superlattice forms, commensurate with the underlying bulk. Similar oxygen surface penetration and layer contraction are observed upon oxidation of the (100) surface. These results demonstrate that the solid state diffusion of oxygen into UO_2 and UO_{2+x} surfaces is facile and that ordering kinetics are relatively rapid, even at room temperature.

Ab initio thermodynamics, which combines density-functional theory calculations with macroscopic thermodynamics, provides insight into the energetics, bonding and oxidation processes that occur as oxygen reacts with the surfaces and diffuses into the solid. Subsurface oxidation is predicted to contract surface-normal layers, consistent with experimental observations.

Extraction of paleo seawater Nd isotope compositions: A case study from the Indonesian Throughflow

ROLAND STUMPF[1,2]*, MARTIN FRANK[2], BRIAN A. HALEY[2,3], STEFFANIE KRAFT[2] AND WOLFGANG KUHNT[4]

[1]Imperial College London, Dept. of Earth Science & Engineering, London SW7 2AZ, UK (*presenting author)

[3]Oregon State University, College of Oceanic & Atmospheric Sciences (COAS), USA

[4]Christian-Albrechts-Universität Kiel, Institute of Geosciences, Germany

Over the past decade, radiogenic Nd isotope compositions have increasingly been used as a paleo seawater proxy for the reconstruction of past ocean currents and water mass mixing. For this purpose, the Nd isotopes have been extracted from various marine archives, such as ferromanganese crusts and nodules, Fe-Mn oxyhydroxide coatings on detrital sediment surfaces, as well as in foraminiferal shells, cold water corals and fish teeth. However, it is still under debate if all these archives reliably preserve unaltered paleo seawater Nd isotope compositions.

In this study, the Nd isotope compositions of reductively cleaned foraminiferal shells (bulk planktonic & monospecific), of Fe-Mn oxyhydroxide coatings leached from the de-carbonated detrital fraction of the sediment, as well as Nd isotope compositions leached directly from the bulk sediment were extracted from carbonate-rich sediment core MD01-2378 (1783 m water depth) located in the outflow region of the Indonesian Throughflow (ITF) in the eastern Timor Sea. We focus on the comparison of the Nd isotope records from these three archives covering the time period of marine isotope stage 3 (~23 – 64 ka B.P.) in order to reconstruct variations of intensity and the relative contributions from different outflow pathways of the ITF.

A comparison of core top Nd isotope compositions extracted from planktonic foraminiferal shells shows good agreement with water column Nd isotope data [1]. Data from a core top sample at a location close to core MD01-2378 showed that there is no significant difference in Nd isotope composition between monospecific (εNd = -4.3) and bulk (εNd = -4.4) planktonic foraminiferal samples.

The Nd isotope variability observed in the downcore planktonic foraminiferal records of core MD01-2378 ranged from εNd = -3.5 to -5.5 with minimum values occurring during the Last Glacial Maximum and either documents variations between different ITF outflow pathways or variable surface water contributions from Northern Australia or even from the Southern Ocean. These data are compared with bottom water Nd isotope variations newly obtained from oxyhydroxide coatings of the same sediment core.

[5]Université de Corse Pascal Paoli, Laboratoire d'Hydrogéologie UMR 6134 SPE, Campus Grimaldi, BP 52, F-20250 Corte, France

Mercury concentrations and main carrier phases were determined in sediments of a 120 cm core from Laguna del Plata (LP). This lake is a part of the Laguna Mar Chiquita (LMC) system as it is connected to LMC itself during water highstands. LMC is one of the largest saline lakes in the world representing a sensitive climatic indicator due to its frequent lake level variations at millennial and interdecadal scales [1], with the most recent major variations during the early 1970s and after 2004. Total mercury (Hg_{TP}) concentrations analyzed by Atomic Absorption spectrometry after sample calciantion in an O_2 stream (DMA 80) varied between ~13 and ~131 $\mu g\ kg^{-1}$ and reflected changes.in water and sediment supply to the LP. Selective extractions performed on the sediments using ascorbate, HCl and H_2O_2 revealed that in the base of the core corresponding to a low water level period, Hg is mainly associated to reactive sulfides. In contrast, in the middle and upper part of the core Hg is rather associated with sedimentary organic matter and was interpreted as reflecting Hg deposition at the watershed scale. Core dating, performed with ^{210}Pb and ^{137}Cs, allowed to determine that the highest Hg peak corresponds to the years 1990-1995. This was attributed to the eruption of Lascar volcano in 1993 in the Central Andes of northern Chile rather than anthropogenic pollution sources.
