Recent investigations on diverse mineral systems suggest formation begins with pre-nucleation clusters and proceeds by particle-mediated growth processes involving amorphous or disordered precursors, with the primary nanoparticles often found to be co-aligned in the final crystal. Little is known, however, about the energetics of pre-nucleation clusters, the role of mineral interfaces in altering formation pathways, or the mechanism by which co-alignment of primary particles occurs. Here we analyze the impact of pre-nucleation clusters on predictions of classical nucleation theory (CNT) and report results of novel *in situ* TEM, AFM and optical investigations of both the early stages of $CaCO_3$ and Ca-phosphate nucleation and post-nucleation oriented aggregation of ferrihydrite nanoparticles.

Our analyses show the classical barrier to homogeneous calcite nucleation is prohibitive even at concentrations approaching the ACC solubility limit [1]. Introducing a population of metastable clusters can dramatically reduce the barrier, but clusters stable with respect to the free ions will increase it. To explore the impact of surfaces on barriers, we examined calcite nucleation on alkane thiol SAMs and found it to be described well by CNT through a reduction in the barrier due to decreased interfacial free energy, which we found scales linearly with SAM-crystal binding free energies, as expected classically. In contrast, AFM data in the Ca-phosphate system [2] shows the amorphous precursor phase forms at supersaturations too low to be sensible within CNT.

To follow intitial growth after nucleation, we investigated the interactions between ferrihydrite nanoparticles using high-resolution fluid cell TEM [3]. The particles undergo continuous rotation and interaction until they find a perfect lattice match. A sudden "jump to contact" then occurs over < 1nm, followed by lateral ion-by-ion addition at the contact point. We show that direction-specific interactions drive oriented attachment and likely result from electrostatic forces.

The composition of the new continental crust through time

BRUNO DHUIME[1,2], CHRIS HAWKESWORTH[1] AND PETER CAWOOD[1]

[1] University of St Andrews, Department of Earth & Environmental Sciences, UK (b.dhuime@bristol.ac.uk)
[2] University of Bristol, Department of Earth Sciences, UK

Recent models on continental growth suggest that ca. 65% of the present volume of the continental crust was present by 3 Ga, and that the rates of continental growth were significantly higher before 3 Ga than subsequently. This change has been tentatively linked to the onset of subduction-driven plate tectonics and discrete subduction zones. If correct this represents a fundamental change in the evolution of the Earth, with implications for the nature of the magmas generated, the efficiency with which crustal material is returned back into the mantle and the cooling history of the Earth.

Because of the poor preservation of rocks and minerals after billions of years of crustal evolution, a major uncertainty remains about the composition of new, juvenile continental crust in the Hadean and the Archaean and hence the conditions and the tectonic setting(s) in which it was generated. One way forward is to evaluate the composition of new continental crust from the time-integrated parent/daughter ratios of isotope systems in magmatic rocks subsequently derived from that new crust.

Crustal differentiation processes produce a large range of highly fractionated Rb/Sr ratios because of the highly incompatible character of the Rb-Sr system. As a consequence mafic crust typically has Rb/Sr at least five times lower than intermediate/felsic bulk crust. We calculated time-integrated Rb/Sr in crustal material with pre- and post-3 Ga Nd model ages. Preliminary data indicate that time-integrated Rb/Sr were, on average, much lower in the Hadean/Mesoarchaean than subsequently. This suggests that new continental crust was principally mafic over the first 1.5 Ga of Earth evolution, that a large volume of pre-3 Ga crust may have been associated with intraplate magmatism, and that ~3 Ga may indeed mark the onset of plate tectonics on Earth.

Simulation of water–rock interaction and porosity evolution in a granitoid-hosted enhanced geothermal system

L.W. DIAMOND AND P. ALT-EPPING

Rock–Water Interaction, Institute of Geological Sciences, University of Bern, Switzerland (*correspondence: diamond@geo.unibe.ch)

Numerical simulations based on plans for a deep geothermal system in Basel, Switzerland are used here to understand chemical processes that occur in an initially dry granitoid reservoir during hydraulic stimulation and long-term water circulation to extract heat. A question regarding the sustainability of such enhanced geothermal systems (EGS) is whether water–rock reactions will eventually lead to clogging of flow paths in the reservoir. A reactive transport model allows the main chemical reactions to be predicted and the resulting evolution of porosity to be tracked over the expected 30-year operational lifetime of the system.

The simulations show that injection of surface water to stimulate fracture permeability in the monzogranite reservoir at 190 °C and 5000 m depth induces strong redox reactions. Although new calcite, chlorite, hematite and other minerals precipitate near the injection well, their volumes are low and more than compensated by those of the dissolving wall-rock minerals. Thus, during stimulation, reduction of injectivity by mineral precipitation is unlikely.

During the simulated long-term operation of the system, the main reactions are the hydration and albitization of plagioclase, the alteration of hornblende to an assemblage of smectites and chlorites and of primary K-feldspar to muscovite and microcline. Within a closed-system doublet, the composition of the circulated fluid changes only slightly during its repeated passage through the reservoir, as the wall rock essentially undergoes isochemical recrystallization. Even after 30 years of circulation, the calculations show that porosity is reduced by only ~0.2%, well below the expected fracture porosity induced by stimulation. This result suggests that permeability reduction owing to water–rock interaction is unlikely to jeopardize the long-term operation of deep, granitoid-hosted EGS systems.

A peculiarity at Basel is the presence of anhydrite as fracture coatings at ~5000 m depth. Simulated exposure of the circulating fluid to anhydrite induces a stronger redox disequilibrium in the reservoir, driving dissolution of ferrous minerals and precipitation of ferric smectites, hematite and pyrite. However, even in this scenario the porosity reduction is at most 0.5%, a value which is unproblematic for sustainable fluid circulation through the reservoir.

Sulfurization of humic acids during early diagenesis in surface sediments of a tropical upwelling system

RUT DIAZ[1*], URSULA MENDOZA[1], MICHAEL E. BÖTTCHER[2] , MANUEL MOREIRA[1], WILSON MACHADO[1], R. CAPILLA[3]AND ANA L. ALBUQUERQUE[1]

[1]Projeto Ressurgência Team, Programa de Geoquímica Ambiental, Universidade Federal Fluminense, Outeiro São João Baptista s/n. - Niterói RJ 24020-150, Brazil (*correspondence: rutdias@geoq.uff.br)

[2]Geochemistry & Isotope Geochemistry Group, Marine Geology Section, Leibniz Institute for Baltic Sea Research Warnemünde, D-18119 Warnemünde, Germany.

[3]Petrobras–Cenpes, Cidade Universitária, Ilha do Fundão, RJ 21941-915, Brazil

The early diagenesis of sulfur and the potential impact on sulfurization of humic acids (HAs) was followed in several short sediment cores from the continental shelf under the influence of a tropical upwelling system (Cabo Frio, Brazil). Besides contents and elemental stoichiometries of organic matter (OM), HAs, and the kerogen fractions, their stable isotope composition of carbon, nitrogen and sulfur was followed and compared, for instance, with the composition of sedimentary pyrite. Based on 210Pb and 14C dating, the investigated parts of the sediments span a range up to 2 ka cal BP.

The stable carbon and nitrogen isotope compositions of OM indicate a dominant marine source with no significant contributions from anthropogenic N sources, as also found in the HA fraction. It is found, that the atomic C/N ratios of HAs increased with depth with a corresponding shift towards negative in the stable sulfur isotope ratios. The sulfur isotope ratios cover a range between -8 and +5 ‰, being significantly enriched in the lighter isotope compared to sea and pore water sulfate (about +21‰), but depleted with respect to co-existing pyrite (between -27 and -42‰). Sulfur isotope latter do not correlate with the S/C ratios, but indicate an increasing contribution of diagenetic sulfur with depth, which is estimated based on a stable sulfur isotope mass balance approach.

Anoxygenic Cyanobacterial Mats in Middle Island Sinkhole, Lake Huron: An Analogue of the Precambrian

GREGORY J. DICK[1,2,*], LAUREN KINSMAN-COSTELLO[1], NATHAN D. SHELDON[1], BOPI A. BIDDANDA[3], DANIEL N. MARCUS[1], ALEX A. VOORHIES[1], MICHAEL J. SNIDER[3], AND TIMOTHY M. GALLAGHER[1]

[1]Dept. Earth and Environmental Sciences ([*]correspondence: gdick@umich.edu), [2]Dept. of Ecology and Evolutionary Biology, University of Michigan, Ann Arbor, MI, 48109, USA, [3]Annis Water Resources Institute, Grand Valley State University, Muskegon, MI, USA

Cyanobacteria are well recognized as the innovators of oxygenic photosynthesis and as critical agents of Earth's oxygenation. Although most of the evolutionary history of cyanobacteria was characterized by low-O_2 and/or redox-stratified environments, little is known about cyanobacteria that operate under these conditions or the potential signatures that they might leave in the geologic record. The Middle Island Sinkhole (MIS) in Lake Huron (USA) provides a valuable analogue of such Precambrian cyanobacterial mat systems. Groundwater rich in sulfur and low in O_2 fosters benthic cyanobacterial mats that thrive under persistent low-O_2, sulfidic conditions. Just beneath the mats is a thin calcite-rich layer of carbonate followed by organic-rich sediments with sulfate-reducing and methanogenic communities [1].

MIS mats are capable of both oxygenic and anoxygenic photosynthesis and have genes for sulfide oxidation (sulfide quinone oxidoreductase) [2]. However, genes for the biosynthesis of hopanoids, a commonly used biomarker of cyanobacteria, are absent [2]. Metatranscriptomic data points to the prevalence of viral predation, transposases, and the production of accessory pigments for light harvesting. To further evaluate potential geologic signatures of anoxygenic cyanobacterial mat systems, we are now characterizing the stable carbon and nitrogen isotope composition of the organic fraction of mats and sediments as well as mineralogy and carbon isotope content of carbonates.

Focused Mantle Melting

H.J.B. DICK[1*] AND H. ZHOU[2]

[1]Woods Hole Oceanographic Inst., Woods Hole, MA 02543 (*correspondence: hdick@whoi.edu)
[2]Tongji University, Shanghai China (zhouhy@tongji.edu.cn)

Na8 and Fe8 represent the composition of mid-ocean ridge basalt corrected for fractional crystallization back to bulk MgO of 8 wt.% (Klein and Langmuir, JGR, 1987). Decreasing Na8 is widely accepted as reflecting increasing extents of mantle melting, while increasing Fe8 greater depths of melting due to higher mantle potential temperature. Variations in these variables over several oceanic rises are consistent with hotter deeper melting with proximity to the associated mantle hotspots. However, this interpretation of Na8-Fe8 does not fit all ocean rises. Some have thin crust over the rise (Zhou and Dick, Nature, 2013) while others have high Na8 and low Fe8 at the peak of the rise, opposite to the prediction based on KL87. Their approach assumed a constant mantle source composition, which thus presents a problem given the variability of mantle mineralogy along ocean ridges. While the rationale for decreasing sodium with extent of melting is well understood and accepted (e.g.: Dick *et al*.., 1984), this is not the case for Fe8. The explanation of KL87 was that melts from different depths would pool and excape the mantle, and thus record an average melting depth. This explanation however appears inconsistent with substantial mineralogic evidence in abyssal peridotites for shallow melt re-equilibration. Thus a thermodynamically consistent explanation for Fe8 has until now not been found.

It is widely accepted that at ocean ridge melt focusing to the ridge axis occurs in the underlying mantle. We have thus undertaken modeling of focused melting beneath ocean ridges using PMELTS (Ghiorso *et al*.., G3, 2002) to see if variations in depth of melting or mantle source composition can provide a thermodynamically consistent explanation for Fe8. This is done by successively removing solid increments while conserving melt during incremental batch equilibrium melting as an analog for the ocean ridge melting regime, This differs from modeling fractional melting, by the same technique, in that we progressively remove solid from the bulk composition rather than melt. This represents an evolving bulk composition in such a way that it explains why Fe8 increases with increasing depth and temperature of melting, but also shows that the effect of varying mantle source composition is at least as important as the effect of temperature. Thus, by varying both temperature and mantle composition we can explain increasing Fe8 with decreasing Na8 over ocean rises with both thick and thin crust.

Osmium isotope records of continental weathering and volcanism spanning the Paleocene-Eocene Thermal Maximum

ALEXANDER J. DICKSON,[1,2] ANTHONY S. COHEN,[2] ANGELA L. COE,[2] MARC DAVIES,[2] EKATERINA SHCHERBININA[3] AND YURI GAVRILOV[3]

[1]Department of Earth Sciences, University of Oxford, South Parks Road, Oxford, OX1 3AN, United Kingdom.
[2]Department of Environment, Earth and Ecosystems, Centre for Earth, Planetary and Space Science, The Open University, Walton Hall, Milton Keynes, MK7 6AA, United Kingdom.
[3]Geological Insitute, Russian Academy of Sciences, Pyzhevsky 7, Moscow 119017, Russian Federation.

The Paleocene-Eocene Thermal Maximum (PETM) was one of several brief global warming events that took place superimposed on a long-term warming trend during the early Eocene. The cause of the rapid warming has been atributed to the introduction of large amounts of carbon dioxide to the atmosphere and oceans, but the trigger for initial carbon release, and the mechanisms that sequestered it back into non-exchangeable reservoirs have been debated.

New osmium (Os) isotope records spanning the PETM are presented from four sites located in the Arctic and Tethys Oceans. All sites exhibit an increase in $^{187}Os/^{188}Os$ ratios during the PETM compared to pre- and post-event background values. The magnitude of this increase is consistent between sites and previously published records, and indicates a ~40% increase in the flux of radiogenic Os from weathered continental rocks to the oceans during the main phase of global warming.

The new Os-isotope data also contain two lines of evidence that support the role of volcanism as a trigger for the PETM. Firstly, the Arctic-Ocean record exhibits a shift to more radiogenic $^{187}Os/^{188}Os$ ratios >50,000 yrs prior to the onset of the PETM (as defined by the negative carbon isotope excursion), associated with volcanic uplift of the North Atlantic Seaway and hydrographic restriction in the Arctic Basin. Secondly, the Tethys sites exhibit a rapid excursion to very low $^{187}Os/^{188}Os$ ratios coincident with the onset of the PETM, indicating a larger flux of unradiogenic (volcanic-derived) Os to the oceans at this time. The new data suggest that volcanic activity became pronounced close to, but preceding, the start of the PETM, and therefore could have set in motion climate-system feedbacks (such as ocean circulation changes) that eventually triggered the release of large amounts of carbon at the Paleocene/Eocene boundary.

Incorporation of a Pertechnetate analog – Perrhenate – by Sodalite in Competition with other Anions

JOHNBULL DICKSON[1], JAMES HARSH[1] AND ERIC PIERCE[2]

[1]Washington State University, Pullman, WA, USA, (j.dickson@wsu.edu)
[2]Oak Ridge National Laboratory, Oak Ridge, TN, USA

Spent nuclear fuel/waste is dubbed "one of the most hazardous substances ever created by humans" and the U.S. is credited with 104 nuclear power plants that have already generated 70,000 metric tons of radioactive waste. Currently these spent nuclear fuel/wastes are being stored in swimming-pool-like tanks, and steel/concrete tanks at reactor sites in 33 U.S. States due to lack of permanent repository (C&EN, 2012). Radionuclide contamination at nuclear sites and power plants are a worldwide hazardous waste problem. Technetium-99 (^{99}Tc), a long-lived radionuclide at select DOE waste sites, presents a major concern due to its long half-life (211,000 y) and high mobility in oxidized subsurface environments. ^{99}Tc contamination has been found in the sediments beneath the Washington State Hanford Site Tank Farms after leakage of caustic, Al-rich, and high ionic strength high-level waste (HLW) solutions. Due to these releases, ^{99}Tc inventory (5.31×10^3 Ci) is predicted to leach into the ground water table at concentrations in excess of the MCL of 53 µg L^{-1}. Interestingly, nearly 50 years after the release of the contaminant into the environment, most of the ^{99}Tc persists in the deep subsurface sediment. We hypothesize that the formation of feldspathoid- type minerals within native Hanford sediment is sequestering ^{99}Tc. Previous studies demonstrated ^{90}Sr and ^{137}Cs incorporation into feldspathoid minerals, such as sodalite, that formed as a result of contact between Hanford primary silicate minerals and HLW solutions [1, 2].To elucidate the role of competing anions on TcO_4^- incorporation, we used ReO_4^- as an analog to synthesize various anionic sodalites. The pure and mixed anion-bearing sodalites were characterized by XRD, XRF, electron microprobe, and wet digestion. ReO_4^- concentrations in the resulting sodalite samples ranged from 13 mmol kg^{-1} in the mixed-anionic sodalites to 760 mmol kg^{-1} in the pure ReO_4^- sodalite. Prolonged aging appeared to increase crystallinity; however, enclathration of ReO_4^- into the sodalite framework with time was inconsistent. Using the 211 x-ray diffraction peak of sodalite, the unit cell parameter linearly increased with increasing anionic radius. These data imply that ^{99}Tc found in Hanford tank waste stream loaded with smaller competing anions (NO_3^-, NO_2^-, Cl^-, SO_4^{2-} etc.) is unlikely to be sequestered into sodalite. As sodalite group mineral can deform to host guest anions of varying ionic sizes, detailed information on the structural refinements for these various mixed anion-bearing sodalites will shed light on the tilting/deformation of sodalite framework structure. Our future work will be directed at elucidating these structural changes and conditions under which Tc incorporation might be favored.

[5]Molecular Foundry, Lawrence Berkeley National Laboratory, USA

Fe(II)-carbonates, such as siderite, form in environments where O_2 is scarce, e.g. during marine sediment diagenesis, corrosion and possibly CO_2 sequestration but little is known about its formation pathways. Precipitates from carbonate solutions containing 0.1 M Fe(II) with varying pH produced broad peaks in X-ray diffraction and contained Fe and CO_3 when probed with X-ray photoelectron spectroscopy.

In pair distribution function (PDF) analysis, peaks are limited to interatomic distances below 1.5 nm. The peaks are well defined compared to those for amorphous calcium carbonate and differ in position from those for known iron carbonates and hydroxides, indicating that a previously unidentified nanocrystalline iron carbonate had formed. Also, Mössbauer spectra differ from that expected for known iron carbonates and suggest a less symmetric structure. Replica exchange molecular dynamics simulations of Fe-carbonate clusters yield PDF peak positions that agree well with those from experiments. PDF measurements of samples aging in solution coupled with refinement with the software PDFgui show that the material transforms to siderite within hours and that the transformation rate depends on pH (Fig. 1).

[2] Laboratoire de Minéralogie et Cosmochimie du Muséum, UMR 7202, CNRS INSU, Muséum National d'Histoire Naturelle, 57 Rue Cuvier, 75231 Paris Cedex 05, France

Monazite is an accessory mineral used for U-Th-Pb dating usually displaying complex chemical and isotopic zoning reflecting physical and chemical changes in the host rock. Chemical variations in the monazite were described at nm-scale while isotopic variations are known at few μm scale. In order to better understand the ages recorded by monazite it is necessary to obtain informations at smaller scale. In this context, the NanoSIMS appears to be the best suited tool. We present ^{89}Y, ^{139}La, ^{208}Pb, ^{232}Th and ^{238}U, mapping on monazite from metapelitic xenoliths enclosed in andesitic lava (Slovakia). The xenolith/lava interaction is characterized by the growth of a plagioclase-bearing corona surrounding the xenolith and the overgrowth of magmatic garnet on partially resorbed metamorphic garnet. NanoSIMS images and LA-ICP-MS trace elements measurements evidenced variations of the HREE, Y and Eu contents in monazite correlated to breakdown and/or growth of garnet and plagioclase. Three domains have been distinguished: a first one corresponding to the core of the monazite grains is inherited from the metapelite protolith (308 ± 9 Ma) and characterized by low Y, HREE content and low Eu negative anomaly. A second domain crystallized during the growth of the plagioclase magmatic corona (high negative Eu*) and the resorption of the metamorphic garnet (low HREE and Y contents). A third domain crystallized with the presence of the plagioclase corona (high negative Eu*) and during the crystallization of the magmatic garnet (low Y, HREE contents) is dated at 13 ± 5 Ma, i.e. the age of the andesitic lava. Owing to its small size, the second domain was not accurately dated. ^{208}Pb/^{232}Th map performed with NanoSIMS demonstrates that it has the same isotopic ratio and corresponding age than the third domain. Thus monazite is able to track and date all mineralogic reactions occuring in the metapelites during the thermo-metamorphism resulting from xenolith/lava contact.

Detection of a dissolved alpha emitter by electro-precipitation

A. DIENER[1], C. WILHELM[1] AND U. HOEPPENER-KRAMAR[1]

[1] Karlsruher Institut für Technologie, Sicherheitsmanagement Analytische Labore, 76344 Eggenstein-Leopoldshafen (correspondence: alexander.diener@kit.edu)

The drinking water distribution system is vulnerable to radioactive contaminations which could arise by nuclear accidents or by terrorist's attack. In this regard, alpha emitters (e.g. Po-210, U-235, Np-237, Pu-239, Am-241) could be brought into reservoirs or water treatment plants. The task of our research is the development of an *in situ* measurement system which bases upon electro-precipitation of the dissolved alphas on artificial surfaces.

Therefore, we wanted to figure out which elements in drinking water disturb our measurements. It consists of the sensor (diamond doped Si-waver), $NaNO_3$ as electrolyte and Am-241 as radioactive tracer. Published median or maximum concentrations for European drinking water were the basis for the synthesis of typical or highly concentrated drinking water for main (HCO_3, Ca, SO_4, Cl, Na, K, Mg, NO_3) and minor elements (Sr, F, Ba, PO_4, Zn, B, Br, Cu, I, Fe, Li, Al).

The results (Fig.1) show that the chemical yield is highest (~25%), if there is only the radioactive tracer next to the electrolyte present in solution. The median concentrations of the main and minor elements disturb only slightly while high concentrations of Ca, Mg, F, Ba, PO_4 let the yield decrease significantly, with a loss of up to 50%.

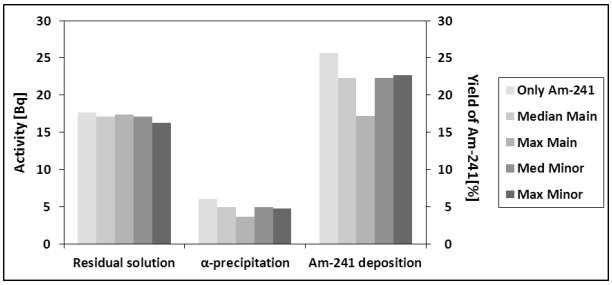

Fig.1: Comparison of the average amount of precipitated Am-241 (initial 21 Bq activity).

Towards *in situ* determination of sulfur speciation in fluids at high P-T at controlled redox conditions

M. DIETRICH[1]*, H. BEHRENS[1], C. SCHMIDT[2] AND M. WILKE[2]

[1]Institut für Mineralogie, Leibniz Universität Hannover, Callinstr. 3, 30167 Hannover, Germany (*correspondence: m.dietrich@mineralogie.uni-hannover.de), (h.behrens@mineralogie.uni-hannover.de)

[2]Chemie und Physik der Geomaterialien, Sektion 3.3, Helmholtz-Zentrum Potsdam, Deutsches Geoforschungszentrum, Telegrafenberg, D 324, D-14473 Potsdam, Germany (christian.schmidt@gfz-potsdam.de), (max.wilke@gfz-potsdam.de)

Sulfur-bearing fluids play an important role in the degassing of magmas and in the formation of certain types of ore deposits. Since high temperature fluids are often not quenchable, central issue in this study is to investigate sulfur speciation in such fluids *in situ* at high pressure and temperature using Raman spectroscopy. Therefore a new sapphire-based cell is developed which allows abrupt or continuous changes of pressure at constant temperature, operating at pressures up to 200 MPa and temperatures up to 800°C. The concept is based on a flexible gold bag which separates the pressure medium from the fluid inside the cell to avoid any reaction between the sample fluid and steel components. Oxygen fugacity (f_{O2}) is a key parameter determining the stability of sulfur species in the fluid. In the experiments the redox conditions are either pre-adjusted by the loaded fluid components or controlled by adding a specially designed open buffer capsule filled with Fe/FeO, Co/CoO, Ni/NiO or other redox pairs. Corundum powder on top of the buffer material acts as a getter for transition metal ions. Thus, penetration of these ions to the volume probed by Raman spectroscopy is avoided. First tests with the Fe/FeO buffer demonstrate the efficiency of the buffer assembly. Raman spectra recorded on the post-experimental solution show mainly HS^- besides a small amount of sulfate. EDX (energy dispersive X-ray spectroscopy) analyses of the buffer after the experiment indicate formation of Fe-spinel in the reaction zone of the capsule but FeO and metallic iron was also found. These observations give evidence that the buffer assembly has high potential to control redox conditions in the spectroscopic cell.

Ambient aerosol measurements and particle characterization at highly frequented motorways in Germany

DIETZE V, BAUM A, KAMINSKI U, SURKUS B, STILLE P, WENZEL M AND GIERÉ R

[4] Institut für Geo- und Umweltnaturwissenschaften, Albert-Ludwigs-Universität, 79104 Freiburg, Germany

Based on projected future climate scenarios (e.g. heat waves with droughts) in combination with the assumption of no additional reduction in particle emissions, the Intergovernmental Panel on Climate Change (IPCC) predicts a general decrease in air quality in the future. A recent study estimates that in central Europe, the contribution of non-exhaust particulate matter (e.g. brake dust, tire wear, as well as suspension and re-suspension from the road surface) to total traffic emissions will increase to 80 – 90% by the end of this decade [1].

With the competence of BASt and DWD, and in cooperation with the Universities Strasbourg and Freiburg, a long-term monitoring program for coarse and fine particulate matter [2] was started in early 2013. To validate in a first approach the above-mentioned prediction [1], intense field measuring campaigns during different meteorological conditions are being carried out. The aim of this study is to determine size and optical density of individual particles (d_p: 2.5 - 10 μm) by using computer-controlled single-particle optical microscopy. For selected samples, the chemical composition as well as geometric and morphological characteristics of individual particulates will be analyzed by manual, semi-automated, and fully computer-aided Scanning Electron Microscopy (SEM) combined with energy-dispersive X-ray (EDX) spectroscopy (Genesis, EDAX). Particles will be classified according to their chemical composition and assigned to, e.g., various mineral classes, which provide source information.

Evidence from *n*-alkanes for ancient organic matter sources in Lake Superior

NADIA DILDAR[1*] AND FRED J LONGSTAFFE[1*]

[1]Department of Earth Sciences, The University of Western Ontario, London, Ontario, N6A 5B7, Canada (*correspondence: ndildar@uwo.ca, flongsta@uwo.ca)

Stable carbon isotopic compositions and abundances of individual *n*-alkanes have been analyzed for sediment cores from the Ile-Parisienne, Duluth and Caribou sub-basins of Lake Superior to investigate the source(s) of organic matter since 11,000 cal yr BP. In Lake Superior, the individual abundances of C_{21} to C_{31} *n*-alkanes are very much higher than obtained for C_{17} or C_{19} *n*-alkanes. The relative contributions of terrestrial versus aquatic organic matter have been estimated using the following ratio of *n*-alkane abundances: [C_{25} to C_{31}]/[C_{17} to C_{23}]. This ratio is highest in the glacial (≥ 8800 cal yr BP) sediments, and then decreases upwards in the postglacial (< 8800 cal yr BP) sediments. This trend suggests a progressive decrease in the relative abundance of terrestrial higher plants versus macrophytes in the post-glacial lake sediments. The carbon isotopic compositions of the C_{25} – C_{31} *n*-alkanes are more or less constant (–32 to –29 ‰) in each core over the entire sampling interval. These results suggest similar sources for these compounds throughout glacial and post-glacial times. However, the C_{21} and C_{23} (macrophytic) *n*-alkanes exhibit a pronounced shift in carbon isotopic composition from –29 to –37 ‰ over a ~800-1100 year period beginning at the boundary between glacial and post-glacial sedimentation. The much lower carbon isotopic macrophyte signature suggests quite different conditions for formation of the C_{21} and C_{23} *n*-alkanes found in the post-glacial sediments. This shift was likely a response to the massive alteration of the climate system, and associated aquatic and catchment ecosystem reorganization – including plant species changes – that occurred during this time.

Pleistocene weathering and climate evolution in southern Italy: data from intermontane basins

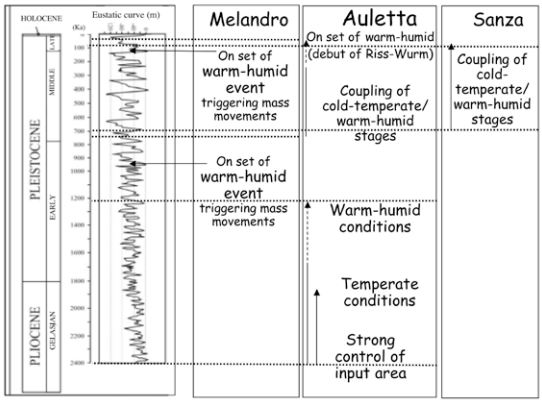
PAOLA DI LEO[1*], SALVATORE IVO GIANO [2], DARIO GIOIA [2], IOLANDA PULICE [1] AND MARCELLO SCHIATTARELLA [2]

[1] CNR-IMAA, Tito scalo (PZ), Italy (*correspondence: pdileo@imaa.cnr.it)

[2] Dipartimento di Scienze, Basilicata University, Potenza, Italy (marcello.schiattarella@unibas.it)

[3] CNR-IBAM, Tito scalo (PZ), Italy (dario.gioia@ibam.cnr.it)

In order to reconstruct the Pleistocene climate- and morpho-evolution of southern Italy, a multidisciplinary approach has been adopted and a multiproxy dataset implemented using geomorphological, mineralogical and geochemical information collected from three intermontane basins of the southern Apennines axial zone (Melandro, Auletta, and Sanza basins, Basilicata and Campania regions). To get this goal, a quantitative evaluation of eroded rock volumes were estimated by comparing uplift and erosion rates using both geological and geomorphological markers such as paleosols, weathering horizons, erosional surfaces, and paleolandslides. Besides, the calculated erosion rates were set in the evolving paleoclimate scenarios defined by means of proxies based on mineralogy (specifically clay minerals distribution) of soils, paleosols, weathering horizons developped onto differently aged erosion/depositional surfaces, and of continental sediments from key areas of southern Apennines, and on geochemical distribution of major, trace, and rare earth elements, and of stable isotopes. Since erosion rates from the three basins investigated are quite similar in a mid- long-term time interval (~1 Ma),



mineralogical and geochemical data may be used as suitable and comparable proxies to decipher the evolution of paleoclimate conditions. Coupling of cold-temperate/warm-humid climate stages seems to be the recurrent condition responsible for the genesis and evolution of ancient landscapes of the orogenic belt – including regional-scale erosional paleosurfaces – as well as a control factor in triggering mass movements.

[6]Federal Office of Topography, Swiss Geological Survey;
[7]Geological Survey of Austria (GBA)
[8]BRGM, Mineral Resources Division

The GEMAS project involved the sampling and analysis of agricultural and grazing land soil over Europe at a sample density of 1 sample per 2500 Km^2. Among the complete database we selected the samples collected in the alpine mountain range partially exceeding the border of the Alpine convention and considering important geographic boundaries as the Rhone rive to the West, the Danube river to the North and the Po River course to the South as major boundaries for sample selection.

We worked either on the total chemical content derived from XRF analysis and on the Aqua Regia data set for a total of 132 sites of grazing land soils and 119 sites for agricultural soil.

The analysis of the data set indicate minor differences between the two soil types. There is a clear control of bedrock geology, even if sample density is too low for the complex geology of the alpine mountain range. There are numerous several point anomalies for single elements associated either to known important mining areas or minor mineralizations or to various kinds of anthropogenic contributions. There are few sites with multi element anomaly in South Tyrol (Ag, Cd, Pb, Zn) located close to a well known mining area, and Slovenia. There are also extensive anomalies covering large area as displayed for example by As that between Switzerland and Italy displays a strong anomaly, important even on a continental scale [1], and recognized also in other matrices such as bottled mineral waters [2]. Also uranium shows a large anomalous area between in the central Alps between Austria and South Tyrol, related to mineralization.

[3] (lanyc822@163.com)
[3] (liutaoze81@163.com)

Sulfuric acid as a weathering agent has been recognized recently as not only enhancing weathering but also lowering CO_2 consumption rates. However, the impact of sulfuric deposition on carbonate weathering is still poorly explored, with most studies mainly focussed on large rivers that generally integrate over a number of processes and often average the situation from various backgrounds. In this study, we investigated the chemical compositions of rainwater and stream water of a karstic rural catchment located in Huanjiang County, Guagxi Province, SW of China to understand the impact of the atmospheric anthropogenic sulfate on carbon uptake by karst at rural area. The results showed that the sum of concentrations of Ca^{2+} and Mg^{2+} ($[Ca^{2+}+ Mg^{2+}]$) of stream water were in excess with respect to HCO_3^- ($[HCO_3^-]$), with a mean $[Ca^{2+}+ Mg^{2+}]/[HCO_3^-]$ ratio of 1.1. Sulfate acid accounted for the excess of Mg^{2+} and Ca^{2+} relative to HCO_3^-. The involvement of sulfuric acid in carbonate weathering caused about 6.5% increase of weathering rates, and meanwhile 14.8% decrease of the CO_2 consumption rates, of which the involvement of atmospheric anthropogenic sulfate accounted for about 9.6%. The data available at present indicate that even in the rural karst region of southwest China, the involvement of anthropogenic sulfate can largely decrease the carbon uptake rate by carbonate weathering.

The Chemical and Isotopic Characters of Suspended Particulate Materials in the Yangtze River and Their Environmental Implications

T. P. DING[1,2,*], J. F. GAO[1,2], G. Y. SHI[3], F. CHEN[3], C. Y. WANG AND X. R. LUO

[1]MLR Key Laboratory of Metallogeny and Mineral Assessment, IMR, CAGS, Beijing 100037, China. [*](Correspondence: tding@cags.ac.cn)
[2]MLR Key Laboratory of Isotope Geology, CAGS, Beijing 100037, China.
[3]Hydrological Bureau, CJW, Wuhan 430010, China

The mineral, chemical and isotopic compositions of the Suspended particulate materials (SPM) in the Yangtze River were determined systematically on the samples collected in the period of 2003 ~ 2007.

Large spacial and temporal variations of SPM contents are observed in the Yangtze River, reflecting the changes of flow speed, runoff and SPM supply. Significant SPM sedimentation in the Three Gorge Reservoir leads to increase of embankment washout in downstream section and reduction of sedimentation in the Dongting Lake, Poyang Lake and the estuary. The difference on mineral compositions indicates that the chemical weathering activity in the Yangtze area is more intensive than in the Yellow River area.

The SiO_2 and Na_2O contents in SPM of the Yangtze are higher than those of the Yellow River, reflecting the difference on weathering conditions. The (CaO + MgO)/SiO_2 ratio in the Yangtze SPM decreases downstream, reflecting also the change of weathering conditions.

The Co, Ni, Cu, Zn, Pb and Cd contents in the Yangtze River SPM are higher than the average values of the upper crust rocks. The contents of Cu, Zn, Pb and Cd in the Yangtze River SPM are several times higher than in the bed sediments, probably reflecting increase of mining activities in recent years. The REE distribution pattern of Yangtze River SPM is similar to that of upper crust, indicating that the source rocks in the Yangtze basin have chemical compositions similar to upper crust.

The $\delta^{30}Si$ variation range (-1.1‰ to 0.3‰) of the Yangtze SPM is similar to that of shale and lower than that of granite rocks, reflecting the silicon isotope fractionation in weathering process. The decrease trend of $\delta^{30}Si$ from upper reaches to middle and lower reaches may be interpreted by the increase of clay minerals downstream.

Sub-continental Nb/Ta and Zr/Hf amphibolites: implications on subduction metamprphism

XING DING[1*] AND WEIDONG SUN[2]

[1]State Key Laboratory of Isotope Geochemistry, Chinese Academy of Sciences, Guangzhou, P. R. China, (xding@gig.ac.cn)(* presenting author)
[2]Key Laboratory of Mineralogy and Metallogeny, Chinese Academy of Sciences, Guangzhou, P. R. China, (weidongsun@gig.ac.cn)

Mobilities and fractionations of high field strength elements (HFSEs), especially Nb and Ta within subducting slab, are important for deciphering the formation of the continental crust (CC)[1-4]. Here we report mineral and geochemical studies on epidote garnet amphibolite facies metagabbro located near the margin of an eclogite zone in the Tongbai-Dabie orogenic belt, central China. The samples were hydrated during prograde metamorphism of the Triassic plate subduction.

Major minerals such as amphibole, garnet, rutile and ilmenite and bulk rocks of the garnet amphibolite show overall lower Nb/Ta and Zr/Hf than the continental crust (sub-continental), suggesting major Nb/Ta and Zr/Hf fractionations during gabbro to amphibolite transformation. Nb/Ta in bulk rocks varies from 9.4 to 15.5, with the average of 11.3 while Zr/Hf changes from 30.7 to 36.3, with the average of 33.8. Notably, Nb/Ta in rutile varies from 11.5 to 24.2, with the average of 15.3 whereas Zr/Hf ranges from 12.7 to 51.7, averaging 23.8. LA-ICPMS *in situ* trace element analyses of rutile and amphibole grains display remarkable chemical zonations. In general, the cores of rutile are usually small with much higher Nb, Ta concentrations and lower Nb/Ta ratios compared to the thick rims. Such HFSE fractionations may be explained by diverse external fluid activities: the gabbro first absorbed low Nb/Ta fluids that were released during blueschist to amphibolite transformation in deeper portions of the subducting slab, followed by acquiring external fluids with elevated Nb/Ta released during amphibolite to eclogite transformation. Fluids with various Nb/Ta signatures can be transferred to cold regions within a subducting plate and also to the mantle wedge through fluid-rock reaction.

Petrological and textural constraints on explosive activity of the last 2ka of Turrialba volcano (Costa Rica)

A. DI PIAZZA[1*], C. ROMANO[1], G. DE ASTIS[2], A. VONA[1] AND G.J. SOTO[3]

[1]Dip. di Scienze, Univ. Roma Tre, Italy (andrea.dipiazza@uniroma3.it)(*presenting author)
[2]Istituto Nazionale di Geofisica e Vulcanologia Roma-1, Italy
[3]Instituto Costarricense Electricidad, San Josè, Costa Rica

We present here a throughout investigation of the last 2ka volcanic activity of the Turrialba volcano (Costa Rica), which shows signs of potential reawakening since 2006. In particular we choose two magmatic end members: a basaltic and an andesitic eruption. Mineral assemblage is composed by abundant plagioclase (An_{30} – An_{72}), clino- and orthopyroxenes, and olivine crystals (Fo69 – Fo80). We studied the stratigraphy of proxymal, intermediate and distal outcrops of the two eruptions. We calculated the parameters describing the vesicles spatial arrangement of our samples (i.e. the size, shape and number), as it records the conditions of ascent and degassing which determined the different explosivity of these eruptions. The andesitic samples were classified in two classes, differing in density and porosity: pumices (0.6 – 1.2 g/cm^3; porosity 79-61%) and scoriae-like clasts (1.5 - 1.7 g/cm^3; porosity 54-32%). Samples show maximum dimension of vesicles between 0.6 and 0.3 mm. The Vesicle Number Density is in the range 2.28–6.60 x 10^8 cm^{-3}, values comparable to those related to Plinian eruptions (e.g. Vesuvius 79 A.D.: 10^8 - 10^9 cm^{-3}). The basaltic magma feeding the last observed eruption at Turrialba, generates highly porphyritic scoriae and bombs, with a final stage made of breadcrust bombs. Vesicle dimensions range between 0.30 – 2.37 mm. VND values range between 9.74 x 10^5 cm^{-3} and 3.9 x 10^6 cm^{-3} (values similar to Stromboli volcano or Hawaian volcanoes activity). We can classify the 1864-66 A.D. activity as a powerful Strombolian eruption. This study highlights a wide spectrum of degassing processes which occurred at Turrialba volcano in the last 2ka, providing new insights into the eruptive behavior of this volcano.

Short crystal history in the recent magmatic system of Santorini volcano, Greece: inferences from micro-Sr isotope data

SARA DI SALVO [1], LORELLA FRANCALANCI [1], TIM H. DRUITT [2] AND ELEONORA BRASCHI [3]

[1] Dipartimento di Scienze della Terra, Universita' degli Studi di Firenze, via la Pira, 4, Firenze, Italy.
[2] Clermont Université, Université Blaise Pascal, Laboratoire Magmas et Volcans, Clermont-Ferrand, France.
[3] CNR-IGG, Sezione di Firenze, via La Pira, 4, Firenze, Italy.

Magma mineral phases retain the history of changing physical and chemical conditions during their growth due to the frequent occurring of mineral/liquid elemental and isotopic disequilibria. In many volcanic systems, indeed, bulk rock compositions often represent a mechanical mixture of various phases with possible different origin. Accordingly, analyses of $^{87}Sr/^{86}Sr$ on core-rim traverses of minerals give us the chance to understand the dynamics and timescales of magmatic processes during the ascent of magma to the surface. Micro-Sr isotope analyses, by microdrilling, have been used, therefore, for better understanding the volcanic system of the last 3.6 ka of Santorini history, from the huge explosive event of the Minoan eruption to the successive Kameni activity. The latter originated the Palea- and Nea-Kameni islets, inside the Minoan caldera, through nine mainly effusive subaerial events, from A.D. 46-47 to 1950. The erupted products are dacitic lavas including basaltic to andesitic enclaves, with Sr isotopes increasing with time in both enclaves and host lavas.

We focussed our micro-analytical study on the plagioclase crystals of the rhyodacitic pumices from the Minoan eruption and of the oldest and youngest post-caldera dacitic lavas. Different types of plagioclase have been identified based on textures and zoning patterns. Anorthite content overall varies between 35-90% in both systems. Contrarily to many other volcanic systems, $^{87}Sr/^{86}Sr$ values of plagioclase do not largely change within the single eruptive event and generally reflect the respective whole-rock values, except for some xenocrysts in Kameni lavas coming from the mafic enclaves. The different crystal types of the Minoan pumices have similar $^{87}Sr/^{86}Sr$ values, which are higher than those of the Kameni plagioclases. Our data suggest that the Kameni plagioclases record a short history, indicating small resident time and possible crystallization during the magma ascent, whereas the Minoan crystals do not testify any relationships with both the coeval mafic magmas and the later Kameni system.

[3]Institute for Advanced Study, Technische Universität München, Lichtenbergstrasse 2a, D-85748 Garching

Microorganisms colonize selectively minerals and organo-mineral complexes. Less well known is whether the complexity of mineral composition of soils might determine microbial communities. The use of artificial soils that differ only in their mineral composition, but not in their organic composition, offers a unique possibility to study these microorganisms-mineral-interactions in soils. For the current study, a series of artificial soils of eight different compositions was designed from simple 2 component systems to more complex 3 to 4 component systems. The components used were the clay minerals illite and montmorillonite, ferrihydrite and boehmite as representation of iron and aluminum oxides, and charcoal. The formation of artificial soils was initiated by incubating these materials with sterilized manure as organic C source and a microbial community extracted from a natural arable soil for up to 18 months at 20°C in the dark. We quantified the enzyme diversity and the abundance of eight groups of bacteria at the phylum or class levels by using qPCR to characterize the function and structure of the microbial community of the original artificial soils. Simple 2 component systems using either illite or montmorillonite as clay component as well as treatments including charcoal showed a trend for lower abundance of soil microorganisms and lower enzyme activities. We detected a microbial succession of the soil microbial community from a dominance of *r* strategist (e.g. ß-proteobacteria) during the first six months of the incubation towards systems with a higher dominance of *K* strategist (e.g. acidobacteria). The succession of enzyme activities gave clear evidence that nutrient limitations developed over time. Multivariate analysis of phospholipid fatty acid patterns revealed that nutrient limitation might also change the specificity of microbial colonization of different artificial soils towards more similar microbial population in all treatments at the end of the incubation.

Analysis of minerals in biofilms Using atomic force microscopy and raman spectroscopy.

MARIA DITTRICH[1*], THOMAS SCHMID[2] AND YONG ZHU[1]

[1] University of Toronto Scarborough, 1265 Military Trail, Toronto, ON, Canada, M1C 1A4 (*correspondence: mdittrich@utsc.utoronto.ca)

[2] Department of Chemistry and Applied Biosciences, ETH, Zurich, Wolfgang-Pauli-Str. 10, HCI D323, 8093 Zurich, Switzerland, (schmid@org.chem.ethz.ch)

Although biofilms play a significant role in geochemical cycling, the detailed structure and composition of biofilms is not known. Minerals within biofilms may be crucial for the transport of contaminants as surface reaction sites, e.g. for adsorption. A better understanding of these processes at the molecular scale will generate the basis for predictions at larger scales. An additional benefit of this approach will be an improved insight into the consequences that these processes have concerning the fate of inorganic pollutants in natural environments.

In order to obtain a better understanding of the structure of biofilms, spatially resolved chemical information is needed. Therefore, biofilms from different origins, e.g. grown in hot springs, and the precipitates from biofilms at the iron-rich spring, Bonifazius-spring (Scuola, Switzerland) were examined by atomic force microscopy (AFM) and Raman spectroscopy.

AFM images of the Fe-precipitates showed that the precipitates size can be from tens of nanometers to tens of micrometers, and their shapes of the precipitate varied from spherical, leaf-shape to irregular polygon. Raman spectra indicate that the spectral features of the precipitate are different, but are originated mainly from Goethite structure (FeOOH).

The AFM images resolved cell and extracellular polymeric substances (EPS) structures in the case of cyanobacterial biofilm. With the distinct Raman spectra, differentiation between EPS and cell material was possible. The Raman spectra at the supposed cell regions showed beta-carotene bands, whereas the other regions did not show any bands or much weaker beta-carotene bands. The obtained Raman map composed of specific marker bands was in good agreement with the different topological features of the AFM image, thus combining topographical and chemical information.

Geochemistry surveying of Kooh Kaftari metamorphism area(Iran_ Shahrood)

DIVAN.Y[1] ., HASSNNEZHAD.A.A[2] AND ZAHIRI.R[3]

1M. S. C. Economic geology, Department of Geology, Damqhan university., [Iran]
2Assistant PROF. Economic geology, Department of Geology, Damqhan university[Iran]
3Assistant PROF. Mineralogist, Department of Geology, Damqhan university.,[Iran]

Metamorphism area of KoohKaftari in central part of Iran Located in 342000 to 348000 east and 3966000 to 3950000 north. This areas metamorphism was regional metamorphism with green schist facies or higher[1]. This study aimed to understand the economically major and minor elements in the region and their potential economic power. 15 prepared samples were sending to Labwest laboratory in Australia to analysis the samples by ICP-MS and ICP-OES for 61 main elements. All of the geochemical sample results mentioned as a group and the average were compared by the Continental Crust Clarke and upper Continental Crust Clarke to find the enrichment ratio of the area. Finally, elements such as Cr, Ba had positive enrichment and elements such as U, Zr had depleted, which indicate a lack of proper mineralization's of U, Zr in metamorphic rocks of there. Results of this comparison are presented in Table 1.

Elements	kooh kaftare	Continental crust		Upper continental crust	
		Clarke	EF	Clarke	EF
Fe%	3.74	5.63	0.66	3.52	*1.06*
Ca%	3.63	4.15	0.87	2.57	*1.1*
Ba	781.28	425	*1.84*	628	*1.24*
Cr	110.14	100	*1.10*	92	*1.20*
Zr	8.67	165	0.05	193	0.04
U	1.37	2.7	0.51	2.7	0.51

Computational studies of hydrolysis reactions of CO_2 and actinides

DAVID A. DIXON,* K. SAHAN THANTHIRIWATTE, JOSHUA MOON, JESSICA DUKE AND VIRGIL E. JACKSON

Department of Chemistry, The University of Alabama, Shelby Hall, Box 870336, Tuscaloosa Al 35487-0336.
*(correspondence: dadixon@bama.ua.edu)

Advances in theory, algorithms, software, and computer architectures have made it possible to begin to calculate reliably the thermodynamics for geochemical processes in solution. The sequestration of CO_2 in geological formations can be used to mitigate global warming. A substantial amount of fundamental chemistry knowledge is still needed to ensure that the CO_2 does not have additional environmental impacts and that it remains in the subsurface. The supercritical CO_2 that is pumped into the ground will interact with H_2O and with various minerals. The properties and reactions of H_2O-CO_2 nanoclusters have been calculated at high levels of electronic structure theory and will be discussed. Issues with the electronic structure methods will be described. A surprising result is that CO_2 clusters can impact the hydrogen bonding in small H_2O clusters, which may impact reactivity. The important role of Lewis acid-base interactions in determining the structure of the clusters will be discussed. The hydrolysis of CO_2 in the presence of geochemically relevant metal ions in aqueous solution will be discussed. The metal cations can reduce the reaction barriers in part by changing the thermodynamics of the relevant reactions. The reactions of UO_2^{2+} with phosphates is of importance for extraction processes and for environmental remediation. The difficulties in predicting reliable properties for such systems will be discussed, especially for the solvation energetics. An important result is the critical role of CN 5 in the equatorial plane for these compounds. We find that there is both monodentate and bidentate binding depending on the nature of the $PO_4H_x^{y-}$ and the number of water molecules in the first solvation shell. These studies have been performed at the density functional theory and correlated molecular orbital theory levels with a self consistent reaction field to model the continuum solvent.

Geochemical evidence for multiple gold mineralisation events in the Witwatersrand Basin

ROGER D. DIXON[1]

[1]Department of Geology, University of Pretoria, Pretoria, South Africa (roger.dixon@up.ac.za)

There are currently a number of competing hypotheses for the origin on the gold in the conglomeratic reefs in the Witwatersrand Basin, from hydrothermal to alluvial and variations between the two extremes. Though it has long been theorised that the gold deposits of the Witwatersrand Basin are at least partially hydrothermal in origin, there has been insufficient trace element analysis of gold and associated minerals from around the basin to evaluate this hypothesis, mainly due to inadequacies of routine analytical techniques.

A basin-wide study looking at the composition of gold produced in the different gold fields in the Witwatersrand Basin, and the composition of individual gold grains from different reefs, has been conducted utilising ICP-OES and LA-ICP-MS, and shows that the gold produced in each goldfield is compositionally distinct and that sediment source area is the main factor in determining the trace element distribution.

Results of the analysis of large gold grains from the Vaal Reef and gold associated with carbon derived from microbial mats in the Carbon Leader Reef, reveals the presence of at least three distinct types of gold.

The first type consists of alluvial gold which has been transported from source area and deposited in the calm conditions of the braided stream depositional environment.

The second type consists of very fine particles of colloidal gold precipitated from suspension during deposition of the sediments. At the same time that the gold was being precipitated from suspension, other elements in colloidal suspension were also being precipitated, such as uranium, thorium, silver, aluminium and iron.

Subsequent to deposition, one or more hydrothermal events remobilised much of the colloidal gold and this was redeposited as a third type of gold with distinct elemental and isotopic trace element signatures. Where carbon was present this redeposition took place almost in-situ, and where carbon was absent gold was redeposited from solution at some distance, in higher reefs and associated with cross-cutting quartz veins.

[3]School of Earth Sciences, University of Bristol, Bristol, UK.
[4]Marine Geosciences, National Oceanography Centre, Southampton, UK.

Recent studies of Cr stable isotope fractionation in experimental and natural systems indicate that Cr isotopes can be used to track past changes in ocean oxygenation [1-3]. A record of dissolved oxygen concentration in seawater is crucial for understanding past climate changes, and for predicting future climate scenarios.

Marine carbonates are enriched in Cr by a factor of 10^4 relative to seawater and have shown potential as a suitable archive phase; they are thought to record the Cr isotopic composition of seawater, however, this assumption needs to be verified. It has been demostrated for other elemental systems e.g. Mg and B, that isotope fractionation can occur during elemental sequestration, thus we set out to determine the molecular mechanism of Cr incorporation into marine carbonates and to quantify any isotope fractionation that occurs during Cr uptake.

Synthetic calcite and aragonite were prepared in the presence of Cr, following the method of Bots *et al*.., 2011 [4]. Precipitates and initial solutions were analysed for Cr isotope composition by MC-ICP-MS. In tandem, selected subsets of the Cr-enriched precipitates were subject to synchrotron X-ray absorption spectroscopy, to determine the oxidation state and local coordination environment of Cr, and thus the molecular mechanism of Cr uptake in marine carbonates.

This work demostrates how a mechanistic understanding of trace element uptake can improve interpretation of empirically determined isotope fractionation factors and provide a theoretical underpinning for a novel and developing palaeo-redox proxy.

Hydrochemical and isotopic study of CO_2 rich groundwater in the Gyeongsang sedimentary basin, South Korea

HYUN-KWON DO[1], SEONG-TAEK YUN[1]*, KYOUNG-HO KIM[1] AND BERNHARD MAYER[2]

[1]Korea University, Department of Earth and Environmental Sciences, Seoul, South Korea (styun@korea.ac.kr)(* correspondence)
[2]University of Calgary, Geoscience, Canada

As a natural analogue study of geologic carbon storage in deep aquifers hosted in clastic sedimentary formations, we investigated CO_2 rich groundwater in the Gyeongsang sedimentary basin, southeastern of South Korea. Data of hydrochemistry and multi isotopes ($\delta^{18}O$-δD of water, $\delta^{13}C$ of dissolved carbonate, $\delta^{34}S$ of dissolved sulfate), together with ^{14}C dates, were collected from 16 naturally seeping CO_2 rich groundwater. The CO_2 rich groundwaters are mainly of Ca-(Mg)-HCO_3 type (average pH = 6.1) and are very high in total dissolved solids (TDS) (up to 3393 mg/L) and alkalinity (up to 2512 mg/L). The concentrations of Ca^{2+}, Cl^- and SO_4^{2-} are also high with the positive correlations with TDS. Thus, it is suggested that CO_2 rich groundwater was evolved through strong water-rock interactions. The results of ^{14}C dating support a long residence time of inorganic carbon (35,720 to 44,780 BP). The $\delta^{18}O$ (-9.2 ± 0.6‰) and δD (-63.0 ± 4.4‰) data indicate that CO_2 rich waters were derived from local meteoric water. The $\delta^{13}C$ values of dissolved carbonates (-9.2 to -1.5‰) indicate the origin of dissolved carbon from mantle-derived CO_2. Careful examination of hydrochemical and isotopic data also indicates that mixing process occurred between uprising CO_2 and shallow groundwater during fluid ascending.

Archaean TTG discriminant criteria applied to Phanerozoic granitoids – significance from a study case in the Getic basement, South Carpathians

ANCA DOBRESCU

Geological Institute of Romania, Bucharest 32, Romania; (ancadobrescu2003@yahoo.com)

A comparison to Archaean TTGs was made on two Ordovician granitoids [1] from Buchin (BG) of I-type and Slatina-Timis (STG) of I-S-type from the Getic basement (NE Semenic Mts.) - South Carpathians, because of peculiar trace elements behavior. Diagnosed as trondhjemites-tonalites-granodiorites-granites, the samples fit geochemically to Archaean TTGs [2] except higher K_2O contents (1.48-3.91%) and slightly lower $(La/Yb)_N$ (10.56-39.93). Low Y (4-12 ppm), mid-high Sr (554-965 ppm) and Sr/Y (48-175), small to no Eu anomalies, (-) Nb-Ti anomalies, low Nb/Ta and HREE (Yb<1.3 ppm) signify variable clinopyroxene, Ti-phase, amphibole, garnet, +/- scarce plagioclase in the residue [2, 3, 4]. The rocks overlap Archaean-Ptz TTG composition [5] close to the amphibolites batch melting products on Nb/Ta-Zr/Sm diagram; alternatively [6] the rocks plot close to the eclogite melting field. The TTG signature tempted us to plot the samples on the discriminant diagrams for Archaean TTGs [7]. The diagrams on immobile elements (Y, Yb, La, Ce, even Sr, SiO_2) plot BGs systematically in the high pressure (HP-TTG) group and STGs in the medium pressure (MP-TTG) group. The diagrams using LILE (K, Eu) plot BGs in the K-group and STGs in the low pressure (LP-TTG) and K-group of enriched sources. MgO, FeO, SiO_2 used as indicators for T^0/degree of melting plot the BGs in and around LP-TTG and K-group. In the BG-STG case as Phanerozoic granitoids, the conclusion on immobile elements behavior refers to pure melts related to source/P-depth conditions, while the rest of elements relate the end-rocks to the subsequent evolution during ascent and emplacement. The HP-MP coupled with moderate T^0 are consistent with early stages of continental collision - proper setting for an origin related either to partial melting of heterogeneous old continental crust eclogitized at its lower part because of wet conditions induced by a former subduction, or to partial melting triggered at the continental crust/oceanic crust/mantle tectonic contact during collision (setting described in [8, 9]).

Asymmetric plate tectonics and asymmetric mantle convection

CARLO DOGLIONI[1]

[1]Sapienza University, Roma, Italy (carlo.doglioni@uniroma1.it)

Subduction zones have hinges which move toward or away with respect to the upper plate. Assuming null the velocity of the upper plate, the velocity of the subduction is given by $V_S=V_H-V_L$, where V_H is the velocity of the subduction hinge, and V_L is the velocity of the lower plate. In case of subduction hinge diverging relative to the upper plate, the subduction results faster than the convergence rate, whereas in case of subduction hinge converging relative to the upper plate, the subuction is slower than the convergence. The dip of slabs, topography, type of rocks, foredeep subsidence rates, metamorphic PTt path, plus a number of other parameters characterize the two end-members of related orogens (Doglioni *et al*.. 2007, ESR). This anthitetic behaviour appears as geographically tuned, i.e., west versus east or northeast. Moving along the tectonic equator described in Crespi *et al*.. (2007, GJI) and Cuffaro and Doglioni (2007, GSA SpPu), slabs having the hinge diverging relative to the upper plate occur dominatly along W-directed subduction zones. This implies a 3-5 times faster subduction recycling of the lithosphere along those margins with respect to the opposed E-or NE-directed subduction zones. Moreover, delamination and thicker asthenospheric mantle wedge occur along W-directed subduction zones. A thicker lithosphere with faster shear waves and few hundreds meters deeper oceanic bathymetry charaterizes the western limb of rift zones (Panza *et al*.. 2010, Geology), suggesting a global asymmetry of plate tectonics, and consequently of the primary mantle convection. This setting reconciles with the westward drift of the lithosphere. However, only a shallow source (LLAMA, Anderson, 2011, JP) of the hotspot reference frame matches the global tectonic asymmetry as the one described, where the net rotation of the lithosphere relative to the mantle amounts to more than 1°Ma. An astronomical input is required in order to satisfy this geodynamic configuration (Riguzzi *et al*.. 2010, Tectonophysics).

Tracing the origin and evolution of the parental magmas of the Grey Porri Tuffs, island of Salina, Italy.

DOHERTY, A.L.[1]*, BODNAR, R.J.[2], CANNATELLI, C.[3], ESPOSITO, R.[3], DE VIVO, B[3] AND MESSINA, A.[3]

[1] University of Mesina, Messina, Italy (*correspondence: doherty.angelal@gmail.com)
[2] Virginia Tech, Blacksburg, VA, USA
[3] University of Naples (Federico II), Naples, Italy

The interbedded scoria-pumice-ash tuffs of Monte dei Porri, known as the Grey Porri Tuffs (GPT), appear to be the result of the mixing of two or more compositionally-different magmas. A more evolved trachyandesite-trachydacite magma, represented by melt inclusions (MI) trapped in feldspar of the pumice, was intruded by a basaltic magma, represented by MI in olivine of the same unit.

H_2O/CO_2 modelling indicates that MI in the feldspars of the pumice units were entrapped at ~0.6 kb. Magma-wall interaction had begun, evidenced by slight positive Zr anomalies and also low volatile element abundances (primarily: 1.7-2.8 wt % H_2O and 1019-1749 ppm S) which may indicate shallow system degassing. Feldspars of the pumice unit also show strong zonation and more sodic compositions than the scoria, which range from An_{58-81}.

The MI in olivine of the pumice units, interpreted to represent the mafic magma, were entrapped at higher pressures, ~1.7 kb, based on H_2O/CO_2 modelling. The olivine hosts had Fo-contents of Fo_{79-83}. The intrusion introduced a large amount of volatile components into the system; it contained 4.1-5.1 wt % H_2O, 3227-4032 ppm S, 187-492 ppm CO_2 and 3149-3855 ppm Cl. The subsequent eruption entrained the feldspar and clinopyroxene from the evolved melt, and the olivine from the mafic intrusion, and deposited the pumice units, which have an andesitic bulk composition.

Subsequent evolution in the mixed remnants of the magma produced a melt with a composition that is intermediate between the previous two. MI in the calcic feldspar (An_{84-93}), olivine (Fo_{71-82}) and clinopyroxene (augite and diopside) show overlapping major and trace element compositions, suggesting they may have had similar evolutionary histories. MI compositions and volatile element abundances approach those of the pumice units (the olivine-hosted MI contain 2.4-3.8 wt % H_2O, 169-570 ppm CO_2, 1495-3587 ppm S and 3165-3705 ppm Cl), suggesting that there may have been continual input from below, with the bulk rock compositions of the erupted GPT scoria units having a low-silica basaltic-andesite composition, more mafic than the majority of the MI from the same units.

Acid rock drainage in Antarctica – importance for global iron cycling in the Southern Ocean

DOLD, B.[1], GONZALEZ-TORIL, E.[2], AGUILERA, A.[2], LOPEZ-PAMO, E.[3], CISTERNAS, M.E.[1] AND AMILS, R.[2]

[1] Instituto de Geología Económica Aplicada (GEA), Universidad de Concepción, Concepción, Chile. (Bernhard.Dold@gmail.com), (mcistern@udec.cl)
[2] Centro de Astrobiologia (INTA-CSIC), Madrid, Spain. (etoril@cbm.uam.es,)(aaguilera@cbm.uam.es), (ramils@cbm.uam.es)
[3] Instituto Geológico y Minero de España (IGME), Madrid, Spain. (e.lopez@igme.es)

We describe biogeochemical processes that lead to the generation of acid rock drainage (ARD) and rock weathering on the Antarctic landmass and describe why they are important sources of iron into the Antarctic Ocean. During three expeditions, 2009 – 2011, we examined three sites on the South Shetland Islands in Antarctica. Two of them displayed intensive sulfide mineralization and generated acidic (pH 3.2 – 4.5), iron-rich drainage waters (up to 1.78 mM Fe), which infiltrated as groundwater (as Fe^{2+}) and as superficial runoff (as Fe^{3+}) into the sea, latter with the formation of schwertmannite in the sea ice. The formation of ARD in the Antarctic was catalyzed by acid mine drainage microorganisms found in cold climates, including *Acidithiobacillus ferrivorans* and *"Thiobacillus plumbophilus"*. The dissolved iron (DFe) flux from rock weathering (non-mineralized control site) was calculated to be 0.45 x 109 g DFe yr-1 for the nowadays 5468 km of ice-free Antarctic rock coastline what is in the order of magnitude of glacial or aeolian input to the Southern Ocean. Additionally, the two ARD sites alone liberate 0.026 and 0.057 x 109 g DFe yr-1 as point sources to the sea. The ARD point sources are between 1000 and 2300 times more efficient than non mineralized rock weathering for iron liberation. The increased iron input correlates with increased phytoplankton production close to the source. This might even be enhanced in the future by a global warming scenario, when more of the Antarctic coastline will be ice-free, and could be a process counterbalancing global warming.

Tracking high-pH reaction fronts in MX-80 bentonite using infiltration techniques and 4D CT

F. DOLDER[1*], U. MÄDER[1] AND A. JENNI[1]

[1]RWI, University of Bern, Geological Sciences, Bern 3012, Switzerland
(*correspondence: florian.dolder@geo.unibe.ch, urs.maeder@geo.unibe.ch, andreas.jenni@geo.unibe.ch

Geological storage of radioactive waste foresees bentonite as backfill material enclosing spent fuel drums. Concrete is proposed as building material for tunnel reinforcement or as backfill. The emplacement of high-pH cementitious material next to clay generates a chemical gradient in pore water chemistry that drives diffusive transport. Laboratory studies and reactive transport modeling predict significant mineral alteration near interfaces [1].

We aim to characterize and quantify the cement/bentonite skin effects spatially and temporally, focusing on the advective-diffusive transport domain resolved at intermediate spatial scales. Equipment made of carbon fiber and plastics holds a cylindrical sample under confining pressure and imposes a constant hydraulic gradient to drive a small advective flux. Compacted and saturated MX-80 bentonite and sand/bentonite mixtures are used. Infiltration of high-pH pore-fluids into the bentonite plug alters the mineral assemblage over time. The related change in phase densities, porosity and local bulk density is tracked by CT scans during ongoing infiltration. The resulting micrographs describe the electron density distribution in 3D and as a function of time. Electron densities are transformed into material densities using reference materials and are calculated on the basis of the data of the NIST [2]. After 1-2 years the experiment is stopped and the samples subjected to post-mortem analysis.
In a first experiment running for >6 months, MX-80 bentonite (ϱ_{wet}=1.875 g/cm^3) is used as starting material, and a synthetic cement pore fluid of pH 13.4. The reaction front is tracked in the CT and appears as precipitations in the thin filter separating bentonite and infiltration fluid, and as an evolving zone of higher density in the bentonite next to it. Simultaneously, hydraulic conductivity is decreasing by 58% over 6 months.

Estimating fluid fluxes from equilibrium properties and transport theory: pitfalls and solutions

DAVID DOLEJŠ[1]

[1]Institute of Petrology and Structural Geology, Charles University, 128 43 Praha 2, Czech Republic
(correspondence: david.dolejs@natur.cuni.cz)

Aqueous fluids are efficient mass transport agents and reactive fluid flow occurs in diverse settings including compaction of porous sediments, thermal perturbations in oceanic crust, prograde metamorphic reactions in continental orogens and subduction zones, or during plutonic and volcanic degassing. We will address several issues pertaining to accuracy and extrapolability of thermodynamic data, magnitude of reaction progress in temperature and pressure gradients, and separation of equilibrium vs. disequilibrium effects, i.e., closed- vs. open-system fluid-mineral interaction. Standard reaction enthalpies and volumes directly provide gradients in mole amounts of reaction progress or mineral precipitated, n, per unit temperature or pressure. Evaluation of mineral solubilities reveals that $\partial n/dP$ are significant and critically moderate $\partial n/dT$ for fluid reactions along geotherms *vs*. at constant pressure. Highly charged species are responsible for retrograde solubility effects during isobaric (lateral) flow, but along geotherms (7-20 ºC km^{-1}) the $\partial n/dT$ are monotonous and nearly identical for a variety of rock-forming phases. Estimation of integrated fluid fluxes is frequently biased towards two limiting approaches: (i) local equilibrium with host rocks, with reaction progress driven by pressure and temperature gradients only, or (ii) dis-equilibrium fluid-rock interaction at constant or variable temperature and pressure. We extend conventional transport theory to include the disequilibrium effects and demonstrate that these two approaches yield the lower and upper limits of the flux, respectively, that may differ by several orders of magnitude. A model application to hydrolytic alteration of peraluminous granites reveals time-integrated fluid fluxes from 10^2 to 10^6 m^3 m^{-2}, which covers the plausible range observed globally. If the magnitude of disequilibrium is constrained by modal proportions or volume conservation, the fluid fluxes become bracketed and smaller, 10^{2-3} m_{fl}^3 m_r^{-2}. We conclude that vein-producing fluid fluxes may be several orders of magnitude lower than previously indicated for fracture- or shear zone-related flow, and low fluxes support alternating periods of episodic flow and stagnant fluid-rock interaction. Such discontinuous flow mechanism is more consistent with cycles of transient permeability enhancement and subsequent chemical or mechanical sealing.

Sr-Nd-Hf-Pb isotope mapping of Tien Shan in Uzbekistan

A. DOLGOPOLOVA[1*], R. SELTMANN[1], R. ARMSTRONG[1], E. BELOUSOVA[2], R. PANKHURST[3], D. KONOPELKO[4] AND R. KONEEV[5]

[1] NHM, Department of Earth Sciences, CERCAMS, London SW7 5BD, UK (*correspondence: allad@nhm.ac.uk)
[2] Macquarie University, GEMOC, NSW, 2109 AUSTRALIA (elena.belousova@mq.edu.au)
[3] BGS, Keyworth, Nottingham NG12 5GG, UK (rjpankhurst@gmail.com)

[5] NUUz, Department of Geology, Tashkent, UZBEKISTAN (ri.koneev@gmail.com)

Sr-Nd-Hf-Pb isotope mapping combined with U-Pb zircon SHRIMP ages and Re-Os sulphide geochronology of granitoids from profiles across terrane boundaries in Uzbekistan reveal distinct reservoir types (cratonic vs turbiditic), corresponding to diverse nature and origin of granitic magmatism and its hosted ore-forming processes. Three main tectonic domains are recognized: Middle Tien Shan, Southern Tien Shan and Karakum microcontinent.

Sr-Nd isotopes (whole-rock) of all domains show a wide range of εNdt (-5 to +7) and ($^{87}Sr/^{86}Sr$)t predominantly between 0.704 and 0.707, indicating involvement of both mantle-derived material (e.g., subduction of oceanic crust) and older crustal sources (Mesoproterozoic model ages).

The large range of Hf-isotope compositions found in zircons of granites from Kurama, Middle Tien Shan, (εHf ~ -6 to +5) suggest recycling of older heterogeneous crustal protolith(s). In the Southern Tien Shan involvement of subducted oceanic crust is examplified by juvenile εHf values of up to +14 (Sultan-Uvais) and +16 (Teksquduk-Kyzylkum). However, Permo-Carboniferous granitoids crossing all terrane boundaries exhibit predominantly crustal signatures indicating Neoproterozoic protoliths.

Pb isotopes (whole-rock) exhibit a present-day range of $^{206}Pb/^{204}Pb$ 18.229-20.718, $^{207}Pb/^{204}Pb$ 15.607-15.823 and $^{208}Pb/^{204}Pb$ 38.077-39.827. These are in full agreement with Sr-Nd-Hf isotopes indicating the dominance of a crustal component as well as crust-mantle mixing processes.

The granitoid samples from Middle Tien Shan, Southern Tien Shan and Karakum microcontinent show a variation of crustal to mixed signatures with a significant contribution of older components. *This is a contribution to IGCP-592 sponsored by IUGS-UNESCO.*

Competitive adsorption/desorption of arsenate and phosphate at the ferric hydroxide-water interface

RONA J. DONAHOE[1]* AND GHANASHYAM NEUPANE[2]

[1]Dept. of Geological Sciences, University of Alabama, Tuscaloosa, AL 35487-0338; rdonahoe@ua.edu
[2]University of Idaho - Idaho Falls, 1176 Science Center Dr., Suite 306, Idaho Falls, ID 83402; gneupane@uidaho.edu

The kinetics of $As_{(V)}$ and PO_4 adsorption/desorption on ferric hydroxide were investigated at pH 4 and pH 8 in 0.1 M NaCl. Individually, these oxyanions showed similar adsorption on the substrate and greater adsorption at pH 4 than at pH 8. In competitive adsorption experiments, greater adsorption of $As_{(V)}$ compared to PO_4 was observed at both pH conditions. Sequential loading of $As_{(V)}$ followed by PO_4, and vice versa, was aimed at studying the co-oxyanion induced desorption kinetics of $As_{(V)}$ and PO_4 (Fig. 1). The kinetic data were successfully fit by pseudo-second order, Elovich, and power-function equations.

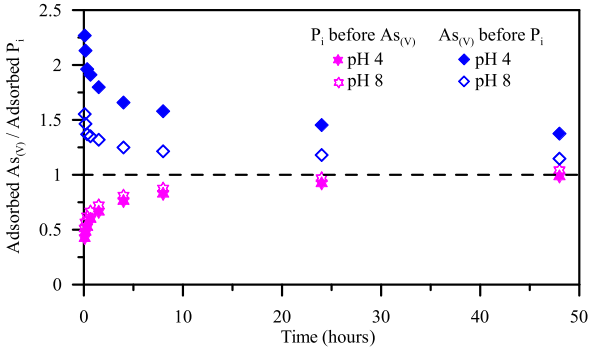

Fig. 1. Molar ratio plots for sequential loading of co-oxyanion after pre-equilibration of As(v) or PO_4 (P_i) on ferric hydroxide at pH 4 and 8.

Selected samples were used for the As K-edge EXAFS spectroscopy to understand the changes in adsorption mechanisms of $As_{(V)}$ with time in the presence/absence of PO_4. EXAFS analysis indicated the presence mononuclear (^2E) and binuclear (^2C) bidentate $As_{(V)}$ surface complexes. Fe coordination numbers (CN) increased with increasing time and decreased with addition of PO_4 into the system. Relatively, the higher proportion of CN associated with ^2E, compared to ^2C, was decreased after the addition of PO_4. The competitive desorption study indicates that the excessive input of PO_4 due to the overuse of fertilizers could mobilize $As_{(V)}$ from contaminated geomedia through competitive desorption.

[3] Università di Bari, Via Orabona 4, 70125 Bari (BA), Italy
[4]Earth Sciences, RHUL, UK

Volcaniclastic layers interbedded in the sedimentary sequences of Marine Isotope Stage (MIS) 5 have been the subject of many tephrostratigraphic studies over the past decades. In particular, two important markers, named the X-5 (105 ± 2 ka) and X-6 (107-108 ka) tephras were recognised in many Mediterranean marine and lacustrine sequences. First identified within Ionian Sea marine cores [1] these marker tephras have since been recognised in Tyrrhenian Sea cores [2] and terrestrially at Lago Grande di Monticchio [3,4].

In a recent paper [5] the two tephras were identified in the lacustrine sequence of Sulmona basin and along the Cilento coastline. Here we present new petrographic and microanalytical data on volcaniclastic deposits outcropping in the Cilento area. Trace element concentration determined on single glass shards by LA-ICP-MS unequivocally confirms these volcaniclastic levels as the X-5/TM-25 and X-6/TM-27 markers tephras. Moreover, additional investigations of a volcaniclastic level outcropping in Valle del Crati (northern Calabria), near the village of Tarsia, allows a correlation of this level with the X-6 marker tephra. The associated age of the X-6 (107-108ka) is in contrast with the previous thermoluminescence age of this level (42-25 ka [6]).

Volcaniclastic deposits with similar characteristics to those along the Cilento coastline have also been recognised along the Lucania and Calabria Tyrrhenian coast. The mineralogical assemblage (alkali feldspar + diopsidic to salitic clinopiroxene + plagioclase + feldspathoids ±- biotite and amphibole) and the trachytic composition of the glasses strongly suggest a correlation of these layer with the X-5 and X-6 tephras. Further trace element analysis is required to reinforce links to the Cilento levels.

Mg and Fe isotope constraints on the genesis of Paleoproterozoic magnesite deposits, NE China

A. DONG, X. K. ZHU, S. Z. LI, Y. WANG, Z. H. LI

Laboratory of Isotope Geology, MLR, Institute of Geology,CAGS, Beijing, 100037, PR China (aiguo.dong@gmail.com)

As the world famous magnesite mineralization belt, the Paleoproterozoic magnesite deposits in eastern Liaoning, NE China, accounting for about 30% of the whole world reserves, have experienced multi-geo-processes (evaporation deposit, regional metamorphism etc.), and the genesis is still in debate: chemical deposition or metasomatism. In this study, Mg and Fe isotope compositions of carbonate and magnesite were determined for tracing the genesis of the magnesite deposits. The δ^{26}Mg values (*ca*. -1.5‰ to DSM3) of the magnesite are in the range of the Mg isotope composition of the carbonate, differing from the magmatic source (δ^{26}Mg values *ca*. -0.25‰) and present seawater (δ^{26}Mg values *ca*. -0.83‰). Furthermore, if consider about recent stimulation experiments that the abiotic chemical precipitation could produce a large rang of Mg isotope fracitionation (*ca*. -2‰ for the calcite precipitatioan and *ca*. -1.19‰ for the magnesite precipitation at 150°C) from aqueous to solid, the Mg isotope results are consistent with a chemical precipitation origin. This view is also supported by the fact that the δ^{56}Fe values of the deposits (range from -1.0 to -0.13‰ to IRMM, with an average value of -0.43‰) are compatible to the Fe isotope composition of the sedimentary carbonates.

[5]Centre of Hydrogelogy and Environmental Geology Survey, China Geolgogical Survey, Baoding, 071051, China

Yinchuan Plain is a newly discovered high-arsenic groundwater area in the Yellow River Basin, China, with an arsenic range of 9μg/L in groundwater. 81 water samples were collected for chemical analysis along the direction from westren Helan Mountain to the central plains, The hydrochemical types gradually change from HCO_3, SO_4-HCO_3 types to HCO_3-Cl and Cl-HCO_3 types. High arsenic groundwater is mainly distributed in the Yellow River floodplain of eastern Helan country and subsidence center area of western Pingluo country, within the depth of 40m in phreatic water.

Arsenic was detected in rocks from Helan Mountains in varying degrees: arsenic in sedimentary rocks, which were significantly influenced by weathering, such as mudstone, sandstone and shale, was respectively 6.5mg/kg, 2.5mg/kg and 5.9mg/kg. Surface water, groundwater and wind transported arsenic in rocks to the plain. The coal-bearing strata in Helan Mountains and arsenic rocks are the main native sources of high arsenic environment in the study area. Analysis results of borehole sediments showed that high arsenic layers appeared in the depths of 18m, 41m and 92m below the surface. Limnetic facies sediments in lacustrine plain were the other essential source of groundwater arsenic. In addition, human activities have accelerated migration and enrichment of arsenic into groundwater.

A Phanerozoic CO_2 history driven by tectonics

Our understanding of the geological regulation of the carbon cycle has been deeply influenced by the contribution of Bob Berner with his well-known model GEOCARB. Here, we will present a fundamentally different carbon cycle model that explicitly accounts for the effect of the paleogeography using physically based climate simulations and using 22 continental configurations spanning the whole Phanerozoic. We will show that several key features of the Phanerozoic climate can be simply explained by the modulation of the carbon cycle by continental drift. In particular, the continental drift may have strongly impacted the runoff intensity as well as the weathering flux during the transition from the hot Early Cambrian world to the colder Ordovician world. Another fascinating example is the large atmospheric CO2 decrease simulated during the Triassic owing to the northward drift of Pangea exposing large continental area to humid sub-tropics and boosting continental weathering. Conversely, our model fails to reproduce the climatic trend of the last 100 Ma. This is due to the highly dispersed continental configurations of the last 100 Ma that optimize the consumption of CO2 through continental weathering. This discrepancy may be reduced if we account for a larger influence of the Earth degassing flux on the atmospheric CO2 evolution, which could come from the increase contribution of the pelagic component on the oceanic crust on the global carbonate flux and from the many sub-marine LIPs occurring during the Late Cretaceous.

First preliminary map of deep CO_2 degassing in Alpine region

MARCO DONNINI[1,2], FRANCESCO FRONDINI[1]*, CARLO CARDELLINI[1], STEFANO CALIRO[3], GIOVANNI CHIODINI[3], IVAN MARCHESINI[2] AND FAUSTO GUZZETTI[2]

[3]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Vesuviano. Perugia, Italy

Processes of CO_2 degassing affect almost all tectonically active areas and metamorphic environments. Here we show the first preliminary map of deep-CO_2 degassing of the Alps based on more than 1000 chemical analyses of springs (both data from litterature and new data). Using PHREEQC, for each point we estimated the total dissolved inorganic carbon (TDIC) and through an isotopic and mass balance approach we estimated the values of Ccarb, carbon deriving from carbonate dissolution, and Cinf, the sum between atmospheric CO_2 dissolved by rainwater and biogenic CO_2. Cdeep, carbon deriving from deep degassing, has been computed considering that [1]: TDIC = Ccarb + Cinf + Cdeep. Ccarb, given by Ca+Mg-SO_4, has been estimated for sprigs fed by carbonate aquifers. The flux of deep CO_2 associated to each spring discharge is given by Cdeep X Q/A, (Q: flow rate, A: recharge area), or by Cdeep X IE, (IE: effective infltration, IE=Q/A). IE for each basin have been estimated using a water balance model [2]. Finally we prepared the CO_2 degassing map using GSLIB [3]. The results show that CO_2 production of Alps is 3 times lower than CO_2 production in Central Italy [4], but locally (like in Engadine, Lucomagno Pass, Valtellina etc..) CO_2 fluxes are one order of magnitude higher than the baseline of geothermal regions [5]. The highest deep-CO_2 degassing areas are located along the more important alpine tectonic structures and in the basins external to the alpine chain. In these areas more detailed investigations should be performed in order to obtain a complete evaluation of the extent and distribution of the CO_2 anomalies of the Alps.

On geological time-scales the fluxes from atmosphere to solid Earth depend on weathering of silicates and carbonates, biogenic precipitation and removal of $CaCO_3$ in the oceans and volcanic gases – seawater interactions. Here we estimate the atmospheric CO_2 uptake by weathering in the Alps, using the dissolved loads of 33 Alpine rivers sampled during dry and flood seasons. The dissolved load of streams originates from atmospheric input, pollution, evaporite dissolution, and weathering of carbonate and silicate rocks. We applied the MEGA (Major Element Geochemical Approach) geochemical code [1, 2] to the chemical compositions of the selected rivers in order to quantify the atmospheric CO_2 consumed by weathering. The steps were: (1) subtracion of the rain contribution, (2) the remaining (Na+K) cames from silicate weathering. The average molar ratio R_{sil} = (Na+K)/(Ca+Mg) was estimated for each basin following well known lithological classification [2, 3], (3) lastly we estimated the (Ca+Mg) originating from carbonate weathering. Depending on time-scales we considered different equations for the quantification of the atmospheric CO_2 consumed by weathering [5]. The results show the net predominance of carbonate weathering on fixing atmospheric CO_2 and that, considering different time scales, there is about one order of magnitude of difference on the atmospheric CO_2 fixed by weathering.

Basalt, granite, rhyolite, and schist weathering as affected by plants and microorganisms

KATERINA DONTSOVA[1,2*], DRAGOS G. ZAHARESCU[1*], CARMEN BURGHELEA[1], JON CHOROVER[2], RAINA MAIER[2] AND TRAVIS HUXMAN[3]

[1]University of Arizona, Biosphere 2, Tucson, Arizona, U.S.A. (dontsova@ email.arizona.edu)(* presenting author), (zaharescu@email.arizona.edu,) (bcarmen@email.arizona.edu)
[2]University of Arizona, Soil Water and Environmental Science, (chorover@cals.arizona.edu), (rmaier@ag.arizona.edu)
[3]Univerisity of California, Irvine, (thuxman@uci.edu)

In order to survive in nutrient poor environments, plants and microorganisms developed a number of strategies to accelerate weathering of the minerals in the soil and rock. This study looks at the role of plant-microbial associations in mineral weathering. Four different rocks, basalt, granite, rhyolite, and schist were used as substrate for growth of Ponderosa pine (*Pinus ponderosa*) and Buffalo grass (*Bouteloua dactyloides*) with and without mycorrhiza. There was also a bacteria-only and killed controls. Two types of mycorrhizal fungi were used, *Rhizopogon evadens*, an ecto-mycorrhiza-forming fungi associated with Ponderosa pine and VAM mycorrhiza-forming *Glomus intraradices* used to inoculate Buffalo grass. Plants were seeded into plastic columns containing rocks inoculated with microbial community obtained from basalt.

To detect changes in soil solution composition resulting from weathering processes, drainage solution was collected and analyzed to determine electrical conductivity, pH, quantify concentrations of organic and inorganic C, total N, anions and cations. After four month a set of columns was sacrificed and root and shoot biomass, concentrations of C, N, and lithogenic elements in plant material, as well as plant root lengths was determined.

All four rocks experienced weathering. Both electrical conductivity and pH of drainage solutions, indicator variables for weathering reactions were higher than measured in water used for irrigation. Electrical conductivity of drainage solution was also higher in planted treatments compared to control, and in pine compared to grass treatment. Concentrations of lithogenic elements in soil solution were also affected by plants, with nutrient cations depleted relative to rare earth elements in planted treatments, compared to microbial and abiotic controls. In addition, it was observed that mycorrhizal infection of the plants affected plant biomass and root length.

Rapid regolith formation over volcanic bedrock and implications for landscape evolution

ANTHONY DOSSETO[1], HEATHER L. BUSS[2] AND P.O. SURESH[3]

[1]Wollongong Isotope Geochronology Laboratory, School of Earth and Environmental Sciences. University of Wollongong. E-mail: (tonyd@uow.edu.au)
[2]School of Earth Sciences. University of Bristol.
[3]Department of Environment and Geography. Macquarie University.

The ability to quantify how fast weathering profiles develop is crucial to assessing soil resource depletion and quantifying how landscapes evolve over millennia. Uranium-series isotopes can be used to determine the age of the weathering front throughout a profile and to infer estimates of regolith production rates, because the abundance of U-series isotopes in a weathering profile is a function of chemical weathering and time. This technique is applied to a weathering profile in Puerto Rico developed over a volcaniclastic bedrock.

U-series isotope compositions are modelled, revealing that it takes 40-60 kyr to develop an 18m-thick profile. This is used to estimate an average regolith production rate of 334 ± 46 mm/kyr (Fig. 1; *[1]*). This value is higher by a factor of up to 30 when compared to production rates estimated for weathering profiles developed over granitic or shale lithologies. This *quantitatively* underpins the lithological control on rates of regolith production (in a neighbouring watershed but over a granitic bedrock, production rates are only ~30-40 mm/kyr). Moreover, by comparing these results to a compilation of soil erosion rates, it is clear that landscapes are controlled by the balance (or imbalance) between regolith production and erosion: soil-mantled landscapes are the result of a relative balance between production and erosion, whereas in cratonic areas, thicker weathering profiles are generated because erosion fails to match regolith production rates.

Cerium isotope systematics of oceanic carbonatites

R. DOUCELANCE[123*], N. BELLOT[123], M. BOYET[123] AND T. HAMMOUDA[123]

[1] Clermont Université, Université Blaise Pascal, Laboratoire Magmas et Volcans, BP 10448, F-63000 CLERMONT-FERRAND
[2] CNRS, UMR 6524, LMV, F-63038 CLERMONT-FERRAND
[3] IRD, R 163, LMV, F-63038 CLERMONT-FERRAND
(*correspondence: doucelance@opgc.univ-bpclermont.fr)

Oceanic carbonatites have been reported only at the Cape Verde and Canary archipelagos, North Atlantic Ocean. Geochemical studies based on stable, radiogenic and noble gas isotopes have led to the general consensus that their parental magmas originate in the mantle. Two contrasted models, however, have been proposed for the origin of the carbon of their source: recycled marine carbonates via subduction [1, 2] vs. primordial carbon [3].

Marine carbonates [4] show REE patterns distinct from those assumed or measured for mantle and mantle-derived reservoirs (D'': [5]; Lower Mantle: [6]; DMM: [7]; MORB: [8]). Notably chondrite-normalized La/Ce and Sm/Nd ratios have inverse values. Consequently old recycled carbonates are likely to display εCe>0 (εCe is the $^{138}Ce/^{142}Ce$ variation relative to the Bulk Earth x10000) and εNd<0 ($^{143}Nd/^{144}Nd$ variation relative to the Bulk Earth x10000) with time, whereas mantle-related materials will show εCe≤0 and εNd≥0. Thus coupled Ce and Nd isotope systematics appear to be a powerful tool to decipher between the two proposed origins for the carbon of oceanic carbonatites.

We have measured Ce and Nd data on carbonatites from the Cape Verde and Canaries archipelagos, together with basaltic samples from the same locations. We have also determined εCe and εNd values for Tamazert carbonatites (Marocco) as it has been proposed that the Cape Verde, Canary and Tamazert carbonatites share a common source [9]. Our first measurements on oceanic samples argue in favor of recycled marine carbonates in the source of oceanic carbonatites.

Dramatic seasonality of biogeochemical signatures in watersheds underlain by continuous and discontinuous permafrost

THOMAS A. DOUGLAS

U.S. Army Cold Regions Research and Engineering Laboratory; 9th Avenue, Building 4070 Fort Wainwright, Alaska 99703; 907-361-9555; (Thomas.A.Douglas@usace.army.mil)

High latitude watersheds experience two extreme seasons: 6-9 months of cold, snow covered winter and a warm, bright, summer. Between these seasons is the spring freshet, a dramatic two to three week period when up to three quarters of the yearly precipitation runs off. The summer to winter transition is far less remarkable as temperatures and light slowly decrease until winter arrives. The intense seasonality and transitions in Arctic rivers are associated with unique biogeochemical signatures, a landscape scale "view" of vegetation, soil, weathering, and water column processes.

Discerning sources or fluxes of compounds out of Arctic rivers is difficult in large rivers because they represent the combined effect of innumerable plot-scale melt water sources, each coming from different soil and vegetation types, each experiencing a slightly different melt timing and evolution, and each following its own timing. Work at Arctic sites typically means field work in remote locations with sparse ancillary data and this provides added challenges.

Spring melt is characterized by an ionic pulse of solutes, dissolved organic carbon and other nutrients (ammonium, phosphate and nitrate) leached by snow melt water from the surface organic mat of vegetation and near-surface soil. Summer and fall flows are comprised largely of shallow flow from a deepening seasonally thawed ("active") layer. During late summer with an expanded active layer or at sites where permafrost is degrading these processes may be associated with an increasing mineral weathering signal into watersheds. The watershed biogeochemical response to precipitation in continuous and discontinuous terrains may also yield insight into subsurface permafrost geomorphological characteristics. Winter processes are the least studied or understood but overflow ice ("aufeis") provides access to deep, old waters.

This presentation will focus on using water stable isotopes, major ion concentrations, and permafrost delineation to identify biogeochemical sources in watersheds draining continuous and discontinuous permafrost. Field sites represent permafrost terrains in Alaska from the North Slope to the Interior. Biogeochemical processes associated with scaling, meteorology, and climate warming will be discussed.

Accretion and differentiation processes in the ureilite parent body

H DOWNES[1,2,3], C L SMITH[2], F A J ABERNETHY[4], J S HERRIN[5] AND A J ROSS[2,3]

[1]Dept of Earth and Planetary Sciences, Birkbeck University of London, UK. E-mail:(h.downes@ucl.ac.uk)
[2]Natural History Museum, London UK.
[3] Centre for Planetary Sciences, UCL, London UK
[4] Physical Sciences, Open University, Milton Keynes UK
[5]Nanyang Technological University, Singapore.

Ureilite are carbon-rich meteorites which provide a wealth of information about early Solar System processes. The ureilite parent body (UPB) accreted from a carbon-rich precursor, but our new step-combustion $\delta^{13}C$ and $\delta^{15}N$ values for pristine ureilite samples strongly support the suggestion [1] that this precursor was not a known type of carbon-rich chondrite. A strong correlation between Fo in olivine and $\delta^{18}O$ is interpreted to result from heterogeneous accretionary mixing between two nebula-derived end-member compositions.

Heat derived from decay of short-lived radioactive isotopes caused the UPB to heat up and to differentiate into an metallic partial melt and silicate mantle. Little evidence of the metallic partial melt remains, other than frozen Fe-Ni metal droplets in some ureilites [2]. These metal droplets often contain Si, indicating extremely reducing conditions [3]. Depletion in Ge, As, Au, Pd, Ni, and enrichment in Ir, Os, Re [4], suggest that these metals may be restites from core formation.

LREE-depletion of the residual silicate mantle, together with silicate melt droplets, melt inclusions, and pyroxene-rich mantle lithologies, suggests that the UPB mantle underwent partial melting to form basaltic magmas. However, the UPB did not heat up sufficiently to reach a magma ocean stage and hence did not homogenize in terms of its mg# and $\delta^{18}O$ [5].

While it was undergoing heating and partial melting, the UPB was disrupted by a major impact. Graphite was transformed to diamond by this event [6]. Following this disruption, a single daughter rubble-pile asteroid formed by reaccretion [7]. This body is sampled by present-day ureilites, providing a fossilised example of early asteroidal accretion and differentiation processes.

Iron and manganese reduction and associated phosphorus release in coastal Baltic Sea sediment

KENNETH DOWNS* AND VOLKER BRÜCHERT

Department of Geological Sciences, Stockholm University, 10691 Stockholm, Sweden
*(correspondence: kenneth.downs@gmail.com)

The long-term release of phosphorus from sediments is considered the central problem for eutrophication of the Baltic Sea. In this study the sedimentary pools and long-term release rates of sediment-bound phosphorus were assessed in relation to iron and manganese reduction rates in the topmost 8 cm of coastal Baltic Sea sediment. We report porewater and solid-phase data of dissolved iron, manganese, inorganic and organic phosphorus from sediment from a near-shore station on the Eastern Swedish coast of the central Baltic with oxygenated bottom water. Rates of iron and manganese reduction were determined from porewater gradients and from anaerobic bag incubations at in-situ temperatures. Anaerobic bag incubation experiments were conducted over 33 days to quantify the changes in pool size of reactive Fe and Mn and phosphorus (ascorbic acid-extractable, citric-acid dithionite extractable, and oxalate-extractable) fractions.

The data indicate high initial rates of iron reduction in the topmost 5 cm, which decreased substantially after 18 days. Manganese reduction rates were insignificant below 1 cm depth. Rates of iron reduction were highest between 1 and 2 cm depth and decreased sixfold to 5 cm depth. Ascorbic acid extractable iron comprised about 50% of the total reactive iron in the topmost cm of sediment and decreased linearly over time. There was a pronounced lag effect of 8 days between the disappearance of reactive iron compounds and the increase in free dissolved iron and phosphorus in the topmost cm of sediment suggesting an intermediate accumulation of an iron-phosphorus complex that was not accessible to the extractions and spectrophotometric analytical methods employed here. Possibly phosphorus accumulated as an iron polyphosphate complex that was subsequently broken down under more reducing conditions. Operationally defined dissolved organic phosphorus (DOP) comprised 50% of the total dissolved phosphorus in the topmost cm of sediment. The initial rates of DOP and DIP release were equal in the topmost two centimeters, but DOP accumulation was significantly slower below 3 cm depth consistent with lower overall carbon degradation rates at depth. These data provide new quantitative constraints on the pool size and rates of phosphorus release from sediments and will improve our predictions of long-term eutrophication effects in the Baltic Sea.

Tracing episodic microbial oxidation of biogenic methane deep in fractured granite using $\delta^{13}C_{calcite}$

H. DRAKE[1]*, C. HEIM[2], M. ÅSTRÖM[1] AND M. WHITEHOUSE[3]

[1]Department of Biology & Environmental Science, Linnaeus University, 39182 Kalmar, Sweden. (*correspondence: henrik.drake@lnu.se, mats.astrom@lnu.se)
[2]Geoscience Centre Göttingen, Georg-August Univ., 37077 Göttingen, Germany. (cheim@gwdg.de)
[3]Laboratory for Isotope Geology, Swedish Museum of Natural History, 10405 Stockholm, Sweden, (martin.whitehouse@nrm.se)

Fossil and active microbial oxidation of methane (AOM) has been described from many settings worldwide, e.g. at cold seeps, and can be traced by extremely depleted $\delta^{13}C$, e.g. of authigenic carbonates (generally -65 to -45‰ [1]). We here show signs of AOM in a substantially less studied environment - deep in fractured granitoids within a shield area (Laxemar, Sweden). Here, the methane gas concentration is currently low, but nevertheless, microbial AOM is evidenced by the most $\delta^{13}C$-depleted calcites ever reported (to our knowledge); down to -125‰ V-PDB (SIMS data). These $\delta^{13}C$ values rule out any other source than biogenic methane. The preferential depth of AOM (-350 to -650 m, cf. [2]) marks the shift from the microbial DOC consumption in the groundwater at shallower depths to methanotrophic at greater depth where DOC is depleted. Marine $\delta^{18}O_{calcite}$ values show that AOM was initiated by intrusion of SO_4^{2-}-rich marine waters causing sulphate reducing bacteria (SRB) to outcompete prevailing methanogens for H_2, and instead methane oxidisers formed concortia with SRB, as shown by SRB-specific biomarkers trapped within the calcites (GC-MS and ToF-SIMS evidence). Low contents of dissolved carbon prevented dilution of $\delta^{13}C_{calcite}$ by other C sources than AOM, explaining why $\delta^{13}C_{calcite}$ is much lower than in other AOM-settings where $\delta^{13}C_{calcite} >> \delta^{13}C_{methane}$ [1]. The extremely large intra-crystal $\delta^{13}C$-variation (up to 109‰) and related $\delta^{18}O$-variation show that AOM was episodic and e.g. succeeded by intrusion of sulphate-poor glacial water ending the AOM activity. The discovered deep AOM-zone must therefore be fossil, i.e. $\delta^{18}O$ and $\delta^{13}C$ of the calcites and modern groundwater are uncorrelated, and instead related to a pre-Holocene transgression of marine waters.

O and Hf isotopic evidence in zircons for crustal recycling in caldera complexes and rifts, Picabo volcanic field, Yellowstone hotspot track

D. DREW[1], I. BINDEMAN[1], K. WATTS[2], A. K. SCHMITT[3], B. FU[4] AND M. MCCURRY[5]

[1]Dept. of Geological Sciences, University of Oregon, Eugene, USA (*correspondence: dld@uoregon.edu)
[2]U.S. Geological Survey, Menlo Park, CA, USA
[3]Dept. of ESS, UCLA, Los Angeles, CA, USA
[4]RSES, Australian National University, Canberra, Australia
[5]Dept. of Geosc., Idaho State University, Pocatello ID, USA

We report oxygen isotope diversity in zircons of large volume rhyolites of the Picabo volcanic field (10.4-6.6Ma) of the Snake River Plain (SRP), highlighting the generation, by shallow remelting, and rapid assembly of diverse magma batches prior to caldera forming eruptions. *In situ* measurements of ε_{Hf} and $\delta^{18}O$ coupled with U-Pb geochronology and whole rock Sr and Nd isotopes elucidate the processes by which large volumes of rhyolite are produced, starting with large-scale (up to ~40-60%) melting of Archean crust followed by plume driven remelting of volcanics in rift zones and caldera complexes. Similar to Heise and Yellowstone, the Picabo volcanic field produced a series of voluminous rhyolites that become progressively lower in magmatic $\delta^{18}O$ (from 7.9 to 3.3‰) and demonstrate increasing zircon $\delta^{18}O$ diversity through time (from <1‰ in early eruptions to >5‰ in late-stage). In contrast, zircon ε_{Hf} remains relatively homogeneous within units, with average ε_{Hf} ranging from -28 to -5.3 (with rare $\varepsilon_{Hf}(0)$=-47 zircons reflecting pure Archean crustal melts). The temporal trend in $\delta^{18}O$ emphasizes the importance of remelting hydrothermally altered intracaldera rhyolites during caldera burial. However, the early appearance and overabundance of low $\delta^{18}O$ rhyolites suggests that hydrothermal preconditioning of the crust was facilitated by Basin and Range extension and metamorphic core complex formation. The preservation of diverse isotopic signatures in zircon, corroborates the importance of rapid batch assembly and eruption of heterogeneous melts with diverse crystal cargoes. Our interpretations highlight the mechanism by which large volume rhyolites are generated, processes applicable to producing rhyolites worldwide that are facilitated by plume driven volcanism in an extensional tectonic regime. Our newly discovered low-$\delta^{18}O$ rhyolites contribute to the growing database of greater than 10,000 km^3 of low and diverse $\delta^{18}O$ rhyolites of the SRP, advancing our understanding of the 16 million year history of silicic volcanism.

Characterization of ternary surface complexes of lead chloride on hematite in dependence of temperature and salinity – experimental versus modeled data

DEJENE LEGESSE DRIBA[1], SIMONA REGENSPURG[1], MARCO DE LUCIA [2] AND STEFAN PEIFFER[2]

[1]GFZ German Research Centre for Geosciences, International Centre for Geothermal Research, Potsdam, Germany, dejene@gfz-potsdam.de, regens@gfz-potsdam.de
[2]GFZ German Research Centre for Geosciences, Section 5.3, Hydrogeology, Potsdam, Germany marco.delucia@gfz-potsdam.de
[2]Department of Hydrology, University of Bayreuth, Bayreuth, Germany S.Peiffer@uni-bayreuth.de

Adsorption of aqueous metal cations onto mineral surfaces can affect metal speciation and mobility in a range of geologic systems. In order to accurately model metal speciation and transport on iron-oxides, the effect of pH, temperature and ionic strength on its adsorption property and stability constants must be determined. The surface complex modeling approach CD-MUSIC (chargedistribution multi-site complexation) requires the definition of many parameters including equilibrium constants for protonation and deprotonation, metal sorption and back ground electrolyte sorption reactions etc. However, the lack of many of those parameter particularly for Pb adsorption onto hematite surface requires the implementation of experimentally determined data.
In this study, Pb+2 adsorption experiments were performed in hematite bearing NaCl solutions as a function of pH value (3-9), ionic strength (0.5M and 5M) and temperature (25-150 °C). The required surface complex parameters (SCP) were derived through an iterative procedure of fitting the experimental data-set with simulation results by implementing the geochemical speciation code PhreeqC coupled with the non-linear optimization program UCODE_2005. Model results reveal that the simulation represents well the experimental conditions and reflects the dependency of Pb adsorption on different experimental parameters. In addition, it was found that lead-chloride ternary complex adsorption configuration provides a good fit to all Pb+2 adsorption data. Accordingly, the derived SCP data set will furnish for the development of a thermodynamically consistent surface complex database to estimate lead sorption in a geological environment of high temperatures and salinities.

The influence of flow field heterogeneity on the observed $\delta^{53}Cr$ fractionation factor during abiotic chromate reduction

J.L. DRUHAN[1]*, K. MAHER[1], K.L. WEAVER[1] AND C.N. MCCLAIN[1]

[1]Department of Geological and Environmental Sciences, Stanford University, Stanford, CA, 94305 (*correspondence: jdruhan@stanford.edu)

Hydrogeochemical processes governing groundwater quantity and quality are often inferred from fluid samples that are the flux-weighted average of a heterogeneous system. The stable isotope ratios of these samples are commonly interpreted through simplified fractionation relationships that inherently assume a homogeneous chemical composition and fluid residence time. Here, we present application of an isotope-specific rate expression for chromate reduction in the CrunchFlow reactive transport code to simulate the steady state distribution of $\delta^{53}Cr$ across multiple realizations of a spatially correlated heterogeneous flow field (Figure). Our results demonstrate that a flux-weighted average value collected across the mean flow gradient yields a variable observed fractionation factor despite a fixed ratio of kinetic rate constants for the isotopologues of chromate. This variability is thus directly attributable to the physical heterogeneity of the porous media. We demonstrate that for a specified correlation function and characteristic length scale of the permeability structure, the observed fractionation factor is predictably linked to the fluid residence time distribution. These simulations serve as the basis for a series of flow-through column experiments using simplified heterogeneity to demonstrate variability in observed fractionation factors.

The adsorptive behaviour of Am and Tc on Fe-bearing minerals

R.DRUTEIKIENĖ*, B.LUKŠIENĖ, V.REMEIKIS, J.ŠAPOLAITĖ AND R.GVOZDAITĖ

Center for Physical Sciences and Technology, Savanorių av. 231, LT-02300 Vilnius, Lithuania
(*correspondence: ruta@ar.fi.lt)

Understanding the migration behaviour of radioactive elements in geological environments is essential for the long-term safety assessment of nuclear waste repositories and in nuclear waste management. The potential of migration of radionuclide at contaminated sites and also from the waste repository depends on their environmental behaviour. In this work, we focuse on the investigation of the behaviour of redox sensitive radionuclides in the heterogeneous system containing well-defined amounts of Fe-bearing minerals under aerobic conditions.

To evaluate sorption of Am(III), as Pu(III) analogue, by geosorbents under aerobic conditions, the batch laboratory method and laboratory column method were carried out. ^{243}Am sorption to geosorbents from aqueous solution was determined being pH-dependent. ^{243}Am sorption onto wustite/magnetite showed negative linear relationship within pH values (pH 2.15; pH 4.00; pH 6.95; pH 9.01), while the adsorption of ^{243}Am ions onto hematite increased with increasing pH values (correlation coefficient R=0.83, R=0.92, R=0.90, respectively).

The tests of TcO^{-4} sorption onto iron oxides were performed under ambient conditions. The investigation of Tc sorption onto hematite under the acidic (pH 3-5) and neutral (pH 6-7) conditions suggested that pH of solution had a very slight influence on the technetium sorption Gradual sorption of technetium, added as TcO_4^-, in aquatic solution onto FeO/Fe_3O_4 mineral under aerobic conditions was observed. The sorption of Tc onto wustite under the acidic (pH 3,6 and 5,6) conditions was rapid - after the first 48 hours <1 % of Tc were left in solution.

Mineral hematite at neutral or slightly alkaline pH under aerobic conditions is devoted to minerals which do not sorb Tc (VII). The presence of biogenic Fe(II) as mineral wustite/magnetite can affect the removal of Tc(VII) from the aqueous solution (pH of 8-9). Results of our experiment with Tc(VII) and wustite/magnetite varies from the general assumption stating that under oxidizing conditions TcO_4^- is stable and consequently mobile [1].

Several small lakes occupy a number of levels in the Galleria delle Stalattiti of Corchia Cave, Italy. An important feature of two such lakes is the presence of actively growing, subaqueous calcite mounds. Drill cores from these mounds have been the subject of investigations for several years. ^{234}U-^{238}U ages from the base of these cores, combined with stable isotope data from U-Pb-dated stalagmites collected metres away, suggest that some of the mounds have been growing since ~1 Ma. To provide baseline data for interpreting the geochemical variations of these cores, we commenced a study of modern lake-water chemistry, including stable isotopes of H, C and O, trace elements and organic matter content. Besides demonstrating the exceptionally stable state of these lake systems, the combining of core-top geochemistry with source-water chemistry allows us to explore water-calcite isotope and trace element partitioning, and to evaluate the suitability of this unusual speleothem-forming environment for clumped-isotope palaeothermometry. Preliminary results will be presented in this poster.

The heat relaxation *P-T-t* path of HP-UHP eclogites from Chinese southwestern Tianshan: constraints from *P-T* pseudo- sections, Lu-Hf and Sm-Nd isochron dating

DU JINXUE, ZHANG LIFEI*, SHEN XIAOJIE AND THOMAS BADER

Key Laboratory of Orogenic Belts and Crustal Evolution, Ministry of Education, School of Earth and Space Sciences, Peking University, Beijing 100871, China (*corresponding author: Lfzhang@pku.edu.cn)

Abstract: The southwestern Tianshan orogenic belt is one of the rare preserved ultrahigh pressure metamorphic belts formed by oceanic subduction in the world. However, its *P-T-t* path is poor constrained. In this study, four representative eclogite samples, i.e., three paragonite-epidote eclogites (Sample 211-3, H505-26 and H76-10) and one glaucophane-phengite eclogite (Sample H711-1), are selected for combined study of Lu-Hf and Sm-Nd geochronology as well as a detailed phase equilibria modeling. Porphyroblastic garnet in these four samples shows well-preserved growth zoning with the content of pyrope increasing and that of spessartine decreasing from core to rim. Phase equilibria modeling indicates that garnet in eclogites from Chinese southwestern Tianshan grew in the lawsonite-bearing eclogite facies during heating accompanied by either compression (e.g. H505-26) or decompression (e.g. 211-3, H76-10 and H711-1). Estimated peak pressures of 24-29kbar with a coesite pseudomorphs suggest that some eclogites underwent UHP metamorphism (e.g. 211-3). Peak temperatures of 490-560°C are below the closure temperature of the Lu-Hf and Sm-Nd systems. The garnet-omphacite-whole rock Lu-Hf and Sm-Nd isochron ages, therefore, are interpreted to reflect garnet growth, i.e., HP-UHP eclogite facies metamorphism. Sample 211-3 yields a Lu-Hf isochron age of 326.9±1.3Ma which represents the first reported Lu-Hf age for UHP metamorphism in Chinese southwestern Tianshan. Another valid Lu-Hf age of 306±11Ma for Sample H76-10 and three consistent Sm-Nd isochron ages of 309±4.6Ma, 306±15Ma and 305±11Ma for Samples H505-26, H76-10 and H711-1 are obtained, reflecting high pressure eclogite facies metamorphism. Based on these new ages, a clockwise *P-T-t* path with heating during exhumation is obtained for HP-UHP eclogites from Chinese southwestern Tianshan, in conjunction with detailed phase equilibrium studies and previous geochronological data. This heat relaxation P-T-t path of HP-UHP eclogites indicates the slow exhumation and long journey for the heavy oceanic HP-UHP eclogite. We propose that subduction of the paleo-South Tianshan ocean began before 346Ma, blueschist-eclogite facies prograde metamorphism of subducting oceanic crust occurred at 346-333Ma, peak eclogite facies metamorphism occurred at 327-305Ma, and buoyancy-driven exhumation of subducted oceanic crust occurred at 296-226Ma.

The δ ^{18}O signals of precipitation and drip water:Two hydrological years' monitoring results from eight caves in monsoon regions of China

W.H. DUAN[1],J.Y.RUAN[2,6] P.Z.ZHANG[3],W.J. LUO[4], D.Z.ZHANG[3],T.Y.LI[5],L.J.TIAN[1],T.TAO[1],G.N.ZENG[4] AND M.TAN[1*]

[4]State Key Laboratory of Environmental Geochemistry,IGCAS, Guiyang 550002
[5]School of Geographical Sciences, Southwest Univ,China,
[6]Lab des Sciences du Climat et de l'Environnement,France.

To better interpret the $\delta^{18}O$ proxy of Chinese speleothems, a joint monitoring program has been carried out at eight cave sites in monsoon regions of China (fig1) since 2011.
Here we outline preliminary conclusions as follows:

1. At any monitoring cave sites, precipitation $\delta^{18}O$ does not show significant amount/temperature effect at seasonal or inter-annual scale.

2. At five of six cave sites in South China, the mean annual precipitation $\delta^{18}O$ is heavier in 2012 than in 2011, which is consistent with that the short-distance source water vapor from West Pacific Ocean to China is larger in 2012 than in 2011[1]. But specially, at Xianren cave site, the $\delta^{18}O$ behaves oppositely versus other five sites, most likely because the West Pacific Ocean is a long-distance water source for this westerly farther location. While at Shihua cave and Wanxiang cave in North China, the mean annual precipitation $\delta^{18}O$ is roughly equal in the two years. Therefore, under inter-annual variation, the monitoring results from the southern caves supports the idea on the "circulation effect" of precipitation $\delta^{18}O$ [2], while, from the northern caves, they are ambiguous.

3. At most of the monitoring sites, the depleted summer precipitation $\delta^{18}O$ signals are greatly smoothed when waters filter into caves. Accordingly, vadose zone plays a significant role in modifying the $\delta^{18}O$ signals of drip waters[3].

Trace element analysis of iron meteorites by ICP-MS

XIAOXIA DUAN[1,2] AND MARCEL REGELOUS[1]

[1] GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Schlossgarten 5, 91054 Erlangen, Germany (correspondence : duan861168@163.com)
[2] Institute of Geology and Geophysics, CAS, Beijing, China

Trace element measurements of iron meteorites provide important information on the processes of formation and crystallisation of asteroid cores, and forms the basis of the classification scheme whereby the number of iron meteorite parent bodies can be determined. Most existing trace element data for iron meteorites were carried out using instrumental or radiochemical neutron activation. These methods allow measurement of 10-15 trace elements in iron meteorites, but are time-consuming and expensive. Recently, attempts have been made to measure trace element concentrations in iron meteorites using inductively coupled plasma mass spectrometry [1-3]. Advantages of ICP-MS analysis include low detection limits for most elements, simple sample preparation and short analysis times. A disadvantage of quadrupole ICP-MS analysis is that molecular interferences, especially those involving Fe which makes up ~90% by weight of most iron meteorites, prevent accurate analysis of several important elements, in particular Ge.

We developed methods to remove Fe from sample solutions using ion exchange, and use a desolvating nebuliser sample introduction system to reduce other solution-based interferences. Samples are dissolved in 8M HNO_3 and loaded directly onto Eichrom TRU-spec resin. ^{56}Fe can be reduced by 2-3 orders of magnitude, with close to 100% recovery of most other elements, excepting Nb, Ta, Th, U, Ti, which are retained on the resin. Measurements are carried out using a Thermo X-Series2 quadrupole ICP-MS equipped with a collision cell and Aridus desolvating introduction system.

Our new method allows rapid, accurate measurement of not only the highly siderophile trace elements (including Os if solutions are not heated) and transition metals, but also many non-siderophile elements. These are not routinely measured in iron meteorites because of their very low abundance, but could nevertheless provide important new insights into the oxygen fugacity at the time of accretion and the original size of iron meteorite parent bodies.

Research on carbon isotopic evolution of pyrolysis methane and its dynamics

YI DUAN

Key Laboratory of Petroleum Resources Research, Institute of Geology and Geophysics, Chinese Academy of Sciences, Lanzhou, Gansu, China, duany@lzb.ac.cn.

In order to understand the genesis of coalbed methane (CBM) as a new energy, closed-system pyrolysis experiments were performed on coals with different maceral compositions and maturities and a peat representing original coal-forming material at different heating rates, and the carbon isotopic evolution of pyrolysis methane and the carbon isotopic dynamic characteristics of CBM from Qinshui Basin were studied. It was found that the carbon isotopic compositions and evolutional history of pyrolysis methane were closely relevant to many factors, such as the properties and coalification levels of coal, initial evolution level of source rocks and heating rate and so on. The correlation between the carbon isotopic compositions of pyrolysis methane and lg(Ro) was suggested. At the same time, the carbon isotopic evolutional history of methane from the Upper Paleozoic coal seam in Qinshui Basin and and its coalbed methane genesis were determined. The results show that the CBM formed by coal with low initial evolution level and high exinite content and under conditions of high heating rate has relatively light carbon isotopic composition. The carbon isotopic compositions of pyrolysis methane from the studied samples at different heating rates were positively correlated with lg(Ro). The carbon isotopic evolution history of methane generated from the Upper Paleozoic coal in Qinshui basin was that $\delta^{13}C$ values of pyrolysis methane from Taiyuan and Shanxi Formation coals and peat in Yangcheng region have a tendency to becoming heaver with burial history, reached to the heaviest at K1 end, and then did not change. The comparative study of the carbon isotopic dynamics of pyrolysis methane showed that peat has lighter isotopic composition than coals. The carbon isotopic composition comparison of CBM from Permian system in Yangcheng region of Qinshui basin with that obtained by this experiments indicated that the carbon isotopic compositions in Yangcheng region is similar to those of CBM evolved from early Cretaceous to now, reflecting that the CBM in Yangcheng region has the feature of staged gas accumulation. Therefore, the carbon isotopic dynamics of methane is an effective method for studying CBM genesis.

Rare Earth Elements in biogenic silica of giant diatoms Ethmodiscus rex

A.V.DUBININ* AND E.D.BEREZHNAYA

PP Shirshov Institute of Oceanology RAS, 117997 Moscow, Russia, (*correspondence: dubinin@ocean.ru)

Biogenic silica plays an important role in rare earth element cycle in the ocean. Trivalent REE distribution in ocean water is very similar to that of dissolved silica. REE content in the biogenic silica currently remains unknown. The earlier data on the REE composition [1] for diatoms *Ethmodiscus rex* from the Indian Ocean sediments were obtained without chemical pretreatment. Thus the purpose of the present work is to consider REE concentrations in the frustules of diatoms. Diatom oozes (Sta. 1537, 19º05.5'S, 24º02.9' W, depth 5000 m) were disaggregated in distilled water to remove sea salts. Fragments of diatom (size fraction >100 μm) were isolated from slurry of oozes by sieving and washing through the polyamide net.

Chemical cleaning of the diatom shells included 4 stages. 1. Dissolving in solution 0.6M $NH_2OH{\times}HCl$ + 1M HCl to remove coatings and micronodules. 2. Filtration through filter Millipore 0.45 μm, washing with 1M HCl and Milli-Q water. 3. Treatment with 6.3M HCl, then solution was diluted with deionized water and after heating was agitated in an ultrasonic bath. 4. Filtering is similar to stage 2. Then samples were dried to a constant weight.

REE were determined by ICP-MS in 2% HNO_3 solution with internal standards In and Re after digestion of biogenic silica in a mixture of HF and HNO_3 (ultrapure grade Fluka) in PTFE beakers. The ratio of background/signal was less than 2% for Sm, Eu, Gd and Tb, for the other REE it was less than 1%.

REE pattern in diatom shells is similar to the composition of the dissolved REE in the ocean water. The surprise is the absence of the anomalous behavior of cerium. REE content in diatom shells is lower an order of magnitude than in the carbonate lattice of foraminifera [2]. The absence of cerium anomaly may be the result of the shell formation in oxygen minimum zone in the ocean water during diatom bloom in the glacial period.

Effect of anharmonic lattice vibrations on the reaction rates in minerals

V.I. DUBINKO [1*] AND J. F. R. ARCHILLA[2]

[1] NSC Kharkov Institute of Physics and Technology, Kharkov 61108, Ukraine (*correspondence: vdubinko@mail.ru)

[2] Seville University, E-41011, Seville, Spain (archilla@us.es)

Chemical reaction rates in minerals are shown to be accelerated by large amplitude lattice vibrations (a.k.a. intrinsic localized modes (ILM's) or discrete breathers (DB's)) that can appear in crystals with sufficient anharmonicity. As a result, Arrhenius law is violated, and the reaction rate averaged over large macroscopic volumes and times including many DB's is increased by a factor that depends on the DB statistics. The breather statistics in thermal equilibrium is considered, and the corresponding reaction rate amplification factor is derived.

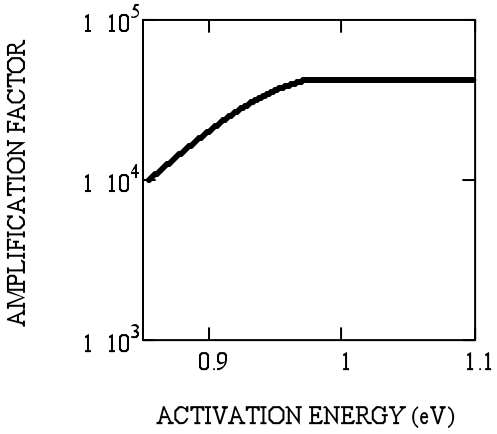

Figure 1. Amplification factor dependence on the reaction activation energy.

The model is shown to explain anomalous low-temperature reconstructive transformations in layered silicates [1] and the brittle to ductile fracture transition in α-uranium at elevated temperatures [2].

Fate of Ni in local reduced environments developed on lateritic Ni ores from New Caledonia

In New Caledonia, the weathering of ultramafic rocks in a tropical climate produced extremely thick laterites (≤ 80m), particularly enriched in metals such as Ni. The main weathering pathway involved the formation of large amounts of goethite (α-FeOOH), and X ray absorption spectroscopy (XAS) showed that the major proportion of Ni is incorporated into the structure of this Fe(III)-oxyhydroxide [1].

However, as previously reported in New Caledonia, reducing conditions can occur locally in the lateritic formations, due to the development of dolines and the accumulation of organic matter [2]. Samples from a lateritic profile characterized by X ray diffraction and ICP-AES showed the occurrence of siderite ($FeCO_3$) in a 4 meters thick horizon, suggesting the local reduction of Fe(III)-oxides into Fe(II)-carbonate. SEM-EDS analysis indicates significant amounts of Ni associated with siderite (~ 0.80 wt% NiO).

The speciation of Ni in this weathering context was then investigated by XAS in the solid phase, at the scale of the whole profile, and by comparison with synthetic analogues. XAS showed that Ni is mainly incorporated into the siderite structure in the reduced horizon, and is in goethite in the unreduced laterite above. This result helps understanding the trace metals behavior in altered lateritic weathering contexts, and shows the importance of local Ni trapping in reduced iron phases.

Long-time alteration of iron slags inferred from paleometallurgical heaps

M. DUBOIS AND A. GAUTHIER[1]

[1]LGCgE, Lille 1 University, SN5 Building, 59655 Villeneuve d'Ascq, FRANCE. Michel.dubois@univ-lille1.fr

Moulière is a large forest (area of 6800 ha) and is located on a plateau between the valleys of the Vienne and the Clain rivers (Vienne, France). Exploration by Abbé de la Croix in the nineteenth century and the work of the ONF (Office National des Forêts) have revealed the presence of numerous slag heaps. These heap associated with the iron metallurgy fall into several areas of the forest sector and outside. They are identifiable on the ground because they form mounds 0.5 to 2 m high and they are usually invaded by typical vegetation (holly - *Ruscus aculeatus* - and hawthorn). The age of these mounds is not known, but more than 10 ironworks were in operation at the time of the reformation of forests by Colbert in 1667. The establishment of the ironworks in the Forest of Moulière is related to the facility offered for logging to operate low blast furnaces. The iron ore is probably also of local origin. Whereas no significant outcrop has been actually observed, an iron-bearing sandy layer is discontinuously present in the forest underground.

A study of the mineralogical and chemical slags was carried out by optical microscopy, scanning electron microscopy (SEM) and Raman microspectroscopy in order to make a characterization, in particular for the presence of an alteration layer. Indeed, the slag storage sites offer the opportunity to study the long-term behavior of vitrified materials subjected to weathering periods of time (several centuries) well above the experimental approach.

High density slags present various dimensions from centimetric to decimetric blocks, rounded surface, sometimes within a matrix strongly the existence vacuole. They are black or red-orange. The samples exhibit a mineralogy consisting mainly of silicates (olivine (Fe_2SiO_4), quartz, feldspar) and oxides (hematite (Fe_2O_3), titanium oxide) in the periphery of the vacuoles or in forming droplets. This great disparity of mineralogical and chemical composition conditions the chemical durability of this material. Experimental studies are conducted to study the behavior of such slags.

Mantle-drip magmatism beneath the Altiplano-Puna plateau, central Andes

MIHAI N DUCEA[12]

[1]Universitatea Bucuresti, Facultatea de Geologie-Geofizica, Bucuresti, Romania
[2]University of Arizona, Department of Geosciences, Tucson, Arizona 85721, USA

Convective removal of continental lithospheric roots has been postulated to be the primary mechanism of recycling lithospheric mass into the asthenosphere under large plateaux such as the Altiplano-Puna. Convective instabilities are especially likely to develop where there is extensive intermediate arc-like magmatism in the upper plate, as the residual masses complementing these magmatic products are typically denser than the underlying mantle. Mafic volcanic rocks erupted on the central Andean Altiplano-Puna plateau during the past 25 My contain evidence of this process. Here we use equilibration temperatures, age data and geochemical constraints—primarily based on transition metals—to show that the most important source materials by mass for this mantle-derived magmatism are pyroxenites from the lower parts of the lithosphere, with only minor contributions from mantle peridotite. Pyroxenites are denser than typical upper mantle whether they are garnet bearing or not, and are therefore likely to contribute to destabilizing parts of the continental lithosphere. The pattern of melting is consistent with the process of foundering/dripping of small-scale (<50 km diameter) density anomalies in the lithosphere, where mafic volcanic fields on the plateau represent the manifestations of individual drips.

Reactivity and chemical reduction of iron oxides nanoparticles in highly alkaline medium

A. DUCHATEAU*, C. CHANEAC, J.P. JOLIVET

*anneduchateau0@gmail.com
Laboratoire de chimie de la matière condensée de Paris Collège de France, UPMC Univ. Paris 6, CNRS, 11 Place Marcelin Berthelot 75005 Paris, France

Iron oxides play an important role in steel industry as precursors of iron. This industry is responsible for 7% of the world CO_2 rejections. Reducing the iron oxides by electrolysis in strongly alkaline medium (18 M) at 110°C is a promising way to lower the CO_2 rejections while improving steel production efficiency, that has been studied for years [1][2]. Obviously, studying the reactivity of iron oxides in this very particular medium and understanding the reduction mechanism is a key study for the process optimization. The experiments are carried out on iron oxides nanoparticles (hematite, goethite, lepidocrocite, akaganeite, magnetite) synthesized according to well known methods in order to have the most accurate comprehension of the phenomenon.

In almost all cases, the ageing of iron oxides nanoparticles in hot concentrated sodium hydroxide solution led to the formation of sodium ferrite $NaFeO_2$, as it was observed by Picard [2]. This phase transformation takes place according to a dissolution crystallization process whose duration is controlled by thermodynamics and depends on the starting iron oxide.

In a second step, we induced the reduction by using hydrazine as a chemical reductive agent in hot concentrated sodium hydroxide solution. At first a competition between reduction of the iron oxide and sodium ferrite precipitation is observed. Then the reduction takes place according to a two-step via solution mechanism: reduction of the starting iron oxide into magnetite, reduction of magnetite into iron.

Investigation of Archean mantle plume components from 2.7 Ga komatiites (Abitibi, Canada)

C. DUCHEMIN[1*], N. MATTIELLI[1], V. DEBAILLE[1], N. ARNDT[2] AND C. CHAUVEL[2].

[1]G-Time, Université Libre de Bruxelles, 1050 Brussels, Belgium. ([*]Claire.duchemin@ulb.ac.be).
[2]ISTerre, BP 53, 38041 Grenoble Cedex 9, France.

Komatiitic flows in Munro Township, Abitibi greenstone belt, are of two types: Al-depleted (ADK), which has low Al/Ti, and Al-undepleted (AUK) komatiites, with chondritic Al/Ti. The different geochemical types reflect source components and melting processes at 2.7 Ga.

We present new data for three thick differenciated lava flows: Fred's Flow and Pyke Hill are AUK with moderate depletion to strong REE depletion $(Ce/Yb)_N$=0.64 and 0.34 respectively. Theo's Flow is an Al-depleted Mg-Fe rich tholeiite with HREE depletion $(Gd/Yb)_N$>1.35) and flat LREE.

REE patterns of these flows reflect their initial geochemical signatures, and indicate differences in sources, and/or depths and degrees of partial melting probably in mantle plumes. To characterize the mantle source components, we modeled their major and trace elements. On the basis of the most primitive cumulus olivine crystals, the minimum eruption temperatures (°C) have been estimated according to calculations of [1]. Forsterite contents of olivine are 89.8% in Fred's Flow, 93.9% in the Pyke Hill flow and 84-86% in Theo's Flow and correspond to 1420±43°C, 1516±45°C and 1325±40°C, respectively. Parental magma compositions (CaO/Al_2O_3≈1) of Fred's Flow and Pyke Hill correspond to partial melts of a fertile mantle peridotite, whereas CaO/Al_2O_3≈1.5 of Theo's Flow suggests a higher pyroxene/garnet ratio in the source, as in pyroxene-rich peridotite [2].

External Pb-Pb isochrons have been obtained for Theo's Flow and Fred's Flow to better understand the evolution of source heterogeneities with time. The ages obtained for Theo's Flow and Fred's Flow are 2686±94My and 2604±102My respectively. Hf and Nd isotopes will be further investigated to propose initial isotopic signatures of the source of komatiites formed in Archean mantle plumes 2.7 Ga ago.

Compositional gaps and melt segregation in magmatic systems: A multiphase dynamics approach

JOSEF DUFEK[1] AND OLIVIER BACHMANN[2]

[1]School of Earth and Atmospheric Science, Georgia Institute of Technology
[2]Department of Earth Sciences, ETH

Compositional diversity in evolving magmatic systems is driven in large part by the multiphase dynamics of melt-crystal separation. Key to quantitative description of these systems is to accurately calculate the rate and timing of crystal-melt separation. This calculation requires accurately computing three separate, but closely linked, problems: heat transfer, phase equilibria, and multiphase dynamics, all of which can play an important role in determining the compositional and melt fraction histories of magmatic bodies. We have developed a multiphase approach to compute extraction in magmatic systems (Dufek and Bachmann, 2010) combined with an enthalpy closure from a callable library based on MELTS (Ghiorso and Sack, 1995). In this dynamics model separate phases are

We use this model to demonstrate dynamics on several different scales: We use this new model to demonstrate dynamics on several different scales: 1. Melt segregation and crystal-melt dynamics in small and moderate scale magmatic systems (using examples from Cotopaxi and the Fish Canyon Tuff), and 2. Thermal evolution on the crustal scale influenced by tectonic forcing, including shortening and extension. In all cases we explore the rate and location of fractionating phases, and the driving mechanisms for fractionation.

We have particularly applied this model to examine the production of compositional (Daly) gaps in a number of tectonic settings. Compositional gaps are common in volcanic series worldwide. The pervasive generation of compositional gaps influences the mechanical and thermal properties of the crust. We show that gaps are inherent to crystal fractionation for all compositions, as crystal-liquid separation takes place most efficiently within a crystallinity window of ~50–70 vol% crystals. The probability of melt extraction from a crystal residue in a cooling magma chamber is highest in this crystallinity window due to (1) enhanced melt segregation in the absence of chamber-wide convection, (2) buffering by latent heat of crystallization, and (3) diminished chamber-wall thermal gradients. This mechanical control of igneous distillation is likely to have played a dominant role in the formation of the compositionally layered Earth's crust by allowing multiple and overlapping intrusive episodes of relatively discrete or quantized composition that become more silicic upward.

Is plutonium being incorporated by magnetite under anoxic conditions?

T. DUMAS[1], D. FELLHAUER[2], X. GAONA[2], M. ALTMAIER[2] AND A.C. SCHEINOST[1*]

[1]HZDR, Inst. of Resource Ecology, 01314 Dresden, Germany (*correspondence: scheinost@esrf.fr, thomas.dumas@cea.fr)

[2]KIT-INE, 76128 Karlsruhe, Germany (david.fellhauer@kit.edu, xavier.gaona@kit.edu, marcus.altmaier@kit.edu)

Magnetite, which forms under anoxic conditions on the surface of corroding steel containers, is able to reduce a range of elements, including radionuclides of high relevance in the context of nuclear waste disposal, e.g. Se, Tc, U, Np, Pu [1]. Aqueous Pu(V) is rapidly reduced by nanoparticulate magnetite to Pu(III), which then forms stable, tridentate sorption complexes on the {111} faces of magnetite [2]. Trivalent lanthanides have been shown to substitute for Fe(III) in magnetite, although their ionic radii are about 1.4 times larger than that of Fe(III) (1.15-1.17 vs. 0.79 Å in six-fold coordination) [3]. To investigate if such an incorporation is also possible for Pu(III) with a similar ionic radius as the lanthanides, we conducted coprecipitation experiments with two Pu loadings of 1000 and 3500 ppm. UV-VIS spectroscopy showed an immediate reduction of Pu(V) to Pu(III) in the initial Fe(II)/Fe(III) chloride solution. After formation of the black magnetite precipitate, Pu(III) concentration in solution was below 10^{-9} M. X-ray Absorption Near-Edge Structure (XANES) spectroscopy confirmed the trivalent oxidation state of solid phase-associated Pu. Extended X-ray Absorption Fine-Structure (EXAFS) spectroscopy was then used to investigate the molecular structure of incorporated Pu(III) in the fresh precipitate as well as after Fe(II)-induced aging [4]. The EXAFS spectra revealed two different spectral components. The first component represents the tridentate Pu(III) sorption complex also observed during sorption experiments. The second component represents Pu(III) in a highly distorted magnetite Oh site. The proportion of the incorporated Pu(III) decreased from about 75% to 40% with Fe(II)-induced aging, while the proportion of sorbed Pu(III) increased correspondingly. Our results suggest, therefore, that Pu can be incorporated by magnetite, but will convert to sorbed species on the long time scales relevant for nuclear waste disposal.

Mineralogy and geochemistry of natural porcelanites

DELIA-GEORGETA DUMITRAS[1]*, ADRIANA ION[1], IOAN MILOSAN[2], STEFAN MARINCEA[1] AND CONSTANTIN COSTEA[1]

Geological Institute of Romania, 1, Caransebes Str., Bucharest, Romania, RO-012271. (*correspondence: d_deliaro@yahoo.com)

Transilvania University of Brasov, 29, Eroilor Bld., Brasov, Romania, RO-500036. (milosan@unitbv.ro)

Natural porcelanites from Filipestii de Pădure, Romania, were analyzed from mineralogical, radiometric and geochemical point of view. These artifacts resulted from the *in situ* ignition of the relic coal in the sterile wastes issued from the mining activity, as well as from the burning of the clay formations in the couch and roof of the coal layers.

The mineralogical associations inferred by X-ray powder diffraction analyzes of 10 samples of porcelanite consist in gypsum, anhydrite, bassanite, quartz, sanidine, tridymite, mullite, cordierite, hematite, spinel, cristobalite, illite, spinel. Cell parameters for the most representative species were obtained by least squares refinement of X-ray power data.

Anhydrite and gypsum are particularly abundant, reaching up to 45 % of the porcelanite volume. FTIR study shows in all the samples the group of bands in the 1000-1160 cm^{-1} region materializing stretching motions of the $(SO_4)^{2-}$ group, as well as bands characteristic to the vibrations of molecular water. SEM photos show that in some cases anhydrite postdates gypsum, pseudomorphs of anhydrite after gypsum conserving the (010) perfect cleavage of gypsum.

ICP-MS analysis pointed out the presence of a large spectrum of REE (e.g. Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Zb, Lu), as well as of U and Th.

The gamma-energy spectrum radiometric measurements showed the presence of the following natural radionuclides (in order of the decreasing abundance): Ra-226, U-238, K-40 and Th-232.

Solubility of CO_2 in rhyolitic melts as a function of depth, temperature, and oxygen fugacity – implications for carbon flux in subduction zones

MEGAN DUNCAN[1,*] AND RAJDEEP DASGUPTA[1]

[1]Dept. of Earth Science, Rice University, Houston, TX, USA, (*correspondence: Megan.S.Duncan@rice.edu)

Partial melt of subducting sediments is thought to be a critical agent in transport of trace elements and water to arc basalt source regions. Sediment melts may also carry CO_2 to arc basalt source regions, however, the carrying capacity of CO_2 in rhyolitic melts of appropriate composition and at conditions relevant for subducting slab is unknown. In particular, the solubility of CO_2 in rhyolitic sediment melt may vary significantly as a function of fO_2, i.e. from graphite-saturated or organic carbon-bearing domains to carbonate/CO_2-saturated conditions. Yet no studies have constrained the sediment partial melt CO_2 carrying capacity under graphite saturated conditions.

We conducted experiments over 1.5 to 3.0 GPa and 1300°C on a model, natural rhylitic melt under nominally anhydrous to hydrous conditions. CO_2 content of experimental glasses in equilibrium with CO_2-rich vapor phase was determined using FTIR spectroscopy. CO_2 was found to be dissolved both as molecular CO_2 ($CO_2^{mol.-melt}$) and as carbonates (CO_3^{2-melt}). Speciation-specific CO_2 solubility data were used to constrain the pressure-dependence of equilibrium constants of the following two dissolution reactions [1] –

$CO_2^{fluid} + O^{2-} = CO_3^{2-melt} - K_{II} = X_{CO32-}/X_{O2-} \times fCO_2$

$CO_2^{fluid} = CO_2^{mol.-melt} - K_{III} = X_{CO2}/fCO_2$

Further, using the thermodynamic framework given by [2], here we calculated the CO_2 content of silicate melt as a function of P, T, and fO_2 for graphite-saturated conditions, by combining the P-dependence of K_{II} and K_{III} constrained in [1] and P-T-fO_2 dependence of K_I of the reaction: $C + O_2 = CO_2^{fluid}$ given by [2]. Experiments at lower temperatures are underway to constrain the T-dependence of K_{II} and K_{III}.

Using the model above, we have calculated the total CO_2 content ($CO_2^{mol.-melt} + CO_3^{2-melt}$) of a sediment partial melt for a variety of subduction P-T paths [3] at fO_2 values at or below the graphite-CO_2 equilibrium. Our study suggests that ≥1 wt.% CO_2 may be dissolved in sediment partial melt at graphite saturation even at fO_2~FMQ-3.

The Caribbean plateau and OAE2: resolution of timing and trace metal release

R.A. DUNCAN[1,2]*, L.J. SNOW[1] AND G. SCOPELLITI[3]

[1]CEOAS, Oregon State University, Corvallis, OR 97331 USA (*corresp: rduncan@coas.oregonstate.edu) and
[2]Geology&Geophysics, King Saud University, Ruyadh, KSA
[3]CFTA, University of Palermo, Palermo, 90123 Italy

Initial volcanism that formed a large part of the Caribbean ocean plateau coincided with ocean anoxic event 2 (OAE2), which occurred close to the Cenomanian/Turonian (C/T) boundary (~94 Ma). Increased trace metal delivery to the surface ocean during volcanic activity associated with this ocean plateau has been suggested as the cause for the depletion of seawater oxygen concentration and deposition of organic rich sediments [1]. This link is supported by isotopic excursions (Sr, Nd, Pb, Os) across the OAE2 that indicate a volcanic source. An interval of trace metal anomalies occurs in pelagic carbonate and black shale sequences of the Rock Creek Canyon section, Pueblo, Colorado at the onset of the $\delta^{13}C$ global positive event [2]. The presence of these metal anomalies and isotopic profiles indicates a relationship between ocean plateau formation and ocean anoxia.

To further explore a direct connection between this ocean plateau and OAE2, we determined the distribution of major, minor and trace element abundances in marine sediments from an additional 7 globally distributed sites (Bass River, New Jersey; central Kerguelen Plateau; Baranca el Cañon, Mexico; Totumo, Venezuela; and Bottaccione, Calabianca and Novara di Sicilia, Sicily). After normalizing element concentrations to Zr, an interval of metal anomalies is present in all 8 sites. The changes in the trace metal patterns and concentrations among these sites is consistent with modeled late-Cretaceous surface circulation and a source of metals being the Caribbean plateau.

Ion exchange and dissolution-precipitation in a zeolitic system

KRISTINA G. DUNKEL* AND ANDREW PUTNIS

Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Corrensstraße 24, 48149 Münster, Germany (*correspondence: kristina.dunkel@uni-muenster.de)

Zeolites are most commonly known for their ion-exchange properties. Previously, much attention has been given to the quantity of, and the necessary conditions for ion exchange. In order to better understand the underlying reaction mechanism, we investigated the reaction between a typical zeolite, scolecite ($CaAl_2Si_3O_{10}\square 3H_2O$), and an Na-rich fluid, with the expectation that in a solution with high Na^+ activity natrolite ($Na_2Al_2Si_3O_{10}\square 2H_2O$), or, with a lower probability, mesolite ($Na_2Ca_2Al_6Si_9O_{30}\square 8H_2O$) would form. The three minerals have very similar structures and the substitution of 2 Na^+ for Ca^{2+} and H_2O can be considered a classical cation exchange.

Against our predictions, mesolite was only observed in longer term experiments. At all reaction times, however, a reaction rim formed consisting of Na,Al-substituted tobermorite ($Ca_{4.5}Si_{5.2}Al_{1.0}Na_{1.3}O_{16}(OH)_2$), a zeolite-like mineral that is of special interest because of its high selectivity for Cs.

A strong textural change from scolecite to both tobermorite and mesolite unambiguously shows that the reaction mechanism did not involve solid-state diffusion. The reaction interfaces are sharp, and the product phases form porous pseudomorphs of the original scolecite, strongly suggesting a coupled dissolution-precipitation process as the reaction mechanism. The formation of the comparatively Ca-rich tobermorite instead of the expected natrolite points to the fact that the solution at the reaction interface is not in equilibrium with the bulk solution. Similarly, it has been observed that Cs-Na exchange of the tobermorite did not start simultaneously in the whole, highly porous reaction rim, but only at the outer part.

Our results demonstrate that reaction between scolecite and a fluid with which it is out of equilibrium takes place by coupled dissolution-precipitation, both when the product phase is isostructural with the parent (as is the case for mesolite) and when it is not (as is the case for tobermorite). Moreover, there is much less fluid mobility around separate crystals in a solution than could be expected, which emphasises the importance of interfacial fluids.

Reactivity of cement and steel interfaces in geological carbon storage

S. DUPRAZ[1]*, A. FABBRI[2] AND S. GRATALOUP[1]

[1] BRGM, 45060, Orléans, France (*correspondence: s.dupraz@brgm.fr)

[2] ENTPE, 69518, Vaulx-en-Velin, France

To some extent, carbon storage in geological environnement is always submitted to leakage threats. Among the different possible scenarios, wells in contact with the storage zone are frequently regarded as the best candidates for CO_2 leakage. Wells materials, namely cement and steel, can both be corroded by the acidity of CO_2 rich fluids. Moreover, the interfaces between those materials are suggested to be the preferential pathways for fluids progressions. In order to assess this specific reactivity, a series of cement/tubing assemblies were submited to storage conditions (150 bar of CO_2 at 65°C) during 6 weeks. Beside the assemblies interfaces, the tested parameters were the cement composition (CEM I, III and V), the cement to water ratio (0.14 to 1.24) and the salinity (0 and 20 $g.l^{-1}$). Carbonation of the cements and corrosion of the steel were quantified in each case as well as the resulting porosity, permeability and chemistry of the solid and liquid phases. As expected, the main conclusion of this approach demonstrate the chief role of the interfaces in the corrosion process and a surprisingly good resistance of the portland cement to such attacks.

Silicon isotope fractionation implying liquid phases at 300K: importance of configurational disorder

ROMAIN DUPUIS[1]*, MAGALI BENOIT[2] AND MERLIN MÉHEUT[1]

[1]GET/OMP, 14 Avenue Edouard Belin, 31400 Toulouse (*correspondence: dupuis@get.obs-mip.fr)
[2]CEMES, 29 rue Jeanne Marvig 31055 Toulouse

Silicon isotope fractionation during Si precipitation in surface environments has received great interest in recent literature [1] for its potential to constrain weathering processes. *Ab initio* methods have the potential to provide independent and useful informations to understand the elementary processes responsible for such fractionations involving liquid phases [2]. In this study, we explored liquid/liquid ($H_4SiO_4/H_3SiO_4^-$) and mineral/liquid (quartz/H_4SiO_4) fractionation of Si at equilibrium within the harmonic approximation [3]. Two 40ps trajectories of H_4SiO_4 (or $H_3SiO_4^-$) + 64 water molecules were simulated at 300K with the CPMD code, using BLYP functional. Then, using DFPT on configurations quenched at 0K, zone-center phonon frequencies were calculated to obtain their fractionation properties ($ln\beta^{30/28}$(Liq.)). In these systems, the effect of configurational disorder on the fractionation properties was studied in details. In parallel, $ln\beta^{30/28}$(Quartz) have been computed to study a mineral/liquid equilibrium fractionation.

Based on a set of 10 independent configurations extracted from the trajectories, significant variations have been observed on the values of $ln\beta^{30/28}$(Liq.). The calculated dispersion (σ) is large : **0.43‰** for H_4SiO_4 and **0.38‰** for $H_3SiO_4^-$. Thus, in the case of Si in solution, the configurational disorder should be taken into account for a realistic computing of fractionation properties.

The mean values of $ln\alpha^{30/28}$(Quartz, H_4SiO_4) = **+2.18±0.14‰** (SE, N=10) and $ln\alpha^{30/28}$(H_4SiO_4, $H_3SiO_4^-$) = **+1.51±0.16‰** (SE, N=10) at 300K have been calculated including the error due to the liquid disorder. Regarding the calculated fractionation in quartz/liquid systems, the solution is predicted to be lighter than the precipitate, inconsistently with every natural observations. Thus, the precipitation is probably a process out of equilibrium in this system. Most importantly, a significant fractionation related to a single proton exchange ($H_4SiO_4/H_3SiO_4^-$ equilibrium), is predicted.

Consequences on the explanation of silicon fractionation during precipitation will be discussed.

Sorption of dissolved organic matter on boom clay

D.DURCE*, C.BRUGGEMAN AND N.MAES[1]

[1]Belgian Nuclear Research Centre (SCK.CEN), B-2400 Mol, Belgium (*: ddurce@sckcen.be)

Dissolved organic matter (DOM) plays a significant role in a geological nuclear waste repository by enhancing or retarding the transport of radionuclides in the environment. It is thus a key aim to understand the equilibriums DOM-rock which govern the DOM mobility. DOM sorption was studied on a large variety of soils and minerals with different DOM sources [1],[2]. However, most of works was carried out after removal of the indigenous DOM, neglecting therefore some key aspects of the sorption. Boom Clay, potential host rock under study in Belgium, is a formation rich in organic matter with 1.7 wt% of TOC. The objective of this work is thus, to study the interactions of the indigenous DOM with the Boom Clay rock in undisturbed conditions. To this end, we propose to use a sequential leaching of the indigenous DOM: from a crushed solid, under a controlled pCO2 and in a synthetic solution representative of the pore water. This method allows to quantify the fraction of soluble organic matter and the equilibrium DOM in solution/DOM sorbed.

Three different rock samples were considered with, for each, four liquid/solid ratios. No influence of the liquid/solid ratios was noticed on the amount of DOM extracted, which was estimated between 0.037 and 0.104 wt% of the total rock according to the origin of the samples. A linear behaviour in desorption was highlighted with Kds in good agreement for all the samples. However, the dimensions of the system were observed to strongly influence the Kd values. Indeed, average Kds of 2.7, 4.3 and 10.3 $L.kg^{-1}$ were measured for liquid/solid ratios of 4, 6.7 and 16.7 $L.kg^{-1}$ respectively. The quantification of DOM sorption is thus dependent on the studied system and the notion of Kd should be considered with care. However, the approach used here offers reference values that account for the different sorption mechanisms encountered in situ, including potential competitive effects. Behind a pure quantification of the interactions DOM-rock, our work aims at understanding the mechanisms involved and notably the influence of DOM molecular weight on sorption. Batch sorption experiments are, indeed, on-going with different size fractions of the indigenous DOM. The results and limits of the sequential leaching approach will be discussed together with the influence of molecular size on the measured Kd values.

Bacterial biofilms often occur in porous media, where they play pivotal roles in medicine, industry and the environment. Though flow is ubiquitous in porous media, its effects on biofilm growth have been largely ignored. Using patterned microfluidic devices that simulate soil, we find that the structure of *Escherichia coli* biofilms undergoes a self-organization mediated by the interaction of growth and flow. Intriguingly, we find that intermediate flow rates trigger the formation of striking preferential flow channels, which convey fluid around large biofilm patches (Fig. 1). At larger and smaller flow rates, biofilms form more compact patches leading to uniform flow through the matrix. A simple network model, based on the competition between biofilm growth and shear induced detachment, correctly predicts our findings. These findings may have important consequences on processes as diverse as biochemical cycling, antibiotic resistance, and water filtration.

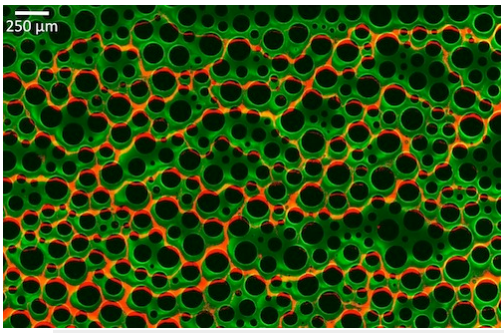

Figure 1: A microfluidic device that simulates soil colonized by *E. coli* biofilm (bacterial auto-fluorescence shown in green). Biofilm patches are intersected by channels of fluid flow (shown in red and shifted slightly downward to reveal the underlying structure), which transport nutrient unevenly through the matrix.

Assessment of the evolution of the redox conditions in a low and intermediate level nuclear waste repository (SFR1, Sweden)

This study evaluates the redox conditions in 15 individual waste package types in SFR1. SFR1 contains heterogeneous wastes, with different activity levels and materials in the waste, matrices and packaging. Steel and concrete-based materials are ubiquitous in the repository. A combination of the individual models is used to assess the redox evolution of the different vaults in the repository. The results of the model indicate that O_2 is consumed through organic matter degradation and metal corrosion. The system is then kept under reducing conditions for long time periods. $H_2(g)$ is generated due to the steel anoxic corrosion and magnetite precipitates as main corrosion product. Steel is depleted after 5,000 y to more than 60,000 y depending on the waste package type. The calculated Eh under the pH conditions imposed by the massive amounts of cements in the repository is about -0.75 V (pH 12.5) but higher redox potentials (up to -0.01 V) can be expected if the system controlling the Eh is not steel/magnetite, but Fe(III)/magnetite. If no oxic disturbances happen Eh would be kept highly reducing. In case of glacial meltwater intrusion magnetite would gradually convert into Fe(III) oxides, buffering system Eh and preventing it from oxidation for long time periods.

Greenhouse gas (CO_2, N_2O, CH_4) emissions from Llobregat (Barcelona) riverbed sediment: Effects of soil moisture and C, N, Fe substrates

T. DUTTA[1], S. RUBOL[1,2], S. A. VALL[1] AND J. A. TIRADO[1]

[1] Hydrogeology Group, Dept Geotechnical Engineering and Geosciences, Universitat Politècnica de Catalunya-BarcelonaTech, 08034 Barcelona, Spain. Email: tanushree.dutta@upc.edu

[2] Dept. DICA, University of Trento, Italy Email: simonetta.rubol@upc.edu

Nutrient input to river water from adjacent agricultural and industrial areas can create soil conditions suitable for greenhouse gas emissions. In this study, we report three major greenhouse gas; CO_2, N_2O and CH_4 emissions from riverbed sediments of Llobregat River, Barcelona. In a 45 day laboratory incubation experiment, we monitored the emissions from the sediments kept at three different soil moisture conditions- 40, 60 and 80% water filled pore space with added carbon, nitrogen and iron substrates. The treatments were DI + N, DI + N + organic C, DI + N + Fe, control with DI and no DI added. Gas and soil samples were collected after 0, 1, 2, 5,7, 10 days after the start of the experiment and then once every week. Gas samples were analyzed in a Gas Chromatograph equipped with TCD, ECD and FID detectors and soil extractants were analyzed for organic C and N. Results show that the soil had less then 1 mg per liter NH_4-N, which increased with the added C and N substrates but then decreased with time. This increased levels of C and N reflected in increased respiration, however both N_2O and CH_4 emissions remained low across all treatments in spite of the increase in C and N at all three different soil moisture conditions, which could be an indication of lack of indigenous methane-producing and denitrifying soil microbial populations.

Exploring the spatial and temporal complexity of the last interglacial sea level highstand

ANDREA DUTTON[1*]

[1]Department of Geological Sciences, University of Florida, Gainesville, FL, 32611, USA (
*correspondence: adutton@ufl.edu)

The future response of Earth's remaining ice sheets remains the most uncertain and controversial aspect of sea level-rise projections. In this context, past climate and sea-level reconstructions present a valuable opportunity to gain insight about the response of the cryosphere to warmer temperatures. Although studies of the timing, phasing, and magnitude of sea level changes on glacial-interglacial timescales have long been studied, conventional paradigms of the dynamics of this process have come under new scrutiny. In particular, studies based on chronologies and proxies derived from corals, speleothems, deep sea cores and ice cores that probe the timing of peaks in sea level as well as the length of the assumed lag between insolation and sea level response are increasingly indicating that the polar ice caps may be more sensitive than previously thought—both in the timing, frequency, and magnitude of response [*e.g.*, 1,2].

The last interglacial period has received much attention in terms of understanding the sensitivity of ice sheets during warm climates, as much for its relevance to future climate conditions as for the accessibility of sea level indicators from this time period. New analyses of open-system U-Th age data of corals, of compilations of coral U-Th age-elevation data, and of absolute chronologies recorded by speleothems and corals are transforming our understanding of the dynamics of polar ice sheets during the last interglacial period. Of particular significance is the emerging consensus that sea level peaked somewhere around 6 to 9 meters above present [3,4], and experienced at least one if not more oscillations in sea level [5].

The state of understanding of the absolute timing, duration, and stability of the last interglacial sea level highstand will be reviewed, with particular consideration given to the unresolved complexities in the spatial and temporal signal of sea level from this time period.

Perturbation to the marine Ca isotope cycle across Oceanic Anoxic Event 2

ALICE D.C.DU VIVIER[1]; ANDREW D. JACOBSON[2]; GREGORY LEHN[2]; DAVID SELBY[1] AND BRADLEY B.SAGEMAN[2]

[1]Department of Earth Sciences, Durham University, Durham, DH1 3LE; alice.du-vivier@durham.ac.uk; david.selby@durham.ac.uk

[2]Department of Earth and Planetary Sciences, Northwestern University, 2145 N. Sheridan Road, Evanston, IL 60208-3130; adj@earth.northwestern.edu; greg@earth.northwestern.edu; brad@earth.northwestern.edu

Several isotope proxies (e.g., C, Mo, Nd, Os, Sr) have been used to examine the effect of OAEs on global climate and elemental cycling. Here, we evaluate the behaviour of Ca isotopes ($\delta^{44/40}$Ca) across the late Cretaceous OAE2 (Cenomanian-Turonian) in the Western Interior of North America (NA), where significant perturbations in $\delta^{44/40}$Ca track the concommitant changes in C and Os isotope records.

We present a high-precision ($2\sigma_{SD}$ = ±0.04‰), high-resolution (±20 kyr) record of $\delta^{44/40}$Ca values from the GSSP Pueblo core. A relatively large, positive excursion in $\delta^{44/40}$Ca values occurs at the onset of OAE2. The maximum extent of variation (~0.30‰) is ~8 times larger than the external reproducibility of the measurements. Several processes could explain this pattern, including mineralogical variations, changes in the fractionation factor, and perturbations to the input and output fluxes of marine Ca. We note that initial Os isotope ratios trend toward unradiogenic values during the same time interval. This trend clearly reflects the input of a mantle-like Os isotope composition, most likely derived from the emplacement of basalts of the Caribbean Large Igneous Province. Because basalts have relatively high $\delta^{44/40}$Ca values (Huang *et al*.., 2010) compared to other marine Ca inputs, such as river runoff and submarine groundwater discharge, we infer that the Pueblo $\delta^{44/40}$Ca record also reveals a large volcanic signature. Previous Ca isotope records for OAE2 from the UK did not record the putative basalt weathering signature (Blattler *et al*.., 2011), and were interpreted to reflect increased terrestrial weathering. The difference in Ca records from NA and the UK may reflect a combination of factors, including proximity to the LIP and an improved MC-TIMS method (Lehn *et al*.., 2013) employed in the present study.

The fate of reactive solutes in soils is the result of complex coupled processes including convective dispersive transport, sorption to organo-mineral surfaces and biochemical transformations. These processes, occuring at different space and time scales, are difficult to identify and rank by classical laboratory experiments.

Multidisciplinary studies were performed to evaluate soil characteristics impacting atrazine fate in two contrasting soil types, namely an Andosol and a Vertisol from Mexico. The 3D-macro pore networks and pore morphological parameters were calculated after imaging intact soil cores through X-ray tomography at 50 μm resolution. Reactive organo-mineral phases such as allophanes, clays, oxydes and organic matter were characterized and quantified. The different processes involved in atrazine fate were studied independently and statically in closed reactors. Displacement experiments in intact cores allowed to mimic natural dynamic environmental and application conditions. A stable oxygen isotope used as water tracer permitted obtaining the convective dispersive parameters.

Water transfer in physical non equilibrium transfer was observed in the surface Vertisol and subsurface Andosol horizons and was correlated to pore shape, connectivity and size. Sorption capacity and degradation rate were compared in static and dynamic experiments. The roles of organic matter composition, clay types and pH variations were assessed. This study shows how the soil physico-chemical and microbial propreties at the pore and pedon scales affect reactive solute fate at the macroscale. It also demonstrates the difficulty to decouple the different processes involved.

Natural organic matter (NOM) is a highly complex mixture of organic compounds abundant and speciated in all environmental compartments (atmosphere, soils, sediments and water environments). The formation and decomposition of NOM is driven by abiotic and biotic reactions and its continual interactions with its environment. Thus the unique NOM signature reflects several key ecosystem characteristics.

Sulphur with oxidation states ranging from -2 to +6 is an essential element for any terrestrial life and an important constituent of NOM. Processes like microbial sulphate reduction, pyrite precipitation and polysulphane formation demonstrate the pivotal role of environmental sulphur chemistry for microbial life and its coupling to abiotic redox cycles. Furthermore, sulphur is crucial for environmental metal binding. The sulphur signature of NOM therefore reveals critical insights into important biogeochemical processes.

As shown recently, Fourier transform ion cyclotron resonance mass spectrometry (FTICR/MS) is a powerful tool to unravel the diverse characteristics of abiotic and biotic complexity of various NOM [1-4]. This contribution will demonstrate the capabilities of high-field FTICR mass spectra to elucidate the significant role of organic sulphur chemistry to hydrothermal springs, which feature ecosystems conditions resembling in many aspects those supposedly found in the early earth's history.

Chemical and Hf/W Isotopic Consequences of Lossy Accretion

CHRISTINA A. DWYER[1]*, FRANCIS NIMMO[1] AND JOHN E. CHAMBERS[2]

[1]Dept. Earth & Planetary Sciences, U.C. Santa Cruz, Santa Cruz, CA 95064 (*correspondence: cadwyer@ucsc.edu)
[2]Dept. Terrestrial Magnetism, Carnegie Institute of Washington, Washington, DC 20015

The late stages of planetary accretion involve stochastic, large collisions [1]. Many of these collisions likely resulted in hit-and-run events [2] or erosion of existing bodies' crusts [3] or mantles [4]. Here we present a preliminary investigation into the effects of lossy late-stage accretion on the bulk chemistry and isotopic characteristics of the resulting planets.

Our model is composed of two parts: (1) an N-body accretion code [5] tracks the orbital and collisional evolution of the terrestrial bodies, including hit-and-run and fragmentation events; (2) post-processing evolves the chemistry in light of radioactive decay and impact-related mixing and partial equilibration.

16 runs were performed using the MERCURY N-body code [5]; each run contained Jupiter and Saturn in their current orbits as well as ≈150 initial bodies. Collisional outcomes are modified from [6,7]. The masses of the core and mantle of each body are tracked throughout the simulation. All bodies are assigned an initial mantle mass fraction, y, of 0.7.

We track the Hf and W evolution of these bodies. Radioactive decay occurs between impacts. We calculate the effect of an impact by assuming an idealized model of mixing and partial equilibration [8]. The core equilibration factor is a free parameter; we use 0.4. Partition coefficients are assumed constant.

Diversity increases as final mass decreases. The range in final y changes from 0.66–0.72 for ≈Earth-mass planets to 0.41–1 for the smallest bodies in the simulation. The scatter in tungsten anomaly increases from 0.79–4.0 for ≈Earth-mass to 0.11–18 for the smallest masses. This behavior is similar to that observed.

We find there is no simple relationship between the single-stage core formation time derived from the final tungsten isotope anomaly and the actual growth history of an object.

P–V–T equation of state of sodium majorite up to 21 GPa and 1673 K

A. M. DYMSHITS [1]*, K. D. LITASOV [1], A. SHATSKIY [1], I.S. SHARYGIN [1], E. OHTANI [2], A. SUZUKI [2] AND K. FUNAKOSHI [3]

[1] Sobolev Institute of Geology and Mineralogy, Novosibirsk 630090, Russia (*a.dymshits@gmail.com)
[2] Tohoku University, Sendai 980-8578, Japan
[3] SPring-8, Japan Synchrotron Radiation Research Institute, Kouto, Hyogo 678-5198, Japan

Garnet is one of the most abundant minerals in the upper mantle and transition zone and comprises about 40% by volume for peridotitic and up to 70% for basaltic or eclogitic lithologies [1]. With increasing pressure garnet becomes progressively enriched in Si and Na, which can be expressed as sodium majorite (Na-maj) component [2].

The *P-V-T* equation of state (EoS) for Na-maj at pressures to 21 GPa and temperatures to 1673 K was obtained by *in situ* X-ray diffraction experiments and a multi-anvil apparatus at "SPring-8" synchrotron facility. Fitting the entire *P–V–T* dataset using a high-temperature Birch–Murnaghan EoS at a fixed $K'_{0,300} = 4$ yielded $V_0 = 1474.7$ (8) Å^3, $K_{0,300} = 185$ (2) GPa, $(\partial K_{0,T}/\partial T)_P = -0.028$ (4) (GPa K^{-1}) and $a = 3.17$ (14) × 10^5 K^1, $b = 0.41$ (21) × 10^8 K^2, where $\alpha = a + bT$ is the volumetric thermal expansion coefficient. Fitting the present data to the Mie-Gruneisen-Debye EoS with Debye temperature fixed at $\theta_0 = 890$ K yielded Gruneisen parameter, $\gamma_0 = 1.31$ and 1.33 at $q = 1.0$ and 1.18, respectively.

The new data on the Na-maj were compared with previous data on majorite type garnets. The entire dataset enabled us to examine the thermoelastic properties of important mantle garnets and these data will have further applications for modelling *PT*-conditions in the transition zone of the Earth's mantle using ultradeep mineral assemblages.

Laser spectroscopic *in situ* measurements of D/H in water vapor onboard a passenger aircraft

C. DYROFF[1]*, E. CHRISTNER[1] AND S. SANATI[1]

[1]Karlsruhe Institute of Technology, Institute of Meteorology and Climate Research, PO Box 3640, 76021 Karlsruhe, Germany (* correspondence: christoph.dyroff@kit.edu)

Water (H_2O) is a key species in Earths atmosphere due to its large radiative feedback and transport of latent heat. For a better understanding, and to improve global climate models, it is vital to study the global hydrological cycle.

Isotope ratio measurements of H_2O can provide additional information to H_2O measurements alone, as they are an indicator of the transport pathways (evaporation, condensation, ice formation) of atmospheric H_2O.

We are presently deploying an in-situ diode-laser spectrometer [1] aboard the CARIBIC passenger aircraft [2]. On flights mostly in the northern hemisphere with occasional crossings of the tropics en route to southern Africa we have obtained the first in-situ meridional cross section of δD at the cruising altitude of the CARIBIC aircraft (Fig. 1). A positive gradient of ~150 ‰ from mid latitudes towards the tropics indicates an increased contribution of convective transport of near-surface H_2O vapor at 10–12 km altitude. Our findings are supported by back-trajectory calculations, and agree well with satellite-borne observations [3].

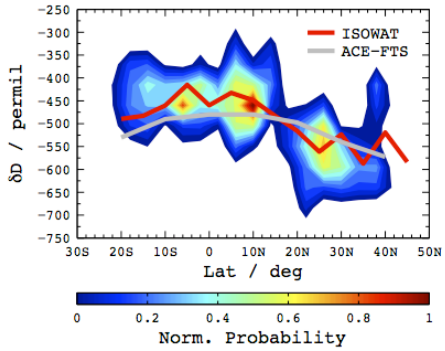

Figure 1: Meridional cross section of δD showing increased convectional transport of H_2O in the tropics. Red line: mean ISOWAT. Green line: ACE-FTS annual mean.

Cosmochemical Constraints on Asteroid Accretion

EBEL DENTON S [1,2], MICHAEL K. EISBERG [1,3] AND ELLEN CRAPSTER-PREGONT[1,2]

[1]American Museum of Natural History, Central Park West at 79th St, New York, NY 10024. (*debel@amnh.org)
[2] Lamont-Doherty Earth Observatory of Columbia University, Palisades, New York.
[3] Kingsborough College, City University of New York.

Multiple lines of chemical, isotopic and textural evidence constrain how kilometer-sized bodies accreted. Km-size chondrite parent bodies were likely precursors to planetesimals and the modern planets. **First**: Chondritic meteorites (~90% of known meteorites) contain widely variant modal abundances of their primary components: Chondrules, Ca-Al-rich inclusions (CAIs), and fine-grained matrix containing insoluble organic matter (IOM) and presolar grains (PSG) including graphite and SiC [1], yet are all "chondritic" in composition [2,3]. **Second**: Chondrules, themselves highly variable in Fe/Si, combine to make rocks with bulk chondritic Fe/Si [4]. **Third**: Chondritic meteorites contain most major elements (Si, Mg, Al, Ca, Ti) and rare earth elements (REEs) in solar proportions, with the most variation in Fe, yet CAIs have highly variable REE inventories [5]. **Fourth**: Oxygen isotopes, CAI abundances, and clast sizes suggest each chondrite group formed under locally distinct conditions. Variations in Fe do not affect the present argument. That extraterrestrial materials universally tend towards chondritic major and trace element abundances is, alone, a powerful constraint on disk processes, that has been dubbed "complementarity" [2-4]. That is, the primary components (chondrules, CAIs, matrix) complement each other to produce "chondritic" bulk meteorite composition. Why is this so?

We will present major and trace element (REE) evidence that the parent bodies of chondritic meteorites accreted from local, gravitationally unstable (overdense) accumulations of material of bulk solar or dust-enriched composition [6], subjected, prior to accretion, to varying degrees of highly local heating that produced melted objects (e.g., chondrules) with varying degrees of efficiency [7].

Deformation-related chemical alteration of meta-pegmatites

TOBIAS EBERLEI[1]*, GERLINDE HABLER[1], RAINER ABART[1] AND BERNHARD GRASEMANN[2]

[1]University of Vienna, Department of Lithospheric Research (*correspondence to: tobias.eberlei@univie.ac.at)
[2]University of Vienna, Department of Geodynamics and Sedimentology

Deformation and chemical reactions often occur contemporaneously in nature and a proper understanding of the feedback between the two is required for correctly interpreting rock microstructures and evaluating the $P–T–t–d$ evolution of rocks. Permian meta-pegmatites from the Austroalpine Matsch Unit in the Eastern Alps were deformed at conditions close to the greenschist–amphibolite facies transition during the Cretaceous [1,2], locally producing proto-, meso- and ultramylonites with finite strain gradients at the cm- to m-scale.

We focus on the relation between the Cretaceous deformation and major element re-equilibration of the major metapegmatite phases. Several white mica and feldspar generations are recognised based on combined microstructural and microchemical characteristics. A spatial relationship between specific deformation-microstructures (kink bands, micro shear zones, cracks, strain shadows) and chemical alteration is reflected by cm-sized white mica and plagioclase clasts. A fine-grained phengitic white mica generation dominates mylonitic foliation domains and compressional quadrants of clasts. Primary K-feldspar (Kfs) shows deformation-related replacement by albite, whereas secondary Kfs together with fine-grained biotite, phengitic white mica, albite and quartz precipitated in micro-fractures and extensional quadrants of large albite and muscovite clasts. Fine-grained plagioclase aggregates in the strain-shadows of albite clasts indicate deformation by dissolution-precipitation creep (DPC). The mineral compositions of fine-grained phengitic white mica co-existing with secondary Kfs, biotite, quartz and albite are consistent with $P–T$ conditions of 480 ± 30 °C and 5 ± 1 kbar.

Our results document the correlation between deformation and chemical alteration and yield quantitative PT constraints on deformation based on syntectonic phase assemblages. The study will be further extended to examine the relationship between deformation and isotopic re-setting of the Rb-Sr system in white mica.

Quantitative analysis of high resolution isotope and concentration data from a toluene-pulse experiment by reactive transport modeling

DOMINIK ECKERT[1]*, SHIRAN QIU[2], MARTIN ELSNER[2] AND OLAF A. CIRPKA[1]

[1]Center for Applied Geosciences, University of Tübingen, Tübingen 72074, Germany (*Dominik.Eckert@uni-tuebingen.de)
[2]Institute of Groundwater Ecology, Helmholtz Center München, München 85764, Germany

A major challenge in the application of compound-specific isotope analysis (CSIA) to quantify biodegradation at contaminated field sites is the separation of microbial- and physical-induced effects on the measured isotope signal. In contrast to simple analytical tools, as the Rayleigh equation, reactive transport models can account for the complex interaction of different fractionating processes.

In this study, we analyze the high resolution toluene concentration and isotope ratio ($\delta^{13}C$) data set of a large-scale laboratory toluene pulse experiment by reactive transport modeling. We uniquely quantify degradation and sorption properties of the system, estimate the contributions of reaction-induced, sorption-induced and transverse-dispersion-induced isotope fractionation to the overall isotope signal and quantify the error introduced by neglecting individual processes (e.g. fractionation by physical processes, Michaelis-Menten degradation kinetics) in the analysis of the data. Our results show that highly resolved data of both concentration and isotope ratios are needed for unique process identification of reactive transport facilitating reliable model calibration and that the combined analysis of these highly resolved data demands reactive transport models with sufficient complexity.

Mantle control on eruption style at Kīlauea Volcano, Hawai'i

M EDMONDS[1], I SIDES[1], J MACLENNAN[1], D SWANSON[2] AND B HOUGHTON[3]

[1]Earth Sciences Department, University of Cambridge, Downing Street, Cambridge CB2 3EQ, UK
[2]Hawaiian Volcano Observatory, United States Geological Survey, Hawaii National Park, HI 96718, USA
[3]School of Ocean and Earth Science and Technology, University of Hawaii at Manoa, Hawaii, USA.

Ocean island volcanoes are associated with melting of a heterogeneous mantle source. Geochemical heterogeneity might be expected to influence the way in which melts ascend and are stored and erupted, with some melts inherently more enriched in incompatible trace elements, and hence volatiles, than others. Contrasts between effusive and explosive (fountaining) behaviour in basaltic magmas has previously been explained in terms of shallow melt-gas segregation, with little geochemical control. Here we present data from a suite of melt inclusions from 25 historical eruptions of Kīlauea Volcano over the last 500 years. The deposits were emplaced via a range of eruptive styles, from effusive lava flows, fissure eruptions, high fountains and transient subplinian (gas-rich) eruptions.

The data show that more explosive styles of eruption (high fountaining and fissure eruptions) are associated statistically with more enriched melts (with higher relative proportions of Light Rare Earth Elements) with higher volatile concentrations, which ascend faster, retain their primitive nature and interact only minimally with the summit magma reservoir. Effusive styles of eruption, on the other hand, are linked statistically with more depleted melts, with lower volatile concentrations, that tend to homogenise, cool and evolve in the summit magma reservoir before eruption.

The ranges in melt volatile concentrations between the "depleted" and "enriched" end member primary melts are approximately 0.28 to 0.87 wt% water respectively and 0.17 to 0.68 wt% carbon dioxide respectively. The more volatile-rich melts are considerably more buoyant, which has a dramatic effect on their transport, storage and eruption, owing to their higher vapour content at low pressure, increasing the likelihood of explosive high fountaining styles of volcanic activity. Over time, Kīlauea's style of eruption and magma supply rate are linked fundamentally to the geochemistry of primary melts: magma explosivity thus might be determined right at the point of separation from its mantle source region.

V.I Vernadsky: Holistic thinker and geochemical pioneer

W.M.EDMUNDS[1]* AND A A BOGUSH[2]

[1]School of Geography and the Environment, Oxford University, Oxford OX1 3GY, UK (correspondence: wme@btopenworld.com)
[2]Institute of Geology and Mineralogy of Siberian Branch of the Russian Academy of Sciences, pr.Koptyuga 3, Novosibirsk 630090. Russia (annakhol@gmail.com)

Vladimir Ivanovich Vernadsky has only recently become recognised internationally [1,2], despite being regarded as one of the greatest names in science of the 20th century in his homeland Russia. There are several reasons for his lack of renown in the west, but mainly that his most important work *"The Biosphere"* was only fully translated into English in 1997 [1,3]. This book and the ideas it contains are now becoming regarded as one of the seminal scientific works of the last century. It defines the biosphere as a unifying, holistic concept for the earth system at a time when reductionism was the driving motivation in scientific research. Above all, for earth scientists, Vernadsky regarded life as the driving geological force. He also adopted the concept of the 'Noosphere' (the evolution of human thought) to emphasis man's role as a geological agent. His publications foreshadow Gaia theory some half a century later.

This paper, coinciding with the 150th anniversary of his birth celebrates his achievements as a pioneering geochemist through his contribution in mineralogy and crystallography, geology and isotope geoscience, geochemistry and biogeochemistry, chemistry and biochemistry, pedology and hydrology, meteoritics and, the history of science and philosophy [4]. His was the first text on geochemistry [5] and also on hydrogeochemistry [2,6] published in three volumes. Vernadsky's ideas also led to the evolution of landscape geochemistry which was promulgated by his contemporaries and students (Polynov, Fersman, Perel'man *et al*.).

Water security in low rainfall areas

W M EDMUNDS[1]

[1]Oxford Water, School of Geography and the Environment, Oxford University, OX1 3GY

Humans have shown a capacity over millennia to adapt to living in water scarce areas under changing climatic conditions. Today the challenges of adaptation are still water-based, but more complex due in particular to energy requirements, food security and population growth. Renewable groundwater of adequate quality is the key to water resource security in arid and semi-arid areas. Excessive and uncontrolled abstraction of mainly fossil water has already led to massive depletion of valuable reserves of groundwater in major aquifers worldwide. Access to safe drinking water supplies however remains the primary issue for most of the world's poorest people.

Geochemistry plays a role in both the quantitative and qualitative aspects of water security. Physical parameters such as recharge estimation can best be estimated or validated using simple tools such as chloride mass balance; importantly such techniques are inexpensive and widely applicable. Residence times can be determined by a mix of radiometric and isotopic tracers as well as CFCs. Natural groundwater is widely recognised as the purest and most reliable water resource but its properties need assessment for harmful substances derived from geological sources. Above all, the needs of one quarter of the world's population with no access to safe drinking water and one third without access to sanitation can be addressed often using basic hydrogeology coupled with simple geochemical measurement.

It is argued that rural communities may have greater opportunities for developing water security as compared with many of those in urban areas. The key lies in creating self-sufficient and productive communities based on water prioritisation. This involves *inter alia*, careful conservation and management of renewable groundwater, rainfall harvesting, underground storage - combined with education and training initiatives benefiting rural society. Policies need to be adapted and implemented to ensure that development is based on water renewability.

Synchrotron X-ray fluorescence reveals the colourful chemistry of fossils

N.P. EDWARDS[1]*, P.L. MANNING[1], H. BARDEN[1], W.I. SELLERS[2], U. BERGMANN[3] AND R.A. WOGELIUS[1]

[1]University of Manchester, SEAES, Williamson Research Centre for Molecular Environmental Science, Manchester, M13 9PL, UK (correspondance: nicholas.edwards@manchester.ac.uk)

[2]University of Manchester, Faculty of Life Science, Manchester, M13 9PT

[3]SLAC National Accelerator Laboratory, Linac Coherent Light Source, Menlo Park, CA, 94025, USA

Despite the widely accepted biogenic origin and composition of sedimentary organic matter, identification of endogenous chemical signals within intact fossil organisms is often met with scepticism. Fossilisation processes (both biological and geochemical) are widely believed to eradicate any original biochemical information, but many studies have identified endogenous chemistry within fossils. However, these studies have predominantly focused on biological structures composed of relatively geo-stable molecules (e.g., lignin and chitin) and have used techniques that have limitations with regards to maintaining sample integrity that preclude many fossils from analysis and provide only small scale or no spatial information. Synchrotron Rapid Scanning X-ray Fluorescence (SRS-XRF) is an advance in XRF imaging that provides decimeter scale, 2D maps of elements in ppm concentrations in large (100x100x30cm) fossils at rapid acquisition rates (~30 s/cm^2 at 100 micron resolution). This allows the non-destructive visualisation of chemical variation of entire fossil organisms and their enclosing matrices *in-situ*, allowing the identification of biologically and geologically derived phases. This technique has shown that certain elements correlate with, and can reveal, discrete biological structures in a range of fossil and extant organisms. Additionally, X-ray absorption spectroscopy shows that the chemical inventory of fossil tissues commonly consists of organo-metallic and organo-sulfur compounds coordinated in a manner similar to comparable extant organisms. These findings support an endogenous origin for the observed fossil chemistry and thus fossil tissues may retain useful biochemical information. For example, previously unknown remnant tooth chemistry (phosphorus) within a 50 Mya fossil reptile has been revealed, and elements (e.g., copper) associated with dark eumelanin pigmentation have been identified and mapped within feathers of an exceptionally preserved 120 Mya Chinese bird.

Coupled Fe-S-P cycling in sediments of an oligotrophic coastal basin and the role of anaerobic oxidation of methane

MATTHIAS EGGER, TOM JILBERT AND CAROLINE P. SLOMP

Department of Earth Sciences, Utrecht University, The Netherlands

Studies of phosphorus (P) dynamics in coastal marine sediments typically emphasize the role of coupled iron (Fe), sulfur (S) and P cycling for sedimentary P burial and release. Here, we present field results suggesting that this model may have to be extended to include interactions of reactive Fe(III) phases with methane (CH_4).

Using pore water and solid phase analyses for sediments from an oligotrophic coastal basin (Bothnian Sea) we provide evidence for the formation of Fe-bound P, possibly vivianite ($Fe_3(PO_4)_2 8H_2O$), below the sulfate/methane transition zone (SMTZ). Solid phase Fe and S profiles indicate that the SMTZ in these sediments has recently shifted upwards to its current position close to the sediment-water interface (< 10 cm). This upward shift is attributed to an enhanced rate of methanogenesis driven by an increased eutrophication over the past decades. Below the SMTZ, extremely high Fe^{2+} concentrations (> 2 mM) are observed, and supersaturation with respect to vivianite is reached. We suggest that the exceptionally high dissolved Fe^{2+} concentrations in this non-sulfidic zone may be explained by anaerobic oxidation of methane (AOM) coupled to the reduction of Fe-oxides. Dissimilatory iron reduction appears to be unlikely due to the presence of relatively refractory organic matter. Instead, the concurrent presence of both abundant CH_4 and reactive ferric Fe rather suggests Fe reduction coupled to AOM. The resulting release of Fe^{2+} into the pore water and subsequent formation of Fe(II)-P provides an important sink for P released during reductive dissolution of Fe-oxides within and below the SMTZ. If this P sink below the SMTZ would be absent this would likely lower the P burial capacity and enhance the diffusive P flux out of the sediment back into the overlying water column.

Thus, while AOM coupled to Fe reduction likely accounts for only a relatively small percentage of CH_4 removal, our study suggests that the impact on the sedimentary P cycle could be large.

Visualisation of detrital zircon age data relative to deposition age and identification of potential provenance regions

BRUCE EGLINGTON[1]*, SALLY PEHRSSON[2] AND DAVE EVANS[3]

[1]University of Saskatchewan, Saskatoon, Canada; (*correspondence: bruce.eglington@usask.ca)
[2]Geological Survey of Canada, Ottawa, Canada; (pehrsson@nrcan.gc.ca)
[3]Yale University, New Haven, U.S.A.; dai.evans@yale.edu

Conventional probability function diagrams are routinely used to illustrate detrital zircon age data. Where numerous samples are available from stratigraphic successions, these probability plots require a lot of space and can not capture the link between zircon age and inferred stratigraphic (depositional) age. We present an alternative view of the probability plots which emphasise the relative stratigraphic age of different samples or lithostratigraphic units while illustrating which time intervals the majority of its detrital grains come from. In effect, one views the probability curves from above with the highest frequency sections of the curves plotted in emphasised ornament and colour relative to lower probability intervals in minimised ornament and shades of grey. This methodology has been built in to the DateView and StratDB online databases and into a standalone software package (FitPDF), all available from http://sil.usask.ca.

Once probability distributions have been associated with lithostratigraphic units in StratDB and DateView, the online software allows users to find all samples in the DateView geochron database which match detrital age peaks. These potential provenance localities may be further refined to take into account sediment transport directions and other geological constraints, after which it is possible to generate a probability plot for the most likely provenance localities for comparison with the actual (sample) detrital age distribution.

Locality information may also be illustrated on palaeogeographic reconstructions so as to enhance the regional provenance interpretation of detrital zircon data.

This approach is illustrated using data from the Kalahari and Pilbara cratons so as to assess different models for the Vaalbara hypothesis and of collision between the Zimbabwe and Kaapvaal cratons.

Geochemistry and the spatial patterns of water management are reflected in human hair

JAMES R. EHLERINGER[1], BRETT J. TIPPLE[1], LESLEY A. CHESSON[1] AND LUCIANO O. VALENZUELA[1]

[1]IsoForensics Inc., 421 Wakara Way, Salt Lake City, Utah 84108 USA (jim@isoforensics.com)

Element concentrations and isotopes of human tissues within urban regions are known to reflect human health, to provide diagnostic dietary information, and to provide region-of-origin information in a linear fashion. Here, we show the importance of isotopes of both oxygen in water and strontium within tap waters to the isotope ratios preserved within hair. We test the concept that oxygen isotopes in hair are predictable based of local drinking water values at the time that hair proteins (keratin) are initially produced within hair follicles, whereas strontium isotopes in hair reflect a progressive input from external tap waters after hair has emerged from the scalp. The contrasting inputs of oxygen and strontium isotopes to hair provide a predictable diagnostic tool that can be used in a wide array of forensics and region-of-origin studies. Since both oxygen isotope and strontium isotopes within drinking water are known to vary independently and spatially across continents in a predictable manner, the simultaneous measurement of both isotopes provides a new and powerful modern tool to reconstruct the region-of-origin of unidentified murder victims in forensic investigations.

Stable silicon isotopes in porewaters off Peru – diatom dissolution versus authigenic clay mineral formation

CLAUDIA EHLERT[12]*, KRISTIN DOERING[3], KLAUS WALLMANN[1], PATRICIA GRASSE[1] AND MARTIN FRANK[1]

[1]GEOMAR, Helmholtz Centre for Ocean Research, Kiel, Germany (*correspondence: cehlert@mpi-bremen.de)
[2]Max Planck Research Group for Marine Isotope Geochemistry, ICBM, University of Oldenburg, Germany
[3]Institute of Geoscience, University of Kiel, Germany

The stable silicon isotope compositions ($\delta^{30}Si$) of dissolved silicic acid and of diatom opal have been used successfully to investigate changes in nutrient utilisation and biogeochemical cycling processes in the present and past ocean. Opal dissolution, however, might have an effect on the preserved $\delta^{30}Si$ signal of diatom opal in the sediment and therefore on the interpretation of paleo $\delta^{30}Si$ records.

To investigate the effects of dissolution processes on the preserved diatom $\delta^{30}Si$ signal we analysed the sedimentary biogenic opal content and dissolved silicic acid concentrations of the porewaters, as well as their $\delta^{30}Si$ signals in the upper 20-50 cm of three short sediment cores from different water depths within the Peruvian upwelling region. The cores show large variations in biogenic opal content ranging from 10-25% in the shallowest core to only 1-2% in the deepest one. The dissolved silicic acid concentration in all three profiles increases with sediment depth. The dissolved $\delta^{30}Si$ signature of the porewaters is unexpectedly high (+1.1‰ to +1.9‰) with the highest values occurring in the uppermost 5-10 cm of the deepest station. These $\delta^{30}Si$ signatures are significantly higher than the diatom opal (+0.6‰ to +1.0‰) and the seawater above (+1.0‰ to +1.5‰). In the shallowest profile the porewater $\delta^{30}Si$ does not show significant variations with profile depth, whereas the deepest profile is characterised by a pronounced decrease in the porewater $\delta^{30}Si$ with increasing profile depth.

Based on these results we suggest that the heavy $\delta^{30}Si$ signatures near the top of the profiles are the result of the precipitation of authigenic clay minerals with a very light Si isotope composition leaving the porewaters isotopically heavy. With increasing profile depth the effect of clay precipitation diminishes and the dissolution of diatom opal becomes dominant. So far we cannot unambiguously conclude on any significant effect of these processes on the preserved $\delta^{30}Si$ of the diatom opal itself and therefore on the interpretation of the downcore paleo records.

Early stage uptake of Se into rice *(oryza sativa jap)* seedlings depending on medium and Se concentration

E. EICHE*, A. NOTHSTEIN AND G. KONRAD

Institute for Mineralogy and Geochemistry, KIT, 76131 Karlsruhe, Germany (*elisabeth.eiche@kit.edu)

Selenium is a ubiquitously present trace element which is of interest because of its essentiality for human nutrition but also because of its toxicity in slightly elevated concentrations [1]. Various factors like pH-/ redox-conditions, organic matter content, microbial activity or competing ions can influence the Se cycling in the rhizosphere [1,2]. In order to investigate and quantify the influence of individual parameters on the Se uptake we carried out simple experiments in artificial and controlled systems.

The early stage uptake of Se into rice seedlings depending on the concentration was investigated in the range of 0 to 50 ppb Se using hydroponic systems. Selenium was added as Selenate (SeO_4^{2-}) to nutrient solution and to phytoagar (0, 20 ppb). The rice plants were grown in a climatic chamber and were harvested after 10 (1st harvest) and 17 days (2nd harvest), respectively.

The results show a linear increase of plant Se accumulation with increasing Se concentration in the nutrient solution. The Se enrichment was >3 times higher after the 2nd harvest compared to the 1st one. Also, 3.7 times more Se was taken up by shoots compared to roots. It is striking that already 50 ppb of Se in the nutrient solution lead to an accumulation of 10 ppm in the rice, a concentration that normally assigned to plants grown on seleniferous soils [3]. An even higher Se content of 17.1 ppm was reached (2nd harvest) if Se (20 ppb) was added to phytoagar. Generally, 6 to 8 times more Se was accumulated if the Se bearing medium was phytoagar and not the nutrient solution. This is probably due to interaction and competition of Se with other ions in the nutrient solution.

Isotopic anatomies of organic molecules

JM EILER[1] AND D KRUMWIEDE[2]

[1]Caltech, Pasadena, CA, USA (eiler@gps.caltech.edu)
[2] Thermo-Fisher Scientific, Bremen, Germany

Most organic molecules exist in an astonishingly large and diverse variety of isotopologues, i.e., considering all possible site-specific and multiple isotopic substitutions. These species are fractionated from one another by physical, chemical and biological processes. Thus isotopic variations of organics must involve an extraordinarily large number of independent compositional dimensions. Full analysis of even a fraction of this diversity presents a complex, challenging problem, but would potentially yield much new information about sources, conditions, reaction mechanisms and perhaps other variables.

Several emerging technologies make such measurements: chemical and/or pyrolytic preparations; IR spectroscopy, SNIF-NMR; and novel instruments and methods of mass spectrometry. Each has strengths and weaknesses, but none to date is capable of examining both site-specific and multiple-substitutions in small quantities (ng-mg) of species larger than ~C3 hydrocarbons. Most isotopic diversity of most organic compounds remains out of reach.

We describe instruments, methods and initial results of an experiment to expand this field to encompass the isotopic anatomies of organics up to ~300 amu, potentially bringing into play fatty acids, amino acids, isoprenoids, and similar sized compounds. The experiment uses the MAT 253 Ultra, a prototype high resolution (M/ΔM~25,000) multi-collector gas source mass spectrometer, and the Thermo DFS, a very high resolution (up to ~80-100,000) single collector gas source mass spec that is generally used for identification of organic compounds. We use the Ultra to precisely determine the intensity ratios of ion beams that include all isotopologues of a given compound (or its fragment ions), free from isobaric interferences by contaminant species, and then use the DFS to perform rapid scans over a narrow mass window, measuring relative proportions of isotopologues of that species at each cardinal mass. Combination of these data constrains proportions of each isotopologue at each cardinal mass. Initial experiments on butane indicate that this approach may be able to constrain $\delta^{13}C$ of ion fragments with precision of ±0.1-0.2 ‰ and δD with precision of ±2-3 ‰. We intend to combine this approach with recently invented methods for analysis of multiply substituted and position specific isotopologues of alkanes on the Ultra to create a set of techniques for characterizing proportions of a large number of isotopologues of moderate-sized organic molecules.

The impact of climate on land derived nutrient fluxes to the ocean

EYDIS SALOME EIRIKSDOTTIR[1],
SIGURDUR REYNIR GISLASON[1] AND ERIC H. OELKERS[1,2]

[1]Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavík, Iceland, (ese@raunvis.hi.is).
[2]GET, CNRS/URM 5563-Université Paul Sabatier, 14 ave. Edouard Belin,, 31400, Toulouse, France.

Weathering and denudation influence greatly the global elemental cycles. There are two main sources of nutrients in the oceans, recycling due to microbial degradation and influx of nutrients from terrestrial runoff [1]. Some elements are essential nutrients for photosynthesis (N, P, Si, Ca, Mg, etc) while other, such as Fe, V, and Mo catalyse biochemical transformations at key points in the carbon and nitrogen cycles. Chemical denudation is positively correlated with runoff and atmospheric temperature [2]. In this study, we demonstrate the different effects climate has on the individual elemental fluxes, derived from silicate weathering in six basaltic river catchments in NE Iceland, of which three are of glacial origin and three are non-glacial rivers.

Concentrations of suspended sediments, major dissolved elements, and some trace elements are discharge dependent while concentrations of most trace metals are discharge independent. Due to the distinct behavoir of the particulate and dissolved elements, some are more sensitve to climate change than others. The climate dependence of elemental fluxes is also different between the glacial and direct-runoff rivers.

Data regression of ~40 years of chemical and flow was used to determine the influence of temperature and runoff on the annual fluxes of elements transported to the oceans. The fluxes of the major elements, and Sr and Mo, depended less on the climate than those of the fluxes of trace elements, including the micro-nutrients Fe and V. A change of one °C changes 1) major element, Sr and Mo fluxes, and 2) micro-nutrient fluxes by 13 – 15%, and 15 – 19%, respectively in the non-glacial rivers and by 4 – 14% and 8 – 19% in the glacial rivers. A 10% incremental runoff increase, within the runoff range of the individual river, changed the same fluxes by 7 – 9% and 10 – 15% in the non-glacial rivers and by 2 – 8% and 9 – 16% in the glacial rivers. These results show that elemental fluxes of glacial rivers are more sensitive to climate change than those of non-glacial rivers.

Metamorphic and magmatic overprint of garnet pyroxenites from the Beni Bousera massif (Northern Morocco): Mineralogical, chemical and textural records

FATIMA EL ATRASSI[1]*, FABRICE BRUNET[2], GILLES CHAZOT[3] AND CHRISTIAN CHOPIN[4]

[1]Laboratoire de G-Time, Université Libre de Bruxelles, Belgium (*Corresponding author : Fatima.El.Atrassi@ulb.ac.be)
[2] ISTerre, Université de Grenoble 1, CNRS, Grenoble, France
[3]Institut Universitaire Européen de la Mer, Brest, France
[4]Laboratoire de Géologie, Ecole normale supérieure, Paris, France

A detailed mineralogical and textural study of two garnet pyroxenites of the Beni Bousera massif, the garnet clinopyroxenite (GP) and the garnet clinopyroxenite containing graphite pseudomorphs after diamond (GGP), indicates a strong metamorphic overprint associated with the massif exhumation. In both pyroxenites, the primary assemblage [Cpx(I) + garnet +/- Opx] records temperatures in excess of 1200°C. Along the exhumation path, Cpx(I) has decomposed under sub-solidus conditions in at least two stages, which led first to pyroxene exsolution lamellae and second to garnet crystallization at the expense of the newly formed Cpx lamellae. These secondary garnets have grown in the 850-950°C temperature range. We show that these conditions are below the blocking temperature of the Mg-Fe exchange between garnet and pyroxene (ca. 1050°C) and above the blocking temperature of Mg-Fe interdiffusion in garnet. Consequently, the original composition of these secondary garnets has not been modified upon further cooling; equilibrium with the appropriate lamellar pyroxene can be used to retrieve meaningful P-T couples.

The late evolution of the Beni Bousera massif is recorded in the pyroxenites by the decomposition of primary garnet porphyroclasts into symplectite intergrowths at around 800-850°C below 10 kbar. These late conditions coincide with a major event: a temperature increase up to ca. 1050°C at most, which led to partial melting in both GP and GGP in the presence of water. The partial melting is evidenced by the presence of silicate films preserved in the graphite aggregates and the occurrence of interstitial amphibole and plagioclase.

Detailed chemical inspection of Gt–Cpx–Opx inclusions in the graphite pseudomorphs using LA-ICP-MS ablation, FEG-SEM and the electron microprobe indicates that (1) these silicates are genetically related to the same minerals in the bulk rocks and (2) they were chemically isolated from the bulk rock (included in diamond and/or graphite).

Ocean Geochemistry and Paleoproxies: Deep ocean carbonate ion through six glacial-interglacial cycles

H. ELDERFIELD

Department of Earth Sciences, University of Cambridge, CB1 1EE Cambridge UK; (he101@cam.ac.uk)

The presence of carbonate cycles in deep ocean sediments has been the subject of longstanding debate with much recent work supporting the view that changes in carbonate ion are responsible. Estimates of palaeo-carbonate ocean chemistry from boron incorporation in foraminifera provide important evidence. [CO_3^{2-}] estimates also play a role in paleothermometry with debate as to the roles of ocean chemistry versus dissolution. Here we present data of behaviour of epifaunal and infaunal benthic species, factors influencing porewater [CO_3^{2-}], and possibly boron coordination and emerging proxies. This is followed by evidence for elevated alkalinity in the glacial ocean with emphasis on sites within Circumpolar Deep Water.

Understanding D/H systematics of leaf wax *n*-alkanes in C_3 and C_4 plants at Stiffkey saltmarsh, Norfolk, UK

YVETTE ELEY[1]*AND NIKOLAI PEDENTCHOUK[1]

[1]School of Environmental Sciences, University of East Anglia, Norwich, UK (*contact: y.eley@uea.ac.uk)

D/H ratios of *n*-alkyl lipids are becoming increasingly popular as indicators of palaeohydrological regimes. The suitability of these compounds for such applications is dependent upon the precise nature of the information they are conveying. Current interpretations of this proxy are limited by an incomplete understanding of the mechanisms responsible for the variation in *n*-alkyl lipid δD values among plant species at individual locations.

To evaluate the relative importance of environmental, physiological and biochemical factors on the D/H composition of *n*-alkyl lipids, we sampled a range of C_3 and C_4 plants at Stiffkey saltmarsh throughout 2012. The results of δD analysis of soil, xylem, and leaf waters suggest that the bulk of interspecies variation in *n*-alkane δD values (>100‰) cannon be explained by environmental and plant physiological factors. Instead, we propose that species-specific D/H fractionation during lipid biosynthesis represents a fundamental control on *n*-alkane δD values of these plants.

Our ongoing work on starch δD will allow us to identify whether variation in carbohydrate recycling may explain the range of lipid δD in key species at our site. Furthermore, we are examining whether seasonal changes in leaf wax composition, including the nature and amount of precursor compounds, affect the *n*-alkyl D/H signal. Finally, our work on chloroplast-bound phytol will allow us to investigate whether the potential existence of different NADPH pools influences the δD of compounds biosynthesized in different plant compartments. Our results indicate an integrated physical and biochemical approach is required to interpret the D/H signals contained in the sedimentary record.

Isotope anomalies of Hf and W in chondrite leachates and residues

B.-M. ELFERS[1,2]*, S.T.M. PETERS[1,2], F. WOMBACHER[1,2] AND C. MÜNKER[1,2]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, 50674 Köln, Germany (*correspondence: elfersb@uni-koeln.de)

[2]Steinmann-Institut, Universität Bonn, 53115 Bonn, Germany

The stepwise dissolution of primitive chondritic meteorites allows to reveal nucleosynthetic anomalies that are otherwise hidden in the bulk rock mix. Leaching experiments for Hf and W have previously been published, but in separate studies that did not include the rare p-process isotopes ^{174}Hf and ^{180}W [1, 2]. Here, we present for the first time combined Hf and W isotope data for acid leachates of several chondritic meteorites, including sufficiently precise analyses of p-process ^{174}Hf and ^{180}W for some chondrites (EET 96026 (R3), MAC 02839 (EL3) and WSG 95300 (H3.3)).

For leaching experiments, sample powders of the different meteorites were treated with 2M HCl and divided into a leachate and a residue fraction. Tungsten and Hf were separated from the same sample split using anion exchange chromatography. The W fraction was subsequently purified with TODGA resin, and Hf was further purified using Ln-Spec. Measurements were performed on a Neptune MC-ICP-MS. For the collection of the small ion beams, amplifiers with $10^{12}\Omega$ resistors were employed. Interferences from Yb, Lu and W, and Hf, Ta and Os isotopes, respectively, were sufficiently low to allow accurate interference corrections. The external reproducibilities on ^{174}Hf and ^{180}W were better than ±60 ppm and ±70 ppm, respectively, but significantly larger for small samples cuts <60 ng Hf and <150 ng W, respectively.

First data reveals that most of the Hf leachates and residues show anomalous s- and r-process patterns that are consistent with the results of [1]. First W isotope s- and r-process patterns are furthermore consistent with data reported by [2]. Neither leachates nor residues exhibit resolvable non-terrestrial ^{174}Hf, whereas both positive and negative ^{180}W signatures are resolved for almost all leachates and residues. The origin of the apparent decoupling between ^{180}W and ^{174}Hf is presently ambiguous, but possibly point towards different carrier phases for p-process Hf and W.

B and O isotopes as tracers of serpentinization along fossil oceanic detachments, Troodos ophiolite, Cyprus

BAR ELISHA[1], YARON KATZIR[1], MEIR ABELSON[2], SAMUELE AGOSTINI[3], JOHN W. VALLEY[4] AND MICHAEL J. SPICUZZA[4]

[1]Ben Gurion Univ. of the Negev, Be'er Sheva Israel, (brelisha@gmail.com) (*presenting author)
[2]Geological Survey of Israel, Jerusalem, Israel;
[3]IGG-CNR, Pisa, Italy
[4]Univ. of Wisconsin, Madison WI 53706, USA

Serpentine lubricated detachment faults strike parallel to two segments of a paleo spreading center that are separated by the Arakapas transform in the Troodos ophiolite, Cyprus. To the north of the transform, serpentinite faulted against gabbro shows bimodal spatial distribution and covariance of B-O isotope ratios. These data indicate overprinting of fault localized, 'high temperature' oceanic serpentinization ($\delta^{18}O$=4 to 6‰; $\delta^{11}B$=-3 to 3‰) by widespread late hydration at lower temperatures, forming abundant chrysotile veins ($\delta^{18}O$=10 to 12‰; $\delta^{11}B$=7 to 13‰). At the Limassol Forest complex, south of the transform, extensive talc-amphibole-chlorite metasomatic zones and rodingitized gabbro boudins occur within strongly foliated serpentinite shear-zones separating an ultramafic section from sheeted dykes. $\delta^{18}O$ values of serpentine from shear-zones in the Limassol Forest have a narrow range and are invariably lower than mantle values(1 to 5.7‰; n=26), consistent with serpentinization during seafloor spreading. $\delta^{11}B$ (Srp) values are more scattered (5 to 27‰) and weakly correlate with boron contents (2 to 60 ppm), which might be accounted for by increase in pH of water as serpentinization progressed.

Absence of the lower crustal section above the mantle and injection of gabbroic magma followed by localized serpentinization, metasomatism and deformation along this discontinuity are major characteristics of oceanic detachments. Isotope systematics strongly resemble those of serpentine recovered from modern oceanic core complexes such as the Atlantis Massif. The mantle sequence of the Limassol Forest is thus suggested to have been exhumed at the footwall of an oceanic core complex. This scenario sheds light on the location of the spreading axis south of the transform and explains the highly complicated structure of the fossil ridge-transform intersection of the Limassol Forest.

Origins of anomalous ridge magmatism near Jan Mayen

L.J. ELKINS[1]*, E.R. RIVERS[1], K.W.W. SIMS[2], J. BLICHERT-TOFT[3], C. DEVEY[4], R. CHERNOW[1], R. DAVIS[1] AND K. MEISENHELDER[1]

[1]Bryn Mawr College, Bryn Mawr, PA, USA (*correspondence: lelkins@brynmawr.edu)
[2]University of Wyoming, Laramie, WY, USA (ksims7@uwyo.edu)
[3]Ecole Normale Supérieure de Lyon, Lyon, France (jblicher@ens-lyon.fr)
[4]GEOMAR, Kiel, Germany (cdevey@geomar.de)

The sustained volcanism at Jan Mayen Island, located immediately south of a major fracture zone (the Jan Mayen Fracture Zone) and adjacent to two slow-spreading mid-ocean ridges (the Kolbeinsey and Mohns Ridges), has been variably ascribed to a small, isolated plume, to material siphoned northward off the larger Icelandic plume, to convection-driven edge effects along a major compositional mantle discontinuity, and to the presence of highly fusable, wet, old, garnet-bearing material derived from veins or pockets of rift-faulted or delaminated Greenland sub-continental lithospheric mantle. The compositions of volcanic rocks from both Jan Mayen Island and the immediately adjacent segments of the Mohns and Kolbeinsey Ridges likewise support the long-term presence of mantle rocks enriched in incompatible elements. While the most recent work on long-lived radiogenic isotope compositions of Jan Mayen Island magmas has supported a complex model invoking several of the above scenarios of melting, no high-resolution sampling and analysis existed for the adjacent ridge segments.

We present geochemical data for new, precisely bathymetrically located volcanic samples from the Northern Kolbeinsey and Southern Mohns segments. Preliminary geochemical and bathymetric findings suggest that both segments host long-lived, localized sources of increased magma flux associated with the most geochemically enriched melt compositions hosted by those ridge segments, which decrease in indicators of geochemical enrichment with distance from Jan Mayen Island. The surface expressions of this high magma supply include large volcanic edifices straddling the axial valleys and walls, as well as evidence for ridge axis relocations in the direction of Jan Mayen Island. This supports a sustained point source of geochemically enriched magmatic activity beneath the region, consistent with a deep-seated mantle plume.

We further provide new U-series isotopic data for all three geographic areas, which place constraints on mantle source compositions and upwelling rates beneath the region.

Dripping, thinning, melt injection, metasomatism: Geochemical consequences of small-scale convection under continents

L. T. ELKINS-TANTON[1]*

[1]DTM, Carnegie Institution for Science, Washington DC 20015 (*correspondence: ltelkins@dtm.ciw.edu)

Through a variety of physical mechanisms, the lower lithosphere is thought to be recycled into the mantle, thinning the lithosphere and creating compositional differentiation. Lithospheric thinning has been inferred from increases in crustal heat flow in specific regions, rapid regional uplift, and from the appearance of signature high-potassium magmas [*e.g.* 1-5]. Seismic studies also support ductile delamination in specific areas [*e.g.*, *6*].

Geochemical arguments appear to require foundering of crustal and mantle lithospheric materials to balance elemental budgets. Though continental crust and mantle are complementary reservoirs with respect to most trace elements, the continental crust is too felsic to be derived directly from the mantle [7,8]. A possible solution is the loss from the continental lithosphere through delamination of mafic residues from fractionation of mantle melts. The same process would explain the significant fractionation of thorium and lanthanum in continental crust, when they are unfractionated during the processes of subducting sediments and producing arc magmatism [9].

A spectrum of physical mechanisms have been proposed for this small-scale convection. The greatest discriminator among them appears to be rheology, that is, how ductile is the material that is sinking away? The most brittle material might sink away in the shape of a plate, while the most ductile drip off as fluids. The feasibility of these processes depends upon composition, pressure, and temperature, and all these combine to affect the surface expression and compositional ramifications, from recycling differentiated compositions back into the mantle, to producing melt that might erupt.

Origin and evolution of volatiles in rocky airless bodies

L. T. ELKINS-TANTON[1]*

[1]DTM, Carnegie Institution for Science, Washington DC 20015 (*correspondence: ltelkins@dtm.ciw.edu)

Large planetesimals or asteroids, the Moon, and Mercury form a size continuum of airless bodies, but their formation histories are thought to be significantly different. While planetesimals formed from relatively lower energy accretionary impacts, they themselves continued to accrete gravitationally in more and more energetic impacts to build larger planets such as Mercury, and finally to produce the giant Moon-forming impact on the young Earth that resulted in the Moon. Despite the significant impact energy that went into producing the Moon, it was not completely dried and devolatilized during its formation [e.g., 1-3].

Part of the original evidence for a dry Moon, overturned by these recent measurements of volcanic materials, was the depleted K/U ratio compared to the Earth [4]. In contrast, Mercury shows a K content similar to the Earth and Mars, and thus may not be as depleted in volatiles as the Moon [5]. Similarly, measurements of meteorite compositions [6] indicate that neither primiive nor differentiated planetesimals were completely dried. Thus, the building blocks (planetesimals), the final planets (Mercury), and their impact debris (the Moon) all retained some fraction of their original volatile content.

In differentiated planetesimals and in the Moon and Mercury the silicate portions of the bodies were likely processed through a magma ocean stage [7]. Retention of volatiles is less likely in a planetesimal interior than it is in a planetary magma ocean. Internal heating from short-lived radiogenic aluminum 26 in small early planetesimals drives off volatiles from planetesimals above a certain size [8].

Fractional solidification in a planetary-sized magma ocean, in contrast, can retain some volatile fraction inside the planet through partitioning with solid phases and sequestration of interstitial melts. Model results for these processes will be compared with measurements from the Moon.

The Global U Isotopic Cycle

TIM ELLIOTT[1], MORTEN ANDERSEN[2]* AND HEYE FREMUTH[1]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK (tim.elliott@bris.ac.uk)
[2]Institute of Geochemistry and Petrology, ETH Zürich, CH 8092 Zürich, Switzerland (*correspondence: morten.andersen@erdw.ethz.ch)

The mobility of U under oxic conditions and its enrichment in the oceanic crust has long led to speculations about the importance of these low tempeature processes in the global distribution of U [e.g. 1]. Notably, the return flux of U from surface to mantle, via subduction, is potentially sufficient to perturb the mantle U abundance. This mechanism has been used as a means to explain puzzling features of mid-ocean ridge basalt (MORB) U-Th-Pb systematics [e.g. 2]. Advances in muti-collector inductively coupled plasma mass-spectrometry (MC-ICPMS) allow the hiterto presumed invariable $^{238}U/^{235}U$ ratio to provide new constraints on this cycle. Recent work has shown that the U in the near surface environment can be fractionated by about 1‰ [e.g. 3,4]. Therefore, recyling of significant amounts of isotopically fractionated U from the surface to the mantle has the potential to perturb not only its U abundance but also its isotope ratio.

In order to explot this potential we have had to tune our torch. Using a ^{233}U-^{236}U double spiking approach and by measuring intense U beams (>1nA), we have obtained precisions of ~0.02‰ on $^{238}U/^{235}U$ ratios of mantle derived samples. This provides sufficient resolution to detect the influence of recyled U in the mantle.

We have determined that the net effects of alteration and subduction leave deep recycled slab with isotopically heavy U [5]. The preferential return of this U into the upper mantle, as invoked to explain the anomalously low Th/U ratio of MORB [e.g. 2], predicts that MORB should be ~0.1‰ heavier than pristine mantle. We show that this prediction is realised in our measurements of MORB glasses relative to ocean island basalts and chondritic meteorites. Thus we provide striking, independent confirmation of the importance of recyling in shaping the U budget of the mantle courtesy of the capabilities of modern MC-ICPMS.

The turnover time of iron in the surface ocean can vary from days to weeks and months, while within cells the turnover time can be on the order of hours to days. Accordingly, the iron isotope ($\delta^{56}Fe$) composition of particulate organic matter should be sensitive to changes in the cycling of iron in the surface ocean and immediately below. Here we present data showing a dynamic change in the $\delta^{56}Fe$ composition of particulate organic matter during the development and subsequent export of phytoplankton bloom material. Our results, obtained from two FeCycle voyages in 2008 and 2012, suggest that before the onset and development of the phytoplankton bloom iron regeneration dominates the dissolved iron signal with lighter dissolved $\delta^{56}Fe$ valves (-0.14‰ at 100 m to 0.07‰ at 500 m) relative to particulate iron (-0.02‰ at 60 m to 0.13‰ at 300m). In contrast, during the development and export phase of the bloom, iron scavenging and/or iron consumption by heterotrophic bacteria community appears to dominate the dissolved iron isotope signal with heavier dissolved $\delta^{56}Fe$ values (0.15‰ at 30 m to 0.16‰ at 500 m) relative to particulate $\delta^{56}Fe$ valves (-0.11‰ at 30 m to -0.33‰ at 300 m). A strong relationship was also observed between particulate $\delta^{56}Fe$ and Fe/Al ratios with lighter values. The dissolved and particulate $\delta^{56}Fe$ results were modelled with Rayleigh-type functions and produced the following fractionation factors: 1.00015 prior to the onset and development of the bloom and 0.99945 during the subsequent export of the bloom material to depth. Taken together our results show that the iron isotope composition of dissolved and particulate material can be used to monitor changes in the biogeochemical cycling of iron in the marine realm.

[4]now at Faculty of Physics, Moscow State University, Russia

Fe-rich layer silicates are rare on Earth, but are a major component of CM2 carbonaceous chondrites. They formed during early aqueous alteration events that affected CM2s' asteroidal or cometary parent body [1]. Bulk magnetometry (300-2 K) has proven useful for characterizing Fe-serpentines' mineralogy, close to the pole cronstedtite in CM2s [2]. Comparison with results from single crystals supports the hypothesis of a variable Fe content of serpentines along the alteration sequence of CM2s [2], similarly to terrestrial serpentinization. Site distribution and valence of iron in serpentines would directly be linked to their growth conditions (T, water-rock ratio or duration [3]). Understanding the conditions in which the reactions occurred on the parent body of CM2s thus relies on a thorough characterization of their crystal chemistry.

Here we present the results of a X-ray Magnetic Circular Dichroism study at the Fe K-edge of oriented single crystals of cronstedtite, showing a strong planar anisotropy. We measured XMCD at various angles between the **c** axis and the applied field. We will show how ligand field multiplet calculations [4] allow one to separate various contributions to the pre-edge. This would yield an estimate of the crystal chemistry of Fe in this multisite (octahedral, Oh, and tetrahedral) and multivalent ($Fe^{2+,3+}$) mineral, allowing for a fine characterization of this alteration mineral in meteorites. Also, XMCD suggests that the anisotropy of cronstedtite originates from the strong single ion anisotropy of Fe^{2+} in distorted Oh sites. Finally, exploring the variations of XMCD with substitutions (mostly Fe-Si) would clarify which parameters control the disruption of a long-range magnetic order in Fe-serpentines, from AF, when only Fe^{2+} is present, in Oh sites [5], to spin-glass like, in cronstedtite [2].

Freshwater resources are becoming increasingly limited in many parts of the world, and decision makers are demanding new tools for monitoring water availability and rates of consumption. Remotely sensed data and especially Landsat imagery provides an estimate of land-surface temperature that allow mapping of evapotranspiration (ET) at the spatial scales. This work presents the utility of satellite imagery in water resource management. General modeling techniques for using land-surface temperature in mapping the surface energy balance are described, including methods developed to safeguard ET estimate. Examples are provided of how remotely sensed maps of ET derived from Landsat thermal imagery are being used operationally by water managers today: in monitoring water rights, negotiating, estimating water-use by invasive species, and in determining allocations for agriculture, urban use, and endangered species protection. To better address user requirements for high-resolution, time-continuous ET data, novel techniques have been developed to improve the spatial resolution of Landsat thermal-band imagery and temporal resolution between Landsat overpasses by fusing information from other wavebands and satellites.

Interactions between Fe(II) and arsenic species during co-sorption onto aluminum oxide and clay mineral substrates under anoxic conditions

EVERT J. ELZINGA*AND YING ZHU

Rutgers University, Department of Earth & Environmental Sciences, Newark, New Jersey, USA. (*correspondence: elzinga@andromeda.rutgers.edu)

Reductive dissolution of Fe(III)-oxides and hydroxides in suboxic and anoxic soils and sediments leads to substantial changes in aqueous geochemical conditions, including a strong increase in the aqueous concentrations of Fe(II) and trace metal(loid) species released during dissolution of Fe(III)-oxide sorbents. The fate of released Fe(II) and trace metal(loid)s is likely to be at least partially controlled by sorption reactions with mineral constituents remaining in the soil matrix, and may further be influenced by redox reactions between Fe(II) and redox-sensitive elements including As. While there have been quite a few studies addressing sorption of Fe(II), As(III) and As(V) onto common soil minerals in binary systems, very little is known about the interactions between these species in ternary systems involving co-sorption.

Here, we use a combination of batch experiments and X-ray absorption spectroscopy to study the co-sorption of Fe(II) with As(V) and As(III) onto aluminum-oxide and clay surfaces under anoxic conditions and at near-neutral pH values typical of reduced geochemical environments. We observe notable differences between the ternary and binary systems as to the extent and mechanisms of Fe(II) and As sorption. The XAS results indicate the operation of several processes, including formation of monomeric surface complexes and precipitation of Fe(II)-Al(III)-layered double hydroxides. Interactions among these processes and the significance of redox reactions in the ternary systems will be discussed.

Co-benefits of tackling poor air quality and regional climate: A focus on ecosystems

LISA EMBERSON[1], KEVIN HICKS[1] AND PATRICK BÜKER[1]

[1]Stockholm Environment Institute, Environment Dept. University of York, York, YO10 5DD, U.K.. (e-mail: l.emberson@york.ac.uk)

A substantial body of experimental evidence exists describing the impacts of ozone (O_3) and aerosols on important ecosystems (agro-, forest and grassland ecosystems). Much of this empirical data has been collected from co-ordinated studies conducted in North America and Europe; and more recently in Asia. Pooling these data allows the development of risk assessment methodologies which can be used to assess the benefits of emission reductions over regional to global scales. This talk describes these risk assessment methodologies focussing both on their strengths (in relation to providing estimates of a variety of ecosystem damage) as well as weaknesss and limitations (primarily associated with limited data availability for key global regions such as Asia, Africa and Latin America).

Within this context results are presented that describe benefits of emission reductions of O_3 and aerosol forming species for crop yields, forest productivity and grassland biodiversity along with benefits for near term climate. Examples of indirect benefits are also given by showing the importance of ecosystems acting as sinks for atmospheric pollution; alterations to this sink under extreme climates (e.g. heatwave type conditions) are exemplified through their influence on net atmospheric pollution concentrations and subsequent human health impacts.

Finally, the importance of considering ecosystem damage and feedbacks to the climate system within a new generation of Earth System Models, currently being developed to understand the implications of climate change, is advocated based on the evidence presented.

Characterization of the effects of grain size to mine water quality and Acid Rock Drainage (ARD) production in Kinetic Testing

R. EMBILE JR.[1,2,3], I.F. WALDER[1], F. MADAI[2], F. MORICZ[2], P. WALDER[1] AND P. RZEPKA[1]

[1] Kjeoy Research and Education Center, Kjeoy 8412 Vestbygd, Norway (*correspondence: rodrigofembilejr@gmail.com)
[2] University of Miskolc, Miskolc H-3515 Hungary
[3] Camborne School of Mines, University of Exeter

The quality of mine drainage from sulfide containing waste dumps is controlled by several factors and surface area (grain size) exposed to weathering conditions is important. However, the textural variation may control the main driving mechanisms for an acid generating or neutralizing reactions. Depending on their rates and intrinsic properties, leachate chemistry for a certain grain size can be characterized through different types of tests and analysis.

Kinetic test using humidity columns is performed on five different grain size ranges of waste rocks from the Recsk porphyry copper-skarn deposit in Hungary. Water leachate quality is analysed on a weekly basis for their pH, alkalinity, conductivity, anions, cations and dissolved metal concentrations. Results showed that finer grains produced near neutral to neutral pH and higher sulfate production rates unlike for coarser grains. This indicates that the rate of sulphide oxidation and neutralization may be only partly controlled by grain size as well as a number of interrelated factors.

Global variability of the ocean's biological pump from *in situ* measurements of the air-sea oxygen flux: A status report

STEVEN EMERSON*, SETH BUSHINSKY AND STEPHEN RISER

School of Oceanography, University of Washington, Seattle, WA, 98195 (*correspondence: emerson@uw.edu; smbush@uw.edu; riser@uw.edu)

The ocean's biological pump is the process by which biological production exports carbon and oxygen from the ocean's euphotic zone. The geographic variability of the biological pump, along with ocean mixing and air-sea exchange, strongly influences the pCO_2 of the atmosphere and maintains the oxygen distribution below the surface ocean. We propose to determine the global variability of the biological pump by measuring the air-sea oxygen gradient using oxygen sensors on profiling floats. Oxygen mass balances at ocean time-series sites indicate the connection between net annual air-sea oxygen flux and biological carbon export and suggest a biological pump of 2 – 4 mol C m^{-2} yr^{-1} with little global open-ocean variability; however, there are only about five locations where there is sufficient data to do this calculation. Global Circulation Models and Satellite color measurements predict the biological pump varies by as much as a factor of four among the equatorial, subtropical and subarctic oceans. A better global coverage of the annual air-sea oxygen flux would provide critical calibration for the predictions based on satellite color. To accomplish this we calibrated the Aanderaa oxygen sensors in our laboratory and modified the Argo profiling instrument package so that the oxygen sensors continue recording when they surface (every five days). The oxygen sensors on our special floats are positioned well above the float body so they are in the air when the float surfaces providing a measure of the air-sea pO_2 gradient. We deployed ten of these floats in March 2013 in the Western North Pacific across the Kuroshio extension. Winkler oxygen measurements were made near the floats after deployment to calibrate them in situ. This abstract was written only two weeks after successfully deploying and calibrating the floats in situ. We will report the results of the first three months of measurements to assess how accurately it is possible to determine the air-sea oxygen flux using *in situ* oxygen measurements on Argo floats. We believe this is the next step in using oxygen mass balance to determine the global distribution of the marine biological carbon pump.

How surface heterogeneity impacts reaction rates in carbonate rocks

SIMON EMMANUEL[1]* AND YAEL LEVENSON[1]

[1]The Hebrew University of Jerusalem, Jerusalem, Israel, (simonem@cc.huji.ac.il)(* presenting author)

Due to the ubiquitous nature of calcite in natural systems, much research has focused on determining the reaction kinetics of calcite dissolution. However, the empirical rate laws derived in such studies assume that the reactivity of calcite crystals typically used in laboratory experiments is the same as the reactivity of natural carbonate surfaces that have been exposed to fluid during diagenesis. In this study, we demonstrate that the difference between polished calcite surfaces and naturally-aged calcite surfaces is significant. Atomic force microscopy (AFM) measurements show that the rate of calcite dissolution within micron-size pores of a limestone sample is much lower than the rate of dissolution in the surrounding calcite surface. In addition, we use numerical simulations to show that this difference cannot be explained using a diffusion - surface reaction model. Instead, we attribute the heterogeneous reaction rates to the high density of tiny asperities on the polished surface surrounding the pore which increase the overall reactivity of the surface. We suggest that the range of reaction rates we observe could be representative of real geological systems, helping to explain the widely reported discrepancy between laboratory and field rates. The implications for weathering, dissolution in carbonate reservoirs, and carbon sequestration are also discussed.

Tracking stable CO_2 isotopes with laser spectroscopy at Jungfraujoch

LUKAS EMMENEGGER, BÉLA TUZSONAND, PATRICK STURM AND STEPHAN HENNE

Empa, Laboratory for Air Pollution / Environmental Techology, CH-8600 Dübendorf, Switzerland (lukas.emmenegger@empa.ch)

Isotope ratios of trace gases contain highly valuable information about their sources, sinks and transport processes from the local to the global scale. While isotope ratio mass spectrometry (IRMS) has been the method of choice, laser spectroscopy is rapidly gaining importance because it can deliver real-time data with unprecedented temporal resolution at moderate cost and instrument size.

We employ a quantum cascade laser absorption spectrometer (QCLAS) and perform continuous monitoring of the stable CO_2 isotopes in the free troposphere since December 2008 at the High Altitude Research Station Jungfraujoch (3580 m a.s.l.), Switzerland [1].The instrument is based on differential absorption technique in the 4.3 μm spectral range. Being a fully cryogen-free setup, it is well suited for unattended field applications, delivering both $\delta^{13}C$ and $\delta^{18}O$ of CO_2 at atmospheric abundance with a precision of 0.02 ‰ for both $\delta^{13}C$ and $\delta^{18}O$-CO_2 at 10 minutes integration time [2].

The high temporal resolution of the $\delta^{13}C$ time series allows the detection of pollution events and the application of the Keeling plot method for source signature identification. Backward Lagrangian particle dispersion simulations are used to determine the spatial origin of these CO_2 emission sources. Furthermore, the long data series permits the analysis of yearly, seasonal and daily patterns. Footprint clustering shows significantly different wintertime $\delta^{13}C$ and $\delta^{18}O$-CO_2 values depending on the origin and surface residence time of the air masses.

We present the development of the instrumental set-up, the improvements of the most critical parts and the resulting performance. Then, we discuss methodologies for calibration and data treatment and illustrate the advantages of measuring high time resolution isotopic signatures of CO_2 in the atmosphere with exemplary results.

Temperature-induced phase transitions in Pb/Sr-lawsonites

M. ENDE[1], B. WUNDER[2], M. KOCH-MÜLLER[2] AND E. LIBOWITZKY[1]

[1]University of Vienna, 1090 Vienna, Austria
[2]Helmholtz Centre Potsdam, GFZ (German Research Centre for Geoscience), 14473 Potsdam, Germany

Pb-lawsonite and itoigawaite ($SrAl_2[(OH)_2|Si_2O_7]\cdot H_2O$) were synthesised using either oxides [1,2], spinel phases with quartz, feldspars or glasses with stoichiometric compositions. The achieved crystal sizes reached 20 μm in maximum for the Pb-lawsonite and about 60 μm for itoigawaite.

For the syntheses a piston cylinder press at GFZ Potsdam, Germany was used. Experimental conditions were 600°C and 3-4 GPa for Pb-lawsonite and 700°C and 4 GPa for itoigawaite. Using Raman spectroscopy temperature-induced shifts of different bands were analysed. For Pb-lawsonite the most interesting one was a band at about 860 cm^{-1}, which probably arises from an $A1O_6$ stretching vibration [3]. It shows a minimum of two discontinuities, which could be interpreted as phase transitions at about 350 and 445 K (Fig. 1). Analyses of a band arising from a ν_{as} SiO_3 stretching vibration [3] reveal a minimum of one phase transition for itoigawaite at about 225 K.

These reversible phase transitions are comparable to those of lawsonite and are mainly caused by changes of OH^- and H_2O groups from disordered, apparently highly symmetric positions to ordered ones at lower temperatures [4].

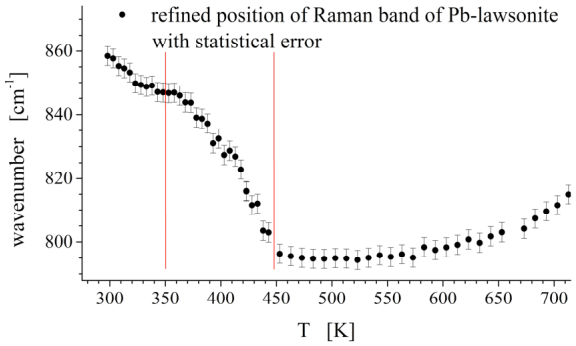

Figure 1: Raman band positions vs. temperature for Pb-lawsonite. Discontinuities probably reveal phase transitions.

Pressure-dependent change of ultraviolet absorption cross section of SO_2 isotopologues and S-MIF

YOSHIAKI ENDO[1], SEBASTIAN O. DANIELACHE[2], YUICHIRO UENO[1,3], SHOHEI HATTORI[4], MATTHEW S. JOHNSON[5] AND HENRIK G. KJÆRGAARD[5]

[1]Earth & Planetary Sciences. Tokyo Institute of Technology, Japan (endo.y.ac@m.titech.ac.jp)
[2]Faculty of Science & Technology, Sophia University, Japan
[3]Earth-Life Science Institute (ELSI), Tokyo Institute of Technology, Japan
[4]Environmental Chemistry and Engineering, Tokyo Institute of Technology, Japan
[5]Department of Chemistry, University of Copenhagen, Denmark

Photolysis of SO_2 is known to produce anomalous sulfur isotope fractionation (S-MIF). The mechanism of the photochemical S-MIF is important for reconstructing chemistry of paleoatmosphere, though has been still poorly understood. It is important to determine isotopologue-specific UV absorption cross section accurately for estimating fractionation factor of the SO_2 photolysis. We used a dual beam monochromator in order to obtain higher accuracy cross section that is complementary to high spectral resolution Fourier transform spectrometer [1]. The results show the peak position for heavier isotopologue is red shifted relative to the lightest $^{32}SO_2$ isotopologue, though rotational structures cannot be seen due to low spectral resolution. The observed cross sections systematically changed depending on the gas pressure at certain specific wavelengths. This may suggest that S-MIF can occur when SO_2 is photolyzed even under optically thin condition and thus not by self-shielding effect in the Archean atmosphere. Also, the observed pressure dependence of cross sections may indicate S-MIF can be changed as a function of atmospheric pressure.

Viruses outnumber prokaryotes in marine subsurface sediments

TIM ENGELHARDT[1], JENS KALLMEYER[2], HERIBERT CYPIONKA[1] AND BERT ENGELEN[1]*

[1]Carl-von-Ossietzky University of Oldenburg, Institute for Chemistry and Biology of the Marine Environment, Carl-von-Ossietzky Straße 9-11, D-26129 Oldenburg, Germany (*correspondance: Engelen@icbm.de, Tim.Engelhardt@icbm.de, Cypionka@icbm.de)

[2]Deutsches GeoForschungsZentrum GFZ, Telegrafenberg, 14473 Potsdam, Germany, Sektion 4.5 Geomicrobiology (kallm@gfz-potsdam.de)

The marine subsurface comprises nutrient-depleted and energy-limited environments, exhibiting a high microbial abundance and diversity. Sources of organic carbon in deeply buried sediments are vanishingly small and the long-term survival of indigenous microorganisms is still enigmatic. Cells are capable to live under energy-limited conditions but controlling factors for cell death in marine subsurface environments remain largely unidentified. Here, the question arises if viruses are controlling prokaryotic mortality. For this habitat, the general role of bacteriophages as a potential driver of microbial ecology was barely addressed so far [1, 2, 3]. Phages are known to contribute to carbon cycling and to control microbial communities in various marine habitats. Furthermore, they mediate horizontal gene transfer and thus, supporting the adaptation of host organisms to environmantal conditions.

We found phages to be highly abundant even in deep, ancient (~14 Ma old) and the most oligotrophic subsurface sediments of the world´s oceans (South Pacific Gyre). The number of viruses always exceeded that of prokaryotic cells and varied by several orders of magnitude within a comprehensive set of globally distributed subsurface sediments. Abundances of phages and cells generally decreased with sediment depth. However, an increasing virus-to-cell ratio is constituted in deeper and more oligotrophic layers, exhibiting values of up to 225 in the deep subsurface of the South Pacific Gyre. The presence of phages in enormous numbers suggests their impact on prokaryotic communities as controlling factor for cell abundance, diversity and life in the marine deep biosphere.

Analysis of internal dynamics in a deep subduction channel

MARTIN ENGI[1], DANIELE REGIS[1,2] AND DANIEL RUBATTO[3]

[1]Inst. of Geological Sciences, Univ. of Bern, Baltzerstrasse 3, 3012 Bern, Switzerland. (engi@geo.unibe.ch)

[2]Dept. of Environment, Earth & Ecosystem, The Open Univ., Milton Keynes, MK7 6AA, UK (daniele.regis@open.ac.uk)

[1]Research School of Earth Sciences, Australian National University, Mills Road, Canberra 0200, Australia

The spatial-temporal scales of tectonic fragmentation and mixing during the evolution of subduction channels need to be resolved. Current thinking nourished by numerical models requires critical testing against data on HP-terrains. However, deciphering natural archives of the time-integrated record of structural and metamorphic processes demands an approach that combines observations from μm- to km-spatial scales.

Our approach is shown for a case study in the Sesia Zone, a classic eclogite facies terrain in the Western Alps, Italy. The control provided by regional structural maps was extended from the meso- to the microscopic scale. Painstaking petrographic documentation was required to recognize the several generations of HP-assemblages, mineral inclusions, textural and chemical domains and to relate these in (relative) time. *in situ* dating by robust Th-U-Pb mineral chronometry was combined with thermobarometry; this allowed several stages of HP-tectonics to be discerned and metamorphic reactions to be related to the polyphase deformation. PTDt-sequences thus derived were mutually consistent for individual sample suites, but substantial differences emerged for different parts of the Sesia Zone. Their regional distribution indicates that tectonic slices (previously unrecognized) exist. Differential mobility between these lasted >20 Myr and one terrane experienced pressure cycling (ΔP ~5 kbar). These dynamics had escaped the many previous studies and predate what has until recently been accepted as "the age" of the Sesia HP-belt, i.e. ~65 Ma.

The major challenge remains to quantify the typical mobility of fragments within this subduction channel. In the Sesia Zone fragmentation at micro- to mesoscopic scale is very common in the eclogitic micaschists; in gneissic parts mylonites are not rare. Yet estimating the total amount of strain or the magnitude of displacements between adjacent units is difficult beyond the deca- to hectometer scale of outcrops. Our ongoing regional work aims to provide better constraints on the geometry and size of mobile tectonic slices, again using the petrochronological approach described.

At this stage of our study, it is clear that (km-size) tectonic fragments were independently mobile within the subduction channel, with vertical cycling rates of 2-3 mm/a.

Challenges connected with experimental upscaling of flow and transport in porous media

A. ENGLERT*, T. VAITL, S. FRANK AND T. GOEKPINAR

Hydrogeology Department, Ruhr-University Bochum, 44801, Germany (*correspondence: andreas.englert@rub.de)

Column and sandbox experiments have a long and successful tradition in estimating flow and transport parameters of porous media. A recently developed methodology based on the combination of column and sandbox experiments might be even capable for upscaling flow and transport as follows: In a first step, a cubic Darcy cell of 0.1 m x 0.1 m x 0.1 m is used to experimentally estimate flow and transport characteristics of an unconsolidated sediment, means flow and transport is experimentally upscaled from the pore-scale to the 0.1 m- scale. In a second step, the sediment filled Darcy cell is frozen and the frozen sediment cube is extracted from the Darcy cell. In a third step, nine frozen sediment cubes are composed in a sandbox model such that a sediment body of 0.3 m x 0.3 m x 0.1 m is formed. Finally the flow and transport characteristics of the sediment body are estimated based on flow and transport experiments. Such procedure could allow for successive experimental upscaling from the pore- to the 0.1 m- to the 1 m-scale of flow and reactive transport.

First tests of the recently developed setup for experimental upscaling showed that it is feasible to form sediment cubes, extract them from the experimental apparatus and assemble them in a sandbox model. It could also be shown that the developed experimental set up is well suited to study flow and transport in single sediment cubes and sediment bodies consisting of assembled sediment cubes. Our ongoing experiments focus on improving the accuracy of the developed set up. So far, we found hydraulic conductivities (Ks) of fine gravel sediment cubes rather constant, and Ks of coarse and middle sand sediment cubes slightly changing pre- and post freezing. We also found from sandbox experiments that sediment bodies formed based on fine gravel or coarse sand sediment cubes to be rather insensitive, but sediment bodies formed based on middle sand cubes to be prone to the formation of preferential flowpath. Through procedures such like tuning of the sediment structure in sediment cubes and bodies, but also optimized drainage of sediment cubes before freezing, we are confident to enhance the developed methodology to reach an accuracy needed for proper experimental upscaling.

Cretaceous Large Igneous Provinces: the effects of submarine volcanism on calcareous nannoplankton

ELISABETTA ERBA*, CINZIA BOTTINI AND GIULIA FAUCHER

Department of Earth Sciences, Università degli Studi di Milano, 20133 Milan, Italy. (*correspondence:elisabetta.erba@unimi.it)

During the Cretaceous the construction of Large Igneous Provinces (LIPs), forming gigantic oceanic plateaus, affected ecosystems at global scale. LIP volcanism was coeval with episodes of oxygen depletion in the oceans with consequent burial of massive amounts of organic matter known as Oceanic Anoxic Events (OAEs). Under these conditions, biota were forced to face excess CO_2 and global perturbations in the ocean-atmosphere system.

In the open ocean, coccolithophores are important carbonate rock-forming organisms, extremely sensitive to changes in physical-chemical parameters of surface waters. They are an ideal tracer for detecting the direct/indirect impacts of submarine volcanism on transient responses and evolution of calcifying biota.

We investigated calcareous nannoplankton assemblages across the early Aptian OAE1a and the latest Cenomanian OAE2, associated to the Ontong Java Plateau (OJP) and the Caribbean Plateau (CP), respectively. Massive submarine volcanism of OJP triggered a disruption in the oceanic carbonate system: excess CO_2 arguably induced ocean acidification that was detrimental to marine calcifiers, with temporary failure, but no extinctions, of rock-forming nannoconids and production of dwarf and malformed coccoliths. Similarly, during OAE2 the excess CO_2 from CP volcanism affected nannoplankton calcification inducing some coccolith dwarfism. Hydrothermal plumes during construction of both OJP and CP introduced biolimiting metals that fertilized the global ocean. However, some toxic metals might have disturbed the functioning of some intolerant coccolithophorid species.

There is a causal link between intervals of LIP submarine volcanism and changes in nannoplankton composition, abundance and biocalcification through OAE1a and OAE2. Changes in ocean chemistry, structure, and fertility during formation of oceanic plateaus might explain observed tempo and mode of nannoplankton evolution: major origination episodes might result from magmas especially enriched in biogeochemically important elements from the mantle.

Some Organic Geochemical Characteristics of Oil Shale Deposits in the Ereğli-Bor Basin, (Konya-Niğde), Central Turkey

M.S. ERDOĞAN[1]*, S. KORKMAZ[1], G. KADINKIZ[2] AND R. KARA-GÜLBAY[1]

[1]Karadeniz Technical University, Trabzon / Turkey (*correspondence: mserdogan@ktu.edu.tr)
[2]General Directorate of MTA, Ankara / Turkey

Upper Miocene-Pliocene aged oil shale sequence, with an average thickness ranging between 72 and 160 m, has been cross-cut during the drilling studies at Ereğli-Bor basin, Central Turkey. In addition, the live oil show has also been observed in this oil shale sequence.

Paleocene-Eocene aged volcanic, volcano-clastic, clastic and carbonate rocks form the base of this basin. This basin is overlain unconformably by the Oligocene-Middle Miocene aged evaporatic rocks, carbonates and clastic rocks. The upper Miocene-Pliocone aged oil shale bearing sequence overlie this unit. The Kızılbayır formation, is overlain by the Katrandedetepe formation which is composed of claystone, sandstone, siltstone, gypsium, anhidrite and oil shale. Sandstone and claystone alternations, known as Beştepeler formation, form the upper part of the sequence. All these units are overlain unconformably by Upper Pliocene-Holocene aged clastic sediments and volcanic rocks.

According to the Pyrolysis analyses results of the selected oil shale samples, total organic carbon contents (%TOC) of the oil shale range between 1.21 and 13.98, with an average TOC value of 4.75. Hydrogen index (HI) and oxygen index (OI) values, ranging between 127-664 and 7-50 respectively, suggest that oil shales are formed by Type II kerogen. Tmax values (ºC) range between 332 and 419. Considering the Tmax values, oil shales are considered to represent the immature stage, although some of them reflect the early mature stage. Pyrolysis data suggest no oil generation in the basin. The live oil show in the basin has probably formed due to the young volcanic rocks cross-cutting the oil shale which resulted oil shales to reach the thermal maturity.

Characterizing the Pb isotopic contribution of dust to seawater

A.M. ERHARDT[12], C-T. CHEIN[2], A.D. JACOBSON[3], C. M. MOY[4] AND A. PAYTAN[2]

[1]Stanford University, Stanford, CA 94305 (*correspondence: erhardt@stanford.edu)
[2] University of California Santa Cruz, Santa Cruz, CA 95064
[3] Northwestern University, Evanston, IL 60208
[4] University of Otago, Dunedin, New Zealand

Different sources of dust to the open ocean have varying effects on seawater chemistry, productivity and plankton community structure due to the release of various amounts of nutrients and trace metals. Pb isotopes in marine sediments have been used to reconstruct these dust sources (provenance). This is typically done by comparing the isotopic signature in the detrital fraction of sediments to the Pb isotope ratios of bulk dust or loess samples from dust source regions. What is missing in these studies is the isotopic composition of the seawater soluble fraction of the dust and its role in the seawater Pb isotope budget.

In this study, we characterized the Pb isotopic contribution of dust to seawater from select source regions to the Pacific Ocean through a direct simulation of dust solubility in seawater. We found that the readily leachable fraction of dust from multiple source regions to the Pacific Ocean is less radiogenic than the bulk source sample or that of the detrital fraction of sediments. Clear differences in the soluble and bulk Pb isotopic ratios of dust between the different source regions were also observed.

Knowing the true dust isotopic contribution to seawater allows for more accurate Pb mass balance calculations and clearer identification of dust sources and/or fluxes. We show preliminary results linking seawater, dust, ferromanganese, and detrital Pb isotope signatures in the Eastern Equatorial Pacific and generate a potential framework for future Pb mass balance calculations.

A comparison of shocked zircon and quartz from the Reis impact structure, Germany

TIMMONS M. ERICKSON*, STEVEN M. REDDY, NICHOLAS E. TIMMS AND ALEXANDER A. NEMCHIN

Department of Applied Geology, Curtin University, GPO Box U1987, Perth, WA 6945, Australia (*timmons.erickson@gmail.com)

Shock metamorphism is well established within the zircon and quartz mineral systems. Shocked quartz has been documented in a number of impact locations on the Earth and the shock deformation mechanisms have been identified, allowing for a well constrained thermobarometer of shock conditions to be developed [1]. Zircon is an important mineral in crustal studies and also records shock metamorphism through crystallographic deformation.

Shocked zircon has been identified from a number of impact structures, however development of a thermobarometer for shock metamorphism in zircon has been limited to one emperical study [2] and work on naturally shocked zircons from the Earth [3, 4, 5] and the Moon [6]. The work of Leroux *et al*. (1999) have determined that zircon exhibits planar microstructures >20 GPa, begins to transform to reidite >40 Gpa, completing conversion >60 GPa. Timms *et al*. (2012) further documented shock metamorphism of zircon and began to develop a shock deformation mechanism map. The aim of this study is to further constrain the development of shock features in zircon through the careful comparison of shocked zircon and quartz from the Reis impact structure.

We have therefore analyzed a suite of thin sections from the 14.4 Ma Reis impact structure in Germany from samples collected between 300 and 1204 m depth in the Nördlingen 1973 borehole. Previous work by Wittmann *et al*. (2006) determined shocked zircons in suevites from Reis exhibit planar microstructres, granular texture and reidite indicating samples were shocked >40 GPa, while other mineral systems indicate pressures >60 GPa. In this study shocked zircon and quartz have been analyzed petrographically and by SEM including EBSD to further resolve the correlation of shock deformation within these two mineral systems.

Petrology, mineral chemistry and Sr–Nd–Pb isotopic compositions of granitoids in the central Menderes metamorphic core complex: Constraints on the evolution of Aegean lithosphere slab

F. ERKÜL[1]*, S.T. ERKÜL[2], E.Y. ERSOY[3], İ. UYSAL[4] AND U. KLÖTZLI[5]

[1]Akdeniz Univ., Vocational School of Technical Sciences, 07058, Antalya, Turkey (*correspondance: fuaterkul@gmal.com)

[4]Karadeniz Teknik Univ., Department of Geological Engineering, Trabzon, Turkey
[5]Center for Earth Sciences, Department of Lithospheric Research UZA II, Vienna, Austria

Salihli and Turgutlu granitoids in the central Menderes metamorphic core complex are most suitable rocks in order to understand the magma forming processes in extended terrains. They are granodiorite in composition and contain monzonitic and monzodioritic microgranular enclaves. Host rocks are geochemically similar to each other while their enclave chemistry is in contrast with low SiO_2 and high Mg≠ values. Mineral chemistry data confirm a chemical equilibriation of distinct magma batches. Geochemical modelling suggests that these granitoids were derived from mixing of mantle and lower crustal components, which were finally modified by upper crustal contamination and fractional crystallization processes. Early-Middle Miocene syn-extensional granitoids across the Aegean region form a magmatic belt associated with roll-back of the Aegean lithosphere slab. Roll-back induced magmatism together with ductile deformation in western Turkey ceased after cooling of the Salihli granitoids at 12.2 Ma as defined in previous geochronologic work. But core-complex related magmatism was continuous in the Cycladic metamorphic core complex during Late Miocene and was followed by an active arc volcanism in the southern Aegean. Such abrupt change in the geodynamic setting of western Turkey can be explained by opening of a slab window on the Aegean lithosphere slab, which would lead to upwelling of fertile subslab asthenospheric mantle, forming transitional and finally OIB-type basalts.

Molybdenum isotopic composition of pre-GOE tidal carbonates

S. EROGLU[1]*, R. SCHOENBERG[1], N. BEUKES[2] AND M. WILLE[1]

[1]University of Tuebingen, Wilhelmstraße 56, 72074 Tuebingen, Germany (*correspondence: suemeyya.eroglu@uni-tuebingen.de)
[2]University of Johannesburg, Auckland Park Kingsway Campus, 2006, South Africa

The Transvaal Basin in South Africa contains one of the best preserved carbonate platforms of the Archaean. This platform was deposited between ~2.58 and 2.50 Ga [1], shortly before the 2.40-2.32 Ga great oxidation event (GOE) and is composed of alternating stromatolithic carbonates and shales. The depositional environment of the Transvaal Basin is very similar to modern tidal areas.

Variations in the isotopic abundance of the redox-sensitive transition metal molybdenum have been used in the past few years to constrain the redox conditions of Earth's atmosphere-hydrosphere system in the present and the past [2, 3]. Interestingly, carbonates and black shales from the slope of the Griqualand West Basin in South Africa, which can be well-correlated to the Transvaal Basin, shift towards heavy $\delta^{98/95}$Mo values, which might indicate an oxygenation of the atmosphere-hydrosphere system some 100 Ma before the GOE [4, 5]. In our study we determine the Mo content and $\delta^{98/95}$Mo composition of tidal carbonates from the platform of the Transvaal Basin, which precipitated in shallow waters and compare them to the contemporaneous deeper platform deposits of the Griqualand West Basin, in order to investigate the influence of sedimentary settings on Mo isotopic signatures. The very low Mo concentration of the carbonates generally lies around 20 ppb and most of our data cluster from +0.2 to +0.6‰ $\delta^{98/95}$Mo, but our preliminary results also reveal highly variable $\delta^{98/95}$Mo signatures between -0.7 and +1.4‰ and indicate an influence of the depositional environment of the stromatolites on their Mo isotopic composition. This observation might be an important aspect for future interpretation of Mo isotopic compositions of chemical sediments.

Geotechnical assessment of the rock masses in Düzyurt area (Trabzon, NE Turkey)

HAKAN ERSOY[1] AND M. OĞUZ SUNNETCI[2]

[1]Karadeniz Technical University, Department of Geological Engineering, Trabzon, Turkey, ersoy@ktu.edu.tr
[2]Karadeniz Technical University, Department of Geological Engineering, Trabzon, Turkey, moguzsunnetci@ktu.edu.tr

In this study, geological, hydrogeological, geotechnical properties of the rock masses in the Düzyurt Area (Trabzon, NE Turkey) were investigated. Engineering properties of geotechnical units were determined in two stages; surface and subsurface studies. Borehole applications, *in situ* testing, scan-line surveys (discontinuity direction, persistence, spacing, opening, roughness infilling material and RQD) and seismic surveys were conducted for description of geotechnical units and determination of vertical and horizontal homogeneity of these units in the site. *in situ* lugeon tests were applied for determination of bedrock permeability. During core drilling, lugeon tests were conducted and permeability of the rock masses is calculated. A total of 16 pumping tests were performed at the site in 5 boreholes. Based on the lugeon test results, permeability coefficients were calculated about 1.88 x 10^{-8} m/s for whole bedrock consisting of mainly limestone. According to the results, 1/2000 scaled engineering geological map was prepared. In the laboratory studies, physical and strength properties were determined on the samples collected from the boreholes and rock blocks in the geotechnical units. Rock mass strength was calculated with Hoek-Brown empirical approach using by data obtained from laboratory studies and scan-line surveys. Engineering properties of rock masses were performed with RMR system and durability of slopes in the area was investigated using kinematic analysis. GSI value for rock masses were calculated as 50. Based on the excavatability analysis of the rocks using seismic wave velocity and geotechnical properties of the rock mass, the excavatability category of rock masses is moderate-hard ripping.

A second rapid sea-level fluctuation during Termination II at Barbados

TEZER M. ESAT[1]* AND ERDEM BEKAROĞLU[2]

[1]Australian Nuclear Science and Technology Org., Kirrawee, Australia (*correspondence: tezer.esat@anu.edu.au)
[2]Ankara University, Sihhiye 06100, Ankara, Turkey

Rapid, centennial or shorter timescale, climate variations are often superimposed over thousands of year duration orbital insolation driven climate cycles. Fast paced Heinrich events of the last glacial period are associated with ice-berg discharges and sea-level oscillations that periodically have triggered changes in the North Atlantic Ocean's thermohaline circulation. The resultant severe climate shifts have been recorded in numerous climate proxies. Such climate variability is not confined to glacial periods but extend through degalciations and possibly into interglacial periods [1]. A definite pattern of climate change is discernible for the last six glacial terminations (T1, TII etc.) each of which appears to have gone through two major and distinct climate events. For T1 these are the Younger Dryas cold period and Henrich event H-1 during the so-called Mystery Interval [2]. Similar features are present at T3 and T4. At T2, there is a very large >60 m sea-level oscillation called the Aladdin's Cave (AC) transition first documented at Huon Peninsula that peaks around 135.3 ka, approximately 10 m below last interglacial sea levels [3,4,5,6]. A number of marine proxy climate records of the time as well as descriptions of European lacustrine deposits of the Saalian period indicate the presence of at least two climate oscillations which would be consistent with similar climate events during TI and TIII [2,6,7]. Along the Gordon Cummins Highway, adjacent to the West Indies University at Barbados, the road cut follows the rising sea-level during TII and there are deposits of fossil coral reefs that grew at the time in response to the rise in sea-level. Here, we have discovered a second peak in sea level at 133.5 ka, distinct from the timing of the original AC transition. The sea-level high-stand is close to the peak of the last interglacial relative sea levels at this location. However, its magnitude cannot be precisely quantified from the available data but may be as much as 90 m.

High frequency network sensors for integrating biogeochemical processes in the Seine River and quantifying the impact of Paris Megalopolis

N. ESCOFFIER[1], N. FLIPO [2], L. VILMIN[2], N. BENSOUSSAN[3], A. LAVERMAN[4], M. RAIMONET[4] AND A. GROLEAU[1]

[1]Géochimie des Eaux. Univ Paris Diderot, Sorbonne Paris Cité, IPGP, UMR 7154, CNRS , F-75205 Paris, France
[2]Centre de Géosciences. Systèmes Hydrologiques et Réservoirs. Mines ParisTech. 77305 Fontainebleau
[3]IPSO FACTO. 4, rue de Tilsit, F-13006 Marseille
[4]CNRS-UPMC UMR 7619 Sisyphe, Boite 125, 4 place Jussieu, 75005 Paris

The CARBOSEINE program, inititated in 2011, focuses on the urban part of the Seine river (Paris, France). It develops an integrated approach based on *in situ* sensors network in order to determine the main parameters controlling the biogeochemical carbon dynamics in the river. To do so, three on-line high frequency (every 15 min) multi-probe stations are devoted to the monitoring of the main hydrogeochemical parameters (weather, CTD, pH, phosphate, O_2, turb., chla) for the River downstream Paris (54 km long).

Carbon dynamics based on diel oxygen concentration variations allow the quantification of river metabolism processes over time. During algae blooms, river ecosystem shifts from heterotrophic to autotrophic on daily periods according to Net Ecosystem Production calculations. Combining Gross Primary Production and chlorophyll biomass leads to quantify the productivity of the autotrophic component, which can heavily differ from one bloom to another. Phosphate *in situ* measurements (4h freq.) demonstrates nutrient depletion without reaching the limitation level. They document the diffusive sources coming from watershed alteration, that allow algae growth upstream Paris. Moreover, these P measurements highlight the human impact variability. Comparison between probes located upstream and downstream the largest European Waste Water Treatment Plant allows to calculate the mass budget resulting from Paris megalopolis activity.

As a generic result, this high frequency observation approach constitutes a powerful tool for understanding and managing aquatic biogeochemistry in anthropic ecosystem. A challenge consists in developping an accurate data treatment strategy to segregate natural variations from human impact, with respect to different observation time scales. Finally, the generated dataset, allows to develop new modelling techniques to better define the processes representation in river numerical models.

Using textural data and fractal analysis to infer crystallization of dacites from Qorveh (W-Iran)

A. ESKANDARY[1]*, R. DE ROSA[2] , S. AMINI[1] AND H. MIRAJ[1]

[1]University of Kharazmi, Mofatteh Street, Tehran, Iran (*correspondence:amir.eskandary157@gmail.com)
[2]University of Calabria, via P. Bucci I-87036 Arcavacata di Rende (CS), Italy (rosanna.derosa@unical.it)

Polybaric crystallization in a volcano feeding system generally produces concave-up trends in diagrams of crystal size distribution (CSD) of the related emitted products, a feature testified both in natural and experimental studies [1,2]. In the present work, CSD technique has been applied to plagioclase crystals in plio-quaternary dacitic lavas of Qorveh volcano (Western Iran).

Crystal size distributions of more than 9000 plagioclases of the six collected samples were plotted in natural logarithmic scale (Ln) as the number of crystals per unit length and per unit volume (n(L); mm-4) vs. crystal lengths (L; mm). According to textural and CSD data, three distinct populations of crystals were identified: 1) phenocrysts (L>0.6) with coarse sieve texture and complex zoning patterns; 2) micro-phenocrysts (0.2<L<0.6) and 3) microlites (L<0.2). Furthermore, CSDs show a fractal behavior, with fractal dimension ranging 2.44-2.75. In addition, based on the box counting method, also distribution patterns of plagioclase crystals present fractal dimensions.

Our study suggests a strong control on size and spatial distribution of plagioclase crystals by complex processes of crystallization related to decompression and degassing, different rates of ascent velocity and depth of crystals nucleation and growth.

Temporal evolution of subduction signatures in a continental back-arc

VENERA R. ESPANON [1,2]*, ANTHONY DOSSETO [1,2] AND ALLAN R. CHIVAS[2]

[1]Wollongong Isotope Geochronology Laboratory,
[2]GeoQuEST, School of Earth and Environmental Sciences, University of Wollongong, NSW (2522), Australia *(vre981@uowmail.edu.au)

The Andino-Cuyana Basaltic Province (ACBP) constitutes part of the Quaternary continental back arc in southern Mendoza, Argentina. This basaltic province is divided into the Llancanelo Volcanic Field (LLVF) to the north and the Payunia Volcanic Field (PVF) to the south. The younger basalts are from the PVF and they range from <10 ka to approximately 50 ka [1], while the flows from LLVF are older Pleistocene basalts [1] lacking any Holocene volcanism. The ACBP presents a range of basaltic flows providing an appropriate setting to investigate changes in back-arc geochemistry during the late Quaternary.

In this setting, this study aims (i) to quantify the relative influence of the Andean arc and subducting slab in the back-arc, and thus (ii) to identify types and timescales of processes controlling back-arc volcanism in the ACBP. For this purpose, we present a suite of geochemical data (major and trace elemental analyses, REE, $^{87}Sr/^{86}Sr$, $^{226}Ra/^{230}Th$, $^{238}U/^{230}Th$) from the two volcanic fields and relate them to existing data from Andean arc basalts.

Our results show that basalts from the LLVF and the PVF have intraplate and arc related signatures with enrichment in LILE, HFSE and REE compared with basalts from the Andean arc. The older basalts from the LLVF and PVF have stronger arc signatures. In the PVF we observed a decrease in arc signatures from approximately 100 ka to 10 ka with a strong enrichment in LILE, HFSE and REE in the young basalts which could be related to metasomatised mantle or continental lithospheric mantle.

Ascent of magmas associated with the Solchiaro eruption Procida Island (Italy) based on melt inclusions and glasses

ROSARIO ESPOSITO[1]*, MATTHEW STEELE-MACINNIS[2], CLAUDIA CANNATELLI[1], ANNAMARIA LIMA[1], BENEDETTO DE VIVO[1] AND ROBERT J. BODNAR[2]

[1]DISTAR, Università degli Studi di Napoli Federico II, Via Mezzocannone 8, Napoli, 80134, Italy (*Correspondence: rosario.esposito3@unina.it, claudia.cannatelli@unina.it, anlima@unina.it, bdevivo@unina.it)

[2]Department of Geosciences, Virginia Tech, 4044 Derring Hall, Blacksburg VA, 24061 USA (rjb@vt.edu, mjmaci@vt.edu)

The Solchiaro eruption on the island of Procida is one of the few trachybasaltic eruptions in the Phlegrean Volcanic District (PVD), Italy.

The goal of this study is to provide information on the magma dynamic associated with the Solchiaro eruption based on hourglass inclusions (HI), glass embayments (GE) and melt inclusions. HI are portions of melt ± vapour connected to the outside of phenocrysts through a narrow neck, and GE are portions of melt ± vapour delimited by an indentation in a phenocryst. We have characterized the major, minor and trace elements and volatile compositions of several HI and GE glasses. The HI and GE are associated with olivines of samples from the Solchiaro eruption, representing different stratigraphic heights.

The results show a good negative correlations between the maximum contents of dissolved H_2O, CO_2 and S of HI and GE and the eruptive time (stratigraphic heights). Reversely, minimum contents of Cl and F of HI and GE show positive correlation with the eruptive time.

The H_2O and CO_2 contents of some of the early-erupted HI are the same as those of early-erupted MI [1, 2] suggesting that residence times of early-erupted olivine were short enough to preserve the original dissolved volatile contents of HI. Alternatively, some HI were quenched to a glass from a great depth (up to 8 km) under equilibrium conditions. We develop a quantitative model to understand the duration of decompression for the Solchiaro eruption based on shape and size of both the HI and the contained bubble(s) as was previously done for the Bishop Tuff [3].

Attachment of aspartic acid at the brucite [$Mg(OH)_2$]-water interface

C. F. ESTRADA[1,2]*, D.A. SVERJENSKY[1,2] AND R.M. HAZEN[2]

[1]Johns Hopkins University, Baltimore, MD 21218, USA (*correspondence: cestrada@jhu.edu, sver@jhu.edu)

[2]Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC 20015, USA (rhazen@ciw.edu)

The interaction of organic molecules at the mineral/water interface could play a key role in the emergence of more complex organic species in origins of life scenarios. In one such scenario, hydrothermal vents, particularly serpentinite-hosted hydrothermal vents, may possibly act as a suitable environment for this process to occur. We conducted a batch adsorption study between a stable mineral product of serpentinization, brucite ($Mg(OH)_2$), and the amino acid aspartic acid at 25ºC. We studied the adsorption of 2-500 μM aspartate onto a pure synthetic brucite at a single pH value of ~10.4 and a solid to ligand concentration of 10 g•L^{-1} under conditions where the brucite was in thermodynamic equilibrium with the aqueous solution. The point of zero charge (pH_{ZPC}) of brucite is approximately 11.0 [1], thus resulting in weak electrostatic attraction between the weakly-positive brucite surface and the negative aspartate. We obtained an isotherm, in which the concentration of aspartate adsorbed onto brucite reached a maximum of about 0.1 μmol/m^2, after increasing linearly with the concentration of aspartate in solution ($[Asp]_{aq}$) from 2-100 μM and leveling off at 250-500 μM. We used an extended triple-layer surface complexation model (ETLM) to acquire a preliminary fit to the isotherm. The data and the ETLM suggest that the surface site density is restricted to a very low value. Model predictions also suggest that the extent of aspartate adsorption onto brucite will decrease with increasing background electrolyte concentration. In comparison with our previous batch adsorption study of aspartate onto rutile (TiO_2) [2], we conclude that aspartate adsorbs to a lesser extent onto brucite than rutile. This is the first study in which we have obtained an adsorption isotherm for a non-oxide, rock-forming mineral and an amino acid. We expect the adsorption data collected for this system at surface conditions to provide a necessary analog for future adsorption experiments at hydrothermal conditions with implications for the emergence of complex biomolecules on Early Earth environments.

Bacterial populations (first record) at two shallow submarine hydrothermal vents off west Mexico

A. ESTRADAS-ROMERO[1], S. DÁVILA-RAMOS[2], R.M. PROL-LEDESMA[1]*AND K. JUÁREZ-LÓPEZ[2]

[1]Instituto de Geofísica, Universidad Nacional Autónoma de México, Ciudad Universitaria, Delegación Coyoacán, 04510 México D.F., México (a_estradas@hotmail.com,*correspomdence: prol@unam.mx)

[2]Instituto de Biotecnología, Universidad Nacional Autónoma de México, Cuernavaca, Morelos. C. P. 62210, México (sdavilar@ibt.unam.mx, katy@ibt.unam.mx)

Thermophilic and metal oxidizing bacteria were identified in shallow hydrothermal vents on the western Mexican coast. The role of these bacteria in biomineralization processes observed in the vents is explained, and the effect of the vents on biodiversity of prokaryotes is discussed. Research was done at two shallow hydrothermal vent sites: Bahía Concepción in the Baja California Peninsula and Punta Mita, in the central Pacific coast. The study focuses on the biogeochemical processes related to the different species of bacteria present in the studied sites, which are involved in the anaerobic oxidation of methane (AOM), seawater sulfate reduction and metal oxidation. Vent water shows different composition in both sites; moreover, different pH and redox conditions control bacteria diversity. The composition of the discharged water ranged from nearly sea water to lower salinity fluids with a pH about 6, and the gas phase in the hydrothermal fluids was mainly CO_2 at the Baja California site, and N_2 and CH_4 at Punta Mita. The detected bacterial lineages represented typical deep vent species.

Physical and chemical characteristics of the geothermal manifestations play a major role in the biodiversity of bacteria in shallow hydrothermal vents. In the case of the submarine vents in Bahia Concepcion and Punta de Mita, the redox conditions determine the presence/absence of distinct species of bacteria: gamma, delta and epsilon bacteria as well as bacteriodetes in the oxidizing conditions of Bahia Concepcion; and thermotogae, aquificae and planctomycetes in Punta de Mita. On the other hand, there are some species that are ubiquitous in shallow vents, as the halophilic and chlorofleaxae bacteria.

Tracing antropogenic Hg emissions in an urban area in Northeastern France

N. ESTRADE[1], C. CLOQUET[1], D. AMOUROUX[2], E. TESSIER[2] , O.F.X. DONARD[2] AND J. CARIGNAN[1]

[1]CRPG, UMR 7358, CNRS-Université de Lorraine, France

[2]IPREM/LCABIE, UMR 5254, CNRS-Université de Pau et des Pays de l'Adour, France (*correspondence: nestrade@crpg.cnrs-nancy.fr)

Mercury (Hg) isotopes are giving new insights into the study of the Hg biogeochemical cycle through large mass dependent and mass independent fractionations (MDF and MIF). A few studies have evaluated the ability to trace atmospheric Hg using both direct atmospheric measurements [1] and indirect bio-accumulators such as lichens [2,3]. Species-specific isotopic compositions of atmospheric Hg display large ranges in both MDF and MIF, and their distinct signatures suggest the occurrence of isotopic fractionation during species conversion [4]. The isotopic compositions of atmospheric depositions potentially recorded in bio-accumulators can be altered through various fractionation processes [3], leading to ambiguous interpretation of Hg isotopic composition to track down atmospheric sources. As regards anthropogenic emissions, different species-specific compositions have been suggested [5] but direct field measurements have not yet been performed.

We report species-specific Hg isotope compositions inside and at the stack of a waste incinerator located in an urban area in northeastern France. Gaseous mercury concentrations and isotope compositions were measured simultaneously in the vicinity of the waste combustor. The main results from the exhaust indicate that oxidized Hg species are slightly enriched in heavier isotopes compared to Hg^0 species and initial Hg (waste). Diurnal variations recorded for Hg concentrations in the atmosphere are not compatible with the incinerator emissions. In contrast to incinerator emissions, isotopic compositions measured over several days of sampling display significant light isotope enrichment and indicate a little contribution of incinerator to surrounding atmosphere. Further interpretation and comparison with previously published urban topsoil and lichen compositions from the same urban area, provide us relevant informations to trace Hg anthropogenic emissions on such local scale.

Nickel isotope fractionation in the soil to hyper-accumulating plant system

N. ESTRADE[1]*, C. CLOQUET[1], T. DENG[2], G. ECHEVARRIA[2], T. STERCKEMAN[2] AND J.L. MOREL[2]

[1] CRPG, UMR 7358, CNRS-Université de Lorraine, Nancy, France (*correspondence: nestrade@crpg.cnrs-nancy.fr)

Nickel stable isotopes are a promising non-traditional stable isotope system for understanding the Ni biogeochemical cycle, especially in contaminated or highly enriched environmental compartments such as ultramafic contexts. Ni hyperaccumulating plant species (e.g. *Alyssum murale*) growing in ultramafic soils can concentrate up to several weight percent in leaves and may be used in phytoremediation or phytomining. In addition to its insensitivity to redox-processes, nickel homeostasis in hyperaccumulating plants is poorly understood. In this work, we used Ni stable isotopes to document the isotopic fractionation range during accumulation processes from soil to Ni-hyperaccumulating plant species in a field investigation.

Sampling was carried out in Albania at four different sites and included the collection of several hyperaccumulating plant species as well as tolerant ones. Using two-step chemistry to isolate Ni and the double-spiking technique to correct for instrumental mass fractionation, we recorded Ni concentrations and Ni isotope compositions along the continuum of ultramafic rock, soil (different horizons), litter, roots, stems, leaves and flowers. In typical Ni-rich soil, root and litter concentrations ranged between 1-3 g kg^{-1} dry matter. Nickel accumulation increased to 3-6 g kg^{-1} in stems and reached up to 20 g kg^{-1} in leaves. In contrast, tolerant species present Ni concentrations in leaves within the 0.1 g kg^{-1} range.

Preliminary results in hyper-accumulator plant samples did not reveal large extent of isotope fractionation between roots and leaves (0.2‰). Further investigation is ongoing to confirm these results and evaluate the entire soils plants variations.

Dusts from metal smelters in Africa: Mineralogy, leaching and contaminant bioaccessibility

V. ETTLER[1]*, M. VITKOVA[1,2], M. MIHALJEVIC[1] AND B. KRIBEK[3]

[1]Institute of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University in Prague, Albertov 6, 128 43 Prague 2, Czech Republic (*correspondence: ettler@natur.cuni.cz, mihal@natur.cuni.cz)

[3]Czech Geological Survey, Geologicka 6, 152 00 Prague 5, Czech Republic

Dry climate and strong winds are believed to be responsible for dispersal of contaminated dust particles in areas affected by mining, mineral processing and smelting [1]. We evaluated the solid speciation, leachability and potential bioaccessibility of metals (Co, Cu, Pb, Zn) and As in fly ashes and slag dusts originating from the metal mining and smelting areas of Zambia (the Copperbelt Province) and Namibia (the Tsumeb area). Dusts were highly enriched in inorganic contaminants (up to 273 g Cu/kg, 8.9 g Co/kg, 39 g Pb/kg, 21 g Zn/kg and 437 g As/kg). Based on XRD, SEM, EPMA and HRTEM investigations, major contaminant-bearing phases were cuprospinel ($CuFe_2O_4$), chalcanthite ($CuSO_4.5H_2O$), delafossite ($CuFeO_2$), arsenolite (As_2O_3) and minor galena (PbS), anglesite ($PbSO_4$), sphalerite (ZnS) and elemental Cu [2, 3]. The pH-static leaching tests indicated that contaminants were released from the fly ash mostly at low pH [2, 3], corresponding to conditions found in laterite soils from this area. We also adopted *in vitro* methods based on simulated gastric fluid (SGF) and simulated lung fluid (SLF). The maximum bioaccessibilities in SLF were relatively low (Co 16%, Cu 2%, Zn 1.2%, As 2.9%), whereas values higher than 20% were obtained for SGF (Co 80%, Cu 50%, Zn 77%, As 83%). The obtained data indicate that a severe health risk related to smelter dust ingestion/inhalation should be taken into account in these areas. This study was supported by the Czech Science Foundation (projects no. 13-17501S and P210/12/1413) and IGCP project no. 594.

Aerosol impact on the stratiform cloud and light precipitation in mid-Korean peninsula

SEUNG-HEE EUN AND BYUNG-GON KIM*

[1]Department of Atmospheric Environmental Sceinces, Gangneung-Wonju National University, Jibyun, Gangneung, Korea (bgk@gwnu.ac.kr)

Many observational and numerical studies have indicated that land cover and aerosol effect modify cloud property, precipitation, and further weather pattern over and downwind of urban region. Because these effects have occurred in the urban region together, it is important to understand each effect over and downwind of urban region. Eun *et al*. (2011) showed increasing trend of precipitation amount and frequency downwind of Seoul Metropolitan Area (SMA) from 1972 to 2007, for particularly light precipitation (less than 1 mm per day) and westerly condition only. It implies the possible influences of land cover change and aerosol on the precipitation in the downwind region of SMA. Based on observed results, we selected golden case (10 February 2009) to investigate the impact of aerosol on light precipitation using the Weather Research & Forecasting (WRFV3.2) model. The sensitivity run sets up 1,000 #/cm^3 for the initial number concentration of cloud condensation nuclei (CCN) at SMA, but the background uses 100 #/cm^3.

The results show that mean horizontal wind from surface to 850 hPa have easterly wind and approximately 5~6 m/s. Cloud thickness is about 500 m, and locates within 2 km. Also the results of cloud properties indicates that the enhanced CCN at SMA is associated with smaller effective radius (re; μm) and more cloud droplet number concentration (Nc; #/cm^3) over and downwind of urban region than control run. Especially after 3-hour, change of re and Nc was distributed much more widely downwind of urban region. On the other hand, precipitation amount appears to widely increase in the downstream region of SMA. In the near future, further sensitivity tests need to be conducted for combined effect of land cover and aerosol effect on the light precipitation.

This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education, Science and Technology (20120007572).

Reconciling seawater Mg/Ca reconstruction with foraminifera geochemistry

DAVID EVANS[1]*, WOLFGANG MÜLLER[1], JONATHAN EREZ[2], SHAI ORON[3] AND WILLEM RENEMA[4]

[1]Dept. of Earth Sciences, Royal Holloway Univ. of London, UK

*(correspondence: david.evans.2007@rhul.ac.uk)

Virtually all Paleogene seawater Mg/Ca (Mg/Ca_{sw}) proxy data suggests values 2-4 times lower than the present day. Despite this, the majority of studies utilising foraminifera Mg/Ca (Mg/Ca_{test}) as a palaeothermometer during this period have argued for ratios around twice as high as the proxy evidence suggests. This is because the use of lower Mg/Ca_{sw} values resulted in unrealistically high palaeotemperature estimates. It has now been shown that this inconsistency is the result of an incorrectly assumed linear relationship between Mg/Ca_{sw} and Mg/Ca_{test}, as detailed in Evans & Müller [2012].

In order to empirically show that this theory is applicable to foraminifera, we have produced the first combined Mg/Ca-temperature and Mg/Ca_{sw}-Mg/Ca_{test} calibrations for the same species, derived from both cultured and field-sampled *Operculina ammonoides*, a shallow-dwelling large benthic foraminifera. We apply these calibrations to Eocene samples from Java and the southern UK; *O. ammonoides* is the closest living relative of the abundant Paleogene *Nummulites*. We utilise laser-ablation ICPMS as a highly spatially resolved analytical technique capable of identifying newly precipitated calcite in cultured material (via a [Ba] spike), and less well-preserved areas of fossil calcite through the simultaneous analysis of proxy and diagenesis-identifying trace elements.

The consistency between our field and culture Mg/Ca-temperature calibration suggests secondary controls on Mg incorporation are less problematic for large benthic foraminifera in comparison to planktic species. Our Mg/Ca_{test}-Mg/Ca_{sw} calibration confirms the power relationship described by studies based on other foraminifera.

By placing reasonable constraints on palaeotemperature, our calibrations enable us to demonstrate for the first time that foraminifera-derived data imply Mg/Ca_{sw} in excellent agreement with other proxy evidence.

Sources of sulfur and sulfur preservation in subducted rocks: An *in situ* sulfur isotope study

K.A. EVANS*[1] A.G. TOMKINS[2] AND J. CLIFF[3]

[1]Applied Geology, Curtin University, GPO Box U1987, Perth, WA 6845, Australia. (*correspondence: k.evans@curtin.edu.au)
[2]School of Geosciences, Monash University, Melbourne, VIC3800, Australia
[3]Centre for Microscopy Characterisation and Analysis, University of Western Australia, WA6009, Australia

A number of lines of evidence suggest that the sub-arc mantle is 1-2 log units more oxidised than mantle elsewhere, though this conclusion is controversial, and the processes that may contribute to sub-arc mantle oxidation are poorly understood. Sulfur has been proposed as a vector for transfer of redox budget from subducting slab to sub-arc mantle. Sulfate may be present in altered ocean crust in significant quantities, and the transfer of 8 electrons as S(+6) in sulfate is transformed to S(-2) in sulfides means that the addition of sulfate to sub-arc mantle could significantly alter mantle redox budget and oxygen fugacity on geologically reasonable timescales. However, little is known of the relative stability or solubility of sulfur-bearing phases under subduction conditions so this possibility is hard to evaluate.

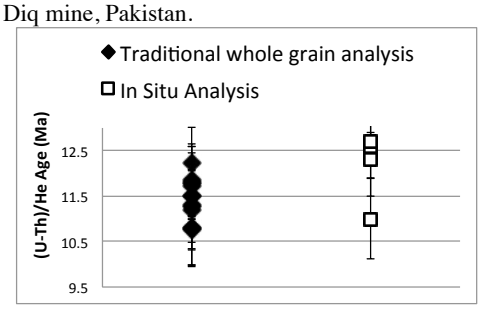
Sulfur isotopes provide one way to investigate sources of sulfur, and the processes that affect sulfur content during subduction. $\delta^{34}S$ of seawater-derived sulfate is around 20‰ while $\delta^{34}S$ of magma-derived sulfides is around 0‰. Calculated fractionation of sulfur isotopes at subduction temperatures for all but the most extreme open system conditions suggest that this difference between sources should be recognisable even after significant devolatilisation. *in situ* sulfur isotope measurements of pyrite associated with high pressure mineral parageneses in high pressure mafic rocks from the Eastern Alps and from New Caledonia were performed. The New Caledonia samples contain pyrite with $\delta^{34}S$ in excess of 5‰, while samples from Pfulwe pass in the Eastern Alps contain pyrite with $\delta^{34}S$ up to 15‰. These elevated $\delta^{34}S$ values suggest that sulfur ultimately derived from seawater is preserved in these rocks to depths greater than 60km.

In situ RESOchron helium dating: Progress, pitfalls and prospects

[1]NOREEN EVANS[1], BRENT MCINNES[1], BRAD MCDONALD[2], PIETER VERMEESCH[3], MIKE SHELLEY[4] AND ESTEPHANY MARILLO SIALER

[1]AuScope GeoHistory Facilty, John de Laeter Centre for Isotope Research, Curtin University, Australia, (noreen.evans@curtin.edu.au);
[2]Department of Earth Sciences, University College London, UK;
[3]Laurin Technic Pty Ltd., Canberra, ACT;
[4]School of Earth Sciences, University of Melbourne, Australia

Recent advances in *in situ* double dating[1-3] prompted us to develop the *RESOchron*, a purpose-built laser ablation U-Th-Pb-He system (see McInnes *et al*., this meeting). Polished zircon grains, mounted in indium, were loaded into an UHV cell where helium was extracted via 193 nm laser ablation for 30 seconds using a 33-75 μm beam at 7Hz. U and Th were subsequently analysed in an adjacent pit using traditional ELAICP-MS methods. Pit volumes were measured on a Zeiss LSM700 confocal laser microscope and (U-Th)/He ages calculated using published methods[1,3]. The mean zircon helium age from the *in-situ* ablation experiment fell within 10% of helium ages obtained using traditional single crystal methods for an 11.4 ± 0.5 Ma subvolcanic stock from the Reko Diq mine, Pakistan.



Improvements in analytical precision require refinement of sample preparation for UHV conditions. Indium, despite being inert under high vacuum conditions, is non-ideal for zircon mounting because its high surface reflectance makes navigating around the mount and focusing the laser difficult. Due to its extreme softness, grains cannot be polished *in situ* and even slight contact can damage the surface and cause grains to shift position. Zonation of U and Th also impacts the accuracy of results, as does the accuracy of pit volume measurements as suggested previously [1-3]. Other mounting media are being explored (eg. FEP teflon) and optimization of laser protocols is underway.

Subseafloor microbial community in the Benguela upwelling area characterized by lipid biomarkers and intracellular DNA

T.W. EVANS[1]*, L. WÖRMER[1], M.-A. LEVER[2], R. ZHU[1], L. LAGOSTINA[2], B. B. JØRGENSEN[2] AND K.-U. HINRICHS[1]

The subsurface biosphere in marine sediments is one of the least understood ecosystems on our planet. Currently, it is even subject to debate which domain of microbial life, Bacteria or Archaea, is dominant. So far, studies based on intact polar membrane lipids (IPLs) have indicated dominance of lipids associated with Archaea [1], while most DNA-based studies have suggested a higher proportion of Bacteria [2]. These contradictory results are thought to result from analytical and/or systematic biases of both techniques. In the case of IPLs, the associated organic matrix may hinder proper HPLC-MS detection due to ion suppression. In addition, both IPLs and DNA analysis may be affected by a potential pool of fossil compounds [3, 4]. To overcome these problems and achieve a more realistic view of the microbial subseafloor biosphere, novel methods were applied to samples of a transect across the Namibian Continental Margin.

We employed a new protocol for separating intracellular DNA (iDNA) from the remaining extracellular DNA-pool. For IPLs, a new method was developed and applied, based on solid phase extraction (SPE) of lipids with a phosphatic head group, resulting in strongly improved detection.

The analysis of iDNA and IPLs showed a distinct change of the microbial community. iDNA- and IPL-data were in good agreement. SPE clean-up of IPLs resulted in the detection of phospholipids that could be attributed to sulfate reducing bacteria. Previously it was not possible to detect any phospholipids in subsurface samples of upwelling areas [5]. Both iDNA and IPL analysis showed a dominance of Archaea in organic-rich sediments below the upwelling cell, while further offshore the sediments were dominated by Bacteria. Further interpretation of these trends and the downcore profile of iDNA and IPL distribution is ongoing.

Revealing the 'blind spot': A simple physical model for the temporal evolution of silicate mineral weathering

JAIVIME A. EVARISTO* AND JANE K. WILLENBRING

Department of Earth and Environmental Science, University of Pennsylvania, Philadelphia, PA 19104, USA (*correspondence: evaristo@sas.upenn.edu)

Closing the gap in the orders-of-magnitude difference between field and laboratory weathering rates has been considered essential to effectively modeling silicate mineral reactivity from centennial and millenial to geologic timescales[1]. However, what if finding the rates in the mid-range (i.e. $10^{1.5}$-$10^{3.5}$ yr) between far-from-equilibrium conditions in laboratory experiments and near-equilibrium conditions in the field is just as useful as what we now know about the two time-dependent rate extremes? We test this hypothesis by comparing the effects of two models ("gap" or blind spot and "filled") of weathering rate constants k to a mineral dissolution model driven only by the physics of reaction-diffusion dynamics. The explicit neglect of intrinsic factors, like chemical composition and mineralogical structure, in this simple model is an attempt not only to put an emphasis on the frequency and, in effect, duration of time with which a mineral surface interacts with pore fluids; but also to test if the reported agreement in phenomenological effective rates $K(t)$ between numerical and analytical solutions in comparable decay systems [2] also hold true for silicate weathering rates. Preliminary findings from our model simulations indicate that (1) there is no marked difference in effective silicate weathering rates $K(t)$ (yr^{-1}) between the two models of rate constants ($4.86x10^{-2}$ t^{-1} and $4.88x10^{-2}$ t^{-1} for "filled" and "gap" distributions, respectively), suggesting that the apparent "blind spot" within the centennial to millennial range may not preclude our ability to predict mineral dissolution at these timescales; (2) the subsequent weathering beyond $t \sim k^{-1}$ exhibits a fall in rates of up to ~3 orders of magnitude since the effective cessation of logarithmic decay, possibly reflecting the onset of a progressively refractory stage due to finite-size effects; and (3) a simple reaction-diffusion model may be able to predict the temporal evolution of silicate weathering as an integral of both field- and lab-derived rate constants, putatively identified by a lognormal distribution and therefore the kinetic heterogeneity associated with mineral dissolution.

The uplift history of the western Andes, north Chile, constrained by cosmogenic ^{3}He in alluvial boulders.

LAURA EVENSTAR[1], FINLAY M. STUART[2] AND ADRIAN J. HARTLEY[2]

[1]Dept. of Geology and Petroleum Geology, University of Aberdeen, Aberdeen, AB24 3UE, UK
[2]Isotope Geoscience Unit, Scottish Universities Environmental Research Center, East Kilbride, Glasgow, G75 0QF, UK
*Now at School of Earth Science, University of Bristol, Wills Memorial Building, Queens Road, Bristol, BS8 1RJ

Accurate timing of uplift of the Andes is essential for understanding continental tectonics processes. Current models vary from gradual uplift of the Andes from the Late Eocene due to crustal shortening/thickening [1] to rapid uplift in the Late Miocene due to large-scale mantle delamination [2]. Existing paleoelevation proxies are afflicted by either large uncertainties or reliance on assumptions about past climate-elevation histories [1]. The production rate of *in situ* cosmogenic isotopes is strongly dependent on elevation and thus has potential to constrain surface uplift histories.

The arid climate in the Atacama Desert, Northern Chile has prevailed since at least 25 Ma [3] leading to low erosion rates and high cosmogenic nuclide concentrations within alluvial boulders overlying the Pacific Planation Surface (PPS). The PPS in the Aroma Quebrada formed at < 13.9 Ma. Alluvial boulders which lie on the PPS, have high concentrations of cosmogenic ^{3}He that suggest deposition soon after surface formation [4]. The concentration of cosmogenic ^{3}He in the boulders are compared to those calculated for Early Miocene and Late Miocene uplift histories. The high concentration of cosmogenic ^{3}He in five boulders cannot be generated by Late Miocene uplift of the Andes (irrespective of scaling factor-production rate). The data require early uplift of the paleosurface prior to 8 Ma. This rules out rapid uplift of the Andes due to mantle delamination in the Late Miocene instead supporting progressive shortening and thickening of continental crust initiating in the Early Miocene or earlier.

Nuclear materials under extreme conditions

RODNEY C. EWING*

University of Michigan, Ann Arbor, MI 48109 USA
(*correspondence: rodewing@umich.edu)

During the past forty years, the materials science of nuclear waste forms has focused mainly on the stability and long-term behavior of nuclear waste glasses and the UO_2 in used nuclear fuel. However, during this time, substantial quantities of Pu, now more than 2,000 metric tonnes, have been produced. Some 200 mettric tonnes of Pu have been separated along with much lesser amounts of "minor" actinides (Np, Am and Cm). The *nuclear solution* is to prepare a mixed-oxide (MOX) fuel of Pu and U or an inert matrix fuel (IMF) to fission transuranium elements in a reactor. The *geologic solution* is to develop very durable materials for disposal in a geologic repository or a very deep borehold. However, radiation damage in the reactor or self-radiation damage due to the alpha-decay of actinides is a concern, as radiation-induced transformations of the atomic structure decrease the chemical durability.

A variety of materials, with mineral analogues, including oxides, silicates and phosphates, have been investigated because they have a high capacity to incorporate actinides, are chemically durable, and in some cases, are resistant to radiation damage. There has been substantial interest in isometric pyrochlore, $A_2B_2O_7$ (A = rare earths, actinides; B = Ti, Zr, Sn, Hf), for the immobilization of transuranium elements. Four radiation-induced transformations may occur: i) periodic-aperiodic, ii) order-disorder, iii) crystalline-to-crystalline, and iv) chemical decomposition. Certain pyrochlore compositions (B = Zr, Hf) remain crystalline to very high doses of alpha-recoil damage, which is mainly caused by ballistic interactions with the alpha-recoil nucleus.

Most recently, the radiation response of pyrochlore has been investigated using relativistic heavy ions for which high energy deposition occurs by electronic excitation. Energetic ions deposit exceptional amounts of kinetic energy (GeV) within an exceedingly short time (less that a femtosecond) into nano-scale volumes. Energy deposition is up to tens of eV/atom, foming damage tracks, very similar to fission tracks in zircon and apatite. These irradiations have been done at high pressures (>50 Gpa) and temperatures (up to 500 °C) within a diamond avil cell (DAC). The combined use of advanced *in situ* (synchrotron X-ray diffraction and Raman spectroscopy) and *ex situ* (transmission electron microscopy) characterization techniques has shown that normal phase relations are changed by the radiation and that most materials can be amorphized.

The effect of nuclear radiation on the structure of zircon

RODNEY C. EWING*

University of Michigan, Ann Arbor, MI 48109 USA (correspondence: rodewing@umich.edu)

In 1955, Heinrich Holland and David Gottfried published a remarkable paper in *Acta Crystallographica* on radiation damage accumulation in a suite of natural zircons from Sri Lanka [1]. The purpose of their study was to investigate the possibility of using radiation damage accumulation as a method of age determination. This was one of the first quantitative studies of damage accumulation and annealing in a complex ceramic and provided a solid basis for extrapolating radiation damage effects in actinide-bearing nuclear waste forms over geologic periods [2,3]. The paper is not only remarkable for the data, measurements of unit cell parameters and optical properties, as a function of increasing dose, but also because the interpretation of the data was in the context of a damage ingrowth model that quantifies the accumulation of amorphous domains, the accummulation of isolated defects, the formation of new crystalline structures and the change in crystallite size. The authors also recognized the possibility of alpha-particles enhancing the effects of damage accumulation and annealing caused by the alpha-recoil atom.

Subsequent studies of radiation effects have utilized Pu-doping experiments [4] and ion beam irradiations (MeV to GeV energies) [5,6]. Most recently, high-energy irradiations have been completed at high pressures using a diamond anvil cell [7]. These studies have provided a fundamental understanding of the radiation damage processes that has supported the use of zircon as an optic wave guide [8], the development of nuclear waste forms for excess weapons plutonium [9] and fission track dating and thermochronology [10, 11]. For all of these applications, the early work by Holland and Gottfried remains the fundamental foundation.

Formation and geochemistry of rutile from garnet gabbros of the Jijal Complex, Kohistan island arc

T.A. EWING* AND O. MÜNTENER

Institut de Sciences de la Terre, UNIL, CH-1015 Lausanne, Switzerland (*correspondence: tanya.ewing@unil.ch; othmar.muntener@unil.ch)

The Kohistan paleo-island arc preserves a ~50 km-thick section of Jurassic–Cretaceous arc crust renowned as one of the best exposures of an exhumed island arc. The lowermost Jijal Complex comprises an ultramafic and a mafic section. The latter is dominated by garnet gabbros, the origin of which is controversial. Formation of garnet in these rocks has been ascribed to dehydration melting of hornblende-bearing precursors [e.g. 1], prograde metamorphic reactions [e.g. 2] or fractional crystallisation at high pressures followed by isobaric cooling [3, 4].

Rutile (TiO_2) is an accessory phase in garnet-hornblende pyroxenites, garnet gabbros, paragonite gabbros and epidote-bearing pegmatites. In some samples garnet cores preserve ulvöspinel inclusions while garnet rims host rutile, suggesting formation of rutile at the expense of ulvöspinel. In paragonite gabbros rutile is associated with epidote–quartz intergrowths and may have formed as a result of the breakdown of clinopyroxene and garnet to form epidote and amphibole. Both reactions are consistent with isobaric cooling.

Garnet gabbros, paragonite gabbros and epidote-bearing pegmatites give Zr-in-rutile temperatures of 650–700°C. A few analysed rutiles are in contact with quartz and have indistinguishable Zr from other rutiles. These lithologies are largely zircon-free and Zr-in-rutile thus gives minimum temperatures. The Zr-in-rutile temperatures are lower than ~800–1000°C Fe–Mg temperatures for the same lithologies, and it is unlikely that this difference can be explained entirely by the lack of equilibrium with zircon. Zr content within individual grains displays little variation, arguing against diffusive re-equilibration, but it remains to rule out complete recrystallisation. Rutile from the Jijal Complex samples has Zr/Hf distinct from that of rutile from lower continental crustal metapelites, pointing to different controls on these geochemical tracers in rutile from different settings.

The complex dynamics of collisional orogens unveiled by numerical modeling

MANUELE FACCENDA[1], TARAS GERYA[2] AND SUMIT CHAKRABORTY[3]

[1]Dipartimento di Geoscienze, Università di Padova (manuele.faccenda@gmail.com)
[2]Institute of Geophysics, ETH Zürich (taras.gerya@erdw.ethz.ch)
[3]Sumit Chakraborty, Institut fuer Geologie, Mineralogie und Geophysik, Ruhr-Universitaet Bochum; (Sumit.Chakraborty@rub.de)

We performed numerical modelling of continental collision following oceanic subduction, and analyze metamorphic processes and the thermo-tectonic evolution of the resulting orogens as a function of key parameters such as crustal strength and radiogenic heating, fluid migration and convergence rate. The common and more important features we found for all models are crustal thickening, formation of mid-crustal partially molten levels extruding laterally, exhumation of medium to high grade metamorphic rocks with clockwise P-T-t paths and a style of post-collisional orogens that ranges from symmetric (stiff lower crust), two-sided collision zone to classical asymmetric orogen (weak lower crust). Crustal radiogenic heating favor the formation of partial melting in the mid-crust and exhumation at the surface of an inverted metamorphic sequence. Fluids affect mainly the plate boundary, reducing the viscosity of the lubricated plate interface leading to one-sided, asymmetric subduction zones. If wetting of the plate interface is very efficient, plate decoupling occurs followed by retreat and delamination of the subducting continental plate.

The results are in good agreement with geological, metamorphic, geochemical and geophysical observations from natural mountain belts (e.g. Himalaya, Western Alps, Apennines) and previous numerical studies of similar geodynamical settings.

The role of oceanic sediments in the metasomatism of subpatagonian lithospheric mantle beneath Cerro del Fraile (Argentina)

FACCINI B.[1], BONADIMAN C.[1], COLTORTI M.[1], GRÉGOIRE M.[2] AND SIENA F[1].

[1]Department of Earth Sciences, Ferrara University, Ferrara, Italy
[2]DTP, CNRS-UMR 5562 Observatoire Midi-Pyrenées, Toulouse, France

A detailed petrological study of mafic and ultramafic xenoliths from the Cerro del Fraile (CF, Southern Patagonia, Argentina) was developed in order to decipher the the nature of the metasomatising agents which infiltrate the mantle wedge above the Antarctic subducting Plate, as well as the role of material dragged down in the subduction zone and recycled within the South patagonian sub-arc mantle.

CF mantle xenoliths comprise peridotites, cumulitic pyroxenites and composite samples. On the basis of HREE and major element mineral melting models, the peridotites record a partial melting degree variable between 10 and 25%. They also experienced a contemporaneous or subsequent refertilisation event, caused by the percolation of SiO_2-Al_2O_3-rich slab-derived metasomatic agents. The similarity between cpx and opx of the pyroxenites and those in the pyroxenitic part of the composite samples suggests that the cumulitic process occurred within the mantle. The reaction of the variously depleted mantle with the incoming melt took place under reduction conditions (ΔlogfO_2 (QFM) -1.21 to -0.34), unusual for mantle wedge settings.

Calculated melts in equilibrium with the most enriched opx and cpx in peridotites and with the pyroxenes of the cumulites have LREE, Zr (Hf), Th and U contents higher than those of AVZ natural adakites. This result speaks in favour of the melting of oceanic sediments, which are composed of a remarkable amount of manganese nodules and micronodules and, possibly, organic matter, in agreement with the estimated low oxygen fugacity conditions. The amount of sediments involved in the genesis of the infiltrating melts is larger than that previously proposed for the genesis of the erupted Patagonian adakites [1]. At mantle conditions the percolation of SiO_2-rich magmas is allowed by their high Al_2O_3 and water content and is favoured by the molar volume reduction due to the growth of opx at the expenses of olivine.

Mesocosms experiments with zeolitite-amended marsh soils to reduce nitrogen leaching

FACCINI B.[1], COLOMBANI N.[1], DI GIUSEPPE D.[1], MASTROCICCO M.[1] AND COLTORTI M.[1]

Physics and Earth Sciences Dep., University of Ferrara, (barbara.faccini©unife.it)

To prevent diffuse nitrogen (N) contamination from agricultural activities the Water Framework Directive institutes a series of good practices for a sustainable agriculture in vulnerable areas. Notwithstanding, N leaching is still a major issue at the European and global scale. To increase N retention capacity of lowland soils, natural zeolitites were ued in an experimental field near the town of Codigoro, in the eastern part of Ferrara province (Italy), pertaining to the Po delta reclaimed marsh soils, actually 3 m below sea level. To test their effectivness a tridimensional model 100 x 50 cm in size (divided in two section of 50 x 50 cm each) was built. Tank was completely filled with soil composed by 8±1% of sand, 49±2% of silt, 42±2.5% of clay and 8±1.5% of organic matter, with a bulk dry density of 1.15±0.05 g/cm^3. In the uppermost 20 cm of one mesocosms, the equivalent of 7 Kg/ha of natural NH_4^+-charged zeolitite was mixed with the soil, whereas the second mesocosm was fertilized with the equivalent of 270 kg/ha of urea. The filling has been done manually, compacting successive layers of about 2 cm each. During this procedure, 5TE Decagon probes were inserted every 8 cm to monitor water content, temperature and bulk soil conductivity. Suction cups were also inserted at the same depths to monitor soil water composition. The two mesocosms were irrigated with a micronizer for 2 months at an average rate of 4 mm/d. The irrigation water was taken from the irrigation channel close to the experimantal field. The regular irrigation created a percolation front slowly moving downward. At the end of the experiment, duplicate core samples were excavated and analyzed for mineral N (NO_3^- NO_2^- and NH_4^+) and for Cl^- and Br^- used as tracers. Soil water samples were also obtained by suction cups.

The mass balance of N within the two mesocosms highlighted that the natural zeolites acted as a strong buffer in N leaching, with most of the mineral N retained in the soil as adsorbed NH_4^+. On the contrary, the mesocosm supplied with urea exibithed the greatest NO_3^- concentrations in both soil solutions and cores.

Aqueous carbonate speciation in equilibrium with Aragonite under subduction zones conditions

SEBASTIEN FACQ[1], ISABELLE DANIEL*[1] AND DIMITRI A. SVERJENSKY[2]

[1]Laboratoire de Géologie de Lyon :Terre, Planètes, Environnement, Université Claude Bernard Lyon 1, ENS de Lyon, CNRS, UMR 5276, 2 rue Raphaël Dubois, 69622 Villeurbanne, France. (*Isabelle.Daniel@univ-lyon1.fr)

[2]Dept. Earth & Planetary Sciences, Johns Hopkins University, 3400 N. Charles St., Baltimore, MD 21218, USA & Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch Road NW, Washington, D.C. 20015, USA.

In the course of subduction, carbonate minerals in the oceanic crust may survive dehydration and partial melting of the subducting slab [1-3] and transfer carbon from the surface into the deep mantle. However, the investigation of the solubility of carbonate minerals and aqueous speciation of carbon under the ranges of temperature and pressure relevant to subduction zones in the upper mantle remains largely unexplored experimentally and theoretically [4]. Here, we report a combined experimental and theoretical study of the equilibrium of $CaCO_3$ minerals with pure water and NaCl aqueous solutions in a larger *PT* range. The carbonate-bicarbonate speciation in the aqueous phase was first studied by *in-situ* Raman spectroscopy in a diamond anvil cell. Experimental solubilities of aragonite and relative amounts of the dissolved C-species were obtained and used to constrain a theoretical thermodynamic model of the fluid speciation and solubility in equilibrium with aragonite. In pure water at 300–400°C, the experimental and theoretical results indicate that CO_2 is a minor species in fluids in equilibrium with aragonite at P > 10 kbar. Instead, the $CaHCO_3^+$ species becomes important until P > 50 kbar, where carbonate ion and $CaCO_3^0$ become the dominant C-species. At higher temperatures, the theoretical model indicates that CO_2 again becomes a major species in fluids in equilibrium with aragonite depending on the pressure. The presence of sodium chloride in the fluid expands the pressure domain where the speciation of carbonate is highly variable.

Tholeiitic vs. Calc-Alkaline Igneous Trends on the Moon: Lunar Meteorite Northwest Africa 773 vs. Apollo 15 Quartz Monzodiorite

T.J. FAGAN, Y. WAKABAYASHI, A. SUGINOHARA AND D. KASHIMA[1]

[1]Waseda University, Tokyo, Japan (fagan@waseda.jp)

Terrestrial igneous rocks exhibit a wide variety of compositions, but many can be linked together as stages of magmatic evolution along chemical trends. Two of the main trends are the tholeiitic (or FeO-enrichment or Fenner) trend and the calc-alkaline (or SiO2-enrichment or Bowen) trend. Lunar igneous rocks also show a wide range of compositions, even if only basalts are considered. Linking lunar rocks together along magmatic trends has proven difficult though, in part due to impact disruption of the surface wreaking havoc on igneous field relations.

However, impact processing can work in our favor by assembling breccias of magmatically related clasts. We use textures, pyroxene compositions (Fe# = Fe/(Fe+Mg)x100 and Ti# = Ti/(Ti+Cr)x100) and zoning relationships to argue that this is precisely what has happened during the formation of lunar meteorite Northwest Africa 773 (NWA 773). Clasts of olivine cumulate (OC) are characterized by pyroxene with low Fe# (20-30) and variable Ti# (10-75). Pyroxene Ti# correlates with proximity to intercumulate pockets with K,Ba-feldspar and Ca-phosphates. This increasing Ti-trend is interpreted as a product of fractional crystallization where the Fe# was buffered by abundant surrounding mafic silicates.

Pyroxenes from other types of clasts in the breccia show a trend of Ti# and Fe# both increasing to nearly 100. Clasts with the highest Fe# and Ti# include fayalite+hedenbergite+ silica symplectites and K,Ba-feldspar+fayalite+silica ±hedenbergite FeO-alkali-rich clasts. These are interpreted as the alkali-poor and alkali-rich products of silicate liquid immiscibility (SLI) after the liquid evolved to ferroan compositions. Igneous (crystallized from liquid) silica occurs only in the FeO-alkali clasts, suggesting that SiO2-enrichment occurred only after extreme FeO-enrichment, comparable to the terrestrial tholeiitic trend.

Igneous silica also occurs in Apollo 15 quartz monzodiorite (QMD), but coexists with pyroxene having moderate Fe# (60-70), more akin to the calc-alkaline trend. Whole-rock compositions of QMD fall on a mixing line between immiscible liquids produced during experiments on a KREEP basalt composition [1], suggesting a role of SLI during formation of QMD.

Late quaternary sedimentary provenances in the Central Arctic Ocean inferred by Nd and Pb isotopes of fine detrital fraction

N. FAGEL*[1], C. NOT[2], J. GUEIBE[3], N. MATTIELLI[3] AND E. BAZHENOVA[4]

[2]GEOTOP, UQAM, Montréal, Canada; (christelle.not@aori.u-tokyo.ac.jp)
[3]G-Time, Université libre de Bruxelles, Belgique ; (nmattiel@ulb.ac.be)
[4]AWI,Bremerhaven, Germany; EvgeniaBazhenova@gmail.com

Nd and Pb isotope signatures of sediments from Central Arctic were analysed to trace detrital particle provenance. Changes in relative contribution of different source-areas were used to reconstruct paleoceanographical changes over the last 250 kyr. Temporal changes in Nd and Pb isotopic composition confirm that sediment supply is controlled by the glacial/interglacial-deglacial variability. Pb mixing calculations suggest a major contribution from Mackenzie and Lena river areas. All intergacial-deglacial samples show isotopic values shifted towards the signature of Mackenzie end-member. Such source is consistent with their carbonate-rich lithology, detrital carbonates being mainly originated from this area and the Canadian channels. Nd mixing signature reports contribution from a third volcanic source; A compilation of trace element content of regional geological sources suggests that the most probable candidate is the Okhotsh-Chutoka province (Eastern border of Siberian platform). Our geochemical data confirm that the sediment provenances in Central Arctic remain close to the Present conditions during the earlier interglacials. Glacial stage 4 and 6 are characterised by the lowest supplies from the American margin, suggesting reduced particle supplies coming from the Beaufort Gyre to the Mendeleeiv Ridge.

Carbon allocation to ectomycorrhizal fungi and bacteria colonising granite

FAHAD Z, MAHMOOD S AND FINLAY RD

Department of Forest Mycology and Plant Pathology, Uppsala BioCenter, Swedish Univ. Agricultural Sciences, Uppsala, SE-75000, Sweden (*correspondence: zaenab.fahad@slu.se)

Ectomycorrhizal fungi have been postulated to mobilize essential plant nutrients directly from minerals through organic acid exudation. [1].

Laboratory microcosms were used to study mycorrhizal mycelial colonisation of granite substrate, release of organic acids, mobilisation of mineral elements and their uptake by *Pinus sylvestris* seedlings under two levels of N deposition. The effects of the mycelium were assessed by comparison with control treatments in which the mycelium was physically disrupted. Patterns of carbon allocation to different microbial taxa colonising the granite were assessed using stable isotope probing.

Colonisation of granite substrate by ectomycorrhizal mycelium resulted in significant production of organic acids after 12 weeks in comparison with uncolonised granite controls. After 24 weeks lower concentrations of a wider spectrum of organic acids were found in the treatment with intact mycelia. Significantly greater concentrations of Fe and Mn were found in the soil solution in mycelium-colonised compartments than those not colonized by mycelium, but no statistically significant effects were found on concentrations of other elements, or on plant biomass.

Energy crop production on mining and smelting impacted arable land - A non-phytoremediation approach

W. FAHLBUSCH*, B. SAUER AND H. RUPPERT

Geosciences Center & Interdisciplinary Center for Sustainable Development, University of Goettingen, Goldschmidtstr. 1, D- 37077 Göttingen, Germany (*correspondence: wfahlbu@gwdg.de)

Up to 10% of the arable land in Germany is potentially contaminated by heavy metals [1]. These areas comprise flood plains of rivers, industrialized areas and also soils in the vicinity of smelter facilities e.g. in the Harz Mountains in Germany, where sulfidic polymetallic ores were mined and processed for at least 2000 years. This mining impacted land faces contamination with several elements (As, Cd, Cu, Pb, Sb, Tl, Zn). Conventional remediation techniques like excavation of the soil are often not economic. The removal of the toxic elements with hyperaccumulating plants (phytoremediation) is also not satisfying because of their commonly low yield. It would take thousands of years to reach acceptable low contamination levels.

Instead of phytoremediation we recommend to produce high yield crops with low uptake of heavy metals to leave the pollutants in the soil. The plants can be used in biogas facilities. To identify crops with a low metal uptake we measured plant and soil concentrations and the mobile/ exchangeable fraction of heavy metals in a variety of polluted soils. An unpolluted soil was used as a reference. Soil material adhering to crops was mathematically corrected using titanium in the soil as a reference element [1].

These low contaminated crops can be used for biogas generation in fermentation facilities without impairing the gas output. Furthermore, the residues of the biogas production can be returned as organic fertilizer to the fields where the plants were harvested. All important nutrients are recycled back to the fields (except nitrogen) and the maximum permissible values for heavy metal in farm fertilisers can be abided. Energy crops with a low uptake of cadmium are for instance the maize cultivar Padrino, the rye cultivar Vitallo and the barley cultivar Christelle. In contrast, amaranth, sunflower and the energy beet Kyros should not be cultivated on contaminated soils for bioenergy production due to their high cadmium uptake [1].

[5]UJF - Grenoble 1 / CNRS, LIPhy-UMR 5588, Grenoble, F-38041, France

We present results of a 4-week laboratory-based campaign to measure CO mixing ratios in the North Greenland Eemian (NEEM) S1 ice core (410 m long) using an OF-CEAS spectrometer (Optical Feedback-Cavity Enhanced Absorption Spectrometry) coupled to a continuous melter system. This analytical setup generates highly precise (0.3 ppbv 1 sigma) and stable measurements of CO mixing ratios. The NEEM-2011-S1 CO record spans 1800 yr and exhibits highly variable concentrations at the scale of annual layers, ranging from 75 to 1327 ppbv. Although the most recent section of this record (i.e., since 1700 AD) agrees with existing discrete CO measurements from the Eurocore ice core and the deep NEEM firn, it is difficult to interpret in terms of atmospheric CO variation due to high frequency, high amplitudes spikes features. 68% of the elevated CO spikes are observed in ice layers enriched with pyrogenic aerosols. Such aerosols, originating from boreal biomass burning emissions, contain organic compounds, which can be oxidized or photodissociated to produce CO in-situ. We suggest that elevated CO concentration features could present a new integrative proxy for past biomass burning history. However, the NEEM-2011-S1 record also reveals an increase in baseline CO level prior to 1700 AD (129 m depth), with the mixing ratio remaining high even for ice layers depleted in dissolved organic carbon (DOC). Overall, the processes driving in-situ production of CO within the NEEM ice are complex and may involve multiple chemical, or biological, pathways.

High sulfur isotopic fractionations in a low-sulfate environment

MARIANELA FALLAS DOTTI* AND DONALD E. CANFIELD

Nordic Center for Earth Evolution (NordCEE) and Institute of Biology, University of Southern Denmark, 5230 Odense M, Denmark (*corr: nela@biology.sdu.dk)

Meromictic Lake Cadagno in Switzerland is an euxinic environment which draws scientific attention because it can be used as a proxy of early oceans. Two sites in the lake have been chosen to study the sedimentary isotopic geochemistry of sulfur. Site 1 is located in the oxic part of the lake with low sulfate concentrations (~0.5 mM). Site 2 is euxinic and it has higher sulfate concentrations than site 1 (~2mM). We explored isotopic fractionation between sulfate and sulfides and evaluated the role that disproportionation could play in these two types of environment. Canfield *et al* 2010[1] have already reported very high fractionations during sulfate reduction in the water column at site 2. However, they did not attribute these results to disproportionation. We show here higher fractionations in the sediments of site 1 than in those of site 2. The low sulfate concentrations at site 1 make it unrealistic to attribute these high fractionations to sulfate reduction alone. Thus, disproportionation seems to influence the distribution of the $\delta^{34}S$ signals in this site.

New constraints on the pre-eruptive storage conditions of the Campanian Ignimbrite (Campi Flegrei, IT)

[1]SARA FANARA, [1]ROMAN BOTCHARNIKOV, [2]DANILO M. PALLADINO, [1]ANIKA HUSEN, [2]GABRIELE MACCHI CECCARANI, [2]SIMONE RIGHI AND [1]HARALD BEHRENS

[1]Institute for Mineralogy, Leibniz University of Hannover, Callinstr. 3, Hannover, D-30167, Germany
[2]Department of Earth Science, La Sapienza University of Rome, P.le Aldo Moro 5, 00185, Rome, Italy

Solubility and phase equilibria experiments were performed on a synthetic trachyte representing the least evolved composition of the Campanian Ignimbrite (CI) eruption. H_2O and CO_2 solubilities were investigated at 1100°C and at pressure from 100 to 500 MPa for approx. 24h in an Internally Heated Pressure Vessel (IHPV). Phase equilibria experiments were performed at 100, 200 and 300 MPa and at temperature between 850°C and 1050°C in the Cold Seal Pressure Vessel (CSPV) and the IHPV under relatively oxidizing conditions (log fO_2=QFM+3.3 for IHPV; log fO_2=QFM+1 for CSPV). Run products were analysed by electron microprobe, spectroscopic techniques, Karl-Fischer titration and Carbon-Sulfur analyser.

For comparison natural samples from the juvenile parts of the CI were collected around the city of Naples and on the island of Procida. The collected products were analysed with the same techniques used for the experimental ones.

It was found that the solubility of water (X_{H2O}=1) increases with pressure from 4.2 wt% at 100 MPa to 10.80 wt% at 500 MPa. The solubility of CO_2 (nominal X_{H2O}=0) increases with pressure as well from 350 ppm at 100 MPa to 2700 ppm at 500 MPa. Comparing our experimental data with previous studies on the melt inclusions of the CI, a pressure between 100 and 200 MPa was evaluated for the melt prior to the CI eruption, indicating a magmatic storage region located between 2 and 6 km depth.

Comparing the paragenesis of the natural samples with those from the phase equilibria experiments, a temperature between 830°C and 880°C was estimated in the pressure range of 100-200 MPa for the magma prior to the CI eruption. Harker diagrams of experimental and natural samples were used to reconstruct the evolution of the CI melt. It is suggested that the crystal fractionation via differentiation plays a major role during the evolution of the magma prior to the CI eruption.

Variations in δD of fatty acids of Piezophilic Bacterium *Moritella japonica* DSK1 reflect biosynthetic pathways

JIASONG FANG[1] AND LI ZHANG[2]

[1]Department of Natural Sciences, Hawaii Pacific University, Kaneohe, HI 96744, USA
[2]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

It is believed that bacterial metabolic pathways, not lipid biosynthesis, exert primary control on the variability of δD of lipids. In this study, we examined the δD of fatty acids in piezophilic bacterium *Moritella japonica* DSK1 that was grown in defined seawater medium with composite glucose as substrate at 30 megapascal. Fatty acids of DSK1 showed vastly varied δD, ranging from +44.4 to –171‰. Short-chain fatty acids (SCFA) had positive δD (average +3‰), whereas long-chain-polyunsaturated fatty acid (LC-PUFA) DHA (*cis*-4,7,10,13,16,19-docosahexaenoic acid) exhibited much depleted δD (–171‰). We show that the significant difference in δD between SCFA and LC-PUFA is a result of bacterial utilization of two distinct biosynthetic pathways that co-exist in the piezophilic bacterium. There was a wide range of hydrogen isotope fractionations between FA and growth water and between FA and substrate, but a nearly constant offset and a perfect correlation between the two fractionation factors, suggesting that the pools of hydrogens in the bacterium were metabolically linked and biosynthetically coordinated in biosynthesis of fatty acids. Thus, bacterial lipid biosynthetic pathways exert dominant, yet well-synchronized control on δD of fatty acids. Given the pressure-dependent carbon and hydrogen isotope fractionations observed in piezophilic bacterium *M. japonica* DSK1, we suggest that δD of fatty acids, together with their $\delta^{13}C$, can be used as a dual biogeochemical tracer to determine the source, diagenesis, and vertical transport of organic matter in the oceanic environments.

Geochemical evidence for volcanic activity prior to and enhanced terrestrial weathering during the Paleocene Eocene thermal maximum

MATTHEW S. FANTLE[1], REBECCA WIECZOREK[1], LEE R. KUMP[1] AND GREGORY RAVIZZA[2]

[1]Dept. of Geosciences, The Pennsylvania State University, University Park, PA

[2]Dept. of Geology & Geophysics, SOEST, University of Hawaii, Manoa, HI

The current study presents geochemical measurements from a gray shale sequence from the Central Basin in Spitsbergen, Svalbard Archipelago (Core BH 9/05) that samples the Paleocene Eocene thermal maximum (PETM) at extremely high resolution. The data, including Re and Os concentrations, $^{187}Os/^{188}Os$, and major element geochemistry over ~60 meters of shale representing ~220 ka, suggest that a significant volcanic episode occurred just prior to or coincident with the onset of the PETM. The precise correlation between the timing of the PETM and the volcanic episode is possible due to previously published, high resolution $\delta^{13}C$ organic carbon data measured in the same core. The presence of a significant volcanic component is indicated primarily by a large drop in $^{187}Os/^{188}Os$ ($\Delta^{187}Os/^{188}Os$ ~ -0.23) and confirmed by elemental mixing calculations. The geochemistry of the inferred ash component, which persists in the sedimentary record for ~8 ka, is distinct and consistent with the geochemistry of contemporaneous ashes in Denmark. Based on the substantial size of the $^{187}Os/^{188}Os$ decrease, the volcanic event must have involved widespread ash deposition in the local catchment and subsequent, rapid weathering of the ash that shifted the $^{187}Os/^{188}Os$ of the basin water column to <0.5. Temporally, the volcanic event coincides with (or predates by a few ka) the onset of the PETM, suggesting northwest European shelf volcanism as the trigger for the PETM.

As the planet warmed, dissolved and detrital indicators of weathering indicate a relatively short-lived <10 ka pulse of more weathered material to the basin. The pulse shifted authigenic $^{187}Os/^{188}Os$ to more radiogenic values and deposited clastic materials with higher Chemical Index of Alteration and lower Na/Ti, suggesting more intense chemical weathering prior to the peak carbon isotope excursion. The pulse is consistent with open ocean observations of changing $^{187}Os/^{188}Os$. In addition, anoxia appears to have initiated close to the onset of the PETM, persisting for ~50 ka and ending abruptly during the recovery stage.

The inheritance of source Hf isotopic diversity in S-type granites

F. FARINA[1*], G. STEVENS[1], A GERDES[2] AND D FREI[1]

[1]Stellenbosch University, PB X1, Matieland 7602, South Africa (*correspondence: fannak@gmail.com).

[2]Institut Für Geowissenschaften, Senckenberganlage 28, D-60054 Frankfurt Am Main, Germany.

S-type granites typically record substantial Hf isotopic diversity within their magmatic zircon population. The 538 Ma old Peninsula pluton (South Africa) typifies this behavior exhibiting a zircon $\varepsilon_{Hf(538)}$ range of 8ε units. In the smallest rock samples investigated (<0.5 dm^3) and within individual thin sections, an $\varepsilon_{Hf(538)}$ range is recorded that is almost as large as that recorded within the whole sample set. At all scales, the ε_{Hf} variability in the magmatic zircon fraction matches well that portrayed by the time evolved inherited zircon population, suggesting that the ε_{Hf} heterogeneity of magmatic zircon is inherited from the source [1]. However, the Hf dispersion exhibited by the inherited zircons is greater (12 ε_{Hf} units) than that shown by magmatic zircons indicating a minor degree of Hf isotope homogenization in the time interval between dissolution of detrital zircon and the growth of the magmatic fraction. Moreover, the $\varepsilon_{Hf(t)}$ frequency of occurrence in the two populations is not identical, with a greater proportion of magmatic zircons having higher $^{176}Hf/^{177}Hf$. This is interpreted to result from the relatively minor contribution of ^{176}Hf from Lu-bearing phases that did not re-equilibrate with zircon during metamorphism and partial melting. These phases have higher Lu/Hf ratios than zircon and thus their break down provides a more juvenile signature to the melt, mimicking the effect of mixing with a mantle-derived magma.

The occurrence of magmatic zircons with diverse ε_{Hf} at the sub-cm scale reflects the existence of micro domains within the melt whose Hf isotopic composition is controlled by the in-situ availability and composition of detrital zircons as well as by the ratio between detrital zircons and other Hf-bearing phases dissolved into the melt. Hf isotopic equilibration between micro domains was poor, due to the very low Hf diffusivity and short residence time of the melt in the source. Moreover, Hf homogenization is not achieved during far-field melt transport suggesting that the magma emplaces prior to any significant dissolution of inherited zircon.

Magnesium isotope composition of globally distributed modern brachiopods: Implications for paleo-seawater δ^{26}Mg reconstructions

JURAJ FARKAŠ[1*], UWE BRAND[2], ADAM TOMAŠOVÝCH[3], KAREM AZMY[4], JAN FIETZKE[5] AND ANTON EISENHAUER[5]

[1]Czech Geological Survey, Prague, Czech Republic, (juraj.farkas@geology.cz) (* presenting author)
[2]Dept. Earth Sci., Brock University, St. Catharines, Canada
[3]Geol. Institute, Slovak Acad. of Sci., Bratislava, Slovakia
[4]Dept. Earth Sci., Memorial University, St. John's, Canada
[5]GEOMAR | Helmholtz Centre for Ocean Research, Kiel, Germany

Magnesium isotope composition (δ^{26}Mg) of marine carbonates can potentially be used as a tracer for constraining past changes in the oceanic Mg cycle. Shells of articulated brachiopods composed of diagenetically resistant calcite [1] have proven to be particularly valuable archives of isotope composition and certain physicochemical properties of past ocean water [2]. Here we present δ^{26}Mg (DSM3) and δ^{18}O (PDB) variations, and trace element (Sr/Ca, Mg/Ca) contents analysed in six different species of modern brachiopods (*T. transversa, T. sanquinea, T. septentrionalis, T. congregata, L. uva, M. pisum*). The sampling locations of the above species cover a global scale, thus representing major water bodies, including: North Pacific (Palau, San Juan Island), South Pacific (Doubtful Sound), North Atlantic (Bay of Fundy, Bonne Bay), and Southern Ocean (Antarctica, South Africa). Accordingly, the mean habitat temperatures (HT) of the studied shallow-water brachiopods cover a wide range from cold (~3°C, Signy Island, Antarctica), through intermediate (~8 to 15°C, Friday Harbour, Doubtful Sound) to warm tropical settings (~29°C, Koror, Palau). Our results indicate that samples, which plot on the '*Global Brachiopod Mg-Line*' (defined by a shell $MgCO_3$ content relative to its HT [3]), show also a coupling between their δ^{26}Mg and δ^{18}O values (R^2 = 0.93; $p < 0.05$). Importantly, the overall temperature sensitivity of δ^{26}Mg in brachiopod calcite is weak (~0.01‰ per 1°C), implying that it may be a suitable archive for paleo-seawater δ^{26}Mg. Brachiopods that fall either below or above the *Global Mg-Line* yielded systematically lighter δ^{26}Mg, and also elevated Sr/Ca ratios, suggesting that these were influenced by processes, such as anomalous precipitation rates (changing growth patterns) or environmental stressors.

Is Late Cenozoic, post-subduction volcanism in the Sierra Nevada (California) a consequence of lithospheric downwelling?

G. LANG FARMER[1*]

[1]Department of Geological Sciences and CIRES, University of Colorado, Boulder, CO 80309 (*correspondence: farmer@colorado.edu)

Physical disaggegation of continental mantle lithosphere can trigger melting either in downgoing lithospheric material, upwelling sublithospheric mantle, or in newly exposed shallow lithosphere. A record of such disaggregation should therefore be decipherable from space-time-compositional patterns in any resulting volcanism. In practice, however, such an assessment is complex, as illustrated by Late Cenozoic volcanism with the Sierra Nevada of eastern California (U.S.). Here, geologic and geophysical observations are consistent with the Late Cenozoic, downward removal of continental margin arc lithosphere subsequent to the development of a slabless window beneath the region. In the southern Sierra Nevada, Late Cenzoic volcanism is entirely post-subduction (<16 Ma), but only a distinctive, short-lived episode of mafic, ultrapotassic volcanism, low ε_{Nd}(T) (~-6 to -9) at 3.5 Ma can be convincingly linked to lithospheric removal. This link relies on chemical and isotopic data from lithospheric xenoliths entrained in older, Miocene volcanic rocks found in the same region [1]. The xenolith data suggest that only spinel peridotites embedded in shallowmost portions of Miocene mantle lithosphere had sufficiently low ε_{Nd}(T) (~-6 to -9) to have spawned the Pliocene volcanism. As a result, physical removal of the mantle lithosphere and exposure of this originally shallow lithosphere to supersolidus conditions is a plausible trigger mechanism for the 3.5 Ma volcanic event. In contrast, no equivalent, low ε_{Nd}(T), ultrapotassic volcanism exists in the northern Sierra Nevada. A transition does occur in volcanic rock compositions at ~3Ma, from continental arc volcanism to high HFSE and high LREE trachybasaltic andesites. Rather than being a result of lithospheric removal, this transition likely corresponds to the opening of a slab window beneath the northern Sierra Nevada and subsequent conductive heating of intact mantle lithosphere. These data illustrate that there are multiple trigger mechanisms for post-subduction magmatism along continental margins, not all of which require lithospheric downwelling or delamination.

Application of multiple S-isotope studies to understanding early Earth environments and biology

JAMES FARQUHAR[1*], JOHN CLI FF[2] AND AUBREY ZERKLE[3]

[1]Department of Geology and ESSIC, University of Maryland, College Park, USA. (*corr: :jfarquha@umd.edu)
[2]Centre for Microscopy and Microanalysis, University of Western Australia, Perth, WA 6009, Australia
[3]DEES, Univ. of St. Andrews, St. Andrews. KY16 9AL, UK.

The use of multiple sulfur isotopes to study biological signatures on the early earth has been a relatively recent development in geochemistry. This approach relies on the information about sulfur cycling that comes from determinations of $\delta^{34}S$, $\Delta^{33}S$, and $\Delta^{36}S$. During sulfate reduction, variations in $\delta^{34}S$ values arise because less energy is required to break sulfate bonds involving ^{32}S than to break bonds involving ^{34}S. Variations for $\Delta^{33}S$ and $\Delta^{36}S$ arise because of mixing and unmixing that occurs during metabolic processing by organisms such as dissimilatory sulfate reducers. On an early Earth, variations for $\Delta^{33}S$ and $\Delta^{36}S$ also were produced by mass independent processes. A key feature of measurements that include $\delta^{34}S$, $\Delta^{33}S$, and $\Delta^{36}S$ is the prospect of disentangling mass dependent biological processing from mass dependent and mass independent abiological processing.

Several approaches have been developed in the past few years to tackle the issue of biological signatures in the sulfur isotope record. These include the use of paired sulfate – sulfide evaluated using sulfur cycle models; the use of microanalytical data provided by SIMS and nanoSIMS measurements; the experimental study of isotope effects produced by pure and mixed cultures of Bacteria and Archaea; and novel approaches that tie variations in isotopic compositions to specific depositional settings.

Work to date has provided evidence for sulfate reducers in the Paleoarchean, and it is not inconceivable that evidence from more ancient rocks will be forthcoming in the future. Recent work has also suggested that sulfate reducers played an important role in the Neoarchean, and may have expressed large fractionations that were masked by the processes associated with pyrite formation. Evidence for sulfur metabolisms in addition to sulfate reduction have been proposed in the early Archaean and Neoarchean. Work to understand, and disentangle, the role and importance of different types of sulfur metabolizing microbes on the early earth represents an important challenge that faces scientists today.

Experimental investigation of CO_2-water-rock interactions under simulated fresh-water aquifer conditions

S.M. FARQUHAR[1]*, G.K.W. DAWSON[1], J.K. PEARCE[1,2], AND S.D. GOLDING[1]

[1]School of Earth Sciences, University of Queensland, QLD 4072, Australia (*correspondence: susan.farquhar@uqconnect.edu.au)
[2]Cooperative Research Center for Greenhouse Gas Technologies, Canberra, Australia

The geochemical effects of supercritical CO_2 (sc-CO_2) injection on a targeted fresh-water storage site [1] located in the Surat Basin, Queensland, Australia, were investigated using experimental reactions at simulated basin conditions. Samples from a potential reservoir, Precipice Sandstone, and from two overlying formations, Evergreen Formation and Hutton Sandstone, were mineralogically and petrographically characterised prior to submersion in purified water and exposure to sc-CO_2 at 12 MPa and 60 °C conditions for 16 days.

Fluids were sampled periodically and analysed for major and trace elements to deduce CO_2-water-rock interactions. These data were related to changes to pre-experiment sample mineralogy and texture, as observed using scanning electron microscopy with energy-dispersive spectrometry (SEM-EDS).

Incremental fluid concentrations show an initial increase in most major (e.g., Fe, Ca, Mn, Mg, Si) and trace (e.g., Sr, Ba, Zn) elements over time, indicating dissolution of minerals during reaction. Increasing dissolved Ca, Mn and Sr (± Mg, Fe) are partly attributed to the dissolution of carbonate minerals, with higher concentrations observed in carbonate-rich samples; extensive carbonate dissolution in calcite-cemented samples is also observed in SEM-EDS.

Relative concentrations of analytes for incremental samples from the Precipice Sandstone experiments are generally considerably lower than those from the overlying Evergreen Formation and Hutton Sandstone, excluding Al and Si, reflecting the relatively clean mineralogy of the Precipice Sandstone. Small decreases in concentrations of several major elements (e.g., Fe, Ca, Mn, Al, Na) within the Evergreen Formation and Hutton Sandstone effluents towards the end of the experiments suggest the onset of mineral precipitation, which is supported by equilibrium modelling of geochemical reactions using the Geochemist's Workbench.

Geochemical investigations of fjord sediments reveal Zr, Ni and Ca as NAO proxies in central Norway

JOHAN C. FAUST[1,2*], JOCHEN KNIES[1], KARL FABIAN[1], ALBA N. RODRIGUEZ[3], MICHAEL BLASCHEK[4], GESA MILZER[5] AND JACQUES GIRAUDEAU[5]

[1]Geological Survey of Norway, 7491 Trondheim, Norway, (*correspondence: Johan.Faust@ngu.no)

[3]Plymouth University, Plymouth, UK
[4]VU Amsterdam, Climate Change and Landscape Dynamics, Amsterdam, Netherlands
[5]EPOC, University of Bordeaux - CNRS, Talence, France,

Sediments accumulating in fjords offer an excellent opportunity for studying land-ocean interactions and can provide high-resolution records of local responses to short-term variability in the Earth's climate. In order to increase the understanding of these records we previously investigated the inorganic/organic geochemistry of sixty surface sediment samples from the Trondheimsfjord in central Norway. By comparing our results with analyses of terrigenous sediments and bedrocks from the Trondheimsfjord drainage area we identified Zr/Al, Ni/Al and $CaCO_3$ as potential proxies for terrestrial input/river discharge.

Instrumental data reveal that the climate in central Norway is mainly driven by the North Atlantic current and the North Atlantic Oscillation (NAO). The aim of this study is to evaluate the applicability of Zr, Ni and Ca as proxies for changes in temperature, precipitation and NAO by comparing geochemical records with instrumental and modelling data of the last sixty years and apply these findings to Holocene sequences. For this purpose we analysed two multicores and three gravity cores from the Trondheimsfjord for their elemental composition, total organic carbon (C_{org}), nitrogen (N_{org}) and organic carbon stable isotopes ($\delta^{13}C_{org}$), grain size distribution and biomarkers. First results show that the instrumental and geochemical records coincide, confirming that Trondheimsfjord sediments provide an excellent geochemical record reflecting the intensity of river discharge and the impact of the NAO. Moreover, we found a continuous climate/weathering signal for at least the last 3000 years. Ongoing statistical verification of the connection between instrumental and sediment records will help to provide a high resolution record of Holocene climate variability in the Trondheimsfjord region.

Distribution of heavy metals and arsenic in soils of an abandoned lead mine (Central Portugal)

PAULO J.C. FAVAS[1,4*], JOÃO PRATAS[2,4], ROHAN D'SOUZA[3], MAYANK VARUN[3] AND MANOJ S. PAUL[3]

[1]Department of Geology, University of Trás-os-Montes e Alto Douro, 5001-801 Vila Real, Portugal; * (correspondence: pjcf@utad.pt)
[2]Department of Earth Sciences, University of Coimbra, 3001-401 Coimbra, Portugal
[3]Department of Botany, St. John's College, Agra 282 002, India
[4]IMAR-CMA Marine and Environmental Research Centre, University of Coimbra

The present study aims to assess contamination and distribution of heavy metals in soil around an abandoned Pb mine in Central Portugal (Barbadalhos mine also known as the Zorro mine). This mine was exploited for Pb by underground mining from 1887 till the 1940s. The mineralogy consists mainly of argentiferous galena and sphalerite (and chalcopyrite and arsenopyrite in small amounts). Samples were collected from two line transects. Line transect 1 is perpendicular to the mineralized veins. Line transect 2 is in nearby nonmineralized zone. Soil samples were collected at 20 m intervals along the line transects. Atomic absorption spectrophotometry was used after acid digestion to determine Fe, Mn, Cu, Zn, Pb, Ni, Co, Cr and Ag concentrations in the soils. To determine As content, a hydride generation system (HGS) linked to an atomic absorption device was used. Metal concentrations in soil ranged from (in mg/kg): 98-9330 (Pb), 110–517 (Zn), 7.1-50 (Co), 69-123 (Cr), 31-193 (Cu), 33400-98500 (Fe), 7.7-51 (Ni), 0.95-13 (Ag), 2.8-208 (As), and 71-2220 (Mn) along LT1; and 24-93 (Pb), 30-162 (Zn), 3.7-34 (Co), 61-196 (Cr), 21-46 (Cu), 24100-59400 (Fe), 17-87 (Ni), 0.71-1.9 (Ag), 4.3-12 (As), and 44-1800 (Mn) along LT2. Mean Pb and As concentrations were nearly 9 and 2 times the threshold for industrial soils suggested by Canadian Environmental Quality Guidelines. One way ANOVA indicated a statistically significant difference in mean content of Pb, Zn, Cu (P<0.001) and Ag, As, Co, Fe and Mn (P<0.05) in soil samples from the two transects. Similar distribution of Cr and Ni along the two transects indicates a non-localized distribution of the metals not limited to the mineralized veins of the region. This was confirmed by one way ANOVA where no significant difference (P<0.05) was observed in mean Cr and Ni content of the soil samples.

Ion imaging of biogenic and abiogenic mineral surfaces

*MOSTAFA FAYEK[1]

[1]Dept. Geol. Sci., Univ. Manitoba, Winnipeg MB R3T 2N2 *(fayek@cc.umanitoba.ca)

Secondary Ion Mass Spectrometery (SIMS) is ideally suited for studies of elemental and isotopic gradients and the localization of isotopically labelled molecules. The Nano-scale SIMS (NanoSIMS) is the only technique available that can measure isotopic distributions with both high sensitivity (ppm) and high spatial resolution (i.e., 50-1000 nanometres), produce single cell images, and analyse a cell in three dimensions [1, 2]. The following two studies combine the unique capabilities of the NanoSIMS with advanced transmission electron microscopy (TEM) techniques to provide compositional and structural details of biogenic and abiogenic mineral surfaces at the nanoscale [3, 4].

Bio-precipitated minerals are typically at the nanometer scale, hydrous, and beam sensitive. We combined the nano-scale ion imaging capabilities of the NanoSIMS and advanced high-resolution (HR) TEM techniques to characterize the surfaces of *Geobacter sulfurreducens* and the bio-precipitated uranium phases, revealing the association between nutrient uptake and uranium mineral precipitation. Bio-sequestration of uranium is enhanced by addition of nutrients, and uranium is precipitated on the surface of the bacteria as nano-size crystals of uraninite (UO_2). Our results show that the biofilm shielded the UO_2 from re-oxidation and that bacteria can immobilize uranium for extended periods, even under relatively oxidizing subsurface conditions [3].

Nanoscale isotope and chemical images of grains of Amelia albite that were reacted with 2 m ^{18}O-enriched solution of KCl show a correspondence between O-isotope exchange and K-Na exchange. The boundary between the core albite and the K-feldspar replacement is sharp and decorated with numerous pores. The distribution of Na and K, determined by electron probe microanalysis, is uniform within the core and rim and has an abrupt discontinuity at the interface. The NanoSIMS shows that the interface is also sharp in the distribution of ^{18}O and ^{16}O. The combined electron probe and NanoSIMS analyses indicate that both cation and isotopic exchange occurred during solution and re-precipitation of the feldspar.

Nano-scale ion imaging combined with HRTEM is a powerful technique for imaging mineral surfaces and interfaces, and tracking the uptake of radionuclides.

Gold associated with Neoarchean alkaline intrusion, Lac Bachelor, Abitibi, Canada

N. FAYOL[1*], M. JÉBRAK[1] AND L.B. HARRIS[2]

[1]UQAM, Montréal, QC, H3C 3P8, Canada (*correspondence: noemiefayol@gmail.com)

[2]INRS-ETE, Québec, QC, G1K 9A9, Canada

Recent alkaline intrusion-related gold deposits have been recognized worldwide (e.g. Cripple Creek, Ladolam). Similar Neoarchean deposits are now recognized in the Canadian Superior Province but their metallogeny is still misunderstood; the Lac Bachelor gold deposit is a key example. It is located within the Desmaraisville basin, a "Timiskaming-type" basin in the Abitibi Greenstone Belt Where it is hosted by a volcano-sedimentary assemblage, mafic and felsic intrusions, and associated with regional NE-SW oblique-slip faults.

Gold mineralization is located on the margin of the O'Brien stock, a polyphase alkaline quartz-syenite body which intrudes andesite and tuff. It displays porphyritic and equigranular textures. Injections of aplitic dykes occurred in late events. The O'Brien stock is mainly composed of Na- and K-feldspars, quartz, and mafic minerals. Purple fluorite is present, both disseminated in the syenite and in quartz-fluorite-pyrite veins that appears as comagmatic.

The Lac Bachelor gold deposit is characterized by several mineralized zones among which the Main zone (ZP) and the B zone (ZB) are the most economically important. A porphyry-style mineralization is present at the stock margin with quartz, quartz-magnetite, quart-fluorite, and pyrite stockwork. Subhorizontal quartz-fluorite veins extend into the host rocks proximal to the stock. The Main and B zones are mainly localized in tuffs at the edges of the pluton and follow pre-existing discontinuities. Gold occurs in association with disseminated pyrite, magnetite, haematite, and rare chalcopyrite and pyrrhotite. In the ZP and lesser in the ZB, the magnetite is oxidized into haematite. Gold is present in highly altered (haematite-carbonate) zones associated with disseminated pyrite. The ZB is less haematized than the ZP, which is consistent with the timing: structural relations between these zones suggest that the ZB was formed first and the ZP occurred after.

The hydrothermal event is clearly related to the intrusion of the O'Brien syenite. However, fluids appear to have followed pre-existing discontinuities that focused mineralization. Results illustrate the complementary roles of magmatic and structural controls during the mineralization processes.

Hydrologic variability in coastal southwest USA

SARAH J FEAKINS*[1], MATTHEW E. KIRBY[2], MONG SIN WU[1] AND LINDA HEUSSER[3]

[1]University of Southern California, Los Angeles, CA 90089, USA (*correspondence: feakins@usc.edu)
[2]California State University, Fullerton, Department of Geological Sciences, Fullerton, CA 92834 USA
[3]Lamont Doherty Earth Observatory, Columbia University, NY 10964. USA.

Understanding hydroclimate variability is a pressing need in the world's drylands, yet it is here that climate projections differ in the sign and magnitude of change in precipitation [1]. Within the southwest USA a different precipitation regime influences the California coast (winter only) and the interior (bimodal winter and summer). Here, we present multi-proxy reconstructions of the hydroclimate of the coastal zone. Sediments from Zaca Lake capture a sub-decadal history of wet-dry oscillations spanning 3ka whereas Lake Elsinore records climatic transitions from 33ka to Holocene.

Hydrogen isotopes in plant leaf waxes provide a record of the changing hydrological regime. Over the last 3ka, δD values of the C_{28} *n*-alkanoic acid are highly variable across −175‰ to −125‰ in Zaca Lake. Grain size records multi-decadal variations in runoff and charcoal reveals the variable history of fire. At Lake Elsinore, a longer term shift from δD values of −190‰ at 19ka, to −120‰ at 9ka, is attributed to a shift from North Pacific to sub-tropical Pacific moisture sources, paralleling the radiative forcing trend out of the last glacial. Similarly, grain size records a long-term decrease in runoff and pollen record a transition from *Pinus* to *Quercus* indicating warming and drying. Southwest climate differs during the Younger Dryas; wet conditions found inland are linked to AMOC forcing [2]; here we show the coast remains dry.

[1] Solomon *et al*., (2009) PNAS, **106**, 1704-1709. [2] Clark *et al*., (2012) PNAS, **109**, E1134-1142.

Diamond dissolution in COH fluids

Y. FEDORTCHOUK

Dalhousie University, Halifax, B3H4R2, Canada (correspondence: yana@dal.ca)

Morphology of surface features on natural kimberlite-borne diamonds indicates their interaction with fluid and greatly depends on the composition of this diamond-destructing fluid. H_2O:CO_2 ratio in the fluid dictates the degree of rounding, intensity of the pit development on {111} face, orientation and morphology of trigonal pits, and presence of other less common etch features (e.g. circular pits, hexagons). A number of different mechanisms have being proposed to explain the diversity of diamond resorption features. Application of experimental findings to natural diamonds demonstrated a relationship between diamond morphology and behavior of volatiles in kimberlite magma. However, absence of a model that relates diamond micro-morphology to the characteristics of the reacting fluid precludes more quantitative characterization of kimberlite volatile system using diamond micro-morphology. Toward this end, we conducted atomic force microscopy (AFM) study of diamond crystals from dissolution experiments with H_2O and CO_2-fluid and from natural kimberlites.

Diamond octahedra were etched in H_2O or CO_2 fluid at 1 GPa and temperature (T) = 1150-1350ºC. AFM data collected in tapping and contact mode demonstrated that outside of few large etch pits (up to 2 um depth) the roughness of the diamond surface is less than 400 nm in H_2O fluid and increases with T. In CO_2 fluid the roughness is between 600nm and 2 um and is independent on T. Trigonal etch pits in H_2O fluid have constant diameter independent on the depth but increasing with T. In CO_2 runs trigonal pits show continuos sizes and positive correlation between the diameter and the depth. In H_2O fluid trigons are mostly flat-bottomed, whereas in CO_2 fluid they develop round bottom at higher T and more pointy-bottom at lower T. The general resorption morphology and presence of hexagonal pits in CO_2-bearing runs could be a result of the different dissolution rate in [111], [100], and [110] direction in fluids with various H_2O:CO_2 ratio. However, the more regular layer-by-layer resorption in H_2O fluid and irregular deeper material removal in CO_2 fluid may also indicate different mechanism of interaction of surface complexes formed in CO_2- and H_2O-dominated media and different rate of removal of 3- and 2-bonded atoms from diamond surface by these complexes. We conducted AFM measurments of trigonal pits on 22 micro-diamonds from four Canadian kimberlite pipes, which different geology indicates different behavior of volatiles. We use this data to examine magmatic fluid and the relative crystallization T.

Transport in active margins: Comparison of results from I^{129} and Be^{10} studies

UDO FEHN[1]

[1]Dept. Earth&Environmental Sciences, U. Rochester, Rochester, NY, 14627 (udo.fehn@rochester.edu)

Active margins are the location of large-scale movement of elements and compounds between crust and mantle, including the potential for transport of marine sediments into subduction zones with subsequent release of elements from volcanoes. Two cosmogenic isotope systems have been applied for the investigation of this question: ^{10}Be (e.g. Morris *et al*, 2002) and ^{129}I (e.g. Fehn, 2012). Although both of these isotopes have similar production modes, they differ considerably in half-lives (1.5 Ma for ^{10}Be; 15.7 Ma for ^{129}I) and geochemical characteristics. Because Be is readily incorporated into mineral phases, ^{10}Be concentrations were determined in solid samples. Results demonstrate that in many cases marine sediments have been carried to the mobilization zone under the main arc, but that less than half of Be is transported back to the surface.

Because iodine is predominantly found in aquatic fluids, investigations were carried out on samples collected from crater lakes, fumaroles and geothermal sites at active volcanic centers. ^{129}I/I ratios in the fluids decrease with increasing slab age, an observation consistent with transport of iodine within marine sediments to the location of re-mobilization under the main volcanic arcs. Sediment-derived iodine was found in all study sites around the Pacific Rim, including some where ^{10}Be was absent. The observed ^{129}I/I ratios reflect values integrated over the full thickness of the marine sediments transported into the subduction trenches, suggesting that iodine is quantitatively released into the volcanic fluids.

Results from ^{10}Be and ^{129}I studies demonstrate transport of marine sediments into subduction zones and the subsequent integration into or release from active volcanoes. Elements such as Be are predominantly taken up by rock forming minerals and only a fraction of it reappears in surface deposits. The presence of iodine derived from marine sediments demonstrates that volatile elements are also transported to the mobilization zone, but that most of those elements are released back to the surface, preventing transport into the mantle.

Tellurium stable isotope variations in chondrites

M.A. FEHR[1*], S.J. HAMMOND[1] AND I.J. PARKINSON[1,2]

[1]Department of Environment, Earth and Ecosystems, Centre for Earth, Planetary, Space & Astronomical Research (CEPSAR), The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK (*correspondence: manuela.fehr@open.ac.uk)

[2]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Wills Memorial Building, BS8 1RJ, UK

Different carbonaceous chondrite groups exhibit distinct stable isotope signatures for several elements including Cr, Cu and Zn reflecting mixing of two isotopically distinct reservoirs in the early solar nebula [1-2]. Furthermore, moderately and highly volatile elements such as Ag, Zn and Cd display relatively large stable isotope variations in unequilibrated ordinary chondrites that are indicative of evaporation/condensation processes due to parent body metamorphism [2-4]. Similar variations are expected also for other moderately and highly volatile elements as e.g. tellurium (Te). Previous studies revealed that Te was homogeneously distributed and well mixed in the early solar system resulting in no resolvable nucleosynthetic or radiogenic Te isotope variations in bulk meteorites [5,6]. The methods used in these studies were not specifically developed or optimized to yield precise and accurate Te stable isotope data, although the data hint at the presence of Te stable isotope variations in unequilibrated ordinary chondrites [6].

Improved methods to derive high precision and accurate Te stable isotope data were developed in this study. Tellurium isotope data are measured using a Neptune MC-ICPMS, whereas mass bias is corrected using a double spike technique. The reproducibility (2SD) of standards consuming 10 ng Te is 0.02 ‰/amu or better, whereas 2 separately processed powders of Allende reproduce to 0.03 ‰/amu. This is an improvement in precision of over 20 times compared to previous analyses that employed standard sample bracketing [6]. Initial data reveals resolvable Te stable isotope variations between different chondrite samples and an overall variability of about 1 ‰/amu. This study will obtain high precision Te stable isotope data for a comprehensive suite of ordinary, carbonaceous and enstatite chondrites.

Deep sediment melts contribute to Southwest Japan adakitic magmas

MAUREEN FEINEMAN[1], TAKUYA MORIGUTI[2], TETSUYA YOKOYAMA[3] AND EIZO NAKAMURA[2]

[1]The Pennsylvania State University, University Park, PA, USA
[2]Institute for Study of the Earth's Interior, Okayama University, Misasa, Japan
[3]Tokyo Institute of Technology, Tokyo, Japan

The Quaternary Southwest Japan Arc is a product of subduction of the hot, young Philippine Sea Plate beneath the Eurasian Continental Plate. The magmas erupted from the Southwest Japan Arc belong to a category of magmas commonly referred to as "adakites". These magmas show trace element evidence for interaction with garnet at depth, and may be associated with partial melting of subducted altered oceanic crust. Also found throughout the southern Sea of Japan and scattered across Southwestern Japan, Korea, and China are alkali basalts with little apparent connection to the subduction zone. We have determined major element, trace element, and Sr, Nd, Pb, and U-Th isotopic compositions for a bimodal suite of lavas erupted at the Daisen volcanic field in the Southwest Japan Arc. These magmas consist of mildly alkaline basalts and a calcalkaline intermediate suite, separated by a ~10 wt. % silica gap. Our data suggest that the basalts are not parental to the intermediate magmas, and contain a small contribution of EM1-like mantle common in Sea of Japan alkali basalts but not apparent in the Daisen intermediate magmas. The intermediate magmas show trace element and isotopic evidence for interaction with garnet, but unlike other adakitic magmas, they show strong trace element and isotopic evidence for incorporation of significant (~25%) partial melt of subducted sediment. Recent studies [1] suggest that the ~350m sediment blanket subducted beneath Southwest Japan (Nankai) may become detached from the slab at temperatures between 650-675°C. The implications of sediment detachment are two-fold: 1) the removal of the insulating sedimentary cover would enable rapid heating of the basaltic slab surface, encouraging slab melting, and 2) the detached sediments may be relaminated at the base of the arc crust [2], where they could contribute partial melts to the slab-derived magma prior to eruption. The uncharacteristically high Al_2O_3 (17-18%) and low MgO (~2%) contents of the Daisen adakites are consistent with assimilation of significant sediment partial melts derived from depths >30km at the base of the arc crust.

Low-dimensional models of complex aerosol-cloud interactions

GRAHAM FEINGOLD[1,*] AND ILAN KOREN [2]

[1]NOAA Earth System Research Laboratory, Boulder, Colorado, USA (*correspondence: graham.feingold@noaa.gov)
[2]Weizmann Institute of Science, Rehovot, Israel, (ilan.koren@weizmann.ac.il)

The radiative forcing associated with aerosol-cloud interactions persists to be one of the largest unknowns of the climate system. To address this problem, both the aerosol and cloud communities have focused on process-level understanding of smaller components of the aerosol-cloud system. While this approach has yielded major advances in the understanding of both aerosol and cloud physics, we have been less successful at addressing the effects of aerosol perturbations on cloud systems, in which constant adjustments (feedbacks) can occur. The problem is exacerbated by the complexity of the adjustments, and the fact that they occur at a large range of spatiotemporal scales. Currently no climate model is able to address the full range of relevant scales and the processes are difficult to constrain with observations.

In this overview we will look at the aerosol-cloud system as a dynamical, self-adjusting entity and attempt to address the question of the resilience of the system to aerosol perturbation. To do so we will use a combination of observations, detailed process-modeling, and low-dimensional models that capture the essence of the system [1]. We will give examples of cloud systems that are relatively robust to aerosol perturbations, and contrast this with cases where the aerosol has locally strong effects, often through leveraging of mesoscale organization. We will highlight the important role that the aerosol plays in sustaining clouds in the very clean marine boundary layer. Finally, we will consider the possibility that aerosol-cloud interactions might be amenable to parameterization in terms of their system-wide behaviour. This may present a fruitful alternative to the current bottom-up approach to parameterization.

Gasanalysis at a geothermal facility: On-line monitoring above ground and measurements in the borehole

ELVIRA FELDBUSCH[1]*, THOMAS WIERSBERG[1], MARTIN ZIMMER[1], HENNING FRANKE[1] AND SIMONA REGENSPURG[1]

[1]Helmholtz Centre Potsdam, **GFZ German Research Centre for Geosciences, Potsdam, Germany.**
elkin@gfzpotsdam.de (* presenting author)

The formation fluid from Permian (Rotliegend) vulcanite and sandstone layers of the geothermal in-situ laboratory in Groß Schönebeck (North German Basin) contains a high volume of dissolved gases (volume ratio of liquid : gas is about 1:1 and increases up to 1 : 1.6 at reservoir conditions). It's mainly composed of nitrogen (N_2; 84-90 vol-%) and methane (CH_4; 10-16 vol-%) with minor concentrations of CO_2, H_2, He, Ethane, Kr, Propane, *n*-Buthane and *i*-Buthane. The fluid is degassed above ground and the gas composition was monitored on-line at the degasser during several circulation tests at the facility. The measurements indicated relatively constant values of gas composition over the whole production time.

Additionally, several deep fluid samples have been collected in the production well at various depths (1700m, 2200m, 4200m) to analyze changes in liquid : gas ratio and in chemical composition of formation gas in dependence of the fluid depth. The collected results show, that the beginning of degassing takes place at about 2200 m depth.

However, some samples at 4200 m appear to be above gas saturation (calculated for a gas mixture with 85 % N_2 and 15 % CH_4 in 5 M NaCl). Thus the presence of free gas in the reservoir seems likely. The impact of free gas on plant operation is still under investigation.

Noble gas constraints on reduced deep subsurface fluids

J. FELLOWES* AND C.J. BALLENTINE

SEAES, University of Manchester, M13 9PL, UK
(*correspondence: jonathan.fellowes@manchester.ac.uk)

The noble gases are conservative tracers of fluid interactions over geological time scales. By applying high precision stable isotope noble gas multi-collector mass spectrometry to deep subsurface free fracture fluids and fluid inclusions, it is possible to discern the origin (e.g. atmospheric, crustal or mantle), age and interactions of these fluids. Two distinct end-member fluids have been found in the deep Precambrian continental subsurface: (i) palaeometeoric water that falls along the global meteoric water line (GMWL) and contains atmospheric noble gas signatures and (ii) highly saline hydrothermal fluids that lie above the GMWL and contain abiogenic hydrocarbons, significant radiogenic noble gas input and fluid components billions of years old [1].

Previous noble gas studies have highlighted disparities between the neon component of free fracture fluids and fluid inclusions [2] and have used high precision heavy noble gas analysis to study free fracture fluids [3].

For this study, gas, water and rock samples have been collected from exploratory boreholes in deep mines within the Precambrian Witwatersrand basin, South Africa and Abitibi greenstone belt, Canada. By combining noble gas mass spectrometry with traditional stable isotope techniques, we aim to fully characterize these samples to relate the free fracture fluid phase with fluids trapped within hydrocarbon-rich quartz-hosted inclusions to provide constraints on the rate of abiogenic gas formation, the extent of the free fracture fluid networks and the degree of communication between deep abiogenic reduced carbon sources and the biosphere.

Here we report on our progress in the development of a sample handling and processing system that will enable us to analyze hydrocarbon-rich free fracture fluids and fluid inclusions using high precision multi-collector noble gas mass spectrometry, a key advance in the application of noble gases to crustal fluid systems.

First-principles investigations of equilibrium calcium isotope fractionation between clinopyroxene and orthopyroxene

C.-Q. FENG [1], T. QIN [1], S.-C. HUANG [2], Z.-Q. WU [1] AND F. HUANG [1]

[1]School of Earth and Space Sciences, University of Science and Technology of China, Hefei, Anhui 230026, China (fcq007@mail.ustc.edu.cn,tian91@mail.ustc.edu.cn,wuzq10@ustc.edu.cn,fhuang@ustc.edu.cn)

[2]Department of Earth and Planet Sciences, Harvard University, 20 Oxford St., Cambridge, MA 02138, USA (huang17@fas.harvard.edu)

Equilibrium calcium isotope fractionations between clinopyroxene and orthopyroxene, the two major Ca-bearing minerals in the upper mantle, are calculated with density functional perturbation theory (DFPT). The results suggest that orthopyroxene has higher $^{44}Ca/^{40}Ca$ ratios than clinopyroxene due to smaller coordination numbers (CN) of Ca in orthopyroxene than that in clinopyroxene (6 vs. 8). We further find that Ca concentration of orthopyroxene significantly influences $\Delta^{44/40}Ca_{opx\text{-}cpx}$ especially when Ca/Mg in orthopyroxene is below 1:15. Our results successfully explain the observations of variable Ca isotopic fractionation between coexisting orthopyroxene and clinopyroxene from Kilbourne Hole and San Carlos mantle peridotites, i.e., $\Delta^{44/40}Ca_{opx\text{-}cpx}$ increasing from 0.36‰ to 0.75‰ with $[CaO]_{opx}$ decreasing from 1.03wt.% to 0.75wt.% (Huang *et al*, 2010). This reveals that crystalline environment such as the average Ca-O bond length parameter may be controlled by Ca content in orthopyroxene when Ca is a minor element. Our calculations also suggest that, although $\delta^{44}Ca$ of orthopyroxene may increase dramatically with decreasing CaO content, the average Ca isotope composition of the upper mantle is relatively constant because $[CaO]_{cpx}$ is much higher than $[CaO]_{opx}$. Furthermore, if Ca content and Ca isotope compositions of clinopyroxene and othorpyroxene are known, Ca isotopic fractionation between clinopyroxene and orthopyroxene can be used as a potential two-pyroxene Ca isotope thermometry.

Evaluating the sulfur cycles in the early Cambrian ocean: An example from the Yanjiahe Formation, Yangtze Gorges area, South China

LIAN-JUN FENG[1]

[1] Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China, (feng.lian.jun@gmail.com)

The Yanjiahe Formation represents the earliest beginning of the Cambrian period in the Yangtze Gorges area, South China. In this study, we first report the sulfur isotope compositions of chromium-reducible sulfur ($\delta^{34}S_{CRS}$) and carbonate-associated sulfate ($\delta^{34}S_{CAS}$) from the Yanjiahe Formation. The difference between $\delta^{34}S_{CAS}$ and $\delta^{34}S_{CRS}$ from the Yanjiahe Formation is similar to that from the other basins worldwide (less than 30 per mil), reinforcing low marine sulfate concentrations across the Ediacaran-Cambrian boundary and into the Cambrian [1].

The Yanjiahe Formation has large-magnitude $\delta^{34}S_{CRS}$ ratios, ranging from 3.3 to 26.1 per mil, similar to the other basins worldwide. However, the sulfur isotope record in pyrite from the upper part (orgnic-rich limestone) shows more positive ratios than that from the lower part (oganic-lean dolomite), probably reflecting local influences.

Observations of atmospheric Hg species and depositions in remote areas of China

XINBIN FENG[1], XUEWU FU[1] AND HUI ZHANG[1,2]

[1]State Key Laboraotry of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China

[2]University of Chinese Academy of Sciences, Beijing 100049, China

From September 2007, we conducted continuous measurements of speciated atmospheric mercury (Hg) and atmospheric mercury depositions at five remote sites in China. Four of these sites were involved in the Global Mercury Observation System (GMOS) as ground-based stations. These stations were located in the northwest, southwest, northeast, and east part of China, respectively, which represent the regional atmospheric Hg budgets in different areas of China. Standard Operating Procedures (SOPs) and QA/QC protocols were implemented at all the sampling sites. Data quality of atmospheric TGM concentration was controlled via periodic internal recalibration with a 25 h interval, and the emission rate of internal permeation source was calibrated every 4 months.

Our measurement data showed that the mean total gaseous nercury (TGM) concentrations were in the range of 1.60 – 2.88 ng m^{-3}, with relatively higher levels observed at sites in Eastern China and Southwestern China and lower levels at sites in Northeastern and Northwestern China. Generalyy, TGM concentrations at most remote sites of China were higher than those reported from background sites in North America and Europe, and this is corresponding very well with the Chinese great anthropogenic Hg emissions. However, at a remote site in Northeastern China, the mean value of TGM concentrations is somewhat lower than the values of 1.7 ng m^{-3} observed in Europe and North America. Gaseous oxidized mercury (GOM) and particulate bounded mercury (PBM) were in the ranges of 3.2 – 7.4 pg m^{-3} and 19.4 – 43.5 pg m^{-3}, respectively. The preliminary result on precipitation showed mean precipitation THg concentrations were in the range of 2.7 – 18.0 ng L^{-1}.

These contineous observations also helps to gain a better insight to the effects of long-range atmospheric mercury transport on TGM variations in ambient air. We showed that Northwestern India was an important source region of Northeastern Qinghai-Tibetan Plateau, indicating this area might also have relatively higher anthropogenic Hg emissions.

Sulfur runs through it: A celebration of Bo Barker Jørgensen's science and a multi-faceted element

T. G. FERDELMAN[1]

[1]Max Planck Institute for Marine Microbiology,Bremen, Germany;
(tferdelm@mpi-bremen.de)

Behind almost every environmentally important redox transformation there lurks a sulfur transformation of some type or another. Through patient observation and elegant experimentation Bo Barker Jørgensen has over the years continuously grappled with this ubiquitous, yet slippery, element. A series of seminal papers in the late seventies set the tone for decades of research in sulfur biogeochemistry, isotope geochemistry and microbial ecology. Employing the highly sensitive radio-label technique, Bo's observation that microbial sulfate reduction is a major process in a wide variety of marine sediments *[1]*, and one that can be tracked into deeply buried sediments (the "deep biosphere"), has provided an important fundament for our understanding of the links between in the carbon, sulfur and oxygen cycles.

Bo's exploration of biotic and abiotic sulfur transformations via sulfur oxidation state intermediates has proved equally influential. Today's research on the microbial ecology in stratified water basins owe a significant debt to the methodological approaches and concepts laid out in a paper written together with G. Kuenen and Y. Cohen, where they examined the microbial cycling of sulfur intermediates in Solar Lake *[2]*. Delving further into the world of sulfur intermediates and microbial ecology revealed the importance of microbial sulfur disproportionation in sediments, and the fascinating links between the giant sulfur bacteria and other element cycles, e.g. oxygen, nitrogen and phosphorus.

These strands culminate in recent studies where Bo has shown that an active sulfur cycle, complete with sulfate reduction, oxidation and disproportionation pathways, functions in the deep methane-bearing zone of marine sediments *[3]*. This research continues to inspire research on the paradoxical and cryptic roles of sulfur intermediates, e.g. elemental sulfur and polysulfides *[4, 5]* in highly reducing sulfidic environments. Sulfur, it seems, is the element that greases the redox cycles in marine environments.

Waste Characterisation of a Uranium Conversion Facility

T. FERNANDES[13], L. DURO[1], T. SCHÄFER[2], P. MASQUÉ[3], A. DELOS[4], J.S. FLINOIS[5] AND G. VIDEAU[5]

[1]Amphos 21, Barcelona, Spain
[2]Karlsruhe Institute of Technology (KIT) – Institute for Nuclear Waste Disposal (INE), Karlsruhe, Germany
[3]Departament de Física & Institut de Ciència i Tecnologia Ambientals. Universitat Autònoma de Barcelona, Bellaterra. Spain
[4]Arcadis, Villeurbanne, France
[5]AREVA, France

At the front end of the nuclear-fuel cycle, the process of conversion of uranium ore concentrate into uranium tetrafluoride generates a waste stream. Understanding the geochemistry of this waste is fundamental for risk assessment of the final disposal.

Here we present the work carried out to characterise uranium in the decanted waste of a uranium conversion facility.

The industrial site of interest is the first step in the treatment of uranium mining concentrate. The process waste, resulting from the conversion of yellowcake into uranium tetrafluoride (UF_4) has been managed in settling basins, which were built on the tailings of a former sulphur mine. The waste contains a variety of chemicals (nitrates, carbonates, fluorides and sulphates) and radioactive elements, of which uranium contributes with 30% of the total alpha activity. The porewaters are characterised by high ionic strength, of up to 2M.

The work comprised static (batch-type) and dynamic (column) experiments of disturbed and undisturbed material obtained from the site to investigate the release of uranium. The chemical form of the uranium was also studied. Thermodynamical modelling was carried out in parallel to the laboratory work.

Static and dynamic experiments show that the release of uranium from the waste is kinetically controlled. Source term characterisation suggests U is present in different degrees of crystallinity. Although the solubility-limiting mineral phase has not been identified, it is likely to be either a U-Si phase or a phase similar to meta-schoepite. An important pH buffer effect from calcite in the waste was observed.

Calibration of the Siderite CO_2 'Clumped' Isotope Paleothermometer

ALVARO FERNANDEZ[1], JIANWU TANG[2] AND BRAD ROSENHEIM[3]

[1] Department of Earth & Environmental Sciences, Tulane University, New Orleans, Louisiana 70118-5698, U.S.A., (afernan4@tulane.edu)
[2] Department of Earth & Environmental Sciences, Tulane University, New Orleans, Louisiana 70118-5698, U.S.A., (jtang@tulane.edu)
[3] Department of Earth & Environmental Sciences, Tulane University, New Orleans, Louisiana 70118-5698, U.S.A., (brosenhe@tulane.edu)

Siderite ($FeCO_3$) is commonly found in lake sediments, paleosol profiles and modern soils. Its presence in the geologic record has been shown to provide a useful archive of paleoclimate variables in environments that are generally exclusive of calcite (e.g. Sheldon and Tabor 2009). Clumped isotope measurements can be used to exploit the paleoclimatic potential of this archive; however, the applicability of this method is held back by the lack of clumped isotope calibrations of mineralogies other than calcite and aragonite. Here we present an inorganic calibration of siderites grown in the laboratory between 22-50º C. Synthetic siderites where precipitated by slow titration (0.15 ml/min) of a sodium bicarbonate solution with an anoxic iron (II) chloride solution followed by active degassing of CO_2 with N_2. We also report measurements of natural siderites collected from Holocene aged sediments of the Mississippi River Delta. We find no difference in the Δ_{47} vs. temperature relationship between synthetic calcites (also measured in our laboratory) and siderites. Our results suggest that the model of Guo *et al* [1] may not accurately predict the difference in acid fractionations between the different carbonate minerals, and instead imply that a single clumped isotope calibration is appropriate for samples of different mineralogies.

Priming effect and isotope ^{13}C dynamics at natural abundance during the biodegradation of lignin in a soil environment

I. FERNANDEZ*

Departamento de Bioquímica del Suelo, Instituto de Investigaciones Agrobiologicas de Galicia, IIAG-CSIC, Santiago de Compostela, Spain. *correspondence: (ifernandez@iiag.csic.es)

For the progress of isotope-based studies of decaying debris in soil profiles, factors that affect isotope ^{13}C dynamics of plant-derived biopolymers during decomposition need to be analysed. Many applied biogeochemical investigations are paying attention to isotope-ratio mass spectrometry, although for obtaining advanced accuracy when using these techniques, particularly for soil organic matter (SOM) studies at natural abundance levels, the appraisal of possible isotopic fractionation occurring during different stages of plant decomposition is essential. New insights into possible fractionation processes occurring during decomposition of a highly resistant plant component such as lignin (which remains during the last stages of vegetal decomposition) would have some important implications for assessing long-term SOM quality. Despite the direct implications for multitude of research lines, C isotopic dynamics during biological transformations of major structural biopolymers remains mostly unexplored and knowledge of the factors affecting the ^{13}C SOM fingerprint are scarce. Thus, this research evaluates the isotopic ^{13}C discrimination during the biodegradation of lignin to obtain more reliable estimates of the contribution of this highly resistant plant component to SOM buildup, as well as the influence of soil environment that may further exacerbate microbial discriminatory actions. Changes in ^{13}C composition during aerobic decomposition of the following substrates: a) hydrolytic lignin, b) soil, and c) soil+lignin mixture, were monitored over a 10 months incubation period. The results indicate that SOM decomposed faster than pure lignin. Also, soil+lignin mixture showed a synergic degradative behaviour with a greater mineralization rate than adding together soil and lignin individual rates, suggesting that priming effects can be produced during in-soil biodegradation of lignin. Isotopic fingerprint of the CO_2 released from lignin during biodegradation showed a lower ^{13}C concentration than the initial substrate and consequently, with ongoing decomposition, the solid residue became progressively ^{13}C-enriched.

Lithosphere-asthenosphere interactions (Middle-Atlas (Morocco): Geochemical highlights

L. FERNANDEZ[1], D. BOSCH[1], H. ELMESSBAHI[2], J.L. BODINIER[1], J.M. DAUTRIA[1] AND P. VERDOUX[3]

[1] Géosciences Montpellier, Montpellier France. *(laure.fernandez@gm.univ-montp2.fr)*
[2]Université Moulay Ismaïl, Meknès, Maroc.
[3]Université de Nîmes ,30035 Nimes Cedex 1

The Neogene-Quaternary Middle Atlas province is the largest and youngest volcanic field of Morocco, bringing up a large variety of mantle xenoliths. The eighteen xenoliths are mainly lherzolites, but also include harzburgite, wherlite and pyroxenite. A major, trace elements & Sr-Nd-Pb-Hf isotopes study was conducted on CPX and host-rocks (WR) coupled petrographic constraints. Lherzolites show flat REE patterns with variable enrichment in LREE ie. various degrees of metasomatism. Harzburgites present a significant MREE enrichment. Sr isotopes of both WR and CPX show low ratios and define a limited range of variation ($0.7023<^{87}Sr/^{86}Sr<0.7035$). Reported on the Nd-Sr diagram, they define a field extending between the DMM and HIMU compositions. Pb isotopic ratios are high and range, for $^{208}Pb/^{204}Pb$, between 38.87 and 40.54, for $^{207}Pb/^{204}Pb$ from 15.59 to 15.64, and for $^{206}Pb/^{204}Pb$ from 19.08 to 20.29. Two Sm/Nd internal isochrons have been calculated for two different volcanic sites and yield Pan-African and Alpine indicative ages. Together, these constraints allow us to propose that Middle-Atlas mantle experienced several lithosphere asthenosphere interaction processses. Such an HIMU signature is common in the european subcontinental mantle sampled by cenozoic volcanism. At last, this study demonstrates that even in geodynamical complex zones experiencing various thinning episodes, preserved old lithospheric mantle can be present in continental lithosphere.

Thermal ageing of sepiolite/ polyamide66 nanocomposites

C. FERNÁNDEZ-BARRANCO[1], A.YEBRA-RODRÍGUEZ[1*], M. D. LA RUBIA-GARCÍA[2], A.B. RODRÍGUEZ-NAVARRO AND J. JIMÉNEZ-MILLÁN[1]

[1]Department of Geology and CEACTierra, Associated Unit IACT (CSIC-UGR), Faculty of Experimental Sciences, University of Jaén, Campus Las Lagunillas s/n, 23071 Jaén, Spain (cfernand@ujaen.es; *correspondence: ayebra@ujaen.es; jmillan@ujaen.es)

[2]Department of Chemical, Environmental and Materials Engineering, EPS, University of Jaén, Campus Las Lagunillas s/n, 23071 Jaén, Spain (mdrubia@ujaen.es)

[3]Department of Mineralogy and Petrology, Faculty of Sciences, Campus Fuentenueva s/n, 18071 Granada, Spain (anava@ugr.es)

Clay/polymer nanocomposites are hybrid materials in which the nanoclay is exfoliated in the polymer matrix providing remarkable physical properties suitable for sophisticated industrial applications[1, 2]. The enhancement of the technical properties has been related to the crystallographic arrangement between the clay minerals and the polymer matrix [3]. Nanocomposites have been used commercially since Toyota first auto parts in the late 1980s. However, further effort has to be done to understand the long-term thermal stability of these materials. The aim of this work is to study the influence of the temperature on the stability (and thus the technical properties) of injection molded sepiolite/polyamide66 nanocomposites. For that purpose pure polyamide66 (PA66-S-0 samples) and sepiolite/polyamide66 nanocomposites with 5 wt.% clay loading (PA66-S-5 samples) were manufactured and injected (BABYPLAST 6/10, CRONOPLAST) to simulate industrial processing. Thermal ageing was carried out at 110 ºC and 150 ºC during 7, 14, 21, 28 and 35 days. Thermogravimetric analyses (TG Mettler Toledo TS 0801R0) were carried out to determine the thermal stability of the materials. Crystallinity index (W_c) was calculated with the help of Differential Scanning Calorimetry (DSC 822e, Mettler Toledo). Infrared spectra (FT-IR Bruker Tensor 27) was used to obtain the carbonyl index. The results indicate that the mass loss is not affected by the ageing. However, in PA-S-5 samples W_c decreases with the ageing and carbonyl index is higher than in pure polyamide66, thus indicating further degradation.

[*] (Alex.Fernandez-Martinez@ujf-grenoble.fr)

Amorphous calcium carbonate (ACC, $CaCO_3{\cdot}H_2O$) is commonly found in the earliest stages of biomineral development and as one of the metastable phases formed during the inorganic precipitation of calcium carbonate crystalline polymorphs. Recently, the existence of different amorphous polymorphs of ACC—proto-vaterite and proto-calcite—that act as precursors of the crystalline polymorphs has been suggested [1]. It has also been shown that the presence of Mg^{2+} in ACC induces an aragonite-like local order around the Ca^{2+} ions [2]. Here we show using high-pressure high-energy x-ray diffraction experiments combined with reverse Monte-Carlo modeling that ACC undergoes a reversible structural transition at ~9.8 GPa adopting an aragonite-like local order when its molar volume is decreased. This has been confirmed by high-pressure Raman experiments that show a discontinuous behavior of the carbonate stretching and in-plane bending modes at ~10 GPa. This finding could be suggesting that cationic substitutions of Ca^{2+} by smaller ions, such as Mg^{2+}, control ACC polyamorphism by reducing the molar volume of the amorphous phase. The fact that the structure is hydrated and that no signs of dehydration are found throughout the compression suggests that water is a key element in the reversibility of the transition. To our knowledge, this is the first reversible amorphous-amorphous phase transition found for an amorphous ionic system. High-pressure x-ray absorption experiments have also been performed to study the evolution of the density under pressure, allowing the first determination of the bulk modulus (K' = 27.2 ± 1.4 GPa) and the density of ACC (2.18 g/cm$^{3.}$

[3] Université Toulouse III- Paul Sabatier, Laboratoire GET-UPS-CNRS-IRD, 14 avenue Eduard Belin, 31400 Toulouse, France

Mantle xenoliths in alkaline basaltic rocks of Neogene-Quaternary age from NE Spain are mainly anhydrous spinel lherzolites and harzburgites. New samples from different volcanoes indicate that lherzolites are more abundant than harzburgites and that they show frequent porphyroclastic and equigranular microstructures, along with protogranular varieties. Since deformation could enhance basaltic melt percolation favouring refertilization of harzburgites, the relationships between microstructures and chemistry of lherzolites are evaluated using major and trace element compositions of whole rocks and minerals.

Lherzolites show very fertile to more refractory compositions grading to harzburgites. The most fertile lherzolites are porphyroclastic, while the least fertile ones show protogranular microstructures. Based on their variable REE patterns, three main types of lherzolite clinopyroxene are distinguished: (1) highly LREE depleted ($La/Yb_N < 0.1$), (2) slightly LREE depleted (La/Yb_N=0.6-0.9) and (3) LREE enriched (La/Yb_N=10.5-29). These patterns are not related to any specific microstructure, although the most LREE enriched clinopyroxenes are from porphyroclastic lherzolites. Clinopyroxene from harzburgites is always enriched in LREE and MREE (La/Yb_N=5.6-23, Nd/Yb_N=5.2-18).

These data indicate that there is no clear relationship between deformation and lherzolite compositions. Some lherzolites could have been formed by percolation of relatively depleted basaltic melts through harzburgites, but both peridotites were affected by a subsequent alkaline metasomatic component. The most depleted lherzolites would have escaped both refertilization process and the later alkaline metasomatism.

Quantum-mechanical calculations on uranium (co)adsorption and reduction on iron and aluminum (oxyhydr)oxides

S. FERNANDO* AND U. BECKER

Earth and Environmental Sciences, University of Michigan, 2534 CC Little, Ann Arbor, MI 48109, USA (*correspondence: sfernan@umich.edu)

Minerals have been shown to promote redox reactions; *i.e.* nanoparticulate hematite catalyzes the reduction of U(VI) by Fe(II), which is otherwise kinetically inhibited in the absence of the mineral.[1] These surface-mediated redox processes are not well-understood though. The proximity effect may explain this phenomenon: a semiconducting mineral can act as a medium for electrons to be transported from one adsorbate to another one, both being spatially separated by a few Å.[2] To investigate the influence of semiconducting properties of iron minerals', coadsorption and reduction processes on these are compared to insulating aluminum isostructures. Aluminum (oxyhdyr)oxides isostructures can be structural analogs for iron (oxyhdyr)oxides while their different electronic properties enable observations of whether electron transfer is more prevalent in semiconducting than in insulating minerals.

The coadsorption of a uranyl complex and a reductant (*e.g.*, Fe(II) or H_2S) onto iron and aluminum (oxyhydr)oxide clusters was studied using quantum mechanical density functional theory (DFT) calculations. These simulations allow for visualization of electron density of states (DOS) and molecular orbitals (MOs) that are involved in electron transfer. Analyses of DOS and MOs for the (co)adsorption of uranyl on a goethite cluster (α-FeOOH, *Pnma*) show Fe *d*-orbitals overlap with U *f*-orbitals. Visualization of the MOs shows the participation of the iron atoms in the coadsorption of uranyl provide a continuous pathway where electrons from the reductant can be transferred through the goethite to the uranyl complex. Conversely, with the aluminum isostructure diaspore (α-AlOOH, *Pnma*), Al *p*-orbitals and U *f*-orbitals do not overlap, consistent with diaspore's insulating behavior.

Hirshfeld, Bader, and Mulliken analyses provide static charge and spin distributions; U(VI) atoms were shown to acquire spin density (<0.1 au) upon (co)adsorption to iron substrates. To better understand the influence of mineral substrates, the electron transfer rate is being quantified using Marcus Theory, showing if pronounced differences in the rate exist for semiconducting and insulating minerals.

[3]Synchrotron SOLEIL, l'Orme des Merisiers BP48 91192 Gif-sur-Yvette CEDEX, France
[4]LMCM, Musée National d'Histoire Naturelle, 61 rue Buffon 75005 Paris, France

In some ancient stained glass windows, the presence of manganese, coupled with the alteration by water and micro-organisms [1], can induce a browning and, consequently, a loss of transparency in stained glass windows. Among the diverse alteration observed on stained glass windows, the browning phenomenon is still poorly documented and its occurrence among stained glass is not completely known.

Small pieces of ancient stained glass windows presenting brown zones at their surface have been collected mostly from French workshops. Samples have been characterized using optical microscopy, Scanning Electron Microscopy coupled with Energy Dispersive System (SEM-EDS) and microprobe analysis. In order to get insight into Mn environment in alterated zones, chemical maps and X-ray Absorption Near Edge Structure (XANES) experiments have been performed at the Mn *K*-edge on the LUCIA beamline (Soleil synchrotron) [2] using a Si(311) double crystal monochromator and fluorescence detection mode. XANES spectra of reference compounds of inorganic and biogenic origin containing Mn under various oxidation states (II, III and IV) have been collected in order to be compared to the spectra of alterated zones.

Chemical maps recorded on historical samples show that the Mn-rich alteration phases develop in Ca- and K-depleted zones. The XANES spectra of the alteration zones show significant differences with the Mn K-edge of fresh glass ensuring that a modification of the Mn environment and oxidation state occurred.

The Pedregal granitoid: a peculiar diatexitic rock (?) in a granite-migmatite complex

FERREIRA, J.A.[1], MARTINS, H.C.B.[1], RIBEIRO, M.A.[1], AND FERREIRA, P.[1]

[1] Centro Geologia, Faculdade de Ciências, Univ. Porto R. Campo Alegre, 4160-007 Porto, Portugal (*correspondence hbrites@fc.up.pt)

The Pedregal granitoid, exposed of an area with of *ca* 3 km^2, is located in the Central Iberian Zone, northern Portugal and belongs to a synorogenic variscan granite-migmatite complex sub-concordant with the regional structures. It has an elongated shape with NW-SE trending sub-concordant with country rocks, and is a fine-grained biotite-rich granitoid with abundant small biotitic nodules (1 to 2 cm) which exhibit a internal foliation, and also metasedimentary xenoliths. The country rocks are represented by a metapelitic sequence of Edicarian age, the "Complexo Xisto-Grauváquico" (CXG).

The Pedregal granitoid is an homogeneous rock, without metamorphic differentiation, and has a isogranular texture without preferred orientation. Besides, the intergranular boundaries are consistent with a metamorphic texture marked by textural reequilibrium in solid state. Accordingly, this rock has peculiar structural/textural features, point out to a diatexitic character. The mineralogical composition of this granitoid is quartz + biotite + plagioclase + k-feldspar + zircon + apatite +titanite ± rutile, and secondary muscovite.

It is noteworthy the presence of pegmatites veins both in the granite and in the host rocks which are concordant with the main foliation of the CXG (NW-SE to NNW-SSE).

Geochemically is a peraluminous granitoid, with low SiO_2 (65 to 69 wt%) and very high Zr (390 to 435 ppm) contents. The Pedregal granitoid REE patterns show LREE enrichment much higher than the associated synorogenic granites and pegmatites (fig. 1).

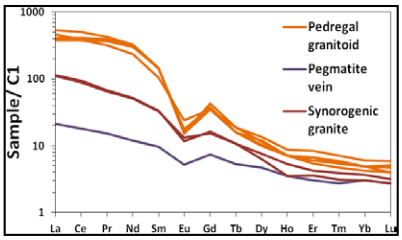

Figure 1 – REE normalized patterns.

[3] University of Technology of Hamburg-Harburg, Hamburg, HH, Germany

Mining activity is responsible for the release of arsenic (As) for the environment, compromising the quality of soils, sediments and surface water [1]. However, the mobility and the bioavailability of As in the environment is influenced by the solid phase which it is associated. In this sense, the study evaluated samples river sediments next a great pit mining area, in the region of Paracatu city, Minas Gerais, SE Brazil, by sequential extraction method [2].

Figure 1: Arsenic speciation obtained by sequential extraction method (mg.kg^{-1} dry weight).

Total concentrations of arsenic recorded are above of the brazilian values for quality of sediments [3, 4] and indicate a high contamination. However, this preliminary evaluation indicates the presence of As is in a form less available. For a conclusive evaluation, further studies on the mobility and bioavailability of As in the study area are needed.

Oxygen isotope exchange (dis)equilibrium at the grain-size scale in metamorphic rocks

J.M. FERRY[1]*, K. KITAJIMA[2] AND J.W. VALLEY[2]

[1]Department of Earth and Planetary Sciences, Johns Hopkins University, Baltimore, MD 21218, USA (*correspondence: jferry@jhu.edu)

[2]WiscSIMS and Department of Geoscience, University of Wisconsin, Madison, WI 53706, USA (saburo@geology.wisc.edu, valley@geology.wisc.edu)

The approach to oxygen isotope equilibrium among minerals at the grain-size scale in metamorphic rocks was surveyed by analyzing 66 minerals (10 different: Cal, Dol, Qtz, Pl, Kfs, Grt, Ky, Di, Wo, Fo) in 20 samples (13 regional, 7 contact) using the CAMECA ims-1280 ion microprobe at the University of Wisconsin. Lithologies include marble, calc-silicate hornfels, pelite, psammite, and metamorphosed marl from California and New England (USA), Scotland, and the Swiss Alps. With few exceptions, 10-40 analyses were performed of each mineral with a 10 μm spot and an average standard deviation of 0.12‰ in silicates and 0.14‰ in carbonates. Generalizations for contact metamorphic rocks are: (1) They are distinctly less well equilibrated. Of 23 minerals analyzed, just 5 are statistically uniform in $\delta^{18}O$; only 1 of the 5 is a silicate (Kfs). (2) The range in $\delta^{18}O$ measured for all grains of the same mineral in a sample is up to 10.7‰ in carbonates (Dol) and 7.4‰ in silicates (Fo). (3) Individual mineral grains of carbonate and silicate can vary in $\delta^{18}O$ by up to 10.1‰ (Dol) and 3.1‰ (Fo). Inter- and intracrystalline variability in $\delta^{18}O$(Fo) scale with crystal number density and hence nucleation rate and overstepping of the Fo-forming reaction. (5) Grain-scale variability in $\delta^{18}O$ obviates meaningful determination of oxygen isotope fractionation between most mineral pairs. Generalizations for regional metamorphic rocks are: (1) They are better but not fully equilibrated. Of 43 minerals analyzed, 17 are uniform in $\delta^{18}O$, including Ky and most Grt. (2) The largest range in $\delta^{18}O$ for a given mineral in a sample is 1.5‰ (Di); the range for all but 2 analyzed minerals is ≤1.0‰. (3) The largest range in $\delta^{18}O$ of a single mineral grain is 1.5‰ (Di); the range for all other analyzed single grains is <1.0‰. (4) Despite a measured range in $\delta^{18}O$(Qtz) of 9.8-21.0‰ in the 13 samples, all mineral pairs in a given sample show consistent oxygen isotope fractionation with $\delta^{18}O$ decreasing in the same order as determined by laboratory experiment: Qtz>Cal>Kfs>Pl>Di>Ky>Grt.

Adsorption and surface complexation study of nucleotides on aluminum oxide surfaces

C. FEUILLIE[1*], D.A. SVERJENSKY[2] AND R.M. HAZEN[1]

[1] Geophysical Laboratory, Carnegie Institution, Washington D.C. 20015
(*correspondance : cfeuillie@ciw.edu) (rhazen@ciw.edu)
[2] Dept. of Earth and Planetary Sciences, Johns Hopkins University, Baltimore M.D. 21218 (sver@jhu.edu)

In the context of the origin of Life, mineral surfaces might been important in the formation of the earliest biopolymers, such as nucleic acids, by trapping and concentrating their elementary bricks, as well as catalysing prebiotic reactions. The interaction of nucleotides with minerals has therefore been the focus of many studies, mainly regarding clay minerals [1] but also metal oxides such as rutile [2] or alumina [3].

Here we investigate the interactions between nucleotides, 5'-GMP, 5'-CMP, 5'-AMP and 5'-UMP, and α-alumina surfaces. We carried out batch adsorption experiments over a large range of pH, ionic strength and surface loading. Alumina adsorbs very high amounts of nucleotides > 2 μmol/m^2. We also performed surface complexation modeling in order to establish the speciation of the surface species, and the stoichiometry and the thermodynamic equilibrium constants for the adsorption of nucleotides on alumina surfaces. We used the extended triple-layer model (ETLM), that takes into account the electrical work linked to the desorption of chemisorbed water molecules during the formation of inner-sphere complexes. Results point to the formation of two surface species on the surface of corundum : a monodentate inner-sphere complex, and a bidentate outer-sphere complex, both involving interactions between the negatively charged phosphate group and the positively charged surface of alumina. This is in good agreement with previous computational results [4].

Sources and chemistry of nitrate in snow at Summit, Greenland

D.L. FIBIGER[1] M.G. HASTINGS[2] J.E. DIBB AND L.G. HUEY[4]

[1]Brown University, Department of Chemistry, 324 Brook St., Providence, RI 02912, USA, dorothy_fibiger@brown.edu
[2]Brown University, Department of Geological Sciences/Environmental Change Initiative, Providence, RI, USA, meredith_hastings@brown.edu
[3]University of New Hampshire, Earth System Research Center, Insititute for the Study of the Earth, Ocean and Space, Durham, NH, USA, jack.dibb@unh.edu
[4]Georgia Institute of Technology, School of Earth and Atmospheric Sciences, Atlanta, GA, USA, (greg.huey@eas.gatech.edu)

Atmospheric nitrate deposition to snow surfaces results from reactions of NO_x (NO and NO_2) with oxidants, which produce HNO_3 that is taken up on the surface of particles or incorporated into precipitation. The concentration and isotopic composition of nitrate (NO_3^-) in ice cores have been studied with the aims of reconstructing past NO_x concentrations in the atmosphere, modeling past atmospheric oxidant concentrations and exploring variability in NO_x sources.

In a campaign consisting of two springtime (May-June) field seasons at Summit, Greenland [72°35'N, 38°25'W], atmospheric and surface snow measurements were made to investigate NO_x sources contributing to the snow NO_3^-. Specifically, we look to use the nitrogen ($\delta^{15}N$) and oxygen isotopic composition of nitrate ($\delta^{18}O$, $\Delta^{17}O$) to track sources, chemistry and processing of the snow nitrate.

In surface snow collected several times each day during the springtime field seasons, $\Delta^{17}O$-NO_3^- ranges from 5-35‰, $\delta^{18}O$-NO_3^- from 35-85‰ vs. VSMOW, and $\delta^{15}N$-NO_3^- from -7 to 13‰ vs. air N_2. No relationship is found between the concentration of NO_3^- in snow and the isotopic composition of NO_3^-. A striking correlation between $\Delta^{17}O$- and $\delta^{18}O$-NO_3^- is found throughout both field seasons, with a slope of ~0.5 and $r^2 > 0.9$. This relationship appears to be a direct result of atmospheric production of NO_3^-, without significant post-depositional processing. Comparison of the $\delta^{15}N$ data with $\Delta^{17}O$ and $\delta^{18}O$ suggest a three-point mixing between three NO_3^- sources with the following isotopic compositions ($\delta^{15}N$, $\Delta^{17}O$, $\delta^{18}O$ (‰)): (1) -8, 27, 74 (2) 6, 40, 100 and (3) 16, 0, 23. While the same three NO_x pools appear to be influencing the deposited nitrate in 2010 and 2011, there appears to be different relative contributions in the two different years. The $\delta^{15}N$ of NO_x sources has not been well quantified, but by combining nitrogen and oxygen isotopic data, we are able to assign tentative identities to the three sources.

Petrology of column experiments on the interaction of young cement leachate with silicate host rock in a geological disposal facility

L. FIELD[1], A.E. MILODOWSKI[1], , K. BATEMAN[1], L. JONES[1], G. PURSER[1], E.B.A. MOYCE[2], C.A. ROCHELLE[1] AND S. SHAW[2]

[1]*British Geological Survey, Keyworth, Nottingham, NG12 5GG, UK*
[2]*The University of Leeds, Leeds, LS2 9JT, UK*

The current UK concept for the disposal of low- and intermediate-level radioactive wastes involves a mined geological disposal facility (GDF) located several hundreds of metres below the surface. The waste material will be encapsulated in a cementitious matrix within steel or concrete containers, and will be placed in disposal vaults backfilled with a cement-based material. After closure, the vaults will saturate with groundwater and become part of a modified regional groundwater flow system. Groundwater will equilibrate with the cement and produce an alkaline leachate. This will migrate from the repository into the surrounding rock and produce a 'chemically disturbed zone' (CDZ) with an elevated pH. Reactions will occur between the alkaline waters and the rock, potentially causing mineral dissolution and precipitation, which will modify the local geosphere prior to possible eventual radionuclide release. These changes in the CDZ will be critical controls on radionuclide behaviour and transport, and thus on the safety and environmental impact of a GDF. Consequently, it is desirable to understand these reactions and their impacts in terms of predicting localised changes to the transport properties of the host rock (porosity, permeability) and changes in groundwater flow, together with alteration of minerals and mineral surfaces that may have an effect on radionuclide migration and retardation. This work focuses on experiments designed to simulate the evolution of the alkaline plume from the GDF, to evaluate the spatial and temporal distribution of mineral alteration within the CDZ, and to quantify its impact on porosity and permeability.

The results presented here represent a summary of the mineralogical observations from Stage 1 of the column experiments, which investigate the interaction of a K-Ca-rich Young Cement Leachate (pH 13.1) with a "model" host rock. Significant interaction is observed within the reacted columns, with physical movement of fines, dissolution of silicate minerals, and the precipitation of secondary K-Al-bearing calcium silicate hydrate phases, all of which will impact on the transport properties of the host rock.

Syringe based flow injection MC-ICP-MS: Rotal sample consumption and rapid sample standard bracketing

M. PAUL FIELD, DAN WIEDERIN AND PAUL WATSON

Elemental Scientific, 1500 North 24th Street Omaha, NE 68110

Sample-standard bracketing is a widely used standardization technique for the determination of precise isotope ratios by MC-ICPMS. The frequency of standard bracketing needed to compensate for mass bias drift increases with required precision and decreasing mass. Many isotope systems below 100 amu necessitate the analysis of a standard after every sample. This combined with low sample flow rates (typically $\leq$ 100uL/min) requires that a significant amount of time is wasted during uptake and wash cycles. A newly designed, syringe driven, flow injection system precisely and accurately loads exact volumes into a loop and syringe injects them at any user defined flow rate (10-1000uL/min). The valve on the flow injection system selects from two discrete parallel flow paths for standard and samples. This allows rapid switching between sample and standard solutions with minimal dead volume between the valve and the nebulizer. During the standard analysis the sample flow path is prepared by, 1) rapidly vacuum rinsing the uptake probe and sample loop, 2) resetting the sample syringe, and 3) accurately and precisely loading the exact sample volume into the loop. Alternatively, during sample analysis the standard side of the system is preparing for standard injection by resetting the standard syringe. The resulting benefits of flow injection MC-ICPMS are; 1) rapid wash out, 2) rapid uptake, 3) rapid sample-standard bracketing, 4) syringe controlled sample volumes, and 5) syringe controlled sample flow rates. This presentation will illustrate the utility flow injection and its benefits with respect to total sample consumption, absolute detection limits and sample standard bracketing.

[4]School of Marine Sciences, Univ. of Maine, USA

Besides accuracy and precision of isotope ratio data spatial information can be crucial to allow for interpretation of natural samples with complex structures. Tools providing this combination may open up a new field of applications in isotope geochemistry. ***L***aser ***A***blation-***M***ulti ***C***ollector-***ICPMS*** offers the analytical preconditions to achieve this challenging task.

Using a recently published method we present the first $\delta^{11}B$ 2D-images in a sample of coralline red algae [1]. The *Clathromorphum nereostratum* specimen used in this study was collected alive in 2004 off the coast of Attu island (Alaska, USA). It had been growing for more than 120 years covering most of the period of anthropogenic CO_2 emission and resulting ocean acidification. Forming annual layers of high-Mg calcite it is a promising climate archive for the high latitudes. Conventional bulk techniques appear inadequate for the determination of $\delta^{11}B$ used as pH proxy when considering the annual growth rate of about 400μm. Using LA-MC-ICPMS we were able to determine the long-term decline in pH (~0.08±0.01 pH units in 100 years). Additionally, a seasonal signal (0.1 pH units) could be identified presumably originating from strong CO_2 consumption during phytoplankton blooms in spring.

Our results clearly show a heterogeneous but systematic distribution of $\delta^{11}B$ within this sample, being the result of different phases of calcite precipitation by the alga. The seasonal cycle and spatial distribution of $\delta^{11}B$ can only be evaluated using high-resolution methods like the one applied here. Bulk techniques only would have picked up the long-term pH trend, but such measurements may have been compromised by mixing sample material from distinct phases, differing in $\delta^{11}B$. Thus, we consider this a good example of the gain in information which can be obtained using high-resolution in-situ techniques in isotope analysis.

[2]School of Marine & Atmospheric Sciences, Stony Brook University, Stony Brook, NY 11794 USA; (robert.aller@stonybrook.edu)

The sulfur cycle plays a key role in regulating Earth's surface redox balance and provides a record of environmental and ecological change over Earth history. As new data are generated, we observe that (1) select records have more stratigraphic variability than expected; and (2) mean isotopic values differ from location to location for both sulfate and sulfide. Interpreting these ancient data is a challenge, in large part because we have only a limited understanding of sulfur isotope systematics in modern depositional environments.

Here we examine variability and mean values in pyrite sulfur isotopes from both modern and ancient strata. In the modern, we analyzed $\delta^{34}S_{pyr}$ from a series of cores taken across a gradient of water depths from the Gulf of Papua deltaic complex. In cores from physically undisturbed locations, $\delta^{34}S_{pyr}$ values were depleted (~-20‰ to 0‰) in the upper sediments, becoming progressively enriched with depth (approaching ~+10‰ to +20‰). In general, these cores were characterized by smooth profiles with little sample-to-sample scatter (< 5-10‰). In contrast, cores overlain by remobilized muds had very enriched $\delta^{34}S_{pyr}$ values (up to +35‰, often within the remobilized near-surface samples) and large scatter in the profiles (variability between adjacent samples up to 35‰). Such drastically different isotopic signatures could easily result in divergent environmental reconstructions without knowing the depositional context of these samples. The magnitude of local, microbially driven variations in S isotopes in modern sediments is sufficiently large that uneven incorporation of these signatures during deposition and lithification can explain much of the observed discordance in chemostratigraphic reconstructions of sulfur cycling over Earth history. To illustrate the impact of depositional conditions in the ancient record, we compare coeval sedimentary strata from two late Ediacaran sedimentary basins: the Nama Group of Namibia and the Ara Group of Oman, where different depositional environments yield strongly divergent $\delta^{34}S$ data. A detailed understanding of depositional context and its impacts on $\delta^{34}S$ signals is essential for robust interpretations of geochemical data.

[6]Department of Chemistry, University of Leicester, Leicester, LE1 7RH, UK
[7]EUPHORE Laboratories, Instituto Universitario CEAM-UMH, 46980, Valencia, Spain

Aqueous phase chemistry of glyoxal (GLY) and methylglyoxal (MGLY) in the presence of inorganic salts has been recently identified as an important source of secondary organic aerosol (SOA) and brown carbon. However, the reversibility and the magnitude of the processes involved is still a matter of debate due to the lack of detailed speciation for such dynamic and complex systems.

In this study, a series of on- and off-line mass spectrometric techniques (FTICR-ESI-MS, LC-ESI-MS^n, ATOFMS) have been applied together with comprehensive gas chromatography with nitrogen chemiluminescence detection (GCxGC-NCD) and bi-dimensional nuclear magnetic resonance spectroscopy (2D-NMR) to identify the major organic products formed in bulk lab solutions with an emphasis on light absorbing organonitrogen species (ONs). The change in composition of the lab solutions as a function of different parameters was investigated. Mass spectral ions were identified as tracers for SOA generated from the uptake of gas-phase GLY and MGLY onto ammonium sulphate seeds and detected in chamber experiments conducted at the European PhotoReactor (EUPHORE). A series of light absorbing ONs, detected for the first time in chamber SOA by using off-line analyses, are presented as potential tracers for GLY- and MGLY-SOA in ambient aerosols. The relative potential of GLY and MGLY to form SOA and brown carbon through aqueous chemistry will be discussed.

Dissolution kinetics of ZrO_2 based innovative waste forms

FINKELDEI, S.*, BRANDT, F., BUKAEMSKIY, A., NEUMEIER, S., MODOLO, G. AND BOSBACH, D.

Institute of Energy and Climate Research, IEK-6, Forschungszentrum Jülich, Germany; (s.finkeldei@fz-juelich.de (*presenting author), f.brandt@fz-juelich.de, a.bukaemskiy@fz-juelich.de, s.neumeier@fz-juelich.de, g.modolo@fz-juelich.de, d.bosbach@fz-juelich.de)

Plutonium and the minor actinides (MA = Np, Am, Cm) are the main contributors to the long-term radiotoxicity of spent fuel. As an alternative to the disposal in glass or the direct disposal of spent fuel ceramic waste forms are under consideration [1]. Regarding the long-term safety, zirconia based pyrochlores ($A_2B_2O_7$) have outstanding properties with respect to their high radiation resistance and their high durability in aqueous environments. As a consequence of radiation damage zirconia based pyrochlores undergo a phase transition to the less ordered defect fluorite structure [2]. Recent publications have demonstrated the possibility to include e.g. Cm and Pu on regular lattice sites of the pyrochlore crystal structure [3,4].

In the open literature no systematic study of the dissolution kinetics of ZrO_2 - Nd_2O_3 pyrochlores and defect fluorites is reported. The dissolution rate is an important property of potential host phases because it defines the source term for the radionuclides in the case of water intrusion into a high level nuclear waste repository.

Here, we present new experimental data regarding the influence of the chemical composition and crystal structure on the dissolution kinetics. The dissolution experiments were carried out using a dynamic setup to ensure far from thermodynamic equilibrium conditions. Moreover, the influence of temperature and pH on the dissolution rate was studied for the defect fluorite and the pyrochlore ceramics. An initial incongruent elemental release for Nd and Zr was observed. At steady state conditions and pH = 1, the dissolution rates of pyrochlore and defect fluorite are congruent and in the range of 10^{-5} to 10^{-6} g□m^{-2}□d^{-1}.

Further insight into the dissolution mechanism is gained by electron microscopy investigations.

Understanding shale gas plays through the application of inorganic geochemistry

A.J. FINLAY[1] AND J MARTIN[2]

[1]Origin Analytical Ltd. 1 Ravenscroft Court, Buttington Cross Enterprise Park, Welshpool, Powys, SY21 8SL. U.K.
[2]Chemostrat Ltd., 1 Ravenscroft Court, Buttington Cross Enterprise Park, Welshpool, Powys, SY21 8SL. U.K.

The rapid increase in interest in exploring shale units for shale oil and gas has highlighted the need to develop a thorough understanding of shale units. Not only does possessing a detailed understanding of shale stratigraphy enable accurate volume calculations to be undertaken, but knowing the mineralogical composition of shale can provide information on rock mechanics to enable greater well completion success. In addition, a comprehensive understanding of anoxia proxies can be used to identify sweet spots in the play. All of this information can be potentially provided through the use of inorganic geochemical techniques.

This paper will discuss the application of a range of analytical techniques to shale gas plays, from rapid and non-destructive analysis by hand held X-Ray fluorescence to highly precise and accurate data produced by inductively coupled plasma mass spectrometers. In addition we will show how inorganic geochemical analysis can be integrated with other techniques such as XRD and TOC analysis to enable extra information to be gained from the analysis, for example enabling rock brittleness, a key parameter for fracking, to be established. Importantly we do not rely on samples to be provided from rare drill core, but we also analyse side wall core or drill chippings.

We will utilise case studies from to UK onshore Bowland shale sections and key US shale to demonstrate the wide variety of ways that the inorganic geochemical data produced can be utilised to aid in the understanding of shale gas plays.

Immobilisation of PTEs by water treatment residual: A potential amendment for contaminated land

N.C. FINLAY*, S.A. ROBERTSON AND K.L. JOHNSON

School of Engineering & Computing Sciences, Durham University, South Road, Durham, DH1 3LE, UK. (*correspondence: n.c.finlay@durham.ac.uk)

"Water Treatment Residual" (WTR) from the drinking water treatment process is a waste product largely composed of amorphous Al or Fe (oxy)hydroxides and organic matter and is commonly disposed of by landfill. Seasonal and geographical variations in WTRs were studied over 12-months at 10 water treatment works (WTWs) in England. Total solids ranged from 15 to 30%, of which organic matter formed 35 to 70%, Fe 25 to 37% and Al 10 to 21%. pH ranged from 4 to 7. Variation between works appears more pronounced than seasonal variation within them.

Immobilization of oxyanions such as P and As from aqueous solutions to Fe- and Al-WTR has been demonstrated [1] but research into immobilization of other Potentially Toxic Elements (PTEs) is limited. Batch experiments using aqueous solutions of Cu(II), Cd(II), Pb(II) and Zn(II) investigated the adsorption behaviour of an Fe rich WTR as a function of time, solid:solution ratio, pH and initial contaminant concentration and demonstrated effective removal of metal ions from solution. The sorption capacity of the WTR demonstrates some pH dependence, but significant sorption is observed in the low pH regime: 24% Cd, 28% Cu, and 45% Zn is sorbed at pH 3.2, 3.5 and 3.5 respectively, whilst Pb immobilisation remains > 98% from pH 3 to 9, using an initial mass load of 8.0 mg/g. The WTR's ability to function as a metal sorbent over a broad pH range may be due to the intimate intermixture of iron (oxy)hydroxides and organic matter [2]. The fractionation of sorbed PTEs within the WTR is being determined using a new sequential extraction technique: "Chemometric Identification of Substrates and Element Distribution" [3].

These results support the hypothesis that WTRs may have potential as an amendment for remediation of contaminated land.

Modelling metal cation-phosphate competitive interactions on iron oxides

S. FIOL[1,*], J. ANTELO[2], R. LOPEZ[1], D. GONDAR[1] AND F. ARCE[1]

[1]Dept. Physical Chemistry. University of Santiago de Compostela. 15782 Santiago de Compostela. Spain (*corresponding author sarah.fiol@usc.es)

[2]Dept. Soil Science and Agricultural Chemistry. University of Santiago de Compostela. 15782 Santiago de Compostela. Spain

The role that iron (oxyhydr)oxides play in the speciation and bioavailability of environmental importance species such as phosphate, arsenate, sulphate, metal cations of trace elements or contaminants, has been extensively studied [1]. These mineral oxides have demonstrated to effectively retain important amounts of inorganic anions and metal cations on their surface and the mechanism of the process has been succesfully explained using surface complexation models. However, the modelling sometimes fails when trying to explain adsorption data for ternary systems of the type iron oxide – inorganic anion – metal cation [2]. The enhancement of metal cation retention on iron oxides by coexisting inorganic anions has been reported by several authors [1,3]. Most of them agree that it is very difficult to establish the mechanism that produces this enhancement and three possibilites have been proposed: electrostatic enhancement, surface precipitation or formation of a ternary complex [1].

The following competitive adsorption experiments have been conducted using synthetic iron oxides: goethite – PO_4 – Cu, ferrihydrite – PO_4 – Cu, hematite – PO_4 – Cu and the same experiments were performed using natural samples with high content of iron and aluminum oxides. Attempts have been made to correct the modelling predictions for binary systems so that the interaction and mutual effect of inorganic anions and metal cations are considered and taken into account.

Geoneutrinos and the interior of the Earth

G. FIORENTINI

Legnaro National Laboratory (LNL-INFN), Via dell'Università, 2 - 35020 Legnaro, Padova, Italy – (fiorentini@fe.infn.it)

The deepest hole that has ever been dug is about 12 km deep, a mere dent in planetary terms. Geochemists analyze samples from the Earth's crust and from the top of the mantle. Seismology can reconstruct the density profile throughout all Earth, but not its composition. In this respect, our planet is mainly unexplored.

Geo-neutrinos, antineutrinos from the progenies of U, Th, and K decays in the Earth, bring to Earth's surface information coming from the whole planet. Differently from other emissions of the planet (e.g., heat, noble gases), they are unique in that they can escape freely and instantaneously from Earth's interior.

Detection of geo-neutrinos has become practical as a consequence of two fundamental advances that occurred in the last few years: a) development of extremely low background neutrino detectors and b) progress on understanding neutrino propagation.

Geo-neutrinos look thus a promising new probe for the study of global properties of Earth, such as the amount and distribution of long lived radioactive elements in the Earth's reservoirs.

The talk is intended as an introduction to the field, explaining to geo-scientists how geo-neutrinos are detected by physicists and to physicists why geo-neutrinos are relevant to geoscience.

Evolution of hydrogeochemical problems in Merzifon (Amasya, Turkey) aquifer with GIS

ARZU FIRAT ERSOY[1] AND FATMA GÜLTEKİN[1]

[1] Karadeniz Thecnical University, Department of Geological Engineering, 61080, Trabzon (firat@ktu.edu.tr)

Groundwater level in the Merzifon (Amasya, Turkey) aquifer has been decreased in recent years because number of wells and over pumping. Some of these wells are used for irrigation and some of are used for drinking purposes. Groundwater bearing alluvium consisting of loose gravel, sand and silt in the Merzifon-Gümüşhacıköy Basin is Plio-Quaternary aged.

Hydrogeochemical studies were conducted to establish groundwater and surface water quality in the Merzifon Aquifer. Mean pH value is 7.61, EC value is 67.59 and TDS value is 376.86 of the groundwater and surface water samples according to the analyze results. The trace element results especially Mn, Cr, Zn, As, Ni and Co are very high values in surface waters in the south of aquifer that is recharge area. Nitrate values are so high and a lot of water samples have below the limits in the aquifer.

To prevent exhausting groundwater in Merzifon Aquifer, groundwater usage should be regulated, and uncontrolled groundwater use must be terminated. Groundwater must be exploited with optimum discharge rate, must not be exceeded maximum rate. Besides, pollutants should be studied which parameters cause groundwater contamination and pollutant factors should be analyzed in water springs with intermittently.

Can we learn about bacterial attachment at mineral surfaces through colloid adsorption experiments?

CORNELIUS FISCHER[1,2]*, MARTIN KÖNNEKE[1], ROLF S. ARVIDSON[1], KAI-UWE HINRICHS[1] AND A. LÜTTGE[1,2]

[1]MARUM, Univ. Bremen, 28359 Bremen, Germany (*correspondence: cornelius.fischer@uni-bremen.de)
[2]Rice University, Houston, TX 77005, USA

Colloid-surface interactions are mainly governed by electrostatic and van der Waals interactions. Nevertheless, surface topography variations on the micrometer and nanometer scale are able to alter significantly the local interaction potential. The resulting variations in the interaction energy at small separation distances may change the general interaction behaviour. Particle retention has been observed for mineral surfaces that are thought to be unable to act as collectors [1], and there is still no fundamental quantitative understanding and predictability for such phenomena. A predictive capability would be particularly important in colloid-mediated transport of radioactive material and the particle retention efficiency of barrier rocks.

Bacteria may be considered as “living particles” in the size range of large mineral colloids. Bacteria are able to modify surface area and topography of mineral and rock surfaces by corrosion. The formation of etch pits by bacteria is an important example that illustrates how bacteria govern and alter quantitatively the kinetics of mineral dissolution [2] and, consequently, the surface energy potential. Here we explore the interaction potential between well-defined surface topographies and microbes. Machined silica surfaces with building blocks in the micron to submicron scale are utilized [3]. The applied pattern results in well-defined variations of the surface energy potential. We apply this variability to study the near-field behaviour of microbes at structured mineral surfaces, i.e., the first step of microbial attachment to surfaces. Analyses using vertical scanning interferometry show the variability of microbial attachment to natural surfaces and provide quantitative constraints to these initial mineral-microbe interactions. The competition in surface interaction between “living” and “dead” colloids may provide the key to understand and predict the variability in surface reaction kinetics that is observed in nature.

Airborne measurements of atmospheric trace gases via infra-red laser absorption spectroscopy

HORST FISCHER

Max Planck Institute for Chemistry, Mainz, Germany (horst.fischer@mpic.de)

Recent laboratory and field studies demonstrated that replacing lead-chalcogenide tuneable diode lasers by cw operated quantum cascade lasers (QCL) results in sensitivity improvements of mid-IR TDLAS systems by a factor 2 to 3. Therefore, the MPI-C three laser TRacer In-situ Tdlas for Atmospheric Research (TRISTAR) was equipped with 3 QCL emitting at 1268.98, 2158.30, and 1759.72 cm-1 to measure CH4, CO and HCHO, respectively. In October 2005 the modified TRISTAR instrument was installed on a Lear Jet 35A as part of a scientific payload to study the photochemistry over the tropical rainforest in South America during the GABRIEL campaign. A second deployment was during fall 2006 and summer 2007 as part of the HOOVER campaign to study HOx and its precursors in the upper troposphere over Europe. Since 2012 the instrument has been successfully flown on the new HALO aircraft during the TACTS/ESMVAL and OMO-Europe missions. These missions investigated the influence of convection and stratosphere-troposphere-transport on the photochemistry of the tropopause region. The performance of the instrument during these airborne campaigns was examined for the three species and precisions for CO and CH4 were measured in the field to be 0.5% and 0.8% respectively (2σ). The 1σ detection limit for HCHO was ~500 pptv for a 2 second average, while post-flight signal averaging over a 2 minute time interval resulted in a 150 pptv detection limit.

Phase diagrams of FeO and Fe-Si alloys

REBECCA A. FISCHER*[1], ANDREW J. CAMPBELL[1], DANIEL M. REAMAN[1], DION L. HEINZ[1], PRZEMYSLAW DERA[2] AND VITALI B. PRAKAPENKA[2]

[1]Department of the Geophysical Sciences, University of Chicago, 5734 S Ellis Ave, Chicago, IL 60637, USA
[2]Center for Advanced Radiation Sources, 9700 S Cass Ave, Building 434A, Argonne, IL 60439, USA (correspondence: rfischer@uchicago.edu)

Earth's core is less dense than pure iron, implying the presence of one or more lighter element(s) [1] such as Si, O, or S [2]. The phase diagrams of iron alloyed with these elements at high pressures and temperatures (*P-T*) are critical input for understanding the thermodynamics of these systems. Here we present results on FeO and a suite of Fe-Si alloys.

High *P-T* conditions (up to 200 GPa) were generated using a laser-heated diamond anvil cell. In situ X-ray diffraction to determine crystal structures was performed at beamline 13-ID-D of the Advanced Photon Source, Argonne National Laboratory. Melting was determined from diffuse X-ray scattering, by laser power-temperature relationships, and by temperature-emissivity relationships.

We have determined the melting curve of FeO [3] and clarified the location and slope of the B1/B8 phase transition [4]. We also identified an insulator-metal transition [5]. The B1 metallic phase of FeO is the stable phase at conditions of Earth's lower mantle and outer core, with possible implications for the high *P-T* character of Fe-O bonds, magnetic field propagation, and lower mantle conductivity.

FeSi has the B20 structure at 1 bar, the B2 structure at high pressures, and a wide two-phase field in between [6]. Fe-9Si has the hcp structure at high *P* and low *T*, and converts to an hcp+B2 mixture and then fcc+B2 with increasing temperature [6]. Fe-16Si has the $D0_3$ structure at low pressures and is an hcp+B2 mixture at higher pressures [7]. We have also measured melting temperatures for each alloy. Phase diagrams in *P-X* and *T-X* space imply that the stable phase of Fe-Si alloy at inner core conditions for compositions that match the observed density deficit is an hcp+B2 mixture [6].

Effects of SO_2-NO_2 impurities in the CO_2 stream on mineral solubility

S. FISCHER[1,2*] AND A. LIEBSCHER[1]

[1]GFZ German Research Centre for Geosciences, Centre for Geological Storage CGS, Telegrafenberg, 14473 Potsdam, Germany (*fischer@gfz-potsdam.de)
[2]Berlin Institute of Technology, Chair of Mineralogy-Petrology, Ackerstraße 76, 13355 Berlin, Germany

Two sets of laboratory fluid-mineral experiments have been performed in order to analyze the effect of SO_2-NO_2 impurities in the CO_2 stream on the chemical reactivity of (A) siderite and (B) illite. For the siderite and illite separates, baseline XRD data with Rietveld refinements revealed a composition of (A) 69.6±1.3 wt% siderite, 26.7±1.2 wt% ankerite and 3.8±0.8 wt% quartz, and (B) 73.5±1.3 wt% illite, 10.8±1.3 wt% Ca-smectite, 11.9±0.4 wt% orthoclase, and 3.9±0.2 wt% quartz, respectively. SEM-EDS analyses yield initial structural formulae of $(Fe_{0.8}Mg_{0.1}Mn_{0.1})CO_3$ for siderite, $(Ca_{1.0}Fe_{0.9\text{-}0.1}Mg_{<0.4}Mn_{0.1})(CO_3)_2$ for ankerite, and $K_{0.5\text{-}0.7}(Mg_{0.1\text{-}0.2}Al_{1.8\text{-}1.9})[Al_{0.4\text{-}0.6}Si_{3.4\text{-}3.6}O_{10}(OH)_2]$ for illite. Baseline experiments were conducted using pure CO_2 and 2 M NaCl brine at 80 °C and 20 MPa. Brine to mineral weight-ratios were 20 to 1. Run durations were one week for siderite and two weeks for illite, respectively. To study the influence of impurities, repeat experiments using identical starting conditions and analogous materials but impure CO_2 are performed. Siderite is reacted with CO_2 containing 5vol% SO_2, while illite is exposed to CO_2 containing 5vol% NO_2.

Based on XRD, SEM and ICP-AES analysis the baseline experiments using pure CO_2 yield (A) stable siderite and dissolving ankerite, and (B) unaffected illite but dissolution of the Ca-smectite component. Foci of the repeat experiments are on the potential formation of sulphates, e.g., anhydrite, during the CO_2-SO_2 runs, and the incorporation of NO_2 into the illite-smectite structure during the CO_2-NO_2 runs.

DEep CArbon DEgassing: The Deep Carbon Observatory DECADE initiative

TOBIAS P. FISCHER,[1]

[1]Department of Earth and Planetary Sciences, University of New Mexico, Albuquerque, NM USA (fischer@unm.edu)

The question whether the net flux of carbon is into the mantle via subduction or out of the mantle via mantle degassing is fundamental because it provides an important framework for understanding the distribution and isotope composition of C in the mantle, the occurrence of abiotically synthesized carbon species in the mantle and crust, the presence or absence of carbon in the Earth's core, the formation of carbonated peridotite as starting material for ocean crust as well as the effect of mantle carbon release to modulate global climate through time. The Deep Carbon Observatory (DCO) Reservoirs and Fluxes Directorate is centered around the flux of carbon between different Earth reservoirs (https://dco.gl.ciw.edu/science/deep-carbon-reservoirs-and-fluxes) to help address some of these issues.

Volcanoes are *the* main pathway of volatiles, including carbon, from the Earth's interior to the atmosphere and hydrosphere, yet the current estimates of global C flux from volcanic regions range from 65 [1, 2] to 540 [3] Mt/yr. This order of magnitude difference in estimates is the difference between massive subduction of surface C into the mantle versus a balance between mantle input and output, with all the implications stated above. The DECADE initiative within the DCO R&F Directorate is bringing together the scientific expertise of geochemists, petrologists and volcanologists to provide constraints on the global volcanic C flux by a) establishing a data-base of volcanic and hydrothermal gas compositions and fluxes linked to PetDB and the Smithsonian Global Volcanism Program, b) building a global monitorig network to continuously measure the volcanic C flux of 10-12 yet to be selected active volcanoes, c) measure the C flux of remote volcanoes, for which no or only sparse data are currently available, d) develop new field and analytical instrumentation for C measurements and flux monitoring, and e) establish formal collaborations with volcano observatories around the world to support volcanic gas measurement and monitoring activities.

The current governance structure of DECADE includes a board of directors, a program coordination committee and several committees responsible for the key areas of the initiative (data base, network, instrumentation, and field campaigns).

Nitrogen recycling through arc volcanism

TOBIAS P. FISCHER[1], LONG LI[2], ZACHARY D. SHARP[1] AND DAVID R. HILTON[3]

[1]Dept. of Earth and Planetary Science, University of New Mexico, USA (fischer@unm.edu)
[2]Dept. of Earth and Atmosph. Sciences, University of Alberta, Canada (long4@ualberta.ca)
[3]Scripps Institution of Oceanography, Univ. of California San Diego, USA (drhilton@ucsd.edu)

Subduction is the main pathway of surface N transfer into the mantle, whereas arc volcanism can short-circuit that transfer via magmatic gas release into the atmosphere. A fundamental question is the efficiency of N recycling at subduction zones. The Central American (CA) and Izu Bonin Marianas (IBM) subduction systems are relatively well charactized in terms of N input and output and are the best candidates for evaluating N mass balance in arcs.

Stable (N) and noble gas (He) isotope and abundance characteristics show that N output at CA is dominated by the slab component ($\delta^{15}N \approx +7‰$, consistent with that of subducted Cocos Plate sediments, 5.7‰ [1]). N output fluxes vary significantly along the CA arc with Costa Rica only contributing ~ $1x10^7$ mol/yr compared to ~ $7x10^8$ mol/yr from Nicaragua [2,3]. The average slab-derived N output from the entire CA arc is estimated at $2.7x10^9$ mol/yr [2], significantly higher than the input sedimentary N of $9.3x10^8$ mol/yr from the Cocos Plate [1]. This imbalance implies additional N must be supplied from AOC [4] and/or subduction erosion [1]. However, both potential sources remain poorly-constrained, preventing further evaluation of N recycling efficiency and excess N delivery to the deep mantle. In contrast, the sedimentary N ouput flux at IBM represents only 11–51% of the input, implying that up to 90% of subducted N is potentially transferred to the deep mantle [5].

The difference in recycling efficiencies is likely related to the different thermal regimes and geometries of the two subduction zones. The contribution of crustal material by subduction erosion may also play a role. More work is needed to further constrain the processes of N release from different lithologies of subducting plates and the variability of volcanic N fluxes in arcs globally.

Sedimentary and genomic insights into the evolution of iron oxidation

WOODWARD W. FISCHER[1], JENA E. JOHNSON[1], JAMES HEMP[1], LAURA A. PACE[2], NOAH J. PLANAVSKY[1] AND SAMUEL M. WEBB[3]

[1] California Institute of Technology (wfischer@caltech.edu)

[3] Stanford Synchrotron Radiation Lightsource

Iron is the most abundant redox-active element on the Earth and provides a rich source of electrons that impacts all biogeochemical cycles. Detailed observations of iron formations (IF) in the geological record demonstrate that this has been broadly true for much of Earth history, though key differences in the facies, textures, geochemistry, and mineralogy define varying styles of geobiological processes and different modes of petrogenesis.

Environmental iron oxidation processes fall broadly into four categories: abiotic photochemical, abiotic and biotic reactions with O_2, and photobiology (e.g. anoxygenic photosynthesis). Oxidation plays an important role in concentrating iron in sediments, either by forming poorly ordered hydrous oxides or ferric and mixed-valance silicate phases. To understand processes of oxidation in ancient IF requires the ability to look through complex diagenetic and metamorphic transformations common to these deposits: in particular, the tendency toward post-depositional reduction by organic matter is common. Late Archean and earliest Paleoproterozoic IF have Fe(III)/Fe(II) that vary with paleoenvironmental depth with more oxidized facies occuring in deeper water, suggesting oxidation by anoxygenic photosynthesis. Mid-Paleoproterozoic iron formations have similar overall valence states, but the depth gradient is reversed and reflects the locus of the major oxidant at that time, O_2. An import process outlier is provided by Neoproterozoic IF, associated with 'Snowball Earth' glacial deposits, are composed of nearly exclusively ferric iron, and reflects simple abiotic titration of environmental O_2.

In this talk, we'll discuss how these geological patterns highlight changing modes of biological iron oxidation processes through time. Since iron oxiation rates vary greatly with pH, acidophilic and neutrophilic aerobic iron-oxidizing microbes have evolved separate biochemical strategies for oxidizing iron. We use phylogenomics to show that both strategies are evolutionarily derived, implying that aerobic iron oxidation is a relatively late innovation. A similar pattern emerges from the secular distribution of filamentous microfossils interpreted to reflect aerobic iron-oxidizing microbes, which appear in the fossil record after the rise of O_2.

Origin of the late veneer inferred from Ru isotope systematics

M. FISCHER-GÖDDE[1], C. BURKHARDT[2] AND T. KLEINE[1]

[1]Institut für Planetologie, University of Münster, 48149 Münster, Germany (m.fischer-goedde@uni-muenster.de)
[2]Origins Laboratory, Department of Geophysical Sciences, The University of Chicago, IL 60637, USA

Elevated abundances of the highly siderophile elements (HSE) in the Earth's mantle are commonly explained by the addition of a chondritic late veneer after cessation of core formation [*e.g.*, 1]. Identifying the source and type of the late accreted material is a particular important issue, because the late veneer may have delivered considerable amounts of volatiles to Earth. Relative HSE abundances and Os isotope compositions of mantle materials are largely similar to those of chondrites, yet establishing a direct link of the late accreted material to a particular type of meteorite has proven difficult [2]. Ruthenium is a HSE and exhibits nucleosynthetic isotope anomalies at the bulk meteorite scale [3]. This makes Ru isotopes a promising new tool for identifying the source of the late accreted material, because the Ru isotope composition of Earth's mantle can be directly compared to that of meteorites.

We have precisely measured Ru isotopic compositions for a wide range of chondrites and iron meteorites, using the Neptune *Plus* MC-ICPMS at the University of Münster. All investigated meteorites, except the IAB irons but including several carbonaceous and ordinary chondrites are characterized by a deficit in *s*-process Ru relative to the Earth. Consequently, none of the meteorites nor a combination thereof can be the source of the late veneer. Our new Ru data in combination with previously published Mo isotope data for the same samples [4] show that all meteorites define a Ru *vs*. Mo isotope correlation [5]. This Ru-Mo correlation passes through the composition of Earth's mantle, implying that the late veneer derives from the same Ru-Mo isotopic reservoir and, hence, from the same type of material as the main building blocks of the Earth. This is because Mo, a moderately siderophile element, was delivered during the main stages of accretion, whereas the HSE Ru was mainly added by the late veneer. The Mo-Ru isotope systematics, therefore, seem to rule out an exotic outer solar system source for the late veneer, but strongly suggest an origin from the same type of inner solar system material that built Earth. The late accreted material thus may simply constitute the 'exponential tail' of accretion.

Earth and Mars building blocks

CAROLINE FITOUSSI[1,*] AND BERNARD BOURDON[1]

[1]Laboratoire de Géologie de Lyon , ENS Lyon, CNRS and Université Claude Bernard de Lyon, France (Correspondence : caroline.fitoussi@ens-lyon.fr)

CI chondrites, which have the closest elemental composition to the solar photosphere, have often been chosen as the reference composition for the Bulk Earth [1,2]. However, from the viewpoint of isotope compositions (e.g. Cr isotopes), it is not plausible for the Bulk Earth to have a CI chondrite composition. Another approach based on isotopic similarities between Earth and enstatite chondrites proposed that these meteorites best represented the Bulk Earth [3]. However, based on silicon isotopes, it was recently shown that enstatite chondrites cannot represent more that 15% of the Earth's mass [4]. In addition, several chemical characteristics of enstatite chondrites are distinct from those of the Earth.

Reports of nucleosynthetic and non-mass dependent isotope anomalies have shown that there is a heterogeneous distribution of isotope compositions in the nebula, and these systems (e.g. O, Cr isotopes) have even become a reliable classifying tool for various meteorite groups [5,6]. We have been looking for possible building blocks of the Earth and Mars, using these isotopic signatures in meteorites.

As target values of our model, we used the Earth and Mars compositions of measured terrestrial samples and SNC (Shergottites, Nakhlites, Chassignites) martian meteorites samples, respectively.

We propose a model that accounts for (i) all isotopic compositions of the Earth and Mars; (ii) the refractory lithophile element enrichment of the Earth compared to CI chondrites, which is one specific characteristic of the composition of our planet [e.g. 7]; (iii) the volatile element budget in Mars, which has been difficult to match, as discussed in previous models of the bulk composition of Mars [8-9]. We will discuss these results with regards to implications on the scenarios for the formation of terrestrial planets.

Spatial Variation of Dissolution at Fracture Boundaries

J.P. FITTS[1*], H. DENG[1], R. TAPPERO AND C.A. PETERS[1]

[1]Princeton Univ., Princeton, NJ 08544, USA (*correspondence: fitts@princeton.edu, hangdeng@princeton.edu, cap@princeton.edu)
[2]Brookhaven National Lab, Upton, NY 11973, USA (rtappero@bnl.gov)

Prediction of fluid flow in fracture networks is critically important to the safe and efficient advance of geologic energy technologies including oil and gas extraction, geothermal energy systems and geologic CO_2 storage. Although pore-scale mineral variation can profoundly affect fracture fluid flow [1] and the mass transfer of organics, metals and salts, major knowledge gaps exist due to the lack of experimental observations of pore-scale processes at fracture boundaries. We conducted core-flooding experiments with fractured carbonate-rich caprock samples and showed that while calcite dissolution is the primary geochemical driver of alterations to fracture geometry, permeability evolves based on a complex relationship between initial fracture geometry, mineral spatial heterogeneity and variation, fluid chemistry and flow rate [2].

To investigate the underlying causes of spatial variability of dissolution and fracture geometry alteration, we developed a new flow-through cell that enables 2D x-ray imaging of mineral-specific dissolution at a fracture surface. The parallel plate design provides an idealized fracture geometry to derive the relationship between flow rate, reaction rate, and mineral spatial heterogeneity and variation. In the flow-cell, a subsample of the carbonate-rich caprock core described above was reacted with acidified brine. The extent of dissolution was spatially correlated with calcite abundance relative to less soluble dolomite and silicate minerals, which is qualitatively consistent with the core-flooding experiment. In a second set of experiments with a limestone specimen, however, the extent of dissolution was not strictly correlated with the occurence of calcite. Instead, the pattern and extent of dissolution suggested secondary causes such as calcite morphology, the presence of argillaceous minerals and other diagenetic features. These experimental results help define the combinations of brine chemistry, caprock mineralogy and flow rates with a high probability for geochemical alterations that increase fracture permeability.

Iron isotopes in seawater from the Southeast Pacific and North Atlantic Oceans

JESSICA N. FITZSIMMONS[1]*, TIM M. CONWAY[2], SETH G. JOHN[2] AND EDWARD A. BOYLE[3]

[1]MIT-WHOI Joint Program in Chemical Oceanography, Cambridge, MA 02139, USA (*correspondence: jessfitz@mit.edu
[2]Department of Earth and Ocean Sciences, University of South Carolina, Columbia, SC 29208, USA; (tconway@geol.sc.edu; sjohn@geol.sc.edu)
[3]Deapartment of Earth and Planetary Sciences, MIT, Cambridge, MA 02139, USA (eaboyle@mit.edu)

Iron is an essential micronutrient for marine photosynthesis and nitrogen fixation, and low dissolved iron (dFe) concentrations limit primary production in large regions of the global ocean. Thus, understanding the sources, sinks, and internal cycling of Fe is vital to constraining its impact on the oceanic carbon cycle. Fe isotope (δ^{56}Fe) measurements of dFe in seawater are a new tracer for Fe provenance and are also emerging as a useful tool for investigating Fe transformations in the open ocean.

This study presents three full-depth δ^{56}Fe profiles from the Southeast Pacific Ocean (~25°S, 70-105°W) ranging from the coastal oxygen minimum zone off of Chile to the middle of the subtropical gyre near Easter Island. Upper 1000m samples demonstrated isotopically light Fe, in contrast to enriched values in the upper ocean of the North Atlantic and Southwest Pacific [1, 2]. A distal hydrothermal vent Fe signal was also detected around 2000m depth at the two offshore stations ([dFe] of 0.86 and 1.45 nmol/kg) and corresponded to an enriched δ^{56}Fe signature of +0.5‰ at both stations.

We also present δ^{56}Fe values of size fractionated dFe at two stations sampled on the U.S. GEOTRACES cruise in the North Atlantic Ocean: one near Bermuda and one near the Cape Verde Islands. Surface dFe (<0.2 μm) δ^{56}Fe values were near +0.5‰ at both stations, while the soluble Fe (<10 kDa) portion of the dFe phase was significantly enriched in excess of +1.0‰. Subsurface soluble Fe was the same or slightly depleted compared to dFe. This demonstrates that, at least in the surface ocean, soluble and colloidal Fe are cycling independently.

Iron speciation in natural and industrial dust: What can we learn from individual particle analysis?

P. FLAMENT[1]*, K. DEBOUDT[1], H. MARRIS[1] AND R. GIERE[2]

[1]ULCO/LPCA, 189A Avenue Schumann, 59140, Dunkerque, France (*correspondence : pascal.flament@univ-littoral.fr)
[2]Institute of Earth and Environmental Sciences, Albert-Ludwigs-Universität, D-79104 Freiburg, Germany

Iron (Fe) is considered as a main biolimiting micronutrient, whose the bioavailability controls the marine productivity in HNLC zones, then the global carbon cycle. But the extent to which human activities impact the transport of bioavailable Fe to the oceans remains a fundamental question [1]. Many recent works have demonstrated that Fe-bearing aerosols may have variable aqueous solubility, then bioavailability, related to Fe chemical speciation. More particularly, the solubility of Fe-bearing particles increases significantly, with the ferrous (FeII) content of those. The Fe-speciation in dust can be studied by transmission electron microscopy (TEM) [2], coupled with electron energy loss spectroscopy (EELS) [3]. While the TEM-EELS technique has a lower energy resolution than other techniques recently used to investigate the red-ox speciation of Fe in aerosols, such as synchrotron based X-Ray spectroscopies [4], the implementation of TEM-EELS analyses is fast and inexpensive, by comparison to synchrotron techniques and provides relevant results in term of Fe speciation with the advantage of an high spatial resolution, at the particle scale.

We present here results obtained both on desert dust collected in Senegal during the AMMA campaign and on industrial dust (Fe-Mn metallurgy plant) collected in the North of France (Dunkirk harbor). In desert dust, Fe can be present as substitution Fe in the crystalline matrix of aluminosilicate, but the existence of Fe oxide nano-inclusions has also been highlighted at the particle scale, with variable oxidation states. In alloy-making emission plumes, Fe-bearing dusts are mostly emitted from the tapping area of the electric arc furnace and Fe shows an intermediate oxidation state, at the particle scale, with an average of 2.7 ± 0.2. It appears that, in a general manner, the iron in the smallest particles is more oxidized than in the coarser ones.

Deep subduction of hot young oceanic slab required by the Syros eclogites

STAMATIS FLEMETAKIS[1], EVANGELOS MOULAS[2], DIMITRIOS KOSTOPOULOS[1]* AND ELIAS CHATZITHEODORIDIS[3]

[1]University of Athens, Department of Geology, Athens 157 84, Greece (*correspondence: dikostop@geol.uoa.gr)
[2]Geological Institute, ETH Zurich, 8092 Zurich, Switzerland
[3]NTUA, Mining & Metallurgical Eng., Athens 15780, Greece

The Cycladic islands of Syros and Siphnos, Aegean Sea, Greece, represent subducted IAT and BABB remnants of the Neotethyan Pindos Ocean that formed during rifting of the southern active margin of Laurussia (Pelagonia) in the mid-Triassic, in response to northward subduction of Palaeotethys. Garnet porphyroblasts (Ø=1mm) in a glaucophane-zoisite eclogite from Kini locality on Syros are compositionally zoned and display a unique prograde heating path from a high-pressure greenschist-facies core with high X_{Sps} and low Mg# via a blueschist-facies mantle with moderate X_{Sps} and Mg# to an eclogite-facies rim with low X_{Sps} and high Mg#. The outermost 35 μm of the garnet rims show flat X_{Sps} with rapidly increasing outwards Mg#. Na-Act-Chl-Ph rimmed by Gln mark the greenschist-blueschist facies transition, whereas Pg rimmed by Omp and the incoming of Rt at the expense of Ttn signify the blueschist-eclogite facies transition.

Raman barometry of quartz inclusions in the eclogitic garnet rims coupled with elastic modelling of the garnet host [1], and Zr-in-Rt and Grt-Cpx-Ph thermobarometry revealed near-UHP P-T conditions of the order of 2.6 GPa/660°C. By contrast, the greenschist-blueschist transition lies at ~0.75 GPa/355°C.

Our new P-T estimates match published T distributions on the slab surface calculated for a subduction velocity of 3 cm/yr, a subduction angle of 30° and an age of incoming lithosphere of ~20 Ma with a shear stress of 80 MPa at the slab-mantle interface [2]. The above are in excellent agreement with published isotopic work on zircons and garnets from Syros eclogites suggesting crystallisation from magmas derived from a depleted mantle at ~80 Ma and constraining the event of eclogitic metamorphism at ~55 Ma. Diffusion modelling of the garnet outermost rims suggests a brief heating pulse of only ~1,000 years at peak T.

Experimental approch of carbonate isotopes fractionation related to kinetic effect during travertine growth

L. FLEURENT[1,2*], E. GIBERT-BRUNET[1] AND F. BARBECOT[2]

[1]UMR 8148-IDES, CNRS-UPS, Université Paris Sud-XI, Orsay, France (*leonora.fleurent@u-psud.fr)
[2]GEOTOP, département des sciences et de l'atmosphère, Université du Québec à Montréal, Montréal, Canada

Travertine are supposed to archive environmental conditions with high temporal resolution up to seasonal, monthly or even daily when finely laminated. It's important to understand the mechanisms of precipitation and the behaviour of isotope and major/trace elements to make environmental reconstruction.

Rate of degassing of CO_2 in rich spring is considered to influence the rate of calcite precipitation and the stable isotope $\delta^{18}O$ and $\delta^{13}C$. Then the isotopic equilibrium is rarely maintained during the deposition of travertine suggesting that the rate of CO_2 degassing may be the main controlling factor of the disequilibrium (1). Combined stable isotope (^{18}O and ^{13}C) measurement on water and on freshly precipitate travertine from rich CO_2 spring under laboratory condition have been developped in order to constrain the non-equilibrium fractionation domain.

In a 80-cm sequence cored in 2008 at the Ours gaseous spring (Massif Central, France), we have observed a disequilibrium between the calculated temperature and corresponding isotopic contents recorded in the laminated travertines, with a apparent shift of 8°C compared to the measured temperature. The main question was thus to understand the precipitation processes that either reflect or not geochemical equilibrium.

In order to understand the processes occuring between rich-CO_2 water, gaz and related travertines such as kinetic of degassing and the geochemical pathways recorded in the carbonates, laboratory tests were conducted. These experimentations allow us to identify the effect on degassing on the behaviour of isotope (fractionation factor) and chemical (partionning) records when precipitation occurs. The isotopic signatures obtained on this core (2) can be thus reinterpreted with a very new geochemical insight of fractionation and interaction processes.

Borosilicate glass dissolution driven by magnesium silicate precipitation

B. FLEURY[1*], N. GODON[1], A. AYRAL[2] AND S. GIN[1]

[1]CEA MAR/DEN/DTCD/SECM/LCLT, BP17171, 30207, Bagnols-sur-cèze, France
*correspondence : benjamin.fleury@cea.fr, nicole.godon@cea.fr, stephane.gin@cea.fr)
[2] IEM, Université Montpellier 2, CC 047, Place Eugène Bataillon, 34095, Montpellier Cedex 5, France (andre.ayral@iemm.univ-montp2.fr)

This study deals with the effect of Mg-silicate precipitation on borosilicate glass dissolution mechanisms and dissolution rate. It has been shown that this precipitation is related to the consumption of elements like silicon from the altered glass layers [1]. Investigations are here performed for better understanding of the kinetically limiting mechanisms.

Leaching experiments of SON68 glass, a Mg-free borosilicate glass, were carried out in initial deionized water at 50°C with a glass-surface-area-to-solution-volume ratio of 200 cm^{-1}. After 29 days of alteration magnesium was added in order to trigger the precipitation of Mg-silicate. Additional experiments were also conducted to investigate the importance of other parameters like pH or dissolved silica on the precipitation mechanisms and their consequences on the glass dissolution rate.

Mg-silicate precipitates immediately after magnesium addition. The total amount of altered glass increases with the added amount of magnesium. It is lower when silicon is added to the solution. Increase of pH above 8 strongly accelerates Mg-silicate precipitation. A time lag is observed between magnesium addition and glass alteration resumption because silicon is first provided from partial dissolution of the previously formed alteration gel. It is finally shown that nucleation process does not limit Mg-silicate precipitation.

Periods of magma propagation and homogenization preserved in an upper crustal pluton over 1.2 Ma

FLOESS D[1*], BAUMGARTNER L[1], BRACK P[2], BRODERICK C[3], CHIARADIA M[3], MUNTENER O[1], PUTLITZ B[1] AND SCHALTEGGER U[3]

[1]University of Lausanne, CH
(*david.floess@gmail.com)
[2]ETH Zurich, CH
[3]University of Geneva, CH

Large, broadly homogeneous plutons are a major component of subduction-related batholiths. The Western Adamello Tonalite (WAT) in the Italian Alps is an excellent example of a homogeneous pluton, featuring rocks with similar texture and composition over 6 kilometers (100 km^2). Locally, heterogeneous zones of up to a few hundred meters wide interrupt the homogeneous tonalite. They consist of basement xenoliths, mafic enclaves, schlieren, and hornblende-rich cumulates and are parallel to the host rock contact. Forty-five igneous samples from two transects perpendicular to the host rock contact were collected and analyzed for major and trace elements, stable and radiogenic isotopes (O, Sr, Nd), and U-Pb zircon geochronology.

U-Pb high precision dating on four samples yields ages of 37.6, 37.1, 36.7 and 36.4 Ma (youngest zircon from each sample), indicating a younging towards the internal parts of the pluton. The age spread within a single sample is over 200 ka, and no overlap between the four samples exists. Thermal models predict that a single batch intrusion of the size of the WAT would cool ten times faster than the age span of 1.2 Ma recorded by the samples. This, along with structural and chemical observations suggests incremental emplacement.

Major and trace elements show a trend towards more SiO_2-rich (evolved) compositions for the younger, internal parts. In contrast, stable isotopes only vary in the first couple of meters close to the host rock contact, indicating wall rock assimilation. A step-like increase of $^{87}Sr/^{86}Sr$ (and decrease of $^{143}Nd/^{144}Nd$) coincides with the observed heterogeneous zones. The change in radiogenic isotopic values occurs over a few hundred meters, whereas the flat plateaus of similar isotope composition persist over areas that are a factor ~5 wider. This suggests that new feeder conduits are rapidly established and successive pulses of magma are isolated from the surrounding host rocks. Two such cycles can be seen in the WAT. We propose that this alternation results from processes at the level of an intermediate crustal reservoir. The general geochemical evolution, in contrast, mainly reflects changes in the deeper magma system.

Precise U-Pb ID-TIMS baddeleyite and zircon ages for the Florianópolis Dyke Swarm and its correlation to Paraná-Etendeka mafic to intermediate magmatism

LUANA MOREIRA FLORISBAL[1], VALDECIR DE ASSIS JANASI[1], MARIA DE FATIMA BITENCOURT[2] AND LARRY M. HEAMAN[3]

[1] Instituto de Geociências, Universidade de São Paulo, Rua do Lago, 562, São Paulo, SP, 05508-080, Brazil. (geoluana@yahoo.com.br; vajanasi@gmail.com)

[3] Department of Earth and Atmospheric Sciences, 1-26 Earth Sciences Building, University of Alberta, Edmonton, Alberta, T6G 2E3, Canada. lheaman@ualberta.ca

The coastal region of Santa Catarina, south Brazil, features abundant mafic to intermediate dykes from the Paraná-Etendeka Magmatic Province (PEMP), which compose the Florianópolis Dyke Swarm (FDS). These are hosted by Neoproterozoic granites which locally show evidence of remelting at the contacts with the mafic dykes. NE-trending, high-TiP dykes akin to the high-Sr Urubici lava-type are predominant, and are locally crosscut by thinner, NW-trending dykes similar to the low-TiP Gramado lava-type. Basalt compositions are largely predominant, but some dykes of intermediate composition occur showing evidence of magma mingling. U-Pb ID-TIMS dates obtained on baddeleyite and zircon from both mafic and intermediate dykes yield precise crystallization ages at *ca*. 134 (±0.5) Ma. These ages coincide with the best current estimates for the climax of volcanic activity in the neighbouring PEMP lava pile, as indicated by both U-Pb and $^{40}Ar/^{39}Ar$ dates. The close chemical and temporal relations with the lavas are good indicators that the dykes must correspond to feeders of the lava pile. The ~20 Ma span of $^{40}Ar/^{39}Ar$ dates (140-120 Ma) reported in the literature for the FDS may be an overestimate of the duration of dyke emplacement in the swarm, possibly reflecting both Ar loss and, in some cases, Ar excess resulting from the contamination of the magmas by K-rich melts derived from the host granites.

Cristallinity, structure and volatile content of Panum Crater's magma

P. FLOURY[1], D. R. NEUVILLE[1], C. LE LOSQ[1] AND R. MORETTI[2,3]

[1]CNRS-IPGP, Géochimie&Cosmochimie, Paris Sorbonne Cité, 1 rue Jussieu, 75005 Paris, France.
[2]Seconda Università degli Studi di Napoli, Dipartimento di Ingegneria Civile, Design, Edilizia e Ambiente, Aversa (CE) ;
[3] Istituto Nazionale di Geofisica e Vulcanologia, Napoli, Italy

Despite the many studies in the literature, the influence of magma physicochemical properties, particularly viscosity, on the building and dynamics of volcanic domes is not fully understood, hitherto. The link between temperature, chemical composition and crystalline content of magmas has been assessed only partially, and still represents a major issue in Earth and Material sciences. Understanding physicochemical properties of crystal-bearing melts is of prime importance for understanding the growth and evolution of volcanic domes, as well as the transition of the eruption toward other eruptive styles. Panum Crater is the most recent dome eruption at the chain of Mono Craters in the north side of Long Valley caldera (California). It is a dome composed of obsidian and pumice, which emplaced in 1350 AD inside a tuff-ring [1]. The coexistence of these products represents an ideal case to assess physicochemical properties at the atomic level of melt structure and their role in eruptive dynamics.

In this communication, we present a large range of physical and chemical properties measurements (determination of the water concentration by Raman and FTIR spectroscopy, viscosity and density measurements, as well as C and H isotopes to have an integral vision of the matter. Our results lead us to propose a piston-like dynamic model for the eruption based on the formation of a shallow (200-300 m), degassed, magma plug overlying a relatively volatile-rich portion of the same silicic magma that rose and expanded under closed system-degassing conditions. In our model, the sudden and preliminary gas release that flashed groundwaters and created the tuff-ring [1], formed the shallow, degassed magma plug, down to a depth determined by a rheological boundary with the lowermost magma portion. The latter acted first as a thermostat, keeping the shallow, degassed, one under superheated conditions, so preventing the onset of crystallization at shallow depth. Subsequently, the rapid expansion of the volatile-rich lowermost magma, allowed the rapid evolution of the shallow magma through the glass transition when rapidly pushed out to surface, thus forming the obsidian body which surround the highly vesiculated pumices. The model can be extended to other volcanic domes of much larger size, provided a deep source.

L2009R2: A Cluster IDP Sampling a Diversity of Formation Conditions

G. J. FLYNN[1], S. WIRICK[2] AND S. R. SUTTON[2,3]

[1]Physics Dept., SUNY-Plattsburgh, Plattsburgh, NY 12901
[2]CARS, Univ. of Chicago, Chicago, IL 60637
[3]Geophysical Sciences, Univ. of Chicago, Chicago IL 60637

We performed XRF, Fe- and Cr-XANES on L2009R2, a large aggregate interplanetary dust particle (IDP) that fragmented dispersing over several hundred micrometers on impact with the stratospheric collector. Most ~8 μm pixels gave Fe-XANES spectra consistent with Fe^{2+} or Fe^{3+}, but the spectrum of one pixel is consistent with Fe or Fe-Ni metal with some structural disorder. Cr-XANES was performed on eleven spots where the Cr concentration was high enough to get good quality spectra. Six areas of L2009R2 are consistent with Cr^{3+} (overplotting chromite or Cr-diopside), while four areas plot between Cr^{2+} and Cr^{3+}. One area overplots the Cr^{2+} spectrum of olivine from the ureilite meteorite CMS04048. This is significant because Cr has been identified in natural terrestrial materials in only the Cr^{3+} and Cr^{6+} valence states [1], with only rare occurrences of Cr^{2+} in extraterrestrial materials. The most reduced Fe was found in the same area as oxidized Cr and the most reduced Cr was found in an area dominated by oxidized Fe. L2009R2 has a CI-like element abundance pattern, suggesting it consists of fine-grained matrix and larger minerals that grains aggregated into this ~50 μm particle. The XANES results on L2009R2 span a wide range of oxidation states, indicating this IDP is an aggregate of grains formed in a diverse variety of environments, some oxidizing and others reducing.

The reduction of elemental sulfur by metal-reducing bacteria under alkaline conditions

THEODORE M. FLYNN*, EDWARD J. O'LOUGHLIN AND KENNETH M. KEMNER

Argonne National Laboratory, Biosciences Division, Lemont, IL 60439 (*correspondence: tflynn@anl.gov)

Metal-reducing bacteria such as *Shewanella*, *Desulfuromonas*, and *Geobacter* are abundant in many terrestrial environments, where their respiration is often linked to the reduction of ferric iron (Fe^{III}). Under alkaline conditions, however, the reduction of Fe^{III} ceases to be energetically favorable and suggests that under these conditions, metal reducers must utilize alternate electron acceptors. One possible alternative is elemental sulfur (S^0), which is produced when ferric minerals react with dissolved sulfide such as that created by microbial sulfate reduction. Using geochemical modeling, we show that unlike the reduction of ferric minerals, the reduction of S^0 becomes more energetically favorable as pH increases. We also show experimentally that, under alkaline conditions, *Shewanella oneidensis* is capable of reducing S^0 to sulfide, which then reacts with ferric minerals to form Fe^{II}. We suggest that in slightly alkaline environments where both sulfate and Fe^{III} are available, metal-reducing bacteria may survive primarily by respiring the S^0 created by sulfate-reducing bacteria.

Global variation in Fe-isotopic composition of arc basalts indicate a variably oxidised and metasomatised mantle wedge source?

JOHN FODEN[1*], PAOLO SOSSI [2,1] AND GALEN HALVERSON [3,1]

[1]University of Adelaide, Geology and Geophysics,
[2]Research School of Earth Sciences, ANU, Canberra ACT
[3]McGill University, Earth and Planetary Sciences,

New Fe-isotope data on basaltic samples from the global network of subduction arcs is used to investigate whether there is systematic variation in Fe isotopic compositions resulting from varying source oxidation. This in turn may reflect variation in slab-derived water flux.

Global arc magmas have elevated $Fe^{3+}/\Sigma Fe$ values in the range >0.1 to 0.5 (our data set has a mean of ~ 0.35), compared to MORB with values in the range 0.1-0.2. [1,2]. For lavas, our $\delta^{57}Fe$ data (vs.IRMM-014) span a range from -0.2 to +0.2 (± 0.04), with a mean around +0.05. This is significantly lighter than the mean for MORB and BABBs (~+0.10) [3], though the arc data sets clearly trend towards heavier values for more fractionated samples. Light $\delta^{57}Fe$ values in arcs may reflect that the mantle wedge in many arcs is more depleted than MORB source [4]. Our $\delta^{57}Fe$ values show moderate positive correlation with $Fe^{3+}/\Sigma Fe$.

Using the subduction thermal parameter (ϕ) [5] which is a proxy for the thermal structure of the down going slab, we find a positive correlation of $\delta^{57}Fe$ where $\phi/100 > 50$, but for values < 50 there seems to be a negative correlation. Interestingly we find that mineral separates from some ultramafic xenolith suites have very light $\delta^{57}Fe$ values (CPX as low as -0.79 & Ol at -0.66) apparently reflecting metasomatism [6] and extending the negative ϕ - $\delta^{57}Fe$ trend.

A possible explaination is that the iron isotopic values and trends of primitive arc basalts reflect three influences; 1. source oxidation, 2. fraction of melting and 3. impact of metasomatism.

Sorption and desorption processes of U(VI) on iron (hydr)oxide phases

H. FOERSTENDORF*, K. HEIM AND N. JORDAN

Helmholtz-Zentrum Dresden-Rossendorf, Institute of Resource Ecology, 01314 Dresden, Germany (*correspondence: foersten@hzdr.de)

In this comparative study, the surface speciation of uranium(VI) on ferrihydrite (Fh) and maghemite (Mh) were investigated by vibrational spectroscopy. The experimental setup allows the monitoring of the surface processes at the water-solid interface in real time with a time resolution in the subminute time range. The performance of the experiments under inert gas atmosphere and under ambient conditions provides further insight into the molecular events of the binary and ternary sorption systems, respectively.

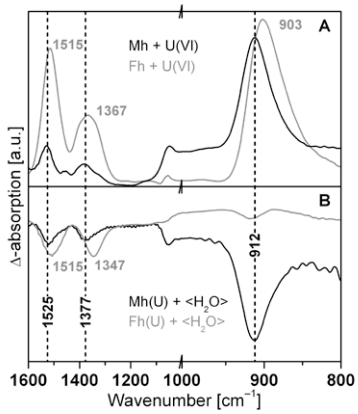

Figure 1: IR spectra of the sorption (A) and desorption (B) processes of U(VI) on ferrihydrite (Fh) and maghemite (Mh) in ambient atmosphere.

The spectra clearly demonstrate a characteristic surface speciation in dependence of the solid phase. On Fh, the formation of ternary inner sphere complexes are observed as it was derived earlier [1]. In addtion, the time-resolved spectra reveal the change of the surface speciation of atmospherically derived carbonate upon U(VI) sorption [2].

From the sorption experiments on Mh, outer sphere complexation of the uranyl ion can be derived. In ambient atmosphere, contributions of carbonate ions to the U(VI) surface speciation on Mh can not be ruled out.

Physical properties of CO_2-rich melts at mantle conditions: A simulation study

N. FOLLIET[1], N. SATOR[1] AND B. GUILLOT[1]

[1]LPTMC, Université Pierre et Marie Curie (Paris 6), Boîte courrier 121, 4 place Jussieu, 75252 Paris cedex 05, France (*correspondence: guillot@lptmc.jussieu.fr)

There are growing evidences that CO_2-rich melts play a key role in the geodynamics, chemical differentiation and degassing of the upper mantle. Experiments at HT-HP on carbonate-silicate assemblages suggest that the onset of mantle melting may start as deep as 300 km in generating carbonatitic melts at very low melt fraction [1]. The electrical conductivity anomalies measured in the astenosphere by magnetotelluric sounding can be explained by the presence of highly conductive phases which could be CO_2-rich [2,3]. On the other hand, the composition of primary magmas at the origin of hypabyssal kimberlites has been recently reevaluated and should be transitional between carbonate and silicate melt with low SiO_2 contents [4]. Furthermore it appears that the role and abundance of the carbonatite volcanism has been underestimated [5], and recent database and world distribution map of carbonatites [6] show that a carbonatitic magmatism was abundant from the late Archean to the Phanerozoic.

However, the physical properties of carbonatites and carbonated silicate melts are poorly known. Here we present an evaluation of the physical properties of CO_2-rich melts by molecular dynamics (MD) simulation. This atomistic approach relies on the development of a realistic force field to describe the incorporation of CO_2 in a silicate melt [7] and that of a silicate component in a carbonate melt, as well. With this force field it has been possible to simulate a large composition range from carbonatites to CO_2-saturated basalts with a special emphasis on the transitional compositions (0-15wt% SiO_2). The EOS, the viscosity and the electrical conductivity of the simulated melts have been evaluated at mantle conditions. It is found that the composition has a large influence on the melt properties, a result which has important geophysical implications.

Aerosol trace metal fractional solubility and chemical composition of marine aerosols at the CVAO

K. W. FOMBA*, K. MÜLLER AND H. HERRMANN

Leibniz-Institut für Troposphärenforschung, Permoserstr. 15, 04318 Leipzig, Germany (*correspondence: fomba@tropos.de)

The atmosphere and ocean interact in various ways that significantly affect the local and global climate. Mineral dust deposition onto the oceans plays a vital role as it provides key nutrients to the ocean biota and thereby influence the oceanic biogeochemical cycle and thus oceanic emissions. In this work we present chemical and trace metal composition of marine aerosol at the Cape Verde Atmospheric Observatory (CVAO) obtained during periods of and without Saharan dust storms.

The data were collected during intensive field campaigns and continuous measurements from January 2007 until now. During this period PM10 samples were collected using a 5-stage Berner impactor for size-resolved measurements and a high volume DIGITEL DHA-80 sampler with PM_{10}-inlets.

Our observations show that about 45% of the year are dominated by remote conditions while the rest was influenced by continental and Saharan dust air masses. Continental air masses contained significant amounts of Saharan dust with trace metals and organic carbon compared to marine air masses. Dust events were observed mostly during the winter months of the year. During the events, the contribution of sea salt to the total PM_{10} mass was found to be low. The sea salt and Saharan dust in the particle were found in the coarse mode fractions while the organics and non-sea salt components were observed mostly in the submicron fraction. Interannual and seasonal variability were observed for nearly all aerosol constituents. Strong seasonal trends were observed for ammonium and non-sea salt sulfate with peaks observed in the spring and summer, respectively.

Significant differences were observed in the trace metal composition (especially iron) between days of Saharan dust outbreaks (about 20.0 Fe, 16.4 Ca, 2.3 Ti, and 0.3 Mn $\mu g/m^3$) and days without (less than 10.0 ng/m^3). Mn was found to be the most soluble trace metal followed by Zn and Fe. Iron was mostly present in Fe (III) form with Fe (II) often found only at lower pH. Dissolution experiments at varying pH (from 5.5 to 2) showed significant increase in metal solubility at lower pH with an increase of over 3 orders of magnitude for both Fe (II) and Fe(III) and about two orders of magnitude for Cu and Mn.

The unexpected 'compatible' behavior of W during mantle melting: Implications for the W/U ratio of the lunar mantle

R.O.C. FONSECA[1]*, G. MALLMANN[2], J. E. SOMMER[1], P. SPRUNG[3], I. M. SPEELMANNS AND A. HEUSER[1]

[1] Steinmann Institute, Universität Bonn, Germany (*correspondence: raul.fonseca@uni-bonn.de)
[2] Institute of Geosciences, University of São Paulo, Brasil
[3] Institut für Planetologie, Universität Münster, Germany

The timing of core formation is essential for understanding the early differentiation history of the Earth and the Moon. Because Hf is lithophile and W is siderophile during metal-silicate segregation, the decay of ^{182}Hf to ^{182}W (half-life of 9 Ma) has proven to be a useful chronometer of these major planetary differentiation events. A key parameter for the interpretation of the ^{182}Hf /^{182}W chronometer is the Hf/W ratio of the primitive (i.e. undepleted) mantle. Since W is incompatible during mantle melting, its ratio relative to U and other similarly incompatible elements in basalts (e.g. Th, Ba) may be used as proxies for their mantle sources. However, the assumption that W and U are equally incompatible may be flawed for petrological systems that equilibrated over a large range of fO_2. Although W is typically perceived as being homovalent, evidence suggests that U is heterovalent over the range of fO_2 experienced in the mantle of the Earth and the Moon respectively .

Here we report partitioning data for W, U, high-field strength elements (HFSE), and Th between clinopyroxene, orthopyroxene, olivine and silicate melt. In agreement with previous studies, we show that these elements behave as homovalent elements at fO_2 higher than QFM. However, both W and U become more compatible at fO_2 lower than QFM, indicating a change in their redox state.

This result is particularly unexpected, because W is thought to be hexavalent even at very low fO_2. However, the much higher compatiblity of W^{4+} as compared to W^{6+}, means that even a small fraction of W^{4+} will increase the overall compatibility of W. Our results imply that under the reducing conditions in which lunar differentiation is thought to have taken place (i.e. ~IW-1), W is likely to become fractionated from U. These newly obtained partitioning data carry with them the potential implication that the W-to-U ratio of lunar basalts does not directly represent their mantle source. More high-precision measurements of W and U abundances in lunar rocks are needed to more precisely estimate the Hf/W of the Moon and thus, the age of the Moon itself.

Geophysical Evidence for Iron Mineral Transformation in a Petroleum Contaminated Aquifer

BRITTANY R. FORD[1]*, ESTELLA A. ATEKWANA[1], GAMAL A. AAL[1] AND ELIOT ATEKWANA[1]

[1]Oklahoma State University, Stillwater, OK, USA (*correspondence: brittany.ford@okstate.edu)

Hydrocarbon-contaminated environments are excellent laboratories for understanding microbial mediated iron reduction. The excess carbon serves as an electron donor, which can stimulate microbial activity if electron acceptors, such as iron, are available. Previous studies have suggested that magnetic susceptibility (MS) measurements are a potential tool to follow microbial Fe mineral transformation. In this study, we investigated the MS and iron content variations that exist at a hydrocarbon contaminated aquifer in order to determine the major magnetic mineral present. Our results show large down hole excursions in the MS at the contaminated location coincident with peak concentrations of Fe(II) and Fe (Total), and the presence of *Geobacter* species. Variability in the down hole MS at the uncontaminated locations are not associated with peaks in Fe(II) or presence of *Geobacter* ; However, Fe(III) dominates the Fe pool. Our results also show high marked increase in the MS values in the vadose zone at the contaminated locations concomitant with higher concentrations of Fe(II) and Fe (Total). This could be evidence for the microbial reduction of Fe(III) minerals, producing magnetic mineral phases. Trace metal data will be used to determine the chemistry of the sediments and identification of the local mineralogy. With this information, we anticipate characterizing the processes that control the biogeochemical cycling of iron and carbon.

Ice age carbon dynamics of the interior Atlantic Ocean inferred from a highly resolved sedimentary depth transect

ALAN FOREMAN[1]*, CHRISTOPHER CHARLES[1], JAMES RAE[2], NIALL SLOWEY[3] AND JESS ADKINS[2]

[1]Scripps Institution of Oceanography, UCSD, La Jolla, California, USA (*Correspondance: aforeman@ucsd.edu)
[2]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, California, USA.
[3] Department of Oceanography, Texas A&M University, College Station, Texas, USA

Many models show that the relative intensity of stratification must be a primary variable governing sequestration and release of carbon from the ocean over ice ages. The observations necessary to test these model-derived hypotheses are not yet sufficient, but sedimentary depth transects represent a promising approach for making progress. Here we present results from a suite of 24 cores spanning water depths of 1000-3700 meters, collected from the Namibian margin. This is an especially suitable location to collect vertical depth transects over ice age cycles, given that it is sensitive to the intersection of the principal water masses involved in the thermohaline circulation of the Atlantic. In aggregate, these cores allow for depth transects that have roughly 100 meter vertical resolution, and “steady state” benthic foraminiferal proxy profiles can be compiled at various points spanning the last full ice age cycle.

In this presentation, we contrast the “steady state” vertical distribution of benthic foraminiferal tracers from Marine Isotope Stages 5e, 5a, 4, and the LGM, compiled from the full suite of cores, with the transient evolution of these tracers over the last and penultimate deglaciation in a subset of the cores. The comparison between purely physical tracers (e.g. $d^{18}O$) and tracers that are sensitive to the carbon cycle (e.g. $d^{13}C$ and B/Ca) offers critical insight to the relationship between deep/mid-depth stratification and global carbon dynamics. The observation of the nonconservative behavior of mid-depth $d^{13}C$ in the South Atlantic during the so-called 'Mystery Interval,' for example, will be examined in light of the suggested carbon inputs external to the ocean-atmosphere system [1].

Lawsonite veins in eclogite as an archive of subduction zone fluids from 45-80 km depth (Sivrihisar, Turkey)

KATHERINE F. FORNASH[1], MICHAEL A. COSCA[2] AND DONNA L. WHITNEY[1]

[1]Earth Sciences, University of Minnesota, Minneapolis USA (forna011@umn.edu, dwhitney@umn.edu)
[2] USGS, Denver USA (mcosca@usgs.gov)

The lawsonite eclogite and blueschist terrane near Sivrihisar, Turkey, is a pristine archive of subduction zone fluids that were present in metabasaltic and metasedimentary rocks at depths of 45-80 km. Few rocks have returned from these depths in subduction zones without extensive overprinting of mineral assemblages and textures; Sivrihisar eclogite, however, contains unaltered lawsonite (lws) and other minerals that equilibrated at pressures of up to 2.5 GPa and 550 C. Major and trace element zoning of minerals in HP veins and host rocks, microstructures of minerals deformed at HP conditions, and the chemical and physical characteristic of lws-bearing veins record episodic mineral-fluid interaction during subduction metamorphism, likely at or near the slab interface with the overlying (serpentinized) mantle wedge. The margins of lws eclogite pods and layers contain networks of mm- to cm-scale veins containing lws + garnet (grt) + phengite (ph) (± paragonite). Eclogite extensively retrogressed to chlorite + epidote contains monomineralic lws veins. Lws-grt-ph veins in eclogite are rimmed by lws-grt-ph-glaucophane zones, indicating that veining occurred at least in part during decompression under lws-blueschist facies conditions. High-precision and -spatial resolution *in situ* UV laser ablation Ar/Ar dating of ph single crystals document a sequence of events, from lws eclogite metamorphism to vein formation to lws blueschist metamorphism and eclogite retrogression over the course of at least 10 million years in the Late Cretaceous.

REE distribution in granulite assemblage from lower crust of the Serre massif (Calabria-Italy)

A. FORNELLI[1*], A. LANGONE[2], F. MICHELETTI[1], A. MUSCHITIELLO[1] AND G. PICCARRETA[1]

[1]Earth science and geo-environmental Dep., Bari University Italy,(annamaria.fornelli@uniba.it)
[2]Institute of Geosciences and Earth Resources (CNR) - U.O.S. of Pavia

Two samples of mafic granulites with porphyroblastic garnet were investigated for REE distribution between accessory and major mineral phases. The granulites were affected by Variscan metamorphism which began with a compressive event around 340-350 Ma and was followed by decompressional stages between 325 Ma and 280 Ma evidenced by re-setting or new growth of zircon [1, 2]. The studied samples differ for the presence/absence of amphibole and biotite. In the sample with amphibole and scarce biotite the porphyroblastic garnet is relatively rich in REE: ∑HREE= 190 ppm at core and ∑HREE up to 702 ppm at rim. The garnet in the sample lacking amphibole shows decidedly higher REE abundances: ∑HREE=2463 ppm at core and ∑HREE up to 14784 ppm at rim. Both garnets show an increase of HREE in the peripheral zone due to consumption of the primary rim during corona formation and sequestration of REE in smaller volumes. The abundance and distribution of REE in the zircons from the two samples are comparable. They show REE fractionated patterns with Lu_N/Gd_N variable from 42.91 to 24.84. Even the orthopyroxenes from the two samples contain similar abundance of REE (∑REE from 6 to 13 ppm). The difference in REE contents in garnet seems to be connected to the presence of amphibole as major mineral phase. So the empirical REE distribution coefficients (D) between zircon and garnet are controlled by REE contents of garnet in the studied rocks and caution should be placed on the use of Dzrn/grt to infer chemical equilibrium between domains of garnet and zircon and to constrain the significance of the zircon ages.

As expected under granulite facies [3], the analysed amphibole is enriched in REE everywhere it occurs (inclusion, matrix, corona). So it appears that in the case study, the equilibrium between garnet and amphibole is indicated by the calculated DREE values which are lower than 1 from La to Dy (0.001-0.9) and higher than unity from Ho to Lu (1.5-15).

The forcing of climate by CO_2 on geological timescales

GAVIN L. FOSTER[1*] AND MIGUEL A. MARTÍNEZ-BOTÍ[1]

[1]Ocean and Earth Science, National Oceanography Centre Southampton, University of Southampton, Southampton SO14 3ZH, UK (*correspondence: Gavin.Foster@noc.soton.ac.uk)

Understanding the role of atmospheric CO_2 in driving global climate is one of the great challenges facing Earth Scientists today. Ultimately we are driven by the pressing need to predict how hot the Earth will get in the near future. There are many ways we can achieve this increased understanding – ranging from examining the most recent historic past to basing our predictions on an understanding of the modern climate system encapsulated in numerical climate models. Increasingly the palaeo-community has been willing to contribute to the debate, since the geological record is littered with examples of warm climate states, in part associated with elevated levels of atmospheric CO_2. Whilst these provide real world examples of how the Earth System responds to CO_2 forcing, no geological period is an adequate analogue for our warm future. Furthermore, climate models suggest that a significant level of state dependency exists for climate sensitivity. Therefore examining the response of the climate system to CO_2 forcing in the Eocene, for example, does not have direct relevance due to the different continental arrangements, ice sheet configurations and vegetation. When these factors are accounted for, it has been recently shown that the available palaeo-data largely confirms the sensitivity of the Earth system to CO_2 forcing determined by climate models alone [1].

Despite this overall conformity, there are several warmer time periods in the geological record (e.g. the Pliocene) that apparently exhibit significantly elevated climate sensitivites (e.g. [1]). Importantly, these are above the range typically, but not always (e.g. [2]), achievable in climate models – clearly suggesting that the Earth can exist in states that appear to be particularly sensitive to CO_2 forcing. Such a state dependency to sensitivity has worrying implications for predictions of our warm future climate. In this contribution we use new data from a number of key periods to further probe the response of the Earth system to CO_2. This provides new insights into the possibility of "hidden" feedbacks and the likelihood of a state dependency to climate sensitivity.

Dual explosive activity revealed by petrochemical and mineralogical data on tephra: Peculiar Roman-age eruptions of Stromboli volcano

L. FRANCALANCI[1,2], E. BRASCHI[1,2], S. DI SALVO[1], F. LUCCHI[3] AND C. M. PETRONE[4]

[1] Dip. Sci. della Terra, Università degli Studi di Firenze, via La Pira 4, 50121, Firenze, Italy

[4] The Natural History Museum, Department of Earth Sciences, Cromwell Road, SW7 5BD London, UK

The Pizzo-Sopra-la-Fossa tuff cone of Stromboli volcano has been investigated by stratigraphic, petrographic, mineralogical, geochemical and isotopic studies. Its deposits are presently the remnant of a collapsed tuff cone formed by a thick pyroclastic sequence of bomb, lapilli and ash fallout and surge levels. The main outcrop is located above the active craters where acid fumarolic gases strongly altered the juvenile clasts. For this reason, the Pizzo-Sopra-la-Fossa sequence was poorly studied, although it represents a key point for recognising the recent evolution of Stromboli. We mainly focused our studies on Le-Croci outcrops characterized by a 6 meters thick sequence of mainly unaltered fall deposits.

Two groups of feeding magmas have been identified, a group constituted by high-K basalts to high-K basaltic-andesites (Pizzo-HKCA) and another formed by shoshonitic basalts (Pizzo-SHO). The two groups can be distinguished on the bases of petrographic, mineralogical and geochemical data. Pizzo-HKCA products have lower phenocryst contents, incompatible trace element abundances and Sr isotopic ratios, with higher $^{143}Nd/^{144}Nd$ values than Pizzo-SHO. They also show differences in mineral phase composition and zoning.

There are also clear evidences that the two magmas were erupted contemporaneously, suggesting the presence of two distinct magma reservoirs, possibly located at different depth.

Based on crucial stratigraphic correlations (S.Bartolo-lavas, Lower-Sequence and Post-Pizzo-series), it has been recognised that this dual explosive activity on top of Stromboli, forming the Pizzo-Sopra-la-Fossa tuff cone, occurred only 2 ka ago (during Roman-age), possibly along the activation of NE-trending eruptive fractures.

The main MORB crustal contaminant: Geochemistry of magma chamber roof experimental anatectic melts, and residues

L. FRANCE[1]; J. KOEPKE[2]; B. ILDEFONSE[3]; C.J. MACLEOD[4]; M. GODARD[3] AND E. DELOULE[1]

[3]GM; Université Montpellier 2; Montpellier; France
[4]School of Earth; Cardiff University; Cardiff; UK

Mid-ocean ridge basalt (MORB) is the most abundant magma type at the Earth's surface. It is widely studied to infer mantle compositions and melting processes. However, MORB liquids are also the complex end-product of a variety of intra-crustal processes such as fractional crystallization, melt-rock interaction, and contamination. Deciphering the relative contribution of these processes is of first-order importance. Contamination at ocean crustal levels is likely, and may occur at magma chamber margins where fresh magmas can interact with previously hydrothermally altered rocks. Characterizing the composition of this crustal contaminant component is critical if we are to understand the relative importance of each component in the resulting MORB liquid.

In this contribution we present the results of experiments that reproduce the natural processes occurring at oceanic magma chamber roofs, by melting a representative sample of the sheeted dike complex. Anatectic melts thus produced represent the main MORB crustal contaminant. We characterize these melts for major and trace elements, showing them to be enriched in B, Zr, Hf, and depleted in Sr, Ti, V. In comparison to MORB series, we also document relative element fractionations, with enrichments of: Th relative to Ba; U relative to Nb; Nd relative to Sr; and Hf relative to Sm. We derive bulk partition coefficients for element partitioning during magma chamber roof anatexis; those are valuable tools for tracking MORB contamination.

Comparison with natural samples from the East Pacific Rise and the Oman ophiolite shows that anatectic melts can crystallize *in situ* to form oceanic plagiogranite intrusions, and that residual assemblages associated with the hydrous partial melting stage are represented by the granoblastic dikes and enclaves (also named beerbachites) commonly recognized at the root of the sheeted dike complex at present-day and fossil oceanic spreading centers.

Balancing chemical and physical erosion in the Ganga basin

CHRISTIAN FRANCE-LANORD[1], VALIER GALY[2], ANANTA GAJUREL[3], JÉRÔME LAVÉ[3], MAARTEN LUPKER[4] AND GUILLAUME MORIN[1]

[4] ETHZ, Zurich, Swizerland. maarten.lupker@erdw.ethz.ch

River basins at various scales undergo both physical and chemical erosion that should be balanced over long time scale. At short time scale of few years to tenth of years, it is however unlikely that steady state of erosion is verified. More likely, under variable climatic or geomorphologic conditions one term of erosion may be favoured over the other. Testing such imbalance is difficult because it requires to compare fluxes of weathering from both dissolved and particle phases.

Here we examine modern budget of erosion of three imbricated Himalayan basins: the Khudi river that is a small stream on south Himalayan flank, the Narayani drainage of central Nepal and the whole Ganga basin. Areas vary from 153 to 872000 km2. This approach is based on daily sampling of suspended sediments that allow refine estimates of average composition of the dissolved and particle loads. We then compare direct weathering fluxes of Na and K deduced from dissolved load to weathering fluxes deduced from the comparison between estimated source rock and exported sediments. Uncertainties are principally linked to the net sediment flux determinations and to the knowledge of average source rock composition. For both Ganga and Narayani, the estimates tend to indicate that physical erosion and chemical erosion are close to balance within uncertainties. In contrast, the Khudi basin show clear imbalance in favour of physical erosion. This is likely due to the exceptional intensity of landslide erosion than to intensified soil erosion in this basin.

Effect of pH and temperature on zeolite precipitation rates and mechanisms from amorphous precursors

P.C.M. FRANCISCO* AND T. SATO

Laboratory of Environmental Geology, Graduate School of Engineering, Hokkaido University 060-8628 Japan
*(correspondence: pcmfrancisco@gmail.com)

The predicted precipitation of zeolites due to the dissolution of bentonite during alkaline alteration in barrier systems for the gelogical disposal of radioactive wastes may alter the properties of the barrier system. It is therefore important to elucidate the formation rates and mechanisms of zeolites over a wide range of conditions in order to predict their crystallization behavior in barrier conditions. Zeolite formation is typically preceded by an amorphous precursor, the transformation of which is seen as a rate-controlling step. However, the mechanism and rates of transformation remain poorly understood. This study focuses on the effect of pH and temperature on the transformation of the amorphous precursor into crystalline zeolite.

Batch zeolite synthesis experiments were carried out at pH ranging from 9.5 to 13.5 and at temperatures ranging from 25°C to 90°C by mixing NaOH, $NaAlO_2$ and $Na_2SiO_3.9H_2O$ at varying proportions to achieve a fluid with the composition of 0.5 M Na, 0.24 Si and 0.03 M Al. The precipitates were extracted at different times by centrifugation and freeze drying. The supernatants were analyzed using ICP-AES for Al and Na and UV-Vis for Si. The solids were examined using XRD, FTIR, Raman spectroscopy and SEM-EDX.

Results show the rapid formation of an amorphous precursor phase, followed by slower transformation into crystalline zeolite. Crystal size distribution data suggest that the dominant transformation mechanism is dissolution and reprecipitation. Higher pH and temperature promotes rapid transformation of the amorphous precursor to zeolite. Spectroscopic data indicate lower degrees of Al substitution and lower amounts of T-OH bonds in solids formed at lower pH. These results indicate that precursor phases formed at lower pH are relatively more stable and less susceptible to dissolution. Therefore, zeolite precipitation is promoted at higher pH due to the rapid dissolution of the amorphous precursor. The results of this study show that pH controls the structure and chemistry, and therefore, the stability of the zeolite precursor phases.

Archean geodynamic: Fingerprinting sagduction vs subduction processes

CAMILLE FRANÇOIS [1,2*], PASCAL PHILIPPOT [1], PATRICE REY [2], DANIELA RUBATTO [3] AND JEAN-FRANÇOIS MOYEN [4]

[1] Institut Physique du Globe de Paris, 1 rue Jussieu, 75238 Paris, France, (*correspondance: francois@ipgp.fr)

[3] Research School of Earth Sciences, The Australian National University, Canberra 0200, Australia
[4] Université de Saint-Etienne, 42023 Saint-Etienne, France

The geodynamic processes responsible for the formation of Archean crust are matter of debate. Contrary to the general belief, sagduction and subduction are not incompatible processes, as both involve the deep burial and exhumation of surface and near-surface rock units. In order to better understand how to distinguish these processes, we investigated mid- to high-pressure metamorphic rocks from two key Early Archean localities: i) the East Pilbara Granite-Greenstone Terrane (EPGGT, Western Australia), considered as a reference model for sagduction [1], and ii) the Barberton Greenstone Belt (BGB, South Africa) either described in terms of subduction [2] or sagduction [3]. These two terranes display narrow belt of greenstone (ultramafic and mafic metabasalts and minor metasedimentary rocks) in association with broad TTG (tonalite-trondhjemite-granodiorite) granitoids. Estimates of the rate of heating/cooling and burial/exhumation of these granite-greenstone belts were evaluated using a combination of structural, metamorphic, and geochronological data coupled with numerical simulations.

In the EPGGT, we confirm that burial and exhumation of cold and dense greenstones is linked in time with crustal melting and granitoid dome formation. Thermobarometric, geochronological and numerical constraints indicate that metamorphism and deformation occurred within less than 10 Ma, thus implying burial and exhumation rates of some centimeters per year. The same approach applied to the BGB yielded a more complex and probably polymetamorphic history and suggest a possible different scenario. Burial/exhumation rates are possibly one order of magnitude slower and more progressive with respect to EPGGT, implying longer process.

Metakomatiites, Dynamical Modeling and the Late Veneer

E.A. FRANK[1,*], W.D. MAIER[2], R.M. CANUP[3] AND S.J. MOJZSIS[1]

[1]University of Colorado, Dept. of Geological Sciences & Center for Lunar Origin and Evolution (CLOE), NASA Lunar Science Institute, Boulder, CO 80309-0399, USA (*correspondence: elizabeth.frank@colorado.edu)

[3]Southwest Research Institute, Planetary Science Directorate, Boulder, CO 80302, USA

During core formation, silicate mantles are stripped of their highly siderophile elements (HSEs) due to strong partitioning behavior into metal. However, the HSEs are present in mantle-derived rocks at concentrations orders of magnitude higher than expected. Analysis of komatiites shows that there is a time-dependent HSE depletion trend in late Archean and early Proterozoic samples [1]. We present data for older (>3.75 Ga) ultramafic schists to (i) show that they are metamorphosed komatiites; (ii) extend the HSE depletion trend into the Eoarchean; and (iii) evaluate models to explain this trend. One hypothesis attributes HSE enhancement to an extraterrestiral source, a late accretion event dubbed the "Late Veneer" (LV) [2]. Assuming a chondritic composition, ~1% of Earth's current mass is required to cause the observed signal. The HSEs are in chondritic relative proportions despite their dissimilar metal-silicate partition coefficients. An LV may not be exclusive to Earth: there is evidence in martian meteorites and lunar samples that these bodies may have experienced their own LVs [3,4], lending credence to an extraterrestrial explanation. Dynamical simulations have shown the presence of planetesimals at the time of the LV to be a plausible reservoir for an LV [5]. To test this possibility, simulations [cf. 6] used four different impact velocities (1.1, 1.2, 1.3, and 1.4 times Earth's v_e), three impact angles (30°, 45° and 60°), and two different impactor masses (1% and 0.1% $M_\oplus$). The 1% mass assumption represents a single LV impactor, while 0.1% Earth mass impactors correlate to one of ten impactors with an equivalent total mass. The results have defined the parameter space that would have allowed large impactors to cause the HSE enhancement observed in the mantle.

Metamorphic-hydrothermal transition in the alteration of pillow and dike basalts from the Rodriguez Triple Junction

H. FRANKE[1], K. HEESCHEN[1] AND U. SCHWARZ-SCHAMPERA[1]

[1] Federal Institute for Geosciences and Natural Resources (BGR), D 30655 Hannover, Germany, (Henrike.Franke@bgr.de)

Alteration processes caused by interactions between seawater and basalt are one of the main effects which modify the geochemical and mineralogical composition of the oceanic crust, alter the mineral assemblages to upper greenschist facies and may form seafloor massive sulfides at mid-ocean ridges.

A series of INDEX cruises explore the intermediate to slow spreading southern Central Indian Ridge. This area is characterized by complex structured rift valleys and isolated active volcanic edifices in the central graben. Active hydrothermal activity is associated with a small satellite volcanic ridge at the eastern rift valley wall (Kairei). Dredges and TV-grabs were used to recover fresh and altered basalt samples in the vicinity of the vent field. This study presents the effects of variable alteration processes, related to (i) high-temperature near-neutral pH seawater and isochemical metamorphic overprinting, and (ii) seawater-derived acidic hydrothermal alteration.

The tholeiitic basalts are represented by sheet flows and pillow basalts with dispersed vesicles up to cm sizes. They can be distinguished into two groups: 1) basalts with an aphyric to porphyritic texture with variable phenocrysts and 2) holocrystalline basalt sample. Both fresh basalt types display a mineral composition of major plagioclase, minor olivine, clinopyroxene, and Cr-spinel. The mineral composition of altered rock samples indicate a range from low temperature basalt seawater alteration up to upper greenschist facies-like temperatures including albite, chlorite, actinolite, epidote(?), sphene while the plagioclase is almost pristine. The seawater altered rocks contain saponite, celadonite, and palagonite within the vitrious groundmass.

Basalts at mid-ocean ridges display a variety of alteration processes which contribute to sustained element fluxes. The Rodriguez triple junction with a variety of rift-related processes is a key region to study the diverse influence of fluid flow along mid-ocean ridges.

Analysis of nanostructures consisting of the Al-pyrocatechol complex using spectroscopic ellipsometry

MARTINA FRANKE

Department of Soil Science, University of Trier, D-54296 Trier, Germany (s6mafran@uni-trier.de)

In this study, spectroscopic ellipsometry was applied by using the photon energy over the range of 1.2-5.4 eV to determine the optical properties n and k from thin films of nanostructures consisting of pure Al and the Al-pyrocatechol complex. In addition, the real and imaginary part of the dielectric function epsilon was determined. During the preparation, two types of mirrored glass were used being of different thickness of the Al film in order to examine the equality of the results. Thin films of the Al-pyrocatechol complex were synthesized by adsorption in a gas-solid phase at 50 °C in the presence of atmospheric pressure for a period of 21 days in total darkness. The modeling of the optical response from the analyzed surfaces resulted in two forms of absorption spectra which showed Al and the Al-pyrocatechol complex. In this calculation, five plots of absorption spectra were determined. At this stage, rough forms of the first spectra were transformed to a smooth form by using a smoothing-spline algorithm. The third spectra were calculated by applying a surface-excess function to eliminate the interfering optical response of Al. Concerning this matter, the second derivative of the surface-excess function was calculated and observed in the fourth absorption spectra. The fifth plot showed the reference spectra of Al. In the UV region of the metal-ligand spectrum, an absorption maximum appeared at 275 nm. Within the Vis region of the spectrum, ligand bands from the complex occurred with an absorption maximum of 525 nm. In consequence of the addition of OH auxochoms in the process of complexation, a rise of the chomophore system occurred causing an increase of the absorption intensity. Fine nanostructures of the Al-pyrocatechol complex were ascertained as a result of the spectroscopic ellipsometry.

Acknowledgement: Christoph Cobet and Norbert Esser, Institute of Solid-State Physics, Technical University of Berlin, Germany, is thanked for the glass mirrors and the spectroscopic ellipsometry.

Carbonatites age of the Tiksheozero massive (North Karelia, Russia)

FRANTZ N.A.[1], RODIONOV N.V.[2] AND LOKHOV K.I.[3]

[1, 3] Saint -Petersburg State University, St.Petersburg, Russian Federation, (nfrantz@mail.ru,)(Kirill_Lokhov@vsegei.ru)

[2] Centre of Isotopic Research, Russian Geological Research Institute (VSEGEI), St. Petersburg, Russian Federation, (nickolay_rodionov@vsegei.ru)

In recent years, a lot of new ages of the Tiksheozero carbonatite massive were obtained. Usually for investigation zircon and baddeleyite has been used.

Baddeleyite dates converge to the age of 1.99 Ga (Rodionov *et al*, 2009; Corfu *et al*, 2011). Age of zircon from carbonatites correspond 1970±5.7 Ma (Ivanikov, Frantz, 2002) and 1959±16 Ma (Rukhlov, Bell, 2010).

It is known that baddeleyites age are reflecting age of the melt crystallization, because of their minimum sensitivity to the overprinting processes. Metamict properties of zircon from Tiksheozero carbonatites do not provide correct estimation of the crystallization age.

Geochemical characteristics of zircons (Frantz *et al*, 2001, Tichomirowa *et al*, 2012) indicate their magmatic-metasomatic origin, leading to a disturbance of U-Pb isotopic system.

We obtained concordant baddeleyite U-Pb data corresponding to an age of 1997±11 Ma. (U–Th–Pb SIMS SHRIMP-II, 20 analysis of 11 baddeleyite grains were used.) Isotopic data on the subconcordant zircon-I (first generation) give exhibit 1992±13 Ma crystallization age . U-Pb data on Zircon-II (zircons overgrows on baddeleyite) and essentially discordant zircons-I can be interpreted as a discordia with parameters 2022±22 and 841±42 Ma. These data show, that zircons were not affected at the time of Svecofennian metamorfism (1764±41 Ma), which was find by isotopic data for major rock forming minerals of the Tikshozero rocks (calcite, phlogopite, amphibole), but suffered some loss of radiogenic lead at Neoprotherozoic event.

Selenate sorption onto bacteria-mineral composites during the progressive addition of Fe(II)

R.E. FRANZBLAU[1]*, C.G. WEISENER[1] AND C.J. DAUGHNEY[2]

[1]Great Lakes Institute for Environmental Research, University of Windsor, Windsor, Canada (correspondence: franzbl@uwindsor.ca)
[2]Institute of Geological and Nuclear Sciences, Lower Hutt, New Zealand

This study is focused on sorption interactions between microbes, minerals, and metals. Laboratory experiments were done to determine the fate of dissolved selenate (SeO_4^{2-}) and Fe at pH 4 during the addition and oxidation of Fe(II) and the subsequent precipitation of iron oxides in the presence of *Escherichia coli*. The experimental results suggest that selenate does not sorb to *E. coli* surfaces, in addition the presence of selenate does not affect iron oxide precipitation. In fact the presence of bacterial cells appear to influence and delay oxidation of Fe(II) and iron oxide precipitation in a mineral-bacteria composite system. In a composite system the bacterial cells also inhibit selenate adsorption onto iron oxide surfaces. Surface complexation models were used to describe the experimental data. This study is the first to show and provide a detailed understanding of metal oxyanion sorption between bacterial cells and minerals as prior studies have focused on metal cation sorption [1,2,3].

Retention of selenate at the water-mineral interface in the context of salt dome repositories

C. FRANZEN[1*], D. HERING[2] AND N. JORDAN[1]

[1]Helmholtz-Zentrum Dresden-Rossendorf, Institute of Resource Ecology, Dresden, Germany (*:c.franzen@hzdr.de)
[2]University of Applied Sciences, Zittau-Görlitz, Germany

One major process controlling the mobility and bioavailability of selenium, a long-lived fission product found in nuclear waste, is the adsorption onto mineral surfaces of both the engineered and geological barrier. In this context, it is important to understand to what extent this sorption is influenced particularly by characteristic parameters as expected in deep underground repositories for high level and long-lived radioactive waste. These parameters include inter alia the presence of different background salts which are important with regard to salt domes as potential repositories.

In the present study, a combination of macroscopic sorption experiments, electrophoretic mobility and in-situ ATR FT-IR spectroscopy measurements was used to study the interaction of selenate with aged γ-Al_2O_3 in the presence of NaCl and $MgCl_2$. From in-situ ATR FT-IR spectra, a change in the symmetry of the aqueous tetrahedral selenate anion can be derived evidencing the formation of a surface complex on γ-Al_2O_3. From batch experiments, we observe a dependence of selenate sorption on the ionic strength and composition of the electrolyte. Additionally, the sorption generally decreases with increasing pH. However, in the presence of 0.1 M $MgCl_2$, the sorption increased again at a pH above 9.5.

The isoelectric point (pH_{IEP}) of γ-Al_2O_3 is located at pH 9.6 for low NaCl background electrolyte concentration (I = 0.1 M). The increase of ionic strength (up to I = 1 M) results in a decrease of the zeta potential for both the acidic and alkaline pH range. However, in the alkaline range the decrease of the zeta potential is more pronounced. Additionally, we observe that the pH_{IEP} is shifted to more alkaline values and finally no charge reversal is observed. In the presence 0.1 M $MgCl_2$, the surface charge of γ-Al_2O_3 is positive throughout the studied pH range (3-11). Above pH 10, a sharp potential decrease occurs due to $Mg(OH)_2$ precipitation. The impact of the varied parameters on the sorption of selenate in the alkaline pH range will be verified in detail.

Saprolites on- and offshore Norway: New constraints on formation processes and age

O. FREDIN[1,2], H. ZWINGMANN[3], J. KNIES[1], R. SØRLIE[4], E.M. GRANDAL[4], J.-E. LIE[4], A. MÜLLER[1] AND C. VOGT[5]

[4]University of Bremen, D-28359 Bremen, Germany

The origin of landscapes in Scandinavia has been debated for more than a century and the discussion is as vigorous as ever today. In short, one school proposes that most of the geomorphology can be explained by glacial and periglacial processes, while others argue that the landscape partly is inherited from earlier etching, stripping and exhumation episodes, and has been preserved through cover of sedimentary rocks and selective glacial erosion. One key argument used by the latter proponents is the relatively widespread occurrences of saprolite in Scandinavia. Here we attempt to characterize and date these saprolites both on- and offshore Norway.

One key locality is the Utsira high, which is an offshore crystalline basement horst in the Norwegian North Sea partly overlain by Paleozoic and Mesozoic strata. The area has received significant attention recently due to large petroleum finds, specifically the Edvard Grieg (16/1-8, 2007), the Johan Sverdrup (16/2-6, 2010) and the Luno 2 (16/4-6 S 2013) discoveries done by Lundin Norway.

Significant areas of the Utsira high basement appear to be deeply weathered and saprolite is found in exploration wells. We utilize K-Ar dating of illite diagenesis and geochemical analysis of the saprolite to characterize weathering age and processes. The data suggest deep weathering of a granitic landscape during late Triassic, followed by a transgression and deposition of sedimentary strata. The K-Ar data thus agrees with the stratigragraphic position of Utsira high saprolite below Jurassic sediments.

Our hypothesis is that the similar landscape and saprolite onshore Scandinavia is of similar origin and age as the offshore equivalent. Preliminary onshore data are inconclusive but more testing will be made.

Simulating Macromolecule Behaviour on Calcite Surfaces

Large molecular interactions with mineral surfaces remain complex to understand due to the range of conformations and multiple binding sites. Yet these molecules are vital for a large range of systems including biomineralisation, biomimetics, and cellular adhesion. Therefore it is key to understand how larger molecules behave at these interfaces.

In this presentation we explore how poly-acrylic acid (PAA) as an analogue of many biological molecules interacts with calcite surfaces. Modelling this binding with atomic scale processes is difficult due to the vast range of conformations that must be considered. We are able to model a PAA molecule of 28 monomers in a variety of conformations via the use of novel metadynamics methods and determine how the surface influences the conformation. By studying the system at a range of pHs we make comparison to experimental studies in solution and at the surface on different calcite particles. The results provide insights into how highly charged large molecules interact with these surfaces and how the structure of the molecule influences this behaviour.

The Use of Fe-Rich Compost for the Amelioration of As-Contaminated Soils

P. FREEZE*, J. HARSH, Z. SHI, R. ABI-GHANEM AND P. OKUBARA

[1] Washington State Univ., Pullman, WA 99164-6420, USA (*correspondence: patrick.freeze@wsu.edu; harsh@wsu.edu; zhenqing.shi@wsu.edu; rita_ag@wsu.edu; pokubara@wsu.edu)

Arsenic (As), a biologically harmful metal, occurs in soil as a result of lead-arsenate pesticide application, smelting, and natural occurrence. Human exposure occurs via plant uptake, dust inhalation, soil ingestion, and drinking water consumption. Heavy metal loads in urban storm-water runoff are the second most common source of lake water pollution nationwide [1]. High Fe biosolids can reduce bioavailable soil As by providing sorption sites that presumably include Fe-(hydr)oxide particles and ternary complexes with organic-FeOH functional groups [2][3] [4]. In this study, we determined (1) the adsorption, retention, and stability of As reacted with Fe-compost, (2) the model for As adsorption on iron oxides, and (3) the compost microbial community as a function of Fe content. Plating and real-time PCR showed the impact of the various iron treatments on isolated microbial species. The sustainable methods and tools utilized in this bioremedial approach to rectifying soil contamination will use organic waste, mitigate the impacts of urban development and subsequent metal loading from storm-water runoff, and ultimately improve soil quality.

Imogolite: An ideal mineralogical substrate for the prebiotic assembly of long polynucleotides?

JASON E. FRENCH[1]*

[1]Department of Earth and Atmospheric Sciences, University of Alberta, 1-26 ESB, Edmonton AB, Canada T6G 2E3 (*correspondence: jef@ualberta.ca)

Imogolite ($HOSiO_3Al_2(OH)_3$)—a key weathering product of volcanic glass/ash—is unique among clay minerals, having the same diameter (20 Å) and long, flexible, filamentous nature as double-stranded DNA [1, 2], a nanotube structure, and a strong affinity for PO_4^{3-} adsorption, which takes place at positively charged AlOH groups on tube exteriors [2–4]. Here I propose that these chemical/morphological traits make imogolite an interesting candidate substrate for the prebiotic assembly of DNA/RNA (i.e., long polynucleotides), and that the free O^- of each phosphate group along the DNA/RNA backbones could represent relict detachment sites left over after the decoupling of single-stranded DNA/RNA from imogolite (Fig. 1d). New evidence to support this idea comes from the recent synthesis of imogolite/DNA hybrid hydrogels, which seem to form by interactions between AlOH groups on imogolite and phosphate groups in DNA [2]. Authigenic imogolite filaments have recently been found within microbe-sized, alpha-recoil track etch-tunnels at the glass-palagonite interface in submarine glasses (Fig. 1; [1]), and so these C- and P-rich 'abiotic' etch-tunnels are a fascinating new analog geological site to consider for the origin of life on Earth.

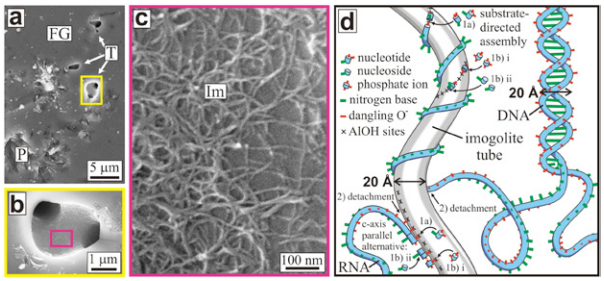

Figure 1: (a–c) SEM images of imogolite and etch-tunnels in DSDP-418A-75-3[120-123] basaltic glass. d) Hypothesis for the prebiotic assembly of DNA/RNA onto imogolite. FG – fresh glass; Im – imogolite; P – palagonite; T – etch-tunnel.

Archean hydrocarbon biomarkers: Archean or not?

K.L. FRENCH[1*], C. HALLMANN[2], J.M. HOPE[3], R. BUICK[4], J.J. BROCKS[3] AND R.E. SUMMONS[1]

[1]MIT, Cambridge, MA, USA; *(correspondence: klfrench@mit.edu; rsummons@mit.edu)
[2]MPI, Jena, Germany; challmann@bgc-jena.mpg.de
[3]ANU, Canberra, Australia; janetm.hope@anu.edu.au; (jochen.brocks@anu.edu.au)
[4]UW, Seattle, WA, USA;(buick@u.washington.edu)

Understanding the origin of oxygenic photosynthesis relative to the Great Oxygenation Event (GOE) is one of the key goals in geobiology today. Archean organic biomarkers provide evidence for oxygenic photosynthesis and eukaryotes predating the GOE [e.g. 1, 2]. However, these results have been challenged and remain controversial [e.g. 3]. Resolving the controversy about the syngeneity of these compounds with their Archean host rock will clarify our understanding of the antiquity of oxygenesis and aerobiosis.

Samples were collected from three diamond drill holes in the Australian Pilbara according to unprecedented protocols during the 2012 Agouron Institute Drilling Program (AIDP). Molecular spikes, tracer experiments, negative controls, and replicate analyses of duplicate samples by multiple independent laboratories were used to constrain results.

To date, a total of seven "biomarker target" samples have been analysed from the AIDP-2 core near Ripon Hills, which intersected the Carawine and Jeerinah Formations, and the AIDP-3 core between Tom Price and Karratha, which intersected the Marra Mamba and Jeerinah Formations. Alkanes, hopanes, and steranes appear to be below detection from the interiors and exteriors of these seven samples. However, multiple samples from the Carawine Formation contain polycyclic aromatic hydrocarbons (PAHs) and diamondoids. These molecules may represent the oldest reported authigenic hydrocarbons, yet the origin of these molecules is uncertain. Replicate analyses of exact duplicate samples by additional organic geochemical laboratories will test the robustness of these current results. Interestingly, analysis of an RHDH2A drill core sample from the Carawine Formation recovered in the 1980s revealed an abundance of hydrocarbons that were absent in the new AIDP-2 Carawine Formation drill core material, suggesting contaminants were introduced during drilling, sampling, sawing, and/or storage.

REE and Neodymium isotopes in sedimentary organic matter

FRESLON N.*[1], BAYON G.[1], TOUCANNE S.[1], BERMELL S.[1], BOLLINGER C.[2], CHERON S.[1], ETOUBLEAU J.[1], GERMAIN Y.[1], KRIPOUNOFF A.[1], PONZEVERA E.[1] AND ROUGET M.L.[2]

[1] IFREMER, F-29280 Plouzané, France
[2] IUEM, CNRS UMS 3113, F-29280 Plouzané, France (*correspondence: nicolas.freslon@ifremer.fr)

Sedimentary Organic Matter (OM) collected from various depositional environments, i.e. rivers (n=25), estuaries (n=18), ocean (n=15), and cold seeps (n=12), was extracted using a mixed hydrogen peroxide/nitric acid solution, after removal of carbonate and oxy-hydroxide phases with dilute hydrochloric acid.

Our results indicate that the abundance of REE in sedimentary OM is six-to-seven orders of magnitude higher than in river water or seawater. The mean REE concentration in the H_2O_2 leachates for samples from rivers, estuaries, coastal seas and open ocean is relatively similar: ΣREE = 107 ± 89 ppm (mean ± s). In comparison, the OM fractions leached from cold seep sediments display higher concentration levels (285 ± 150 ppm). The H_2O_2 leachates for most sediments exhibit remarkably similar shale-normalized REE patterns, all characterized by a mid-REE enrichment compared to the other REE. This suggests that the distribution of REE in leached sedimentary organic phases is controlled primarily by (bio) geochemical processes (i.e. complexation), rather than by the composition of the source from which they derive (e.g. pore water, river or seawater).

The Nd isotopic compositions for OM leached from river sediments are very similar to those for the corresponding detrital fractions. In contrast, OM extracted from marine sediments display εNd values that typically range between the εNd signatures for terrestrial OM (inferred from the analysis of the detrital fractions) and marine OM (inferred from the analysis of local surface seawater). An interesting exception is the case of cold seeps OM leachates, which sometimes exhibit εNd values markedly different from both terrigenous and surface seawater signatures. This suggests that a significant organic fraction in these environments may be derived from chemosynthetic processes recycling pore water REE characterized by a distinct isotopic composition.

Overall, our results suggest that organic matter probably play an important role in the oceanic REE budget, through direct scavenging or remineralization within the water column. In addition, the use of Nd isotopes in sedimnetary OM phases could offer interesting future applications in paleoenvironmental studies.

Crustal evolution and petrogenesis of silicic plutonic rocks within the Oman ophiolite – petrological and geochemical investigations

SARAH FREUND[1*], MARTIN ERDMANN[2], JÜRGEN KOEPKE[2], FOLKMAR HAUFF[3] AND KARSTEN M. HAASE[1]

[1]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Germany, (*correspondence: sarah.freund@fau.de)
[2]Leibniz University Hannover, Germany
[3]GEOMAR Helmholtz Centre Kiel, Germany

Silicic (56-79 wt. SiO_2) plutonics from mantle and crustal (plagiogranites s.l.) sections of the Oman ophiolite suggest multiple petrogenetic processes during the accretion of the Oman paleocrust at a fast-spreading ridge system, affecting major and trace elements as well as radiogenic isotopes. The mantle granites are distinctly enriched in SiO_2, K_2O, Ni and Cr but depleted in Al_2O_3, FeO, CaO and TiO_2 for a given MgO content compared to silicic crustal rocks. The mineral assemblage differs because biotite, alkalifeldspar and opaqes occur in the mantle granites but are absent in comparable crustal rocks. Trace elements display high LILE, Nb, Ta and LREE contents in the silicic plutonic mantle rocks along with an increasing depletion of middle toward the HREE relative to the crustal plagiogranites. In contrast, the silicic crustal rocks are enriched in Hf, Zr and Y compared to their mantle counterparts. Furthermore, the crustal plagiogranites display a MORB-like range in Hf and Nd isotope compositions but with slightly higher $^{87}Sr/^{86}Sr$, similar to their mafic host-rocks, whereas the mantle granites possess distinctly lower εHf, negative εNd values and in most cases very high Sr isotope ratios. We suggest formation of the silicic crustal intrusives by fractional crystallization and crustal partial melting processes during Oman ocean crust formation whereas the mantle granites are most likely related to subduction or obduction processes and thus must be younger.

TRACE: A multi-tracer analysis of shallow aquifers to improve geothermal potential assessment

F. FREUNDT[1]*, S. AL NAJEM[2], W. AESCHBACH-HERTIG[1], M. ISENBECK-SCHRÖTER[2], B. KOBER[2], M. KRAML[3], R. GROBE[3] AND A. WENKE[4]

[1] Institute of Environmental Physics, Heidelberg University, 69120 Heidelberg, Germany (*corr: ffreundt@iup.uni-heidelberg.de)
[2] Institute of Earth Sciences, Heidelberg University, 69120 Heidelberg, Germany
[3] GeoThermal Engineering GmbH, 76133 Karlsruhe, Germany
[4] Statoil ASA Nord-Norge, Molnholtet 42, 9414 Harstad, Norway

The assessment of geothermal potential for deep geothermal energy production currently relies on expensive 3D reflexion seismic methods to identify adequate fault zones and geometry of the geothermal aquifer. However, this analysis does not allow the estimation of hydraulic permeability of active faults nor provides a characterisation of the chemical properties of the deep aquifer fluid. Both factors play an important role in optimising siting of fault related geothermal wells and operation of geothermal power plants.

The TRACE project aims to combine methods from hydrogeochemistry and isotope hydrology in the analysis of shallow groundwater to develop a low cost method for deep geothermal energy exploration. The main goal is to constrain the interest area with further methods supporting geophysical exploration methods. The approach introduced in this contribution includes the measurement and evaluation of a wide range of natural isotopic and geochemical. To assess the fault permeability, the groundwater $^3He/^4He$ ratio will be analysed for mantle signatures pointing to deep water circulation and upward flux [1]. The hydrogeochemical analysis and transport modeling will be used to characterise the origin and flow path of the thermal water [2] and to assess its suitability for industrial scale energy production.

The Upper Rhine Graben was chosen as the project's study region, focusing on three different local areas with preexisting well and 2D/3D seismic data to allow for comparison and validation of the study results. Preliminary results from the first sampling campaign show promising data, indicating an area of increased interest where elevated helium ratios coincide with characteristic geochemical data, fault location and a previously known saltwater anomaly.

Microbial-soil organic matter linkages in response to climate warming

S.D. FREY

Department of Natural Resources & the Environement, University of New Hampshire, Durham, NH 03824 USA (correspondence: serita.frey@unh.edu)

Soils are the largest repository of organic carbon in the terrestrial biosphere and represent an important source of CO_2 to the atmosphere, releasing 60-75 Pg C annually through microbial decomposition of organic materials [1, 2]. Current carbon-climate models predict increased soil organic matter decomposition as global climate warms, with higher than normal soil CO_2 fluxes to the atmosphere eliciting a positive feedback to climate [3, 4]. However, results from several field studies demonstrate that while soil respiration is initially stimulated by warming, this effect often diminishes over time, with elevated soil respiration in chronically warmed soils returning to ambient levels within a few years [5, 6, 7]. Microbial decomposition of soil organic matter is responsible for as much as half or more of the CO_2 released from soils [1], and so a thorough understanding of how soil microorganisms respond to temperature is needed to accurately predict how climate warming may alter soil CO_2 fluxes [8]. This talk will synthesize data on microbial responses to climate warming, with an emphasis on microbial physiology as a driver of soil organic matter dynamics [9].

Mass-related U isotope fractionation during alteration of oceanic crust and release of U in subduction zones – implications for deep recycling of oceanic crust

HEYE FREYMUTH[1], MORTEN ANDERSEN[2] AND TIM ELLIOTT[1]

[1]Bristol Isotope Group, University of Bristol, Queen's Road, Bristol BS8 1RJ, UK (glxhf@bristol.ac.uk)
[2]ETH Zürich, Inst. f. Geochemie und Petrologie, Clausiusstrasse 25, 8092 Zürich

The modification of material during seafloor alteration and subsequent processing within subduction zones is of primary importance for assessing the composition of deeply subducted material and it's influence on mantle heterogeneity. It has long been known that U is added to the oceanic crust during both low and high temperature alteration of the oceanic crust, whilst some of the subducted inventory of U is returned to the surface in arc lavas. The advent of techniques to measure mass-related $^{238}U/^{235}U$ isotope fractionation with sufficient precision allows us to investigate the effect of alteration and subduction zones processes on the isotopic composition of U. This is a key step in evaluating the potential of U isotope measurements to trace deep crustal recycling. Thus we have measured the U isotopic compositions of samples from the altered, mafic, oceanic crust (AOC) at ODP site 801 as well as lavas erupted at the volcanic front of the Mariana arc. The former represents a reference site for studying the time-integrated influence of seafloor alteration and the latter constitute a well characterised sample set for which the role of slab-derived 'fluid' and sediment components can be separately recognised.

The altered oceanic crust is compositionally variable with $^{238}U/^{235}U$ similar to seawater in the top ~100 m and isotopically heavier in deeper parts. These differences are likely to be caused by oxidizing conditions in the top part of the AOC and reducing conditions in deeper parts of the AOC and isotopic fractionation occurring during the alteration of the oceanic crust. The Mariana arc lavas span a range of ~100 pm in $^{238}U/^{235}U$ and vary systematically between seawater-like compositions in samples that have been previously identified as 'fluid-rich' and heavier values similar to fresh mantle basalts in the more sediment-rich samples. These systematics indicate that either the light U in the upper mafic crust is preferentially lost to the arc lavas or that during slab dehydration of the AOC, U is fractionated to generate an isotopically light fluid and heavy residue. In either scenario the deep-subducted material is left distinctively, isotopically heavy and should be an effective tracer of deep recycled material.

Dynamics of sulfur degassing in alkaline magmas illustrated with melt and fluid inclusions

MARIA LUCE FREZZOTTI[1] AND FRANCESCA TECCE[2]

[1]Dept. Earth and Enironmental Sciences, University Milano Bicocca, Italy (maria.frezzotti@unimib.it)
[2]Istituto di Geologia ambientale e Geoingegneria, CNR Roma, Italy (francesca.tecce@cnr.it)

The dynamics of sulfur transfer into the magmatic fluid phase in a long-lived shallow magma reservoir has been investigated using melt and fluid inclusions in syenite xenoliths from the Sabatini K-rich volcanic complex (0.8-0.04 Ma; Roman magmatic province, Italy). Silicate melt inclusions (MI; up to 100 μm) in clinopyroxene and in sanidine have compositions in the phonotephrite-phonolite-trachyte spectrum, similar to erupted rocks. MI in sanidine argue convincingly that the pre-eruptive alkaline melt was oversaturated with respect to a sulfate-rich melt phase, and to a vapor-rich aqueous phase. Most MI show a large bubble/glass ratio and contain several pinkish-yellowish globules (1-5 μm), rich in SO_3 (6-7 wt %), SiO_2, Al_2O_3, alkalis, and CaO. Raman spectroscopy of globules reveals an alkali-silicate glass structure containing oxysulfur species dominantly as SO_4^{2-}, with subordinate CO_3^{2+} groups, and absence of S-S bonds. Magmatic vapor-rich brine inclusions have a microthermometric behavior consistent with the presence of up to 25 wt% sulfate in solution. Sulfur species in liquid water include an hydrated double alkali-Ca sulphate ± anhydrite, $(SO_4)^{2-}$ and $(HSO_4)^{-}$ ions, and SO_2; CO_2 is detected in the inclusion bubble.

This case study suggests that during crystallization, sulfur supersaturation in oxidized alkaline magmas induces liquid immiscibility between silicate and sulfate melts. At these pre-eruptive stages, significant amounts of S partition as SO_2 and SO_3 (or H_2SO_4) in magmatic aqueous-rich fluids.

Isotopic constraints for sources and sinks of NO_x in the city of Berlin

M.FRIEBEL[1] AND U. WIECHERT[1]

[1]Freie Universität Berlin; Germany
(*correspondance: mfriebel@zedat.fu-berlin.de)

Atmospheric NO_x causes various problems in urban environments such as tropospheric ozone production and the formation of secondary aerosols. The isotopic composition of atmospheric nitrates can help to identify the sources of NO_x ($\delta^{15}N$) [e.g. 1] and to understand its reaction pathways and sinks in the atmosphere ($\delta^{18}O$) [e.g. 2].

Here, we report the results of isotopic measurements of nitrates from precipitation collected during single storm events in Berlin between March 2007 and January 2008. $\delta^{15}N_{NO3}$ ranges from -11.6 to +2.0; mean = -4.5 (relative to AIR) and $\delta^{18}O_{NO3}$ values range between +8.9 and +67.2; mean = +32.6 (relative to V-SMOW). The $\delta^{15}N$ values show a high variation between each rain event and can be separated into groups with values of -4.3 to +2.0 (mean = -1.2) and -11.6 to -5.1 (mean = -8.0). The $\delta^{18}O_{NO3}$ values show a bimodal distribution with one maxima in June-July 2007 and the second in January 2008. The measured $\delta^{18}O$ values are low, especially during the spring of 2007 (+8.9 to +23.4), compared to those reported in other studies [e.g. 2].

The nature of the observed isotopic variations is complex. More positive $\delta^{15}N_{NO3}$ values may represent NO_x originating from fossil fuel combustion (mostly fuel NO_x) and more negative $\delta^{15}N_{NO3}$ values may be related to volatilization of nitrogen compounds from fertilized soils. This variation in the $\delta^{15}N_{NO3}$ values could be associated with long distance transport of air masses from different source regions, since the lifetime of NO_x is approximately one day [e.g. 3] and its deposition as nitrate (residence time of 1-2 days [e.g. 3]) can be hundreds of kilometres from the nitrogen source. $\delta^{18}O_{NO3}$ serves as a fingerprint for the reaction pathways of NO_x to nitrate. High $\delta^{18}O$ values are consistent with a high proportion of NO_x oxidised by ozone, whereas low $\delta^{18}O$ values indicate preferential oxidisation by peroxy and/or OH radicals [e.g. 2]. The results show that isotope ratios of atmospheric nitrates contribute important constraints in conjunction with local concentration measurements and storm track information on the sources and fate of tropospheric NO_x and O_3 and their dynamics in the urban environment of Berlin.

Tracing weathering and reverse weathering in floodplains using Si isotopes and Ge/Si ratios

PATRICK J. FRINGS[1]*, ERIC STRUYF[2], WILLIAM GRAY[3], CHRISTINA DE LA ROCHA[4], ROGER MORMUL[5], PABLO URRUTIA[6], SARA EKSTRÖM[6] AND DANIEL J. CONLEY[1]

[1]Department of Geology, Lund University, Sweden (*correspondence: patrick.frings@geol.lu.se)
[2]Biology Department, Antwerp University, Belgium
[3]Department of Geography, University College London, UK
[4]Institut Universitaire Européen de la Mer, Brest, France
[5]Universidade Estadual de Maringa, Brazil
[6]Aquatic Ecology Unit, Lund University, Sweden

The role of high mountainous areas as the loci of the majority of chemical weathering (i.e. CO_2 consumption) is ambiguous due to their relatively minor surface area. Low relief areas, including floodplains, are increasingly recognised as important for river weathering flux formation, based on e.g. studies that consider longitudinal changes in water chemistry and/or suspended particulate matter composition as large rivers cross their floodplains. The integrated signals imply aging of sediment in floodplains. But in some cases, floodplains may alter weathering fluxes through chemical sedimentation, i.e. removal of elements from solution.

To directly investigate the processes occurring, we analysed material from field campaigns in two tropical floodplains – a cross-floodplain borehole survey of the upper Paraná in southern Brazil and a longitudinal survey of the terminal wetlands of the Okavango River in northern Botswana. We focus on tracing biological and weathering processes with the isotopes of Si and with Ge/Si ratios, interpreting Ge as a 'pseudoisotope' of Si. We analysed these, together with major and trace element concentrations, for surface water, groundwater/porewater, separated sediment fractions and aboveground vegetation.

In the Paraná, mobile elements are enriched downcore - the older sediments have accumulated e.g. K, Ca and Mg. $\delta^{30}Si$ of floodplain groundwaters is enriched by up to 1‰ relative to river water, implying in situ formation of a lighter phase. In the Okavango, observed changes in water chemistry and a $\delta^{30}Si$ decrease (~0.6‰) in dissolved Si can be interpreted as weathering of isotopically light primary and/or secondary minerals, or as intense biological recycling. Conversely, the surface water geochemistry suggests an elemental (K, Ca, Mg) sink via mineral authigenesis.

Our data suggest large floodplains are areas of both weathering and reverse weathering, adding complexity to our emerging understanding of floodplain weathering dynamics.

Mineralogical pathways involved in the formation of hydrous Mg/Ni silicate ores (New Caledonia)

New Caledonia hosts one of the biggest Ni-laterite deposits in the world. Highest Ni grades are related to hydrous Mg/Ni silicate ores [1], which are best preserved at depth along serpentinized faults in the saprock. Despite their importance, the mechanisms involved in the formation of the Ni silicate ores (garnierites) are still a matter of debate.

Series of fracture-controlled clay and silica infillings were investigated by optical and electron microscopy, Raman spectroscopy, X-ray diffraction and electron microprobe analyses. The first infilling stage consists of residual well-crystallized ophiolitic serpentines intimately mixed with poorly ordered serpentine-like and talc-like minerals. Talc-like minerals predominate in a second stage of infillings whereas quartz druses prevail in the ultimate infilling stage. Two crystal-chemistry pathways are attributed to the early redistribution of Ni and differentiation of white and greenish patched along the reactivated faults. In the white Ni-free deweylites, the compositional variation of clay minerals is distributed along a mixing line between Mg end-members of the serpentine-like (α-kerolite) and talc-like (β-kerolite) minerals. In the greenish patches of Ni-rich garnierites, it is distributed along a second mixing line between an Mg end-member of serpentine-like minerals and a Ni end-member of talc-like minerals (pimelite). Our results then evidence a multistage leaching of Mg and increase of the Ni and Si activities of the infilling solutions during post-obducted tectonic pulls, in agremment with a recent thermodynamic study [2].

U-Pb zircon ages from granites in the Iapetus Suture Zone in Ireland and the Isle of Man

TOBIAS FRITSCHLE[1], J. STEPHEN DALY[1], MARTIN J. WHITEHOUSE[2], BRIAN MCCONNELL[3] AND STEPHAN BUHRE[4]

[1]UCD School of Geological Sciences, Belfield, Dublin 4, Ireland (tobi.fritschle@gmx.de, stephen.daly@ucd.ie)
[2]Laboratory for Isotope Geology, Swedish Museum of Natural History, Stockholm, Sweden (martin.whitehouse@nrm.se)
[3]Geological Survey Ireland, Beggar's Bush, Dublin 4, Ireland (brian.mcconnell@gsi.ie)
[4]Institut für Geowissenschaften, Johannes Gutenberg-Universität, Mainz, Germany

Late Caledonian syn- to post-orogenic granites located in the Iapetus Suture Zone (ISZ) in Ireland and Britain have been related to A-type subduction and possible slab breakoff following the Laurentia-Avalonian collision. Lack of reliable age data (especially in Ireland) has inhibited petrogenetic investigations of these rocks. Hence, ion microprobe U-Pb analyses on zircons from Irish and Isle of Man granites have been undertaken to provide better constraints on this episode of the Caledonian orogeny.

Three stages of granitic magmatism (c. 428, 417, 397 Ma) are indicated by U-Pb dating of oscillatory-zoned magmatic zircons. The Crossdoney, Kentstown, Drogheda, Ballynamuddagh and Dhoon granites together with a rhyolite from Glenamaddy have yielded U-Pb concordia ages, interpreted as intrusion-ages, between 419.1±2.4 Ma (Ballynamuddagh) and 415.6±2.5 Ma (Dhoon) with a weighted average of 417.2±1.7 Ma (MSWD = 1.3). The Foxdale Granite and a sample from the Rockabill Granite yielded younger ages of c. 397 Ma, whereas another Rockabill sample yielded an older concordia age of 427.7±3.4 Ma.

Inherited zircons (487 to 453 Ma) occur in all three age groups, and are interpreted to have been derived from Ordovician arc magmatic rocks accreted within the ISZ. A younger group of c. 440 Ma inherited zircons occurs in the c. 417 Ma Crossdoney and Ballynamuddagh granites. These grains could be related to continued or renewed Silurian arc magmatism.

Granites in the 417 Ma age group are the most 'primitive', being metaluminous with high Mg# and low Ti, Cr, Ba and Sr concentrations, and are mineralogically I-Type, consistent with a major contribution from older arc sources. Relatively few analyses are available but granites of the 428 and 397 Ma age groups have some characteristics of S-type granites, consistent with predominantly sedimentary source rocks or contaminants.

Experimental efforts to understand deep mantle melting

D.J. FROST[1], D. NOVELLA[1], R. MYHILL[1], C. LIEBSKE[2], AND R.G. TRØNNES[3]

[1] Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany
[2]Institute for Geochemistry and Petrology, ETH, Zürich, Switzerland
[3]Centre for Earth Evolution and Dynamics (CEED) and Natural History Museum, University of Oslo, Norway

There is evidence from seismology and from metasomatised mantle xenoliths for the presence of melting in the mantle at depths significantly greater than 50 km. At the very base of the mantle the detection of ultra low shear wave velocities may indicate melting due to the thermal boundary layer at the core mantle boundary, or may be evidence for chemical heterogeneity at the base of the mantle. On the other hand, melts that modify the roots of cratonic continental lithosphere arise from the presence of volatiles in the deep mantle. Understanding the implications and consequences of such melting requires the ability to determine the compositions and temperatures at which melting occurs under pressure.

We have performed experiments to examine simple melting relations in the systems MgO-FeO-SiO_2 and examined the effects of H_2O, CO_2 and other components on the depression of melting temperatures. The relatively simple phase relations are amenable to the thermodynamic treatment of silicate melts, which can be used to then extrapolate melting relations over much wider ranges of pressure and temperature. In addition by modelling experimental data some idea of the mechanisms by which components are incorporated in melts can be gained.

We show that melting relations of bulk silicate earth compositions at high pressure can be well described on the basis of phase relations of a simple ternary at high pressures. These results can be used to examine a partial melt origin for the existence of low shear wave velocities at the core-mantle boundary. Models for the effect of volatiles on melting relations are used to examine how melt fractions will vary throughout the upper mantle as a function of bulk volatile concentration.

The stability of carbonate melt in eclogite rocks with respect to oxygen fugacity

D.J. FROST[1], V. STAGNO[2], C.A. MCCAMMON[1] AND Y. FEI[2]

[1] Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany
[2]Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC, USA.

The redox relationship between carbon and iron species in eclogitic rocks is important for the earth's internal carbon cycle and the formation of diamond. Using a sliding Fe-Ir redox sensor the oxygen fugacity at which carbonate melts are reduced to either graphite or diamond was measured in eclogitic rock compositions. Multianvil experiments were performed between 3 and 6 GPa and temperatures between 1000-1300°C. The oxygen fugacity corresponding to the equilibrium between graphite/diamond and carbonate melt was determined. Oxygen fugacities normalized to the FMQ buffer were found to decrease with temperature, most likely as a result of dilution of the carbonate liquid with silicate as temperatures increase. In contrast to previous arguments, the carbonate melt stability field was found to extend to lower oxygen fugacity in eclogitic rocks compared to peridotite rocks.

The same set of carbonated eclogite experiments also contained monomineralic layers of clinopyroxene and garnet that allowed the ferric Fe contents of these minerals to be measured using Mössbauer spectroscopy. A relatively simple model was derived for determining the oxygen fugacity of eclogitic rocks from the compositions of garnet and clinopyroxene coupled with determinations of the garnet ferric Fe content. The model was able to reproduce the experimental data to within 0.5 log units. The equilibrium was used to estimate the oxygen fugacity of eclogitic xenoliths from the Siberian and Kaapvaal cratons. These rocks were found to record ranges of oxygen fugacity that are very similar to those recorded by peridotite xenoliths from the same localities. By assuming a typical bulk ferric Fe content of oceanic crust, we calculate that subducting eclogitic rocks would remain in the carbonate stability field until depths of at least 300 km. Ferric iron contents of cratonic eclogites appear to be lower than would be expected if they are sections of subducted oceanic crust.

Rate dependence of $^{44}Ca/^{40}Ca$ fractionation during inorganic aragonite precipitation from seawater

FRUCHTER, N.[1], EISENHAUER, A[1]., DIETZEL, M.[2], EREZ, J.[3], BOEHM, F.[1], FIETZKE, J.[1] AND NIEDERMAYR, A.[4]

[1]GEOMAR, Helmholtz Centre for Ocean Research Kiel, Kiel, Germany.
[2]Institute for Applied Geosciences, Graz University of Technology, Graz, Austria.
[3]The Hebrew University of Jerusalem, Jerusalem, Israel.
[4]Ruhr University of Bochum, Bochum, Germany.

In order to examine the relationship of Ca isotope fractionation and precipitation rate for inorganic aragonite formation a set of lab experiments were conducted. Therefore the CO_2 diffusion rate technique was applied (*1*) using natural seawater (sw). The range of precipitation rates (R = 40-4700 μmol·h^{-1}) was achieved using different initial carbonate ion concentrations (130-1080 μmol/kg sw) at temperatures of 15, 25 and 30°C.

We measured $\delta^{44/40}Ca$ of sw and the inorganic aragonite on a TIMS (TRITON, ThermoFisher) using the $^{43}Ca/^{48}Ca$ double spike method (*2*). In accordance with results for inorganic aragonite in diluted aqueous solutions (*3*) our data show that $^{44}Ca/^{40}Ca$ fractionation in aragonite is positively correlated to precipitation rates. Thus no significant difference in $^{44}Ca/^{40}Ca$ fractionation due to different salinities is observed.

The impact of precipitation rate on Ca isotope fractionation during aragonite formation is similar to observations in calcite by (*4*), but opposite to experimental studies and modelling results for calcite by (*5*) (*6*). Possible mechanisms for the discrepant behaviour of Ca isotope fractionation in calcite and in aragonite are discussed.

Experimental research on isotope effects in photodissociation of O_3

MARION FRÜCHTL[1], CHRISTOF JANSSEN[2] AND THOMAS RÖCKMANN[1]

[1]Institute for Marine and Atmospheric Research Utrecht, Princetonplein 5, 3584 CC Utrecht, The Netherlands (m.fruechtl@uu.nl, t.roeckmann@uu.nl)

[2]Laboratoire de Physique Moleculaire pour l'Atmosphere et l'Astrophysique, 4 Place Jussieu, 75005 Paris, France (christof.janssen@upmc.fr)

Ozone (O_3) has a strong influence on the radiative balance and chemical processes in the Earth's atmosphere and also exhibits a very peculiar isotopic composition. It is highly enriched in both ^{17}O and ^{18}O and shows a clear offset from the mass dependent fractionation line (quantified as $\Delta^{17}O = \delta^{17}O - 0.52 * \delta^{18}O$), i.e. it possesses excess ^{17}O over what is expected based on ^{18}O abundances. The O_3 formation reaction is the most prominent example for a reaction that leads to the formation of such mass independent isotope compositions. To what degree O_3 destruction reactions contribute to the isotopic anomaly in O_3 is still not fully understood. In particular, it has not been possible to isolate the isotope effects in the photolysis reaction (R1) from the subsequent reaction of O with O_3 (R2). In addition, the three-body recombination reaction (R3) can interfere and complicate interpretation.

(R1) $O_3 + h\upsilon \rightarrow O(^3P) + O_2$

(R2) $O(^3P) + O_3 \rightarrow 2\ O_2$

(R3) $O(^3P) + O_2 + M \rightarrow 2\ O_2 + M$

Within the project INTRAMIF (Initial Training network on Mass-Independent Fractionation) we are investigating the isotope effect resulting from photodissociation of O_3. We attempt to suppress reaction (R2) and (R3) by using carbon monoxide (CO) as bathgas, which reacts with $O(^3P)$ (R4).

(R4) $CO + O(^3P) + M \rightarrow CO_2 + M$

In the experiments, O_3 is produced by electric discharge and exposed to different types of radiation with and without addition of CO. After reaction, the remaining O_3 is collected in a cold trap at the triple point temperature of nitrogen (63K). In order to measure the oxygen isotopes of O_3 using isotope mass spectrometry, O_3 is converted to O_2.

In this presentation we show first results of O_3 photodissociation with visible light, using CO as $O(^3P)$ quencher.

Geochemical Modeling of Glass Alteration in Mg rich ground water

FRUGIER PIERRE[1], JOLLIVET PATRICK[1] AND GODON NICOLE[1]

[1]CEA Marcoule, DEN/DTCD/SECM/LCLT, BP17171 - 30207 Bagnols-sur-Cèze, (pierre.frugier@cea.fr,) (patrick.jollivet@cea.fr,)(nicole.godon@cea.fr.)

Coupling interdiffusion, through a layer passivating the glass surface, with dissolution of this layer has been the objective of a glass alteration model named GRAAL (Glass Reactivity in Allowance for the Alteration Layer) [1]. It has been implemented within the CHESS/HYTEC code. The interesting point is that GRAAL equations handle the nanometer scale interdiffusion phenomena through the passivating layer while the finite-element chemistry-transport code handles the centimeter scale transport through fluids. The model has been applied to many long term batch glass alteration experiments in Mg rich ground waters and various surface areas to solution volume ratios (S/V), following a work initiated in [1, 2]. Magnesium silicate precipitation has been proved to be a significant mechanism sustaining glass alteration. Magnesium silicate also consume hydroxide ions and its apparent solubility increases with the pH decrease. Glass alteration provides not only silica but also hydroxide ions required for magnesium silicate precipitation to go on. The strong coupling at work, visible through pH, Si and Mg variations as a function of time and glass S/V, illustrates the need for a geochemical model. Sensitivity studies on Si/Mg ratio in the magnesium silicate show that a precise knowledge of Si distribution between the depleted gel, the passivating layer, and the magnesium silicate is required for a precise prediction of pH and therefore glass alteration rate.

Precursory Soil Radon Anomalies Related to the Major Earthquakes in Taiwan

*CHING-CHOU FU[1] TSANYAO FRANK YANG[1] TSUNG-KWEI LIU[1] CHENG-HONG CHEN[1] VIVEK WALIA[2] TZU-HUA LAI[3] AND CHI-YEN CHEN[3]

[1]Department of Geoscisences, National Taiwan University, Taiwan (*correspondence: d95224008@ntu.edu.tw, tyyang@ntu.edu.tw, liutk@ntu.edu.tw, chench@ntu.edu.tw)

[2]National Center for Research on Earthquake Engineering, *NAPL*, Taiwan (walia@ncree.narl.org.tw)

[3]Central Geological Survey, *MOEA*, Taiwan (hua@moeacgs.gov.tw, zychen@moeacgs.gov.tw)

Several automatic stations for soil gas monitoring were constructed on sensitive sites at the fault zone of Taiwan. Significant changes in soil-gas radon of four stations were recorded two weeks efore the Jiasian earthquake (Mw = 6.4, March 4, 2010). Recurrent anomalies were observed prior to one week before precede the Wutai earthquake (Mw = 6.4, February 26, 2012) and the Nantou earthquake (Mw = 6.4, March 4, 2010) occurred at more than two stations, respectively.

The main shock occurred at 15-26 km depth, in a relatively low background seismicity rea, in the middle to low crust, implying ductile beneath Central Range. Assuming that stress magnitudes are consistent with the pore-fluid pressure, a high conductivity zone at depth, which is interpreted to transfer the compressional driving force across the brittle-ductile transition, with more efficient stress interconnectivity in the high strain domain. Moreover, variations of soil gas can reflect a change in the stress-strain state of rocks, such as useful tools for earthquake surveillance.

Hence, there is obvious that the soil radon anomalies originated in stress accumulation preceding the major earthquakes. Variations of soil radon at several stations show precursory signals simultaneously that can conduce to expect the approximate location of the impending seismic event with high confidence. Continuous monitoring will allow us to better understand the relationship between soil gas variations and regional crustal stress/strain in the area.

Elemental and Os isotope variations across the K/T boundary in a marine Fe-Mn crust

YAZHOU FU[1*], JIANTANG PENG[1], WENJUN QU[2], RUIZHONG HU[1], XUEFA SHI[3] AND JIEHUA YANG[1]

[1] State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, China ([*]correspondence: fuyazhoucas@gmail.com)

[2] National Research Center of Geoanalysis, Beijing, China

[3] First Institute of Oceanography, State Oceanic Administration, Qingdao,China

Marine Fe-Mn crusts grow slowly and contain distinctive laminar growth layers which have potential to document the evolution of ocean chemistry and major geologic events. The K/T boundary (KTB) is associated with the mass extinctions of terrestrial and marine organisms, most likely caused by a bolide impact or/and the Deccan volcanism. In this study, we explored the elemental and Os isotope variations in successive layers across the KTB in a marine Fe-Mn crust, MP2D06, from Line Seamount in Central Pacific Ocean.

The Fe-Mn crust has been dated using Co flux-based age model and Sr isotope stratigraphy. Then the successive layers samples from the crust spans the time interval from about 58 to 74 Ma were analysed. The element composition was determined along continuous sections of the crust using EPMA and LA-ICP-MS. The $^{187}Os/^{188}Os$ ratios were measured by acid digestion and ID-HR-ICP-MS.

Preliminary data show that the Ir peak does not correspond with the low Pt/Ir and Os/Ir ratios in the sections. This implies that it is difficult to decide the exact location of KTB in the Fe-Mn crust just using the concentration variation of PGE. There is a rapid decrease in $^{187}Os/^{188}Os$ from values 0.683 to 0.336, then followed by an increase to 0.453. The large amplitude Os isotope excursion has distinctive features to help improve the reliability of Os isotope stratigraphy in Fe-Mn crust age determinations. Mass balance estimation indicates that the $^{187}Os/^{188}Os$ minimum across KTB was caused by both bolide impact events and the eruption of the Deccan flood basalts.

This study was supported by NSFC (40803003, 41173020).

Experimental constraints on the magma evolution of the basanite-phonolite series from Cumbre Vieja volcano (La Palma, Canary Islands)

P. FUCHS[1]*, R. ALMEEV[1] AND A. KLÜGEL[2]

[1]Institute of Mineralogy, Leibniz University Hannover, Germany (*p.fuchs@mineralogie.uni-hannover.de)
[2]Geosciences Department, University of Bremen, Germany

Eruptive products of the recent Cumbre Vieja volcano (CV) cover a large spectrum of alkali-rich rocks ranging from basanites to phonolites. A model of the magma plumbing system is largely based on barometric studies of phenocrysts and xenoliths and includes three major intervals of magma stagnation and fractionation at mantle and crustal depths [1]. However, the relative influence of different thermodynamic parameters on phase equilibria is still unknown. We present results of an experimental study aimed for evaluating p-T-aH_2O-fO_2 conditions in the genesis of a basanite-tephrite-phonolite system. High pressure and temperature experiments (700 and 400 MPa; 1000-1175°C) in the presence of H_2O-CO_2 fluid (X_{H2O} varied between 0-1, keeping fO_2 between ~FMQ and FMQ+3.3) were conducted in an internally heated pressure vessel using two natural basanites with 13.7 wt.% and 9 wt.% of MgO, respectively, representing two differentiation stages in the evolution of CV magmas.

The natural phase assemblage (Ol+Cpx+Spl) was reproduced at 700 and 400 MPa, 1150-1100°C and 0.7-2.9 wt.% H_2O in the melt (H_2O^m) for the primitive basanite and at 400 MPa, 1150-1125°C and 2.2-2.7 wt.% H_2O^m for the evolved basanite. Tephritic residual melts were produced by Ol+Cpx+Spl crystallization at 400 and 700 MPa and low H_2O^m (1.4-2.9 wt.%). Phonotephritic melts were generated by Cpx+Ol+Krs+Mt crystallization at 400 MPa, 1075-1100°C and 0.7-3.1 wt.% H_2O^m. Tephriphonolitic melts were produced by Cpx+Pl+Krs-Mt+Ap crystallization at 400 MPa, 1050°C, 0.7-1.1 wt.% H_2O^m.

Our results indicate that differentiation from basanites to tephrites is possible in a pressure range of 400 to 700 MPa at least. Pl crystallization in basanites at 700 MPa is suppressed indicating that tephriphonolitic or phonolitic melts can only be generated at lower pressures or from a parent more evolved than basanite. Krs is an amphibole that can be stable even in melts with <1 wt.% H_2O^m (>0.1 X_{H2O}), suggesting that CV melts are CO_2 rich and H_2O-poor even in evolved magmas. It also requires low fO_2 (~FMQ): higher fO_2 results in extensive Mt crystallization leading to qz-normative residual liquids instead of Ne-normative.

Dunefield chronology in the Simspson Desert, central Australia, revealed by cosmogenic nuclide and luminescence dating

TOSHIYUKI FUJIOKA[1*], GERALD NANSON[2], STEPHEN TOOTH[3], ROBERT CRADDOCK[4], DAVID PRICE[2], BRENT PETERSON[2] AND CHARLES MIFSUD[1]

[1]Australian Nuclear Science and Technology Organisation, Sydney, Australia, tyf@ansto.gov.au (* presenting author), cxm@ansto.gov.au
[2]School of Earth and Environmental Sciences, University of Wollongong, Wollongong, Australia, (gnanson@uow.edu.au, dprice@uow.edu.au, brentp@uow.edu.au)
[3]Institute of Geography and Earth Sciences, University of Aberystwyth, Ceredigion, UK, (set@aber.ac.uk)
[4]Smithsonian Institution, Washington, US, craddockb@si.edu

Dune fields are among major features in arid–semiarid Australia, but our knowledge of their origin, formation mechanism and development history are incomplete. Chronology is essential for comprehensive understanding of the evolutionary history of dunefield, but conventional dating has been limited by its age range, e.g., up to ~50 ka for radiocarbon and ~300 ka for luminescence dating. In this study, we employ cosmogenic nuclide burial dating, based on ^{10}Be and ^{26}Al measurements, to determine the dune ages within the Simpson Desert, central Australia. Total 14 sand core samples, collected from three dune ridges and associated swales, have been measured for cosmogenic ^{10}Be and ^{26}Al. All samples show depressed $^{26}Al/^{10}Be$ ratios of 2.2–4.3; with distinctive contrast to the expected ratio of 6.7 for a simple exposure sample, the measured ratios indicate the model burial ages from 0.6 to 2 Ma. Near surface samples (<5 m depth) exhibit consistent ^{10}Be or ^{26}Al concentrations between drill holes, with a uniform burial signal of ~0.8 Ma. This observation suggests that i) sand at the site is well mixed and ii) sand particles inherit burial signals from either previous episode(s) of dune formation and/or storage in river floodplain during sediment transport. The nuclide inventory can be changed from this 'regional average' near-surface concentration only when sand particles are isolated from surface mixing (i.e., by burial under a stable sediment column within dunes). Assuming that sand now buried under dunes had nuclide concentrations similar to the current surface sand, 'inheritance corrected' burial ages can be calculated, which represent the time since the sand has been isolated from surface mixing. The corrected burial ages range 0.24–1.21 Ma. The Simpson Desert dunefield, while still active, appears to have developed over at least the last 1 Ma.

Deciphering crustal evolution from metamorphic and geochemical signatures in calc-silicate gneisses

ISIS FUKAI[1], BARBARA DUTROW[1*], DARRELL HENRY[1], PAUL MUELLER[2] AND DAVID FOSTER[2]

[1]Louisiana State University, Baton Rouge LA, USA (*correspondence : dutrow@lsu.edu)

[2]University of Florida, Gainesville, FL, USA

Field relations, petrographic textures, whole-rock geochemistry, and thermobarometry of calc-silicate gneisses from the Sawtooth Metamorphic Complex (SMC) in central Idaho, USA, preserve details of several important stages of crustal development along the western margin of Laurentia, including: contiguous deposition of a calcareous sandstone-to-marl sequence (Fig 1), peak metamorphism to lower-granulite facies (M1; Fig. 2), followed by widespread deformation at high P-T (D1), an amphibolite-facies thermal overprint (M2), and a late-stage, heterogenous, brittle-ductile mylonitic deformation event (D2). M2 temperature estimates of ~660±40ºC from Hbl-pl thermometry are similar to conditions calculated using Ti-in-biotite (TiB) thermometery and pseudosections, suggesting these methods can be used in calc-silicates to provide useful constraints on metamorphism.

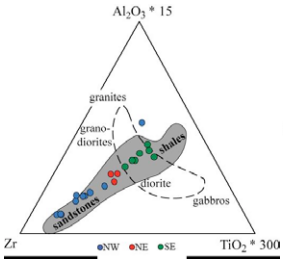

Fig. 1. Calc-silicate whole-rock geochemistry [1]

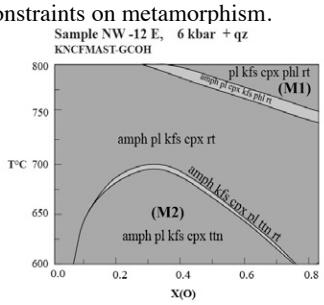

Fig. 2. Calc-silicate T-X(O) pseudosection [2]

The presence of abundant ~1150-1050 Ma Proterozoic detrial zircons in SMC quartzites and quartzofeldspathic gneisses reported in other recent work [3], coupled with protolith compositions near PAUCC, suggests calc-silicate gneisses record continuous sedimentary deposition and multiple metamorphic/deformation events that may be related to the formation/breakup of supercontinent Rodinia. As such, calc-silicates can provide valuable insight into tectonic and metamorphic events in a region.

[6]Univ. of the Ryukyu, Nishihara-cho, Japan, tak@sci.u-ryukyu.ac.jp

[7]Yamagata Univ, Japan, i-motoyama@sci.kj.yamagata-u.ac.jp

During the last glacial maximum, the atmospheric partial pressure of CO_2 (pCO_{2atm}) was very low, 180-190 ppm and rapidly increased to 280 ppm during the last deglacation [1]. During glacial periods, strengthened productivity and an efficient biological pump in the North Pacific, equatorial Pacific, and Southern Oceans may have contributed to low pCO_{2atm}[2]. However, there is still some controversy as to whether marine productivity was high everywhere during glacial periods. To resolve this controversy, more data are required from many regions regarding temporal changes in past export fluxes of biogenic materials. The eastern South Pacific Ocean including the Chilean marginal region, where active biological production is observed at present is target area of this study. The aim of this study is to identify changes in the ^{230}Th-normalized export flux of biogenic components commonly used as proxies for paleoproductivity-namely total organic carbon (TOC), total nitrogen (TN) and biogenic opal (Si_{opal}) from two sediment cores collected at 36°S, off central-south Chilean covering the past 22 kyr (PC-1) and at 52°S near the mouth of Strait of Magellan, Pacific side over the past 13 kyr (PC-3). ^{230}Th-normalized fluxes of biogenic components of sediments at 36°S and 52°S off the Chilean coast imply that the biological pump was effective during 14–8 kyr BP off central Chile, and after 5 kyr BP off central and southernmost Chile; and less effective during 22–14 kyr BP off central Chile and during 13–6 kyr BP off southernmost Patagonia [3]. That is to say, off central Chile, the weakness of the biological pump during the LGM contributed to the global rise of pCO_{2atm} at that time. During 14–8 kyr BP, the increasing effectiveness of the biological pump at the PC-1 site off central Chile contributed to the global rise of pCO_{2atm}. At the PC-3 site, the weakening of biological pump contributed to the rise of pCO_{2atm} during 13–6 kyr BP. After 6 kyr BP, the active biological pump did not contribute to the rise of $pCO_{2atm.}$ In this presentation, we will also report ^{230}Th-normalized fluxes of biogenic components at the 55°S collected from the Drake Passage sediment.

Desorption behavior of cesium from smectite by major cations

K. FUKUSHI[1], Y. YAMASHINA[1], Y. AOI[1] AND H. SAKAI[1]

[1]Kanazawa University, Kanazawa, Japan, (fukushi@staff.kanazawa-u. ac).jp (presenting author)

The radiocesium released from the Fukushima Daiichi nuclear power plant is retained at the surface soils around the power plant (Tanaka *et al* 2012GJ). The expandable clay minerals such as smectite and vermiculite are thought to be the one of the candidate for the host phases of radiocesium. The sorption behavior of cesium (Cs) on smectite has been widely studied (Cornell, 1993JRNC). On the other hand, the desorption behavior of trace Cs from smectite has not been well understood. The understanding of Cs desorption from the soil clay minerals are essential for the prediction of the migration of Cs in the surface environment. In present study, the desorption behavior of Cs from Cs bearing smectite by major cations (Na^+, K^+, Mg^{2+}, Ca^{2+} and NH_4^+) were systematically examined in laboratory.

The suspension of the Cs bearing smectite was prepared by reaction of 1 g/L smectite with 75 nM Cs^+ solution in NaCl solutions at neutral pH. The desorption of Cs were examined by adding the major cations of which concentrations ranged from 10^{-3} to 10^{-1} N to the smectite suspensions.

All cations except for K^+ lead to the desorption of Cs from smectite when the concentrations of the added cations increased. The order of the ability for the desorption of Cs from smectite by the major cations was summarized as follow: $Ca^{2+} \approx Mg^{2+} > NH_4^+ > Na^+$. The selectivity coefficients based on Gaines-Thomas convention relative to Na^+ were estimated from the macroscopic drsorption results. The estimated selectivity coefficients were almost consistent with previously reported values. This indicates that the exchanges of Na^+, Mg^{2+}, Ca^{2+} and NH_4^+ to Cs^+ in smectite are reversible reactions.

On the other hand, K^+ plays a role for inhibition of Cs desorption from smectite. It is well documented that K^+ lead to the shrinking of the layer space in smectite (Morodome *et al* 2009CCM). The shrinking probably makes the Cs inside the smectite layers undesorbable. Some recent studies indicated that the radiocesium in the soils affected by Fukushima Daiichi nuclear plant accident was merely leached by the high concentrations of cations (Qin *et al* 2012GJ). The effect of K in natural water is thought to be the one of the possible mechanism for the fixation of radiocesium in the soils.

Chromium solubility in chlorite and implications for subduction zone dynamics: an experimental study in the CrMASH system up to 6.5 GPa, 900°C

P. FUMAGALLI[1]*, J. FISCHER [1], M. GEMMI[2], M. MERLINI[1] AND S. POLI[1]

[1] University of Milan, I-20133 Milano, Italy (*correspondence: patrizia.fumagalli@unimi.it)

[2] Center for Nanotechnology Innovation@NEST, Istituto Italiano di Tecnologia, Pisa, Italy

Chlorite is known to form nearly monomineralic hybrid rocks at the slab-mantle interface at subduction zones. In hydrated ultramafic systems, chlorite containing 13 wt.% of H_2O represents a good candidate for transferring water beyond the stability field of antigorite, being stable up to 4-6 GPa, 700-800°C. Although pressure-temperature stability of clinochlore has been widely investigated in the system MgO-Al_2O_3-SiO_2-H_2O, the role of Cr in modifying phase relationships is poorly assessed at the low-temperatures characteristic of subducting slabs. Despite chromium is a minor constituent of the Earth Mantle, being incorporated in almost all major mantle phases, it is expected to affect phase equilibria and to extend chlorite stability. This study mainly aims to experimentally investigate the solubility of chromium in chlorite as a function of pressure, temperature and bulk composition and evaluate its effect on phase relations.

Three different compositions with X_{Cr} = Cr/(Cr+Al) = 0.075, 0.25 and 0.5 respectively, have been investigated between 1.5-6.5 GPa, 650-900°C. Cr-chlorite only occurs in bulk with X_{Cr} =0.15. It coexists with enstatite up to 3.5 GPa, 800-850°C, and with forsterite, pyrope and spinel at higher pressure. At P>5 GPa other hydrates occur: a Cr-bearing phase HAPY [1] is stable in assemblage with pyrope, forsterite, and spinel; Mg-sursassite coexist at 6.0 GPa, 650°C with a new Cr-bearing phase, named SAD, forsterite and spinel.

Chromium strongly partitions into spinel (X_{Cr}=0.8806), followed by orthopyroxene (X_{Cr}=0.1428), Cr-chlorite (X_{Cr}=0.0815) and garnet (X_{Cr}= 0.0339).

Cr affects the stability of chlorite by shifting its breakdown reactions towards higher T and P, but Cr solubility at high P results to be reduced as compared with low P occurrence in hydrothermal environments.

Equation of state for silicate melts: Static vs. shock compression

N. FUNAMORI* AND D. WAKABAYASHI

Department of Earth and Planetary Science, University of Tokyo, Tokyo 113-0033, Japan
(*correspondence: funamori@eps.s.u-tokyo.ac.jp)

We have recently proposed a simple and easy-to-use equation of state for silicate melts, which is applicable to a wide range of chemical composition at the pressure condition of the deep upper mantle [1]. To derive the equation of state, we assumed that silicate melts have a densified network structure (intermediate-range order) based on the knowledge from the behavior of densified SiO_2 glass under high pressure [2]. The equation of state is consistent with all the available density data of silicate melts with an SiO_2 content of about 35-55 mol% measured with large-volume presses between 8 and 22 GPa. However, the equation of state cannot explain shock-compression data. As demonstrated in Fig. 1, there are systematic differences between static- and shock-compression data. Investigation to clarify the reason of the discrepancy is now ongoing.

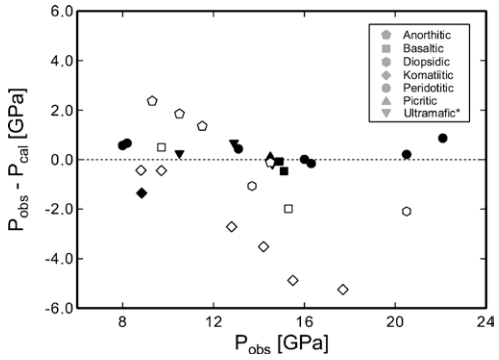

Figure 1: Deviation of experimental data from the equation of state proposed in Ref. [1] for silicate melts. Solid and open symbols represent static- and shock-compression data, respectively. (*) No specific name is given for the ultramafic data.

Element quantification in chondritic components by LA-ICP-MS

C. FUNK[1*], F. WOMBACHER[1], R.GLAUS[2], D. TABERSKY[2], J. KOCH[2] AND D. GÜNTHER[2]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, Germany. (cfunk0@uni-koeln.de) (*presenting author)
[2]Laboratory of Inorg. Chemistry, ETH Zurich, Switzerland

Chondrites comprise the most primitive solar system materials available for laboratory studies. Major and trace element distribution and abundances in different chondritic components provide insights into the early evolution of inner solar system materials. Chondrites are composed of different components (e.g. chondrules, matrix, CAIs etc.) which in turn consist of heterogeneously distributed fine-grained silicates, oxides, sulfides and metals typically on the μm up to some tenth of μm scale. The different phases exhibit different laser ablation characteristics and therefore impair an accurate quantification of elemental concentrations in chondritic components. The use of femtosecond lasers that generate only minimal thermal effects during sampling, produce uniform and fine aerosols, and offer reduced matrix effects compared to nano second laser ablation can diminish this difficulty.

The small-scale chemical heterogeneity of chondritic matter makes the accurate determination of suitable internal standard elements (e.g. by electron microprobe) challenging. This problem can be circumvented if the ablation yield is calculated by the total ablated material [1]. For this purpose, all relevant major elements are analysed relative to an external standard and recalculated as oxides, sulfides, and metals. The ablation yield is then calculated from the sum of major elements. This procedure however requires a suitable external standard for major element calibration in chondrites. Compared to chondrites the commonly used NIST SRM 61x glasses have extremely low amounts of Mg, S and Fe and are therefore poorly suited for this kind of yield correction.

Considering the aforementioned problems, we purchased a nanoparticle based standard material produced by flame spray pyrolysis. This calibration material comprises major and most of the minor elements in approximately CI chondritic abundances with ablation characteristics analogous to NIST SRM 612. Quantitative analysis of the calibration material by solution nebulization ICP-MS showed good agreement with CI chondritic abundance for most elements. Measurement setup, data evaluation and applicability of the approach, composition and homogeneity of the new reference material will be presented and discussed.

Evidence for chondritic lunar water and nitrogen trapped in Apollo 17 volcanic glasses

E. FÜRI[1*], B. MARTY[1], E.DELOULE[1] AND A. GURENKO[1]

[1]CRPG-CNRS, BP20, 54501 Vandoeuvre-les-Nancy, France (*correspondence: efueri@crpg.cnrs-nancy.fr)

The notion of a largely devolatilized lunar interior has been challenged by the discovery of trace amounts of water in lunar volcanic glasses (LVGs) [1], melt inclusions [2] and apatites [3-5]. However, the caveat in the search for indigenous lunar volatiles (e.g., H_2O and N) is that any sample collected at the Moon's surface likely also contains volatiles implanted by solar wind (SW) irradiation and certain volatile element isotopes produced by spallation reactions.

Here, we first assess the proportion of solar, cosmogenic, and indigenous water (hydrogen) trapped in single Ti-rich 74002 LVGs by coupling SIMS measurements of water abundances and D/H ratios with CO_2 laser extraction-static mass spectrometry analysis of noble gases (He, Ne, Ar). Our noble gas results show that the large single Ap17 LVGs have been exposed at the lunar surface for ≤36 Myrs, and that they contain a negligible amount of SW-derived volatiles. Therefore, the detection of water in these primitive melts confirms the presence of a non-anhydrous mantle source within the Moon, with a chondritic isotopic signature.

Secondly, nitrogen was extracted from different 74002 grain size fractions by CO_2 laser heating. The surface-correlated N component shows a $\delta^{15}N$ value of +4.4 ± 7.8 ‰ relative to air. This value likely reflects the isotope composition of N-bearing volcanic vapor that condensed onto the surface of the LVGs, and it represents a minimum estimate of the $\delta^{15}N$ signature of the melt source. Preferential loss of light isotopes from the melt, followed by condensation of isotopically light vapor [6], as well as addition of SW-derived N, may have lowered the initial $\delta^{15}N$ value. Nonetheless, the isotopic composition of indigenous nitrogen in the lunar mantle appears to be comparable to the values observed in carbonaceous chondrites (e.g., [7]).

Effects of oxide ions on the stabilization of pentoses

YOSHIHIRO FURUKAWA[1]*, MANA HORIUCHI[1], SAKIKO NITTA[1] AND TAKESHI KAKEGAWA[1]

[1]Department of Earth Science, Tohoku University, 6-3 Aza-aoba, Aramaki, Sendai, Japan (*correspondance: furukawa@m.tohoku.ac.jp)

Ribose, an aldopentose, is an essential component of RNA that has been regarded an important organic compound for the origin of life [1,2]. Thus, the formation and accumulation of ribose on the prebiotic Earth may be a requisite for the emergence of primordial RNA. However, pentoses including ribose are unstable under alkaline conditions where they typical form [3]. Formation of complexes between pentoses and several oxide ions such as borate, silicate, and molybdate, have been investigated. In particular, stabilization of pentoses by borate and silicate were demonstrated in previous studies [4,5]. However, it is still unclear which oxide ion more effectively stabilize pentoses and which pentose, among the four aldopentoses, is stabilized.

We conducted incubation experiments of each aldopentoses under several oxide ion concentrations at a fixed temperature. The experiments were conducted under an alkaline condition (pH~12) with continuous stirring. The incubation solution was sampled at a pre-determined time interval and quantitatively analyzed for residual and produced pentoses with liquid chromatography-mass spectrometry.

We confirmed the formation of pentose-borate complexes, but the pentose-silicate complexes were below the detection limit. The concentration of all residual pentoses gradually decreased with the incubation time. Both borate and silicate reduced the decrease of pentose concentration, but the stabilization effect was greater with borate. This result suggests that borate played an important role in the accumulation of pentoses on the prebiotic Earth and formation of primordial RNA.

Volatile content in melt inclusions of Vulcanello's explosive activity: Implications for the last 1000 years of activity at Vulcano Island (Aeolian Archipelago, Italy)

R. FUSILLO [1] *, F.DI TRAGLIA [1], A.GIONCADA [1], M. PISTOLESI [1], M.ROSI [1] AND P.J. WALLACE [2]

[1] Dipartimento Scienze della Terra, Università di Pisa, Via Santa Maria 53, 56126, Pisa. Italy (*correspondence: Raffaella.Fusillo@bristol.ac.uk); present address: School of of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's Road, BS8 1RJ, Bristol. United Kingdom

[2]Department of of Geological Sciences, University of Oregon, Eugene, OR 97403-1272. United States

We analysed major element and volatile (H_2O, CO_2, S, F, Cl) concentrations in olivine-hosted melt inclusions(MIs) from tephra of Vulcanello's explosive activity in order to estimate magma chamber depth. We also investigated possible petrological links with the last 1000 years of La Fossa Cone activity.

Major element compositions of MIs range from 52 to 62 wt% SiO_2, and olivine host compositions are Fo_{65-70}. Water concentrations in the MIs are variable (0.2 -1.4wt% H_2O), while CO_2 concentration is below 50 ppm for all the samples. Halogens concentration ranges from 0.1 wt% to 0.4 wt%, while S content ranges from 0.02 to 0.04 wt%.

The results showed a very shallow magma chamber (≤1 km) beneath the Vulcanello centre, as already hypothesized for la Fossa Cone [1]; major elements, S and Cl concentrations in MIs from Vulcanello's tephra are in fact comparable with those from the products of the contemporaneous activity from La Fossa Cone .[2, 3].

From stratigraphic evidences [3] and MI data we hypothesize that Vulcanello and La Fossa Cone activity was fed by the same magma reservoir. We provide new data on the magmatic evolution of the last 1000 years of Vulcano's activity [4]. Our hypothesis has also implications in regard to the assessment of volcanic hazard of a resurgent volcano as La Fossa Cone.

The anthropogenic contribution to carbon dioxide dissolved in seawater

F. GÄB[1]* C. BALLHAUS[1] AND J. SIEMENS[2]

[1]Steimann Institut, Universität Bonn
(*fgaeb@uni-bonn.de, ballhaus@uni-bonn.de)
[2]Bodenwissenschaften, Universität Bonn
(jsiemens@uni-bonn.de)

Emissions of anthropogenic CO_2 not only enhance greenhouse effects in the atmosphere and contribute toward global warming. Atmospheric CO_2 also reacts with surface ocean waters and causes ocean acidification, to an extent that marine organisms may face difficulty in sequestering $CaCO_3$ to build their shells. To assess how far the rate of acidification may progress in the future, reliable forecasts are needed as for the future emissions of CO_2. In addition, it must be known how much CO_2 is being exchanged across the atmosphere/ seawater interface at any given pCO_2, in order to define the proportion of inorganic carbon stored in the ocean water that is anthropogenic in origin.

Exchange experiments between atmosphere and seawater are reported to quantify how much CO_2 can be exchanged between the Earth's atmosphere and ocean surface water at any given CO_2 partial pressure. The seawater came from the Aegean sea. Its total alkalinity was determined at 2698 ± 24 μmol/kg. The gases to simulate the Earth's atmosphere were commercial N_2-O_2 (4:1) gas mixtures with CO_2 ranging from < 10, 200, 280, 390, 1000, 2,000, 5,000, 20,0000 and 100,000 μatm CO_2. At the present atmospheric level of CO_2 (400 μatm) about 18% of the inorganic carbon (DIC) inventory dissolved in surface seawater is due to direct exchange across the water-atmosphere interface. By far the largest proportion of the DIC in seawater, i.e. more than 80%, is derived from sources other than the atmosphere, and the concentration in seawater of this fraction is independent of short-term (human-scale) variations in pCO_2. The human contribution to the DIC of ocean surface water is defined as the carbon content that may be exchanged across the water-atmosphere interface between 280 and 400 μatm CO_2. It is quantified at ~ 115 ± 18 μmol carbon per kg seawater, or 4.5% of the total present-day DIC of surface ocean water.

That concentration is a higher than the anthropogenic contribution in mid-latitude Atlantic surface water (~ 60 μmol kg^{-1}), but (1) Aegean seawater is more alkaline than Atlantic water hence more capable of absorbing CO_2 via hydrolysis reaction; (2) the 60 μmol kg^{-1} C dates from 1994, when the pCO_2 was only 355 μatm; and (3) any DIC derived from direct measurements of natural surface ocean waters may be a steady-state rather than an equilibrium concentration.

Secular variations in seawater chemistry controlling water-rock interaction in shallow reflux systems

T. GABELLONE* AND F. WHITAKER

School of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's Road, Bristol, BS8 1RJ, UK
(*correspondence: tatyana.gabellone@bristol.ac.uk, fiona.whitaker@bristol.ac.uk)

Secular variations of seawater composition influence both the primary mineralogy of marine non-skeletal carbonates and also the dolomitization potential of seawater-derived fluids. Using 1D reactive transport modelling we explore the role of seawater composition in controlling early carbonate diagenesis during reflux of brines, contrasting aragonitic and calcitic seawaters based on modern and Mississippian with Mg/Ca of ~5 and ~2 respectively.

Dolomite forms from reflux of modern brines by replacement of calcite, increasing the porosity. When replacement is complete, dolomite can continue to form as primary cement ("overdolomitization") and porosity is reduced. Increasing evaporative concentration in the brine pool enhances reaction rate independent of the effect on enhanced density-driven flow. Reflux of brines formed from Mississippian seawater leads to synchronous primary dolomite cementation and replacement of calcite, with net porosity occlusion. Release of Ca^{2+} by replacement dolomitization drives gypsum precipitation from both modern and Mississippian brines of >150 ‰ salinity, particularly at higher temperatures, further occluding porosity.

Temperature is an important control on dolomitization kinetics even at relatively low temperatures, with complete replacement of calcite occurring within 130 ky at 35°C, more than twice the rate at 30°C. Fine-grained calcitic sediments characteristically have a high effective surface area and may dolomitise at rates >10 times those of coarse-grained sediments. However, this effect may be offset by the lower permeability of finer sediments which limits rates of fluid flow for a given density head drive. The effect of microbial processes appears to be critical in generating nucleation sites ("seed dolomite"), as well as altering fluid chemistry. Neither secular variations in seawater chemistry associated with changing atmospheric pCO_2, nor biological induced alkalinity variation, appear to significantly influence dolomitization.

Concentrations of trace and minor elements in marine and terrestrial calcite have the potential to yield information on environmental conditions during crystallization. However, thermodynamic and kinetic effects on element partitioning in calcite are not well understood. The phenomenon of sectoral zoning (geometrically distinct distribution B, Mg, Sr, and Ba in non-equivalent vicinal faces of calcite crystals) has been reported in several studies [1-3, etc.]. The potential factors controlling element partitioning between different calcite faces and fluid include: structural difference of atomic layers at the calcite near-surface region and elements diffusion rates in those layers, difference in growth rate of crystal faces, and chemical speciation at the calcite - fluid interface [2,4,5, etc.].

We used the growth entrapment model (GEM) together with experimental data explore B heterogeneity within single calcite crystals. The GEM describes disequilibrium fractionation of elements and isotopes between a crystal and its growth medium as a consequence of the "capture" of a chemically and isotopically anomalous near-surface region of the lattice during crystal growth [5]. We show that crystal zoning could be explained by different diffusion rates of B in the near-surface layer of the non-equivalent faces of calcite - which is not inconsistent with the extreme anisotropy of the calcite crystal structure. In addition to our B results, we will present GEM simulations for divalent cations in calcite in the context of sectoral zoning.

Low latitude ice cores offer unique and detailed paleoclimate information from high elevations. However, as most of the accessible low latitude drilling sites have already been explored and as glaciers are melting worldwide, it is difficult to identify ice fields that contain novel and intact ice core records. The "Ortles Project" is an international scientific effort gathering a dozen institutes from six nations with the primary goal of obtaining a high altitude climate record from Southern Europe. Atmospheric temperatures in the entire alpine region are currently increasing at twice the rate of global temperatures and this change may be amplified at the highest elevations. Unfortunately there is a scarcity of paleo-climate information from high altitudes in the Alps to place the current rapid climate change in a paleo-perspective. To fill this gap we drilled in 2011 four ice cores on Alto dell'Ortles (3859 m, South Tyrol, Italy) the highest glacier in the eastern Alps. We have found an annually preserved climatic signal (in terms of stable isotopes, dust and major ions) embedded in the deep cold ice of this glacier. Alto dell'Ortles is the first low-accumulation alpine drilling site where both winter and summer layers can be clearly identified. From the seasonal layers in the ice core record we estimate an average accumulation rate of ~ 850 mm of water equivalent per year during the last 50 years. Preliminary annual layer counting and two absolute time markers suggest that the time period covered by the Ortles ice cores may span from several centuries to a few millennia.

Reading the melt inclusion record of pre-eruptive magmatic volatiles

GLENN A GAETANI[1]*, CLAIRE BUCHOLZ[1], ESTELLE ROSE-KOGA[2], NOBUMICHI SHIMIZU[1], KEN KOGA[2] AND BRIAN MONTELEONE[1]

[1]Department of Geology and Geophysics, Woods Hole Oceanographic Institution Woods Hole, MA, 02543, USA (*correspondence: ggaetani@whoi.edu)

[2]Laboratoire Magmas et Volcans, Clermont Université, Université Blaise Pascal, BP 10448, 6300 Clermont-Ferrand, France

Olivine-hosted melt inclusions are one of the most important sources of information on pre-eruptive magmatic volatiles. Although the strength of the olivine largely protects inclusions from decompression and degassing during ascent and eruption, post entrapment processes can affect the concentrations of magmatic volatiles in the included melts. We investigated experimentally the potential for post-entrapment modification of H_2O, CO_2, S, F, Cl and $Fe^{3+}/\Sigma Fe$ in olivine-hosted melt inclusions. Our results demonstrate that diffusion re-equilibrates H_2O and $Fe^{3+}/\Sigma Fe$ in a matter of hours at magmatic temperatures. Pressure drops within the inclusions during diffusive loss of H_2O decrease the solubility of CO_2 – and to a lesser extent S – in the silicate melt. This leads to decreased concentrations in the included melt as CO_2 and S are partitioned into vapor bubbles. The concentrations of F and Cl are not affected by either diffusive loss through the host crystal or partitioning into the vapor phase.

Effects of diffusive re-equilibration were assessed by dehydrating natural inclusion-bearing olivines from Cerro Negro volcano, Nicaragua (initial H_2O = 3.8±0.3 wt%) and Mauna Loa volcano, Hawaii (initial H_2O = 0.375±0.006). Experiments were conducted using both a vertical quenching furnace and a Vernadsky heating stage. Run products were analyzed for major elements by electron microprobe and for H_2O, CO_2, S, F, Cl and D/H ratio by SIMS. $Fe^{3+}/\Sigma Fe$ was determined by μ-XANES.

Our results demonstrate that post entrapment modification may significantly impact the concentrations of H_2O and CO_2 in included melts. The consqeuences of this are far less severe for olivine-hosted melt inclusions with initially low H_2O. In this case the external magma loses very little H_2O during degassing so that a H_2O fugacity gradient does not develop to drive diffusive loss. This is supported by a global compilation of melt inclusion data which show that low-H_2O melt inclusions are capable of recording entrapment pressures consistent with the upper mantle, whereas the internal pressures for melt inclusions with initially high H_2O contents never exceed crustal values.

Microorganisms in flooded underground uranium mines of East Germany

CORINNA GAGELL AND THURO ARNOLD

Institute of Resource Ecology, Helmholtz-Zentrum Dresden-Rossendorf e.V., P.O. Box 510119, D-01314 Germany, (c.gagell@hzdr.de)

After the German reunification the Wismut GmbH, formerly the 3rd largest U producer of the world, started to remediate the legacies of their U mining activities. As part of the remediation strategy the pit body was flooded to induce reductive processes. Although flooding of the mines Pöhla and Schlema-Alberoda was already finished about ten years ago, the mine water still contains elevated concentrations of toxic metals such as U, As and Ra. Thus, expensive and long-lasting monitoring and waste water treatment is required. Since microorganisms can influence the toxicity of metals directly or indirectly, one alternative approach is to use them for bioremediation. Here, the diversity of the indigenous microbial community of the mine water from Pöhla and Schlema-Alberoda is reported. *Bacteria* as well as *Archaea* were analyzed by state-of-the-art pyrosequencing of the 16S rRNA gene. Mine water samples were either filtrated or harvested from a flow cell. For the filtrated Pöhla mine water, the Pöhla flow cell, the filtrated Schlema mine water, and the Schlema flow cell 485, 697, 325 and 527 sequences, respectively, were divided into 98, 189, 188 and 89 operational taxonomical units (OTUs), respectively, belonging mainly to *Bacteria*. The bacterial sequences from the Pöhla mine were classified into *Proteobacteria*, *Verrumicrobia*, *Bacteriodetes*, *WS3*, *Chloroflexi*, *Firmicutes*, *Acidobacteria*, *SR1*, *Actinobacteria*, *Spirochaetes* and *OD1*. For the Schlema mine *Proteobacteria*, *Acidobacteria*, *WS3*, *Bacteriodetes*, *Chloroflexi*, *SR1*, *Chlorobi*, *TM7* and *Acinobacteria* were found. The dominant bacterial phylum in all samples are the *Proteobacteria*. Higher bacterial diversities were observed in flow cells in comparison with filtrated waters. A dataset of 15786, 17872, 11404, 7780 sequences revealed 639, 643, 769 and 455 OTUs, respectively, mainly for Archaea of the filtrated Pöhla mine water, the Pöhla flow cell, the filtrated Schlema mine water and the Schlema flow cell, respectively. The archaeal sequences of the Pöhla as well as the Schlema mine water belong to the class of *Methanobacteria*, *Thermoprotei*, *Methanomicrobia*, *Thermoplasmata* and *Halobacteria*.

U-Pb geochronology and geochemistry of the granulite-amphibolite complex in the Asinara Island (Italy)

LAURA GAGGERO[1], GIACOMO OGGIANO[2], LEONARDO CASINI[2] AND MASSIMO TIEPOLO[3]

[1]DISTAV-UNIGE Corso Europa 26, I-16132 Genoa, Italy, gaggero@dipteris.unige.it
[2]Dept. Botanics, Ecology, Geology - UNISS, Via Piandanna 4, I-07100 Sassari, Italy
[3]IGG-CNR, Via Ferrata 1, I-27100 Pavia, Italy

In Sardinia, the Posada – Asinara mylonitic mélange zone gathers eclogitic relicts with N-MORB affinity, high-grade and medium-grade continental complexes (Carmignani *et al*, 1992, 1994), interpreted as the southern margin of Armorica and northern margin of Gondwana, respectively. In the Asinara Island, an intermediate to high-grade granulite crust section (Oggiano and Di Pisa, 1988) attains the deepest exposed level at Punta Scorno, where a basic complex, interleaved by cm to m thick felsic layers occurs. The felsic layers were selected for U-Pb radiometric dating by ELA-ICP-MS on zircons at CNR – IGG Pavia. In the granulite-amphibolite complex, each felsic layer yielded different ranges of Concordia ages, from Neoproterozoic (672 ± 12 to 588 ± 16 Ma) until a Cambrian system closure (514 ± 22 to 506 ± 15 Ma). Early Ordovician ages spans between 491 ± 13 and 474 ± 12 Ma. Late Ordovician – Early Silurian ages fall in the 461± 10 to 435 ± 12 Ma interval; Devonian and Carboniferous age values also result. This points to a long-lasting, sequence of metamorphic events with episodes of partial melting, in the lower crust.

Investigation of the methanotrophic activity in the soils of a geothermal site of Pantelleria Island (Italy)

GAGLIANO A.L.[1] D'ALESSANDRO W.[2], QUATRINI P.[3] AND PARELLO F.[1]

[1]University of Palermo, Dept. DiSTeM, Palermo, Italy (*corrisponding author antoninalisa.gagliano@unipa.it; francesco.parello@unipa.it)
[2]Istituto Nazionale di Geofisica e Vulcanologia, sezione di Palermo, Palermo, Italy (w.dalessandro@pa.ingv.it).
[3]University of Palermo, Dept.STEBICEF, Palermo, Italy (paola.quatrini@unipa.it).

Yearly, 22 Tg of CH_4 are released in to the atmosphere from several natural and anthropogenic sources [1]. The total CH_4 emission from geothermal/volcanic areas is not well defined since the balance between emission through degassing and consumption through soil microbial oxidation is poorly known.

Our pourpose was to explore the methanotrophic potential and the bacterial diversity of the soils of Favara Grande, the main geothermal area of Pantelleria island, (Italy), whose emissions are in the order of 2.5 Mg/y [2]. Two of the three sites analysed, show high methane consumption (up to 950 ng/g/h), temperatures from 58 to 75 °C and pH from 5 to 6.

The total bacterial diversity analysed by PCR-TTGE of the 16rRNA gene revealed similar profiles in these two sites. The culturable methanotrophic alphaproteobacterium Methylocystis sp. was isolated by enrichment cultures from soil samples of the most active site. The isolated species shows a wide range of tolerates pH values from 3 to 8 and temperatures tolerance a least up to 37 °C and has a methane oxidation rate of 450 ppm/h. A larger diversity of (α- and γ-) proteobacterial and verrucomicrobial methanotrophs was detected by using a culture-independent approach based on the the amplification of the methane mono-oxygenase gene (*pmoA*).

Understanding the ecology of methanotrophy in geothermal sites will increase our knowledge of the role of soils in methane emissions to the atmosphere.

[3]Cornell University. 14853 New York, United States

Whether Early Earth oceans were acidic or alkaline and, if so what such a difference would imply in the further evolution of atmosphere and life, has been -and still is- a subject of great controversy. Because of the primitive ocean was in equilibrium with an atmosphere mainly composed of CO_2 it has been assumed the Hadean ocean was probably acidic. Alternatively, it has been suggested that reactions between sodium-rich silicates and atmospheric CO_2, leading to the formation of Na_2CO_3, may have produced an early soda ocean [1]. Both hypotheses are mainly supported by mass-balance calculations performed under the assumption of equilibrium conditions, while neglecting kinetic effects as well as simultaneous redox evolution resulting from reaction with volatiles other than CO_2.

The aim of this work is twofold: beginning with the alkaline scenario, derived from the interaction of basalt bearing minerals with water, to explore the coeval evolution of both acid-base and redox states in an ocean approaching circumneutral pH, i.e., the actual steady state. This was done through kinetically controlled geochemical calculations including transitional halogen species (ClO^-, HClO) and iron superoxides ($FeO_4^{=}$, Fe^{4+}=O^{2-}). Second, perform micro and nanostructural analysis through laboratory. Silica garden structures (SG), built from iron salts, were used as an instantaneous mixing device for acidic iron-rich and alkaline silica-rich regions and were used as a laboratory analogous. Resulting textures, solid phases and species forming at the acidic-alkaline interface, on both, oxic and anoxic conditions, were analyzed by UV-VIS, HREM and optical microscopy. Results of geochemical modeling show that Fe-superoxides are formed transitionally along the evolution from alkaline-oxidant conditions to neutral pH values. Significantly, the model demonstrates that, although Fe-species are not soluble in alkaline conditions -the main argument against an Early soda ocean- superoxides are. Their desestabilization near neutral pH conditions may induce precipitation of Fe^{+3} solid phases, together with O_2(g) as a byproduct and gives rise to the formation of Fe-Si composites, selforganized as layered structures.

Hydration energies contribute significantly to the stability of hydrated clay minerals. However, thermodynamic data of hydration for clay minerals are still poorly known. The present study aims to improve our comprehension of the hydration processes of sodic smectite MX80, and to implement a new methodology for extracting thermodynamic data of hydration of the smectite.

A first approach consists in applying a global hydration model to extract the thermodynamic data of total adsorbed water (G, H and S) from adsorption/desorption isotherms at 25°C and 45°C. The results are in good agreement with calorimetric data at 84 and 91% RH, from [1]. As capillary water, which is present in the intergranular porosity of the clay sample, does not contribute to the thermodynamic stability of the hydrated clay mineral, a refined calculation method has been implemented to discriminate hydration water from capillary water in the total adsorbed water. The so called "hydration water" refers to interlayer water and surface recovering water of the smectite. Contrary to capillary water, the amount of hydration water depends on the nature of the smectite (nature of interlayer cations, layer charge and location of the charge). The thermodynamic properties of capillary water are calculated according to [2]. The present method allows (i) to estimate the respective amounts of hydration and capillary waters and (ii) calculate the energies of formation of the hydration water.

This work is to be extended to other hydrated clay minerals in order to refine the solid solution model from [3] and to finally provide a global predictive model for clay mineral hydration energies.

Li isotopes : The ideal weathering tracer?

J. GAILLARDET[1], M. DELLINGER[1] J. BOUCHEZ[2] A CALMELS C. CLERQUE[1], J.P. LOUVAT[1], C. DESSERT[1,] AND C. GORGE[1]

[1]IPGP – CNRS, Université Sorbonne Paris Cité, Paris, France
[2]GFZ - Helmholtz Centre Potsdam, Potsdam, Germany

The development of MC-ICPMS techniques has led to a considerable increase of Li isotopic data availability. Lithium has two isotopes, ^{6}Li and ^{7}Li which are particularly fractionated during low temperature water-rock interactions. The residence time of Li in the ocean is about 3 Myr which makes it a very good tracer of global surface geodynamics over geological time. Records of Li isotopes in the ocean are now available [1]

We have investigated the behavior of Li isotopes through the continental water cycle, by analyzing Li in large river materials, both solid and dissolved, as well as Li in smaller catchments.

Compared to other non-traditionnal isotopes, Li isotopes are highly discrimated during water rock interaction at the surface of the Earth, with a systematic enrichment of ^{6}Li in the solid residue of weathering and a complementary ^{7}Li enrichment in the dissolved load. Li is well partitioned between the solids and the dissolved phase, allowing us to measure isotopic differences between the weathering residue and the parent rocks and to establish and use mass budgets.

From our new data set, we infer that:

Li isotopes in the dissolved load are controlled by the precipitation of secondary minerals, occuring eiher in soils or in weathering “hot spots” in large watersheds (e.g. floodplains). Although shown in the data, the involvment of Li in the biological cycle is very weak.

Li in the river sediments traces the mixing between present-day weathering products and weathering products inherited from the geological past. Therefore, Li isotopes open the *pandora box* of the importance of geological legacy and continental reclycing on chemical weathering fluxes at the the global scale.

According to these conclusions, Li and its isotopes hence constitute an extremely powerful tracer of chemical weathering integrated over geological time.

Evidence for elevated Iron flux to the Early Phanerozoic Ocean

ROBERT R. GAINES[1], RACHEL E. HAVRANEK[1], KYLE S. METCALFE[1] AND SHANAN E. PETERS[2]

[1]Geology Department, Pomona College, Claremont CA, 91711 USA, robert.gaines@pomona.edu
[2]Department of Geoscience, University of Wisconsin, Madison, WI 53706, USA, peters@geology.wisc.edu

The Great Unconformity marks the end of a protracted episode of continental denudation that affected most of Laurentia and other continents worldwide. The processes that ultimately led to the formation of this geomorphic surface exposed crystalline basement rocks to atmospheric weathering over an area that is unprecedented in the rock record. An elevated flux of continental weathering products, immediately prior to and during the Sauk Marine Transgression, is suggested to have resulted in unique seawater chemistry during the terminal Ediacaran and Cambrian. In this study, we used whole rock geochemical data to quantify the patterns of alteration of basement rocks underlying the Great Unconformity to better constrain the chemical weathering flux to the oceans during this critical transition in the history of life. We analysed samples from seven weathering profiles developed into both felsic and mafic basement rocks at three localities in Colorado and Arizona. Our results are similar to those of Driese *et al* (2007) who also studied Cambrian weathering profiles below the Great Unconformity. Observed cation losses are similar to those found in modern weathering profiles, with the exception of Fe, which was depleted in these profiles. Thus, under Cambrian weathering conditions, Fe was preferentially leached, rather than accumulated. These results imply an elevated weathering flux of Fe^{3+} to the oceans from an exceptionally large area of exposed crystalline basement. This flux may have had several important consequences, including stimulation of primary productivity and enhanced burial efficiency of C-org, and thereby may have contributed to a rise in pO_2 during the Terminal Neoproterozoic-Early Ordovician.

Consumption-regeneration cycle of micronutrients and their isotopes in seawater

S.J.G. GALER[1]* AND W. ABOUCHAMI[1,2]

[1]Biogeochemistry Department, Max Planck Institute for Chemistry, 55128 Mainz, Germany (*steve.galer@mpic.de)

[2]Westfälische Wilhelms Universität, Institut für Mineralogie, 48149 Münster, Germany

The vertical cycling of micronutrients in seawater is well understood qualitatively, following early work by Boyle, Bruland and others. However, more quantitative models of the consumption-regeneration process are sorely needed in order to evaluate concentration profiles, and relate these to stable isotope fractionation of essential micronutrients, such as Cd, Zn, Fe and Ni, during biological utilization. Here, we have derived a mathematical formulation of micronutrient-limited cycling in the water column, where nutrients are consumed by a single phytoplankton species in the mixed layer (photic zone), and are regenerated/remineralized at depth by oxidation of sinking organic matter. This has been done within the framework of a simple 1-D advection-diffusion model of the water column, parameterized in terms of the upwelling velocity w and diapycnal mixing (eddy diffusion) coefficient κ. Simple expressions are derived for the micronutrient profiles at steady state, along with the corresponding stable isotope effects. It is shown how the depth profiles are related to those of conservative tracers (S, T) as well as AOU.

The rate of biological uptake of micronutrient in the mixed layer is assumed to follow Michaelis-Menten (Monod) kinetics. At steady state, the micronutrient consumption rate by the phytoplankton crop is balanced by the regeneration rate due to crop mortality. Interestingly, the micronutrient concentration in the mixed layer is governed by this kinetic balance and, paradoxically, not by the rate of supply of micronutrient from below. The biomass size in the mixed layer and the absolute primary production does depend on the micronutrient influx, however. This simple conceptual model suggests that there exists a self-regulating limiting micronutrient concentration for a given phytoplankton species. In reality, external factors will play a role too; these include light, which influences growth rates, and zooplankton grazing and removal from the photic zone by eddy diffusion which adversely affect mortality, as well as the mixed layer depth. Such effects, along with nutrient co-limitation and aeolian input, can easily be incorporated to yield a more realistic micronutrient cycling model.

Evaluating the role of microscopic pyrite for budgets of vital metals in Precambrian Carbonate

MEABH GALLAGHER AND BALZ S. KAMBER[1]

[1]Geology Department, Trinity College Dublin, Ireland megallag@tcd.ie

The measurement of redox sensitive trace metal abundances and their stable isotope compositions is a popular tool for reconstructing the Precambrian environment. Of all Precambrian sediments, carbonates hold the best promise for reconstruction because their sedimentological origin can be inferred relative to modern analogues (e.g. microbial carbonates, abiotic carbonates, dolomites, etc.). The redox state of ancient seawater can be reconstructed from the REE pattern in Precambrian carbonates as can be connectivity to the open ocean via Sr isotopes. It is thus tempting to apply transition metal tools to well studied Precambrian carbonates.

Here we report on trace metal distribution in previously charactertised carbonates of Precambrian age. Specifically our study investigates the role of microscopic to sub-microscopic sulphides (mainly pyrite) that are often encount-ered in microbial carbonates. A first-order mass balance was carried out to establish how much of the metal found in the bulk rock is actually hosted in pyrite vs. carbonate. Pyrite is a dominant host of Cu but insignificant in its V and Zn content.

Apart from mass balance, a key question is whether the pyrite incorporates its metal inventory from the microbial mats, genetically older carbonates or diagenetic fluids. This was investiagted with metal profiling across spheroid pyrite of sulphate reducing bacterial origin (SRBO). For the ele-ments V, Co, Ni, As, Mo, Pb and Bi, the profiles showed concentric zonations. In the case of V, the bell-shape profile indicates uptake from surrounding rock matrix but for Co, Ni, As, Mo, Pb and Bi, the W-shaped profiles suggest that metal was likely sourced from pore water (as was S). In this latter case, it is likely that the geochemistry of the carbonate itself reflects the marine ambient condition whereas the sulphide chemistry might reflect the diagenetic environment and erro-neous conclusions could be drawn from combining the two sources of information when performing bulk rock analysis.

Finally, previous sulphur isotope studies have highlighted a variety of possible origins for the ubiquitous if minute sulphides. Our study also aimed to investigate whether one can distinguish pyrites of different origins (i.e. biogenic vs. late diagenetic forms) based on their trace metal abundances. Preliminary anlysis of the dataset suggests that small grained matrix pyrite is characterised by enrichment in Mn, Co, Ni and As wheras pyrite of SRBO is depleted in these metals.

Clumped isotope thermometry of Neoproterozoic cap carbonates from northwest and southeast China

TIMOTHY M. GALLAGHER[1]*, NATHAN D. SHELDON[1], AND SHUHAI XIAO[2]

[1]University of Michigan, Dept. of Earth & Environmental Sciences, Ann Arbor, MI 48109, USA (*correspondence: tgallag@umich.edu)

[2]Virginia Tech, Dept. of Geosciences, Blacksburg, VA 24061, USA

Cap carbonate sequences are widely associated with Late-Neoproterozoic glacial deposits. They are of great scientific interest and have been used for stratigraphic correlation as well as for reconstructing paleoenvironmental conditions. More recently, the extent of post-sedimentary alteration of these rocks has become of great concern, calling into question whether they represent reliable environmental indicators[1].

Post Marinoan-age cap carbonates were analyzed from the Doushantuo Formation in southeast China and the Zhamoketi Formation in northwest China. Samples from two different sections of the Doushantuo Formation were analyzed to assess regional variability, while samples from the Zhamoketi Formation were included to assess variability between cratons.

To characterize the thermal history of the cap carbonates, we utilized carbonate clumped isotope thermometry. We measured the excess of mass-47 isotopologues (Δ_{47}) in order to quantify the crystallization temperature of these rocks.

Elevated temperatures (70-100°C) were found at all 3 sites. These results are lower than the maximum temperatures previously documented for the Doushantuo Formation[1,2], but are consistent with the temperature measurements of dolomicrite[2]. In addition, the Δ_{47} analyses of the Zhamoketi cap carbonate record a thermal gradient, with maximum temperatures recorded at the top of the cap carbonate and declining towards the base. Temperatures also decline within a few meters above the cap carbonate. Our results better constrain the thermal diagenesis within these two formations and underscore the point that post-sedimentary thermal alteration is potentially a problem for cap carbonates on multiple cratons.

Subduction-related to post-arc magmatism and Cu-Au-Te metallogeny in the Carpathian orogen, Romania

D.GALLHOFER[1], A. VON QUADT[1], I. PEYTCHEVA[12], I. SEGHEDI[3] AND C.A. HEINRICH[1]

[1]IGP, ETH Zurich, Switzerland (gallhofer@erdw.ethz.ch, vonquadt@erdw.ethz.ch, heinrich@erdw.ethz.ch)

[2]Geological Institute, BAS, 1113 Sofia (peytcheva@erdw.ethz.ch)

[3]Romanian Academy, Institute of Geodynamics, Bucharest, Romania (seghedi@geodin.ro)

The Banat Region and Apuseni Mountains are the northernmost segments of the Cu-Au mineralized Apuseni-Banat-Timok-Srednogorie (ABTS)-belt in southeastern Europe. The ABTS magmatic arc formed due to northward subduction of Neotethys beneath the European continental margin during Late Cretaceous times and is accociated with some of Europe's largest porphyry Cu-Au and epithermal Cu-Au deposits. Moreover, this Mesozoic subduction most likely metasomatized the Apuseni source region for a later, temporally distinct phase of magmatism. Miocene extension and consequent partial melting of the mantle source gave rise to non-arc Cu-Au-Te mineralizing calc-alkaline magmas in the South Apuseni Mountains [1].

New major and trace element whole rock data of Late Cretaceous igneous rocks show calc-alkaline to high-K calc-alkaline magma compositions and normalized trace element patterns characteristic of magmas generated in subduction zones. Samples with adakite-like signatures (Sr/Y≥40 and Y≤18) are rare. $^{87}Sr/^{86}Sr_{80Ma}$ WR ratios (0.704243 to 0.707074), $^{143}Nd/^{144}Nd_{80Ma}$ WR ratios (0.512374 to 0.512663) and initial εHf values of zircons point to a mantle source of the magmas that was variably contaminated by crustal components. Geochemical fingerprinting will test the possibly common source of post-subduction magmas.

In situ U-Pb CA-LA-ICP-MS dating and single-grain CA-ID-TIMS dating were conducted on zircons from igneous rocks from Banat Region and Apuseni Mts. All zircons were treated by chemical abrasion (CA) prior to dating [2]. Late Cretaceous magmatic activity in Banat Region covers a time span from 81.4 to 71.2 Ma. A distinct age zonation with younging of the magmatism from east to west is observed in the southern Banat Region.

GMS2 type station for geochemical continuous multi-parametric monitoring on Etna volcano

G. GALLI[1], F. QUATTROCCHI[1]*, G. DI STEFANO[1], S. GIAMMANCO[2], V. LONGO[2] AND F. PONGETTI[1]

[1]Istituto Nazionale di Geofisica e Vulcanologia. Sezione Sismologia e Tettonofisica. Roma. Italy (*correspondence: fedora.quattrocchi@ingv.it)

[2]Istituto Nazionale di Geofisica e Vulcanologia. Osservatorio Etneo. Catania. Italy (salvatore.giammanco@ct.ingv.it)

During the last twelve years three GMS2 (Geochemical Monitoring System 2) monitoring stations have been operating in three water wells on Mt. Etna: "Acqua Difesa" and "Currone" (on Etna's south flank) and "Ilice" (on Etna's east flank). GMS2 stations (Figure 1) every 10 minutes collect a data record composed of an array of chemical-physical parameters measured in groundwater. These data contribute to enrich our knowledge on an active volcanic system such as Mt. Etna, regarding, in particular, the chemical and physical effects of the interaction between up-rising magmatic fluids and shallow aquifers and the detection of possible pre-eruptive signals.

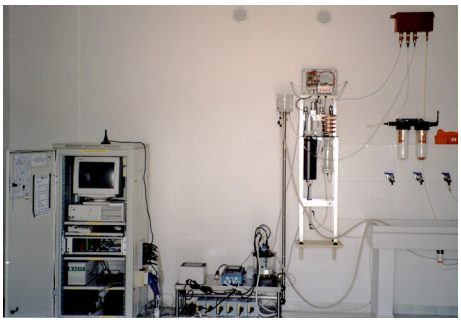

Figure1: Field set-up of GMS2 monitoring station located at "Currone" water well (Catania, Italy)

So far, a huge quantity of data regarding temperature, conducibility, pH, redox potential, dissolved CO_2 and dissolved radon have been acquired. The peculiarity of modular GMS2 acquisition system is that it allows: 1) to operate with great simplicity during maintenance, repair and replacement of elements; 2) to gather remote data through telephone relay using mobile phone structures; 3) to control data directly from INGV Roma offices, to verify their quality and to maintain the station if necessary. GMS2 data are validated by similar, discretely acquired, geochemical data. Examples of GMS2 data are shown.

An original microscopic approach of UV-visible-near infrared spectroscopy

GALOISY L.[1], LELONG, G.[1], CALAS G.[1] AND GUILLAUMET M.[1]

[1]Institut de Minéralogie et de Physique des Milieux Condensés, Pierre and Marie Curie University 4, place Jussieu 75005 Paris [1]laurence.galoisy@impmc.upmc.fr

We present an original microscopic scale approach of UV-visible-near infrared spectroscopy of minerals and glasses bearing transition elements. It is based on, a microscope built with Cassegrain mirrors and coupled to a UV-visible-near infrared double beam spectrophotometer. This setting enables the collection of spectroscopic data with an adjustable spot between 120 and 20 μm, over the 250- 2600nm range. An important point is the link of the microscope to the *double beam* spectrophotometer using a spot size aperture mechanically coupled in both reference and sample beams. The angle of incidence is distributed in the range 17.8° to 32.2° with an average angle of 25.0°± 0.1°.

Inside the spectrophotometer, the microscope can be associated, to a Linkam furnace to record spectroscopic data *in situ* at temperatures up to 1500°C. High pressure data can also be recorded *in situ* using a diamond anvil cell with internal pressure calibration via a laser.

Microscopic measurements at microscale and high T or P will be used to investigate the spatial evolution of element speciation in mineral and glasses.

[4]Institute of Materials Science, University of Silesia, 75 Pułku Piechoty 1A, 41-500 Chorzów, Poland
[5]Institute of Geochemistry, Mineralogy and Petrology, Warsaw University, al. Żwirki i Wigury 93, 02-089 Warszawa, Poland

Oldhamite is widespread mineral of spurrite, larnite and apatite-calcite pyrometamorphic rocks of the Hatrurim formation. Pyrometamorphic rocks of the Hatrurim formation („Mottled Zone") are located along the framing of the Dead Sea transform fault on the territory of Israel, Jordan and Palestine [1]. Oldhamite shows stable composition close to stoichiometric formula CaS. Oldhamite rarely occurs in larnite rocks enriched with copper sulphides. Larnite, brownmillerite, fluorellestadite, ye'elimite, new mineral - nabimusaite $(K,Ba)Ca_{12}(SiO_4)_4(SO_2)_2(O,F)_3$ [2] and potencially new minerals of mayenite supergroup of the series $Ca_{12}Al_{14}O_{32}F_2$ - $Ca_{12}Al_{14}O_{32}[F_2(H_2O)_4]$ [3] are the main minerals of these rocks. Periclase, vorlanite $CaUO_4$ and new phase Ca_3UO_6 are noted as accessory minerals. In one case oldhamite was detected as inclision in chalcocite. Around oldhamite a phase with empirical crystal chemical formula $Ca_{0.99}Cu_{2.02}S_{1.98}$ forms. EBSD and Raman studies showed identity of this phase to the synthetic thiocuprate $CaCu_2S_2$ [4].

[5]Systematic Mineralogy, 44, 11th line V.O., apt.76, Saint-Petersburg 199178, Russia

Two potentially new mineral species with the end-member crystal chemical formulae $Ba_3(VO_4)_2$ and $BaAl_2Si_2O_8$ were detected in vein-like bodies of paralavas composed by coarsed-graned aggregates of rankinite, melilite, pseudowollastonite, schorlomite, fluorapatite, magnetite hosted by melilite hornfels. These rocks are confined to pyrometamorphic rocks of the Hatrurim formation in the Negev Desert, Israel [1]. Ba-minerals being in association with $Ba_3(VO_4)_2$ and $BaAl_2Si_2O_8$ are represented by the following mineral species: barioferrite $BaFe_{12}O_{19}$, barite $BaSO_4$, walstromite $BaCa_2(Si_3O_9)$ and the next potentially new minerals of the $BaCa_6[(SiO_4),(PO_4),(VO_4),(SO_4)]_4F$ series. The studied minerals show similar characteristics, for example EBSD patterns and Raman spectra (Fig. 1), as their well-known synthetic analogous [2, 3].

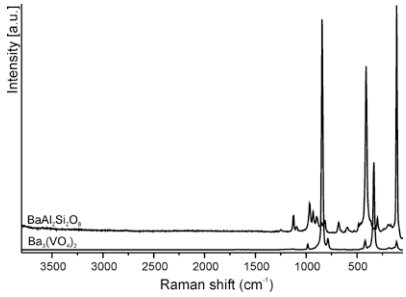

Figure 1: Raman spectra of two potentially new Ba-minerals.

Graphite formation by calcite reduction during subduction

MATTHIEU GALVEZ[1], OLIVIER BEYSSAC[2], ISABELLE MARTINEZ[3] AND KARIM BENZERARA[2]

[1]IMPMC Paris, France. Now at Geophysical Laboratory. matthieu.galvez@gmail.com
[2]CNRS IMPMC Paris, France. Olivier.Beyssac@impmc.upmc.fr
[3]IPG Paris, France.

The geochemistry of organic carbon in subduction zones may be strongly affected by mineral equilibria. We investigate here the geochemistry of carbon in siliceous-marbles at the direct contact with serpentinites in the Alpine lawsonite-blueschist meta-ophiolithic units of northern Corsica (France). We apply a set of spectroscopic (Raman) and isotopic methods to describe both the organic and carbonate components of the rocks across a reaction front where the equilibrium $CaCO_3+SiO_2+2H_2=CaSiO_3+C+2H_2O$ is evidenced.

The continuous reaction zone is composed by a centimeter thick pale nephrite layer at the contact with the serpentinites, followed by a thin wollastonite layer and a 5 to 20 cm thick dark zone composed of wollastonite, graphitic carbon, quartz but no calcite. There is a sharp (<0.5cm) transition to the overlying original metasediment composed of calcite+quartz which is significantly less rich in graphitic carbon. Raman spectroscopy shows that the graphitic carbon is better crystallized in the reaction zone compared to the non-reacted rock. Significant isotopic differences are observed apart the reaction front with $\delta^{13}C$ (graphitic carbon) and $\delta^{13}C$ (calcite) around -15‰ and 1‰ respectively in the pristine sediment far from the reaction zone, whereas $\delta^{13}C$ (graphitic carbon) is around 0‰ in the reaction zone.

We interpret the graphite in the reaction zone as formed from the destabilization and reduction of calcite under reducing conditions, possibly sustained by the underlying serpentinite body. Mass transfer calculation supports this hypothesis and shows that a complete reduction of calcite might have occurred. In addition, the temperature (430°C) of formation for this graphite is extremely low compared to any other natural process for graphite formation.

Pb isotopic composition of Himalayan Sediments

A. GALY[1,*], J. GATTACCECA[2], A.M. PIOTROWSKI[1,3] AND M. FRANK[4]

[1]University of Cambridge, UK (*correspondence: ajbg2@cam.ac.uk)
[2]BRGM, France, (julie.gatta@gmail.com)
[3](amp58@cam.ac.uk)
[4]IFM-GEOMAR, Kiel, Germany (mfrank@ifm-geomar.de)

Pb- and Nd- isotopic time-series from the authigenic fraction of Central Indian Ocean sediments have been interpreted as responding to changes in the relative amount of Himalayan weathering during the Neogene [1-3]. Such interpretation relies on the lack of change in the isotopic signature of the weathering in the Himalaya. Based on detrital records from the Bengal deep-sea fan, the Nd isotopic composition of the eroded rocks remained nearly constant for the last 20My [4, 5]. However, the associated variations in the Pb-isotopes are not known, and a more precise reconstruction is hampered by the lack of information about temporal changes in the isotopic composition of dissolved Pb and Nd carried by rivers draining the Himalaya.

We present Pb- and Nd-isotope time series, from the bulk detrital and silt-sized fractions as well as the authigenic fraction of deep-sea sediment from Ocean Drilling Program Sites 717 and 718 in the Bengal fan, along with Pb- and Nd-isotopic compositions of Himalayan river bedloads. The oldest ODP samples (7-17My) have relatively uniform Pb- and Nd-isotopic compositions, characteristic of a stable input from the High Himalaya Series. The youngest samples (<1Ma) are also fairly uniform with a shift towards more radiogenic values, implying a greater contribution of the Lesser Himalaya Series. During the Pliocene (1-7Ma) the detrital fraction have more variable Pb- and Nd-isotopic composition associated with a decoupling between the bulk and silt-sized fractions. In detail, Pb-isotopic composition of the detritial is controlled by 1) the source (and correlated with εNd), 2) the sorting and the mineralogy as witnessed by relationship with Zr, and 3) weathering and preferential loss of radiogenic Pb. Our results suggest a strong variability in the erosion and weathering regime of the Himalaya over the Neogene with implication on the interpretation of the authigenic records in the signature of deep water of the Central Indian Ocean.

[5]GFZ, Potsdam, Germany, (hovius@gfz-potsdam.de)

The temporal evolution of the $\delta^{13}C$ of marine carbonate bears contains valuable informations about on the global size of the organic carbon (OC) pool. C-cycle models based on the coupling of atmospheric CO_2 consumption and the fertilisation of coastal seas by continental silicate weathering enhanced by mountain building, suggest a rise in the marine OC burial rate for the entire Neogene that played a role in global cooling [1]. However, such tectonic-climate link relies primarily on the inorganic cycle, which has proven to be particularly inefficient to drawdown atmospheric CO_2 in the Himalayas [2] and only enhanced in the late Miocene as recorded in the Indian Ocean [3]. Other hypothesis linking OC burial and global cooling have been suggested, requiring changes in the biogeochemistry of the ocean [4]. Here, we show that terrigenous OC could play a role since its export from land is climatically sensitive. In Taiwan, the climatic control on the erosion and export of OC from the biosphere is moderated by the catchment geomorphology (proportion of steep hillslopes) [5]. In the Swiss Alps, we find that supply of OC from soil becomes active at a moderate threshold and runoff delivers OC to the stream with a long-term efficiency comparable to Taiwan [6]. As observed in the modern Bay of Bengal depositional system [7] or in the mid-Miocene turbidites of the Apennine (Italy), burial efficiency of terrigenous OC is particularly high. The respective role of climate and tectonic forcing and their feedbacks will be discussed with implications for the preservation of C3 biomes.

Bauxite metallurgical tailings (red mud from alumina production) were provided by Aluminium of Greece S.A. plant at central Greece (www.alhellas.gr) and characterized by using a combination of microscopic, analytical, and advanced spectroscopic techniques (SEM-EDS, XRF, ICP-OES/MS, HR γ-ray Spectrometry and EXAFS). Particular emphasis was given on investigating actinides, and other elements of potential environmental interest. According to XRF (performed at the PANalytical laboratories) and ICP-OES/MS measurements, the material contains Cr (2025 ppm), V (1081 ppm), Ni (933 ppm), As (164 ppm), Pb (120 ppm) and Th (111 ppm). The latter, and also minor U (15 ppm) are responsible for radioactivity (352 and 134 Bq/Kg for ^{232}Th and ^{238}U respectively) with total dose rate 285 nGy/h. Specific leaching experiments, using seawater from Greece, in conjunction with ICP-MS (performed at the INE/KIT), indicated significant release of V, which seems to be the most mobile element. Minor quantities of As and Cr may also be released in seawater. On the other hand, the release of Th, and therefore of significant radioactivity, was found to be negligible. The immobility of Th can be explained by its position in the crystal structure of Ti-oxides, as proved by the the Th L_{III}-edge EXAFS data, obtained at the ANKA Synchrotron Radiation Facility (KIT) and evaluated using the ATHENA and the EDA software packages.

Tracking down the Ediacaran isotope anomalies in a sedimentary section from Kazakhstan

ANTONIA GAMPER[1]*, ULRICH STRUCK[1] AND GAPPAR ERGALIEV[2]

[1]Museum für Naturkunde, Invalidenstr. 43, D-10115 Berlin, *antonia.gamper@mfn-berlin.de
[2]Institute of Geological Sciences, Almaty 050010, Kazakstan

The Ediacaran-Cambrian period marks one of the most significant and vital epochs in the evolution of the Earth's ecosphere. Multicellular life, hard-shelled organisms and a bioturbating lifestyle evolved during a time of tectonic instability and fundamental biogeochemical changes in the oceans. Three major global carbonate carbon isotope excursions are assumed to be crucial for the evolution of early animal life.

Excellent preserved Ediacaran to early Cambrian strata crop out commonly in sections around the area of Zhanatas in southern Kazakhstan. However, geochemical and geochronological data from these rock sections are scarce. We determined carbonate carbon, organic carbon and nitrogen isotope data from the ~200 m thick Kyrshabakty Section including the basal late Cryogenian Aktas Tillite (Marinoan-age glacial deposit), the Ediacaran Kyrshabakty Member and the overlying lower Cambrian Chuluktau Member of Malyi Karatau Range. The section shows a high-resolution geological record of a carbonate-siliciclastic nearshore environment. Isotope data of the shallow water deposits reveal three major negative $\delta^{13}C_{carb}$ excursions. The basal Cap Carbonate overlying the Tillite shows a negative shift down to -2.4‰ which corresponds with other sections worldwide. The middle section comprises an excursion with a nadir of -9.5‰ possibly corresponding to the Shuram-Wonoka $\delta^{13}C_{carb}$ excursion (e.g. Oman, Australia). The uppermost strata are associated with a negative $\delta^{15}N$ excursion of -2.5‰ co-occurring with a pronounced negative $\delta^{13}C_{carb}$ excursion (down to -6.7‰) reflecting the global carbon isotopic trend of the Precambrian-Cambrian boundary interval (e.g. Namibia, Australia, China, Siberia). Our results suggest that the sedimentary deposits of the Kyrshabakty Member exhibit geochemical and isotopic variations of the three major profound biogeochemical fluctuations as seen in other sections worldwide. They also confirm a previously found negative $\delta^{15}N$ excursion at the Ediacaran-Cambrian transition from South China as a large to global scale anoxic event possibly accompanied by photic zone anoxia. This anoxic event may have influenced the following Cambrian Explosion of biota significantly.

Temperature dependence of water activity in organic aerosols

G. GANBAVALE*, C. MARCOLLI, A. ZUEND, U.K. KRIEGER AND T. PETER

Institute for Atmospheric and Climate Science, ETH Zurich, Zurich, Switzerland (*correspondence:gouri.ganbavale@env.ethz.ch)

Atmospheric aerosols are complex mixtures of organic and inorganic compounds and influence significantly the Earth's climate. Knowledge of the composition and physical state of aerosols is essential since they play significant roles in atmospheric processes such as heterogeneous and multiphase chemistry, cloud formation, scattering and absorption of visible light and infrared radiation. At low temperatures the organic aerosol fraction is expected to be present in a liquid or glassy state since the large number of organic components depresses the temperature at which crystalline solids form [1, 2]. In the upper troposphere homogeneous ice nucleation and cirrus cloud formation take place on aerosols which grow into ice crystals by dissipating supersaturated water vapour. Homogeneous ice nucleation in supercooled aqueous solutions is independent of the nature of the solute but depends on water activity (a_w) and hence a_w of a solution is a crucial parameter for homogenous ice nucleation [3]. Activity coefficients of organic compounds in solutions may exhibit a considerable temperature dependence that has to be parameterized by models in order to achieve accurate predictions at temperatures other than room temperature.

To measure a_w over a wide composition range while focusing on low temperatures, we used different measurement techniques and instruments such as a dew point water activity meter, differential scanning calorimetry (DSC) and an electrodynamic balance (EDB). In addition we developed a setup to measure absolute vapor pressure of solutions at low temperatures. Water activity measurements were performed for aqueous organic mixtures containing the functionalities typically found in the organic aerosol fraction such as alcohol/polyol, carboxylic acids, ketones, ethers, esters, and aromatic rings. These data was used together with literature data to improve the temperature dependence of activity coefficients at low temperature in the thermodynamic group-contribution model AIOMFAC (Aerosol Inorganic-Organic Mixtures Functional groups Activity Coefficients) [4, 5].

Chemical composition of the Western Arctic Ocean sediments: Recommended element abundances and potential reference material

*GAO AIGUO[12] AND ZHAO DONGMEI[1]

[1]College of Ocean and Earth Sciences, Xianmen Univeristy, 361005, China (*correspondence: aggao@xum.edu.cn)
[2]State Key Laboratory of Marine Environmental Science, Xiamen University, China

The Western Arctic Ocean is the major continental margins and deep-sea system of the Earth with weathering and sedimentary characteristics similar to glacial environment. It is characterised by the broadest continental shelves, extreme environment and minimal effect of human activities so that it is much less constrained in comparison to other oceanic regions. Arctic Ocean sediments represent an outstanding archive to investigate global change and high-latitude marine geochemical processes. However, no clear understanding of their element abundances has been achieved yet. In this study, six marine sediments samples have been collected from the Western Arctic Ocean shelves and the Canada Basin, in order to provide a comprehensive representation of Arctic sediments. Samples are homogeneously mixed and analysed by ICP-MS, ICP-ES, INAA and 16 other analytical methods in 14 top geochemical institutes in China to ensure that measurements are reproducible over time and among laboratories. The abundances of 71 components (all the major and trace elements) have been determined through 3128 analyses. Owing to extensive inter-laboratory calibrations and statistical analysis, 64 of 71 elements have the highest possible standards of reliability and reproducibility and can therefore be used as recommended values for Arctic Ocean sediments, while the rest 7 components (Br, I, In, Te, C, CO_2 and H_2O^+) are sufficiently homogeneous and stable to be used as indicative values. The results show that the elemental abundances of the Western Arctic Ocean sediments are controlled by material sources and sedimentary environments which are unique when compared with the upper continental crust or mainland and shallow-sea sediments in China. These element abundances can serve as a recommended guideline for environmental assessment, resource exploration, and global change research. Moreover, it can be used as a potential sediment standard for high-latitude/glacial geochemistry study.

Determination of the Early Palaeozoic Strata in Eastern Heilongjiang Province, NE China: Constraints from Geology and Detrital Zircon U-Pb ages

FUHONG GAO, YANG YANG, FENG WANG, AND HONG FENG

College of Earth Sciences, Jilin University, Changchun 130061, China (gaofh@jlu.edu.cn)

It has been a controversial issue whether did the Early Paleozoic strata occur in the Songnen-Zhangguangcailing Massif, NE China. This paper provides the LA-ICP-MS zircon U-Pb dating results from the Chenming Formation in the eastern Heilongjiang Province, NE China. Combined with the formation timing of the overlying strata, it is suggested that an Early Paleozoic strata is firstly determined in the NE China. Most of detrital zircons from the Chenming Formation are euhedral-subhedral in shape and display striped absorption or fine-scale oscillatory growth zoning in CL images, implying their magmatic origin. The others show dark accretionary rim formed by metamorphism. The dating results indicate that the detrital zircons from feldspathic quartz sandstone in the upper part of the Chenming Formation yield age populations of 561 Ma, 621 Ma, 683 Ma, 752 Ma, 803 Ma, 822 Ma, 851 Ma, 900 Ma, 922 Ma, 954 Ma, 1781 Ma, 1865 Ma, and 1933 Ma, suggsting that the sedimentary processes of the Chenming Formation could take place after 561 Ma.

In the study area, the Baoquan Formation occur as overlying strata over the Chenming Formation with the unconformity relationship. The detrital zircons from argillic siltstone in the lower part of the Baoquan Formation yield age populations of 425 Ma, 450 Ma, 485 Ma, 900 Ma, and 1750 Ma (Meng *et al*, 2010) whereas the rhyolite in the upper part of the Baoquan Formation formed in 383 Ma. Taken together, we conclude that the Chenming Formation formed between 561 Ma and 425 Ma, i.e., Early Palaeozoic. Additionally, the age population of detrital zircons from the Chenming Formation reveal that the Neoproterozoic as well as Paleoproterozoic terranes could occur within the Songnen-Zhangguangcailing Massif besides the Paleozoic terranes. Combined with the distribution of geological terranes around the study area, we consider that the provenance of the Chenming Formation mainly come from the Paleozoic igneous rocks and minor Precambrian basement remnant around the study area. This is a firstly discovered Early Palaeozoic strata with the exact geochronological evidence in the eastern Heilongjiang Province, NE China.

Multi-stage gold mineralization at the Hollinger-McIntyre deposit: A LA-ICPMS mapping study

J-F. GAO[1]*, S E. JACKSON[1] AND B. DUBÉ[2]

[1]Geological Survey of Canada, Ottawa, ON, K1A 0E8, Canada (*correspondence: Jianfeng.Gao@NRCan.gc.ca)
[2]Geological Survey of Canada, 490 De la Couronne Street, Québec City, QC, G1K 9A9, Canada

The Hollinger-McIntyre gold deposit, Timmins, Ontario, is the second largest Archean quartz-carbonate vein system in the world, with a total gold production of ~1000 tonnes Au[1]. The deposit consists of two mineralization types: an early-stage intrusion-related Cu-Mo-Au-Ag mineralization telescoped by a syn-deformation Au-pyrite-quartz-carbonate vein system that constitutes the bulk of the ore[2].

We used a new LA-ICP-MS elemental imaging technique to map pyrite grains from the Au-pyrite-quartz-carbonate vein system. The elemental maps have revealed at least three paragenic stages (Figure 1): (1) early stage, where invisible Au was enriched in As-rich pyrite; (2) lowering As associated with increasing Ni; Au, Cu and Zn were depleted in this stage; (3) native Au filling fractures in early pyrite grains or discrete grains associated with sphalerite and chalcopyrite in quartz veins; Ni and As were depleted in this stage. The early-stage pyrite at Hollinger-McIntyre is enriched in As and Au different from those of pyrite from Carlin-style deposits[3], but similar to those from porphyry Au-Cu deposits (unpublished data). The latter would be compatible with the early intrusion-related Cu-Mo-Au-Ag stage.

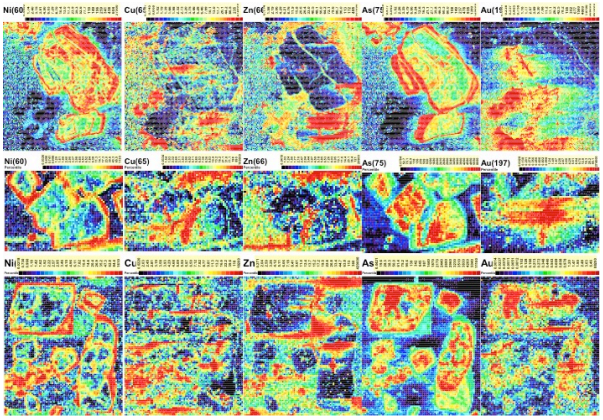

Figure 1. Mapping of selective elements for gold ore from the Hollinger-McIntyre Au deposit (Scales are in ppm).

Modeling of modern δ^{30}Si distributions in the oceans and in marine sediments

S. GAO*, D. A. WOLF-GLADROW AND C. VÖLKER

Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Am Handelshafen 12, 27570 Bremerhaven, Germany (*correspondence: shuang.gao@awi.de)

δ^{30}Si is used as a proxy for reconstruction of marine silicic acid utilization and Si cycling in the geological past. A better understanding of modern δ^{30}Si distribution and its control mechanism is imperative for applying this proxy with confidence.

It has been a decade since the first modeling effort on global marine δ^{30}Si distribution was accomplished [1]. There are much more field studies that have been conducted since then, which facilitates model validation and model-data comparison. In this study, we present a more sophisticated model setup compared to previous modeling studies [1, 2], aiming at representing a realistic global pattern of oceanic and sedimentary δ^{30}Si distributions and revealing possible controlling mechanisms.

Our model results suggested that surface δ^{30}Si in the North Atlantic and in the Southern Ocean (Figure 1) are largely controlled by seasonal variations of mixed layer depth and diatom primary production. The difference is up to 0.3‰ between summer and winter months, which should be considered when measuring oceanic δ^{30}Si.

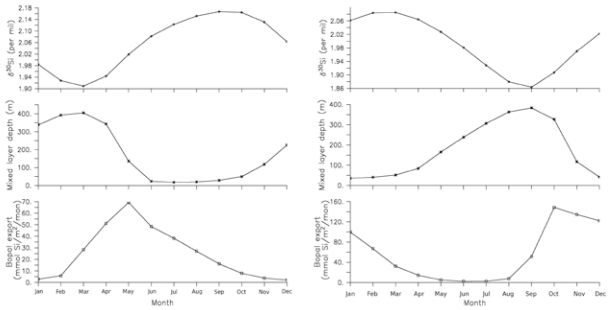

Figure 1: The seasonal variations of surface δ^{30}Si (upper 100 m), mixed layer depth and biogenic opal export in the North Atlantic (left) and in the Southern Ocean (right).

Characteristic of Fluid Inclusion of the Xujiahe Formation in the Central Sichuan Basin, China

XIAOHUI GAO, SHIZHEN TAO AND XIA ZHAO

[1]Research Institute of Petroleum Exploration & Development, Petrochina , gxh2008@petrochina.com.cn
[2]Research Institute of Petroleum Exploration & Development, Petrochina ,tsz@petrochina.com.cn
[3]Research Institute of Petroleum Exploration & Development, Petrochina , zhaox601@petrochina.com.cn

The Sichuan Basin is an inner plate basin at the west of Yangzi Plate. It is a large petroliferous basin with marine carbonate deposition and terrestrial clastic deposition. Its gas bearing area can reach $18\times10^4km^2$, and the gas proven reserves, gas fields number and gas production are all the No.1 in China[1,2].

In our project we chose more than 80 samples of fluid inclusions from tight sandstone reservoirs of Xujiahe Formation in 28 wells, all of which are located in gas bearing intervals from gas fields in middle Sichuan area. The conclusions are as follows□

1.In the center of the Sichuan Basin, the maturity of source rock in the Xujiahe Formation is not high, with Ro value ranging from 0.8% to 1.2%. However, the gas reservoirs nowadays show characteristics of high gas-oil ratios and low condensate oil content (3.8~91.9g/m^3 on average). There are abundant gas hydrocarbon inclusions developed in the reservoir, with few liquid hydrocarbon inclusions, which shows that the coal measures have given priority to gas.

2.In the fluid inclusion group, the CH_4 accounts 79.62~96.42%, and C_2H_6 is about 10%, the content of C_3H_8 ranges from 3% to 5%. As to the carbon isotope of CH_4, $\delta^{13}C_1$= -44.59~-39.31‰, $\delta^{13}C_2$= -24.82~-28.05‰, $\delta^{13}C_3$= -21.39‰, $\delta^{13}C_4$= -22.05~-20.2‰, $\delta^{13}Cco_2$= -9.14~-13.86‰. The gas component and isotope in fluid inclusions coincide with the carbon isotope in the gas reservoirs today, showing that the gas hydrocarbon in the fluid inclusions can represent the residue gas in the gas reservoirs. The residue gas is mainly formed and preserved in the late stage.

3.The He and Ar associated with natural gas are positively related in content. $^{40}Ar/^{36}Ar$ and $^3He/^4He$ also has a positive correlation. He and Ar isotopic composition analysis shows that, R/Ra ratio is less than 0.5, the majority of 0.1 or less , reflecting the crust was stable then, no deep large faults or deep-source gas mix, the natural gas was mainly from the shallow crust.

Li isotopes in zircon: Effects of Li substitution and kinetic fractionation

*YU-YA GAO[12], XIAN-HUA LI[1], WILLIAM L. GRIFFIN[2] SUZANNE Y. O'REILLY[2] AND NORMAN J. PEARSON[2]

[1]State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, China Academy of Sciences, China (*correspondence: yuya.gao@mq.edu.au)
[2]ARC Centre of Excellence for Core to Crust Fluid Systems and GEMOC National Key Centre, Dept of Earth and Planetary Sciences, Macquarie University, Australia

In situ SIMS (Secondary Ion Mass Spectrometry) analysis of Li isotopes in zircon shows potential for studying the origin of crustal magmas. However, it is controversial whether δ^7Li in zircon reflects the magmatic sources of the zircon, or was modified by later processes. To understand Li behaviour in magmatic systems, δ^7Li and Li abundance have been investigated in whole-rock samples and zircon crystals of several standards (Temora, Plesovice, Qinghu) as well as two A-type granites from Suzhou (aluminous A-type granite) and Taohuadao (peralkaline A-type granite), east China. The measured δ^7Li values range from -12 to -1‰ for Temora, and -4 to -1‰ for Qinghu; in both cases δ^7Li is weakly correlated with ppm Li, indicating a relatively slow rate of Li diffusion. However, Plesovice (δ^7Li = -4 ~ +3‰) and M257 (*in situ* zircon Li isotope standard, δ^7Li = 2.1±1‰) show no sign of diffusion. This suggests that the Li diffusion rate might be controlled by the trace-element composition of zircon. Large variations in Li abundance (up to 10 ppm) and δ^7Li values (26‰) have been measured in zircons from per-alkaline and more aluminous A-type granites samples. The Li abundance in zircon from the Suzhou pluton is 10x to 100x higher than in the Taohuadao pluton. The measured δ^7Li values from Taohuadao range from -21 to 2‰ and are positively correlated with ppm Li, while the δ^7Li values of Suzhou range from -7 to +7‰ and correlate negatively with Li content. In contrast, the whole-rock lithium concentrations and isotope ratios show a more narrow range (+2 to 5‰). The possible explanation for the large variations in Li and δ^7Li values in zircon is that the diffusion of Li is controlled by different substitution mechanisms that involve other trace elements, resulting in kinetic fractionation of the Li isotopes. However, Li abundances in zircon could be a petrogenetic tracer to identify different sources of A-type granites.

First occurrence of dumortierite in Croatia: A potential evidence of tetrahedral Ti substitution for Si

V. GARAŠIĆ[1]*, B. LUGOVIĆ[1], M. SEKUŠAK[1], H.-P. MEYER[2], M. VRKLJAN[1] AND R. SCHUSTER[3]

[1]University of Zagreb, Faculty of MGPE, Croatia (correspondence: vesnica.garasic@rgn.hr)
[2]University of Heidelberg, Germany
[3]Geologische Bundesanstalt, Vienna, Austria

Dumortierite $(Al,\square)Al_6(BO_3)Si_3O_{13}(O,OH)_2$ occurs in a pegmatite vein cutting S-type granite in the Late Cretaceous magmatic-metamorphic complex of Mt. Moslavačka gora, in the SW part of the Pannonian Basin, Croatia. The granitoid pluton intruded Abukuma type series of metamorphic rocks associated with migmatites. Dumortierite-bearing vein, up to 6 cm thick, consists of coarse-grained quartz, orthoclase, microcline and albite, less abundant muscovite, biotite, pinkish andalusite and blue-coloured dumortierite. The microscopic studies identified two types of dumortierite crystals: Dum I and Dum II. The Dum I crystals are subhedral prismatic up to 16 mm in size, strongly pleochroic ranging from colourless to azure blue. The Dum II type represents bundles of parallel fibrous or acicular crystals, up to 1,4 mm long, strongly pleochroic from colourless to red violet. The Dum I crystals have lower contents of Mg (0.033-0.055 pfu) and Ti (0.001-0.011 pfu) than Dum II crystals (0.047-0.087 pfu and 0.043-0.064 pfu, respectively) whilst differences in Fe abundance (0.038-0.072 pfu vs. 0.037-0.057 pfu) and Al/Si ratios (2.35-2.47 vs. 2.27-2.49) are not significant. A Si deficiency (< of 3.0 pfu) is found in 95% of EPMA spot analysis of the dumortierite. The Si tetrahedral deficiency has been conventionally balanced by Al. A moderate correlation between 3-Si and Al (r = 0.606), and between 3-Si and Ti (r = 0.609) exists in the analysed dumortierites. Strong correlation between 3-Si and Al+Ti (r = 0.968) suggests that Ti in dumortierite replaces not only Al in octahedra as generally accepted, but also may substitute Si in tetrahedra.

Temperature driven stable carbon isotope ratio in marine aerosols

A. GARBARAS[1]*, D. CEBURNIS[2], A. MASALAITE[1], W. MAENHAUT[3], J. OVADNEVAITE[2], C.D. O'DOWD[2] AND V. REMEIKIS[1]

[1]Center for Physical Sciences and Technology, Vilnius, Lithuania (*correspondance: garbaras@ar.fi.lt or darius.ceburnis@nuigalway.ie)
[2]School of Physics and Center for Climate and Air Pollution Studies, Ryan Institute, National University of Ireland, Galway, Ireland
[3]Institute for Nuclear Sciences, Ghent Univ., Ghent, Belgium

Stable carbon isotope ratio mass spectrometry is evolving as a powerful tool in aerosol source apportionment studies due to unique capability of discriminating among various carbon sources [1, 2].

Stable carbon isotopic analysis was performed on the aerosol particles that were collected from 3 December 2006 until 4 March 2007 in Amsterdam Island (37.81◦S, 77.5733◦E), which is an atmospheric research station located in the southern Indian Ocean far from continents. The aerosol particles were sampled in fine and coarse modes. The $\delta^{13}C$ values in the fine mode ranged from -27.5 ‰ to -20.4 ‰, and in the coarse mode from -28.2 ‰ to -22.6 ‰. The concentrations of organic and inorganic species were measured in the both size fractions as reported by Claeys *et al* [3].

The measured $\delta^{13}C$ values, salts and organic carbon concentrations in the fine and coarse size fractions were combined with the isobaric air mass back trajectories, the corresponding chlorophyll concentrations and the sea surface temperature (SST). Correlation between organic carbon isotopic ratio of atmospheric aerosol and the sea surface temperature was found, corroborating significant differences in biogenic processes in the Southern Ocean.

Clumped isotope thermometry on ultramafic-hosted magnesium carbonates

PABLO GARCÍA DEL REAL[1]*, TOBIAS KLUGE[2], CÉDRIC M. JOHN[2], NATALIE C. JOHNSON[3], KATE MAHER[1], DENNIS K. BIRD[1] AND GORDON E. BROWN, JR[13]

[1]Department of Geological & Environmental Sciences, Stanford University, Stanford, CA 94305-2115, USA. gdelreal@stanford.edu (*presenting author)

[2]Department of Earth Science and Engineering, and Qatar Carbonate and Carbon Storage Research Center, Imperial College London, UK.

[3] Department of Chemical Engineering, Stauffer III, Stanford University, Stanford CA 94305

Magnesite ($MgCO_3$) and other magnesium carbonates hosted in serpentinized peridotite rocks record the final fate of CO_2-rich fluids in shallow crustal environments and provide constraints on low-temperature carbon capture and storage in ultramafic rocks. Here we determine *clumped* temperatures of mineralization for magnesium carbonates from a variety of natural ultramafic environments, and we couple our results with a laboratory-based calibration of synthetic magnesite. Our samples include: (*a*) massive (10's of meters thick and >100's of meters in length and depth) homogeneous, cryptocrystalline magnesite veins from the Red Mountain Magnesite Mine in the Del Puerto ophiolite of the California Coast Ranges (T = 21.5±4°C, n=7, with a maximum temperature of 31°C); (*b*) surficial nesquehonite ($MgCO_3 \cdot 3H_2O$), hydromagnesite ($Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$), dypingite ($Mg_5(CO_3)_4(OH)_2 \cdot 5H_2O$) and artinite ($Mg_2(CO_3)(OH)_2 \cdot 3H_2O$) from the peridotite-serpentinite belt of the California Coast Ranges (T = 21±4°C, n=6); (*c*) additional ultramafic-hosted magnesite deposits (Turkey, Austria, Iran) analogous to Red Mountain (T= 30.5±5°C, n=3), and (*d*) magnesite produced from carbonation of olivine at 60°C, 100 bars pCO_2, 0.5M NaCl, and variable (20:1 and 50:1) water-rock ratios (T=52±6°C, n=2). We use our results to constrain the $\delta^{18}O$ composition and origin of the mineralizing fluids of the magnesite deposits at Red Mountain. Nearly identical *clumped* isotope signatures among worldwide magnesite deposits suggest that a similar set of geological processes were associated with carbonation in crustal ultramafic rocks.

Characterization of complex Fe-Mn phosphates by LA-ICP-MS methods

S. GARCÍA DE MADINABEITIA[1], E. RODA-ROBLES[2], A. PESQUERA[2], M.E. SÁNCHEZ[2] AND J.I. GIL IBARGUCHI[2]

[1]SGIker-Geochronology, UPV/EHU, Spain (*correspondence: sonia.gdm@ehu.es)

[2]Dpt. Mineralogy-Petrology, UPV/EHU, Spain (encar.roda@ehu.es)

Ca-phosphates in any of their variants (apatite, merrillite, etc.) are the subject of increasing interest in petrogenesis and mineralogenesis studies of igneous and metamorphic rocks from different geological settings. Their trace element characterization has been sought for and is usually done using LA-ICP-MS methods. Less abundant Fe-Mn phosphates and fluorophosphates are potential indicators of deposits of economic interest but have been so far less investigated for their trace element composition. In an attempt to improve the current knowledge on the latter type, we have analyzed complex phosphates of the triplite-zwieselite $(Mn^{2+},Fe^{2+},Mg,Ca)_2(PO_4)(F,OH)$, triphylite-lithiophilite $Li(Fe^{2+},Mn^{2+})PO_4$ and graftonite-beusite $(Ca, Fe^{2+}, Mn^{2+})_3(PO_4)_2$ series. For each series we have attempted to analyze phosphates covering the widest possible Fe-Mn compositional range. To set up the procedure we first analyzed igneous and metamorphic apatites including the classic specimens from Cerro Mercado (Durango, Mexico), initially on mineral separates and then on thick petrographic preparations. The procedure was subsequently optimized for the analysis of the Fe-Mn phosphates also in thick section. This involved the use of XSeries 2 and UP213 instruments, a SuperCell device, He as transport gas, enhanced vacuum and NIST glasses and Durango apatite for calibration and quality control purposes. Although the absence of specific CRMs implies some limitations, the method set up allows to obtain reliable results for most trace elements in the ppm range and reveals marked differences for the studied series of primary Fe-Mn phosphates, with significant variations also related to the different geological settings. Members of the triphylite-lithiophilite series present extremely low contents in all the analyzed elements, except for Zn (570-8990 ppm). In contrast, members of the triplite-zwieselite series are enriched in Nb (78-537 ppm) and Zn (437-4093 ppm), with variable contents in HREE (0-124 ppm), Ta (4-176 ppm), Y (0-280 ppm), Zr (6-233 ppm), and U (7-50 ppm). Finally, members of the graftonite-beusite series are the richest in REE, with ΣHREE up to 300 ppm and of ΣLREE up to 345 ppm. Other trace elements, such as Zn (1508-4238 ppm), Sr (3-91 ppm) and Y (0-509 ppm) occur also in significant amounts.

Modelling of Cs adsorption in natural mixed clays and the effects of ion competition

M. GARCÍA-GUTIÉRREZ[1], TIZIANA MISSANA[1], ANA BENEDICTO[1], CARLOS AYORA[2] AND KATRIEN DE-POURCQ[2]

[1]CIEMAT, Avenida Complutense, 40, 28040 Madrid (Spain)
[2]IDAEA-CSIC, Jordi Girona, 18-26, 08034 Barcelona (Spain)

Cesium-137 (half-life, ~30 years) is an important fission product from the irradiation of uranium-based fuels and it has been released in the past to soils and waters as a result of nuclear accidents or weapon testing. Radiocesium is particularly relevant from an environmental point of view because it always exists as the monovalent cation Cs^+, which presents very high solubility.

Cesium migration in the environment is mainly controlled by sorption onto mineral surfaces; in particular, it is rather strongly adsorbed onto clays by ionic exchange. Thus, with the objective of designing a geochemical reactive barrier to treat Cs-137 pollution in a salt marsh zone, several natural clayrocks were analysed as possible sorbent. The composition of the rocks was variable and within the clayey fraction the mayor clay minerals were illite, smectite and kaolinite.

The high salinity of natural waters presents in the zone obliged the understanding and quantification of the the effects of competitive ions, which may hinder cesium adsorption. Furthermore the water chemical composition variability leads to significant differences in distribution coefficients (K_d).

The semi-empiric approach in the analysis of experimental data, above all when sorption is non-linear (as in the case of Cs) is unsatisfactory.

Thus, the development of sorption models, validated by experimental data, obtained under conditions representative of the site is needed. A multisite cation exchange model, considering both the solid (mixed clays) and water composition was used to successfully explain cesium sorption in the analysed natural clayrocks and the effects of highly competitive ions present in the aqueous phase, in particular K^+, NH_4^+ and Na^+.

Removing the "heavy mineral effect" to obtain a new Pb isotopic value for the upper continental crust

M. GARÇON[1]*, C. CHAUVEL[1], C. FRANCE-LANORD[2], M. LIMONTA[3] AND E. GARZANTI[3]

[1]ISTerre, Université de Grenoble, France
[2]CRPG-CNRS, Vandoeuvre-lès-Nancy, France
[3]Laboratorio di Petrografia del Sedimentario, Università di Milano-Bicocca, Italy (*correspondence: marion.garcon@ujf-grenoble.fr)

Knowing the average Pb isotopic composition of the continental crust is crucial to constrain the evolution of the Earth since its formation. Current estimates are rare. Some come from Earth evolution models but most are based on data acquired from river or oceanic sediments. The latter assume that sediments are representative of their continental sources but bias can be introduced if sedimentary mineral sorting is ignored. Several authors already demonstrated that Hf isotopes are fractionated by the so-called "zircon effect", i.e. preferential concentration of unradiogenic Hf-rich zircons in coarse sediments which produces finer sediments with much more radiogenic Hf isotopes than their continental source. Because heavy minerals have sometime extremely radiogenic Pb isotopes, we evaluate the impact of the "heavy mineral effect" on Pb isotopes of sediments.

Here, we report Pb isotopic compositions of Himalayan river sediments as well as those of several grain-size fractions and pure mineral separates. We demonstrate that Pb isotopes of both bedloads and suspended loads are biased towards more radiogenic values than their source rocks due to a "heavy mineral effect" caused by mineral sorting during fluvial transport on continents. The sparse zircons, monazites and allanites present in all samples (< 1 wt%), including suspended loads, generate a Pb isotopic variability ($37.85 < {}^{208}Pb/{}^{204}Pb < 43.16$; $15.62 < {}^{207}Pb/{}^{204}Pb < 16.18$; $17.83 < {}^{206}Pb/{}^{204}Pb < 22.58$) as large as that observed in the Earth's mantle. Our new data suggest that mineralogical effects must be corrected for sediment Pb isotopes to be used as provenance and anthropogenic tracers. After correction of the mineralogical effect, we propose an average value for the composition of the upper Himalayan crust and a new Pb isotopic value for the Earth's upper continental crust i.e. ${}^{208}Pb/{}^{204}Pb = 39.16$; ${}^{207}Pb/{}^{204}Pb = 15.73$; ${}^{206}Pb/{}^{204}Pb = 18.95$.

Geochemical investigations of saltwater intrusion into the coastal carbonate aquifer of Mallorca, Spain

C.GARING*, L. LUQUOT AND P. GOUZE

Géosciences Montpellier, UMR 5243 CNRS/INSU, CC60, Université de Montpellier 2, Pl. E. Bataillon, 34095 Montpellier cedex 5, France
(*correspondence : charlotte.garing@gm.univ-montp2.fr)

Coastal aquifers often display seawater intrusion resulting in the formation of a salty water wedge progressing inland. Complex geochemical processes are likely to occur in the freshwater – seawater mixing zone of carbonate aquifers where the water becomes in disequelibrium with the rock forming carbonates [1]. The induced diagenetic activity, such as calcite dissolution and/or dolomitization [2,3,4,5], may result in significant hydrodynamic changes [6,7].

This study investigates the mass tranfers in a current mixing zone located in the South-East part of Mallorca Island (Spain). Investigations were conducted in two boreholes, separated by 5 m, where repeated electrical conductivity logs of the formation and of the saturating fluid, as well as regular pore-water sampling and permanent downhole multi-parameters monitoring of the water were performed over a period of 9 years.

In the mixing zone, the significant acidification, the calcite saturation index profile and the calcium concentration profile cannot be explained by conservative mixing nor by dissolution-precipitation reactions only. Conversely, the analysis of organic carbon content and of the distinctly different time-resolved pH profiles measured in the two boreholes suggests the development of perennial biomass that enhances the calcite dissolution. Moreover, the presence of biomass seems to be correlated with the permeability and vertical connectivity at meter-scale. We speculate that the mechanism could be self-activated because the microbiological activity induces calcite dissolution and tends to increase porosity and permeability that favors biomass development.

Proton behavior at water/silica interfaces: Reactions and proton transport

STEPHEN H. GAROFALINI* AND GLENN K. LOCKWOOD

Interfacial Molecular Science Laboratory, Department of Materials Science and Engineering, Rutgers University
(*correspondence:shg@rutgers.edu)

A robust dissociative water potential has been used in molecular dynamics simulations to study water adsorption and reactions on silica surfaces, dissolution, and proton transport. This potential matches many structural and dynamic properties of bulk water and, when transferred to nanoconfined situations, shows the high thermal expansion of nanoconfined water. The simulations of water/silica interfaces show the appropriate dissociative chemisorption and silanol (SiOH) formation consistent with experimental data, enhanced H_3O^+ ion formation during surface reactions, and the location of weakly binding highly acidic proton adsorption sites on the silica surface, with results similar to ab-initio molecular dynamics simulations of small systems. The simulations also showed increased proton transport that is consistent with electrochemical studies that showed increased proton conductivity in mesoporous silica exposed to moisture.

In order to evaluate the proton transfer mechanisms seen at the water/silica interface, we studied proton transport in bulk water, where previous data exist. Without changing parameters used in our previous simulations mentioned above, the simulation results show proton transport in bulk water involving Eigen and Zundel complexes consistent with ab-initio calculations and H_3O^+ ion lifetimes consistent with experimental data and ab-initio calculations. H_3O^+ ion lifetimes in both the femtosecond regime and the picosecond regime are observed. The first is indicative of proton rattling between the H_3O^+ ion and an adacent water molecule while the second is indicative of the timescale for proton transport.

The activation barriers for proton transfer between the H_3O^+ ion and an adjacent water molecule in bulk water observed in the simulations are similar to the ab-initio calculations and also show the decreasing barrier height with decreasing O-O spacing between the interacting molecules.

Genesis of quartz-rich geodes from peculiar aqueous fluids in a Cu-Zn-Pb skarn (Temperino mine, Italy) and relations with ore bodies

P.S. GAROFALO[1] AND T. PETTKE[2]

[1]Univ. of Bologna, Dept. of Earth and Environ. Sciences
[2]Univ. of Bern, Institute of Geological Sciences

The Temperino deposit is an historical Cu-Zn-Pb skarn located in the the Tuscan magmatic province of Italy. It consists mainly of massive lenses of sulfide bodies, enclosed within white marble, from which chalcopyrite, sphalerite, and galena were exploited in the past [1, 2]. These bodies occur close to trachyandesite and rhyolite porphyry dikes and within NNW-SSE trending, en-echelon and discontinuous ilvaite and hedenbergite skarn masses.

A peculiar characteristics of this deposit is the presence of quartz-rich geodes wthin the ilvaite and hedenbergite skarns. The geodes occur close to the sulfide lenses, have variable volumes (range: from 10-20 cm^3 to 2-3 m^3), and are enclosed within the massive ilvaite and hedenbergite skarns. They represent the end of the main mineralizing event at Temperino. In addition to large euhedral quartz crystals (up to 15 cm in legth), geodes contain ilvaite, calcite, epidote, and small propostions of ore minerals.

We determined the physical-chemical properties of the geode fluid combining microthermometry, Raman spectrometry, EMPA, CL imaging, and LA-ICP-MS of fluid inclusions entrapped at several stages of euhedral quartz growth. The crystals show alternations of 100 μm- to 1 mm-thick bands variably enriched in Al, Na, Li, Rb, Sr, Sb, Ba, Mn, B, Cs, and Zn, so they are chemically zoned. This zoining was accounted for in the determination of inclusion compositions. Fluid inclusions host two- (L, V) to five phase (L,V, and 3 solids) aqueous fluids. Depite this, their estimated bulk salinity is unexpectedly low (0.4-2.9 wt% NaCl eq.) and does not change systematically within the crystals. The *T*h(total) of all fluids is consistently in the 220-260 °C range and homogenzation occurs mainly by bubble disappearance. The main inclusion components are (in order of relative abundance) Na, K, B, Sr, Sb, Ba, Mn, Rb, Cs, Zn, Pb, and Cu, *i.e.*, the same that make the quartz zoning.

Molybdenum in ancient glacial tillites of different ages and its bearing on atmospheric oxygenation

R. GASCHNIG[1], R. RUDNICK[1] AND W. MCDONOUGH[1]

[1]Department of Geology, University of Maryland, College Park, MD 20742 (gaschnig@umd.edu;rudnick@umd.edu; mcdonoug@umd.edu)

Molybdenum is an important redox indicator because of its ability to exist in either insoluble +4 or soluble +6 states. The abundance and isotopic composition of Mo in black shales have been used to make inferences about global atmospheric oxygenation. While an unambiguous and dramatic rise in oxygen occurred during the ~2.3 Ga Great Oxygenation Event (GOE), Mo systematics in shales suggest that the oceans and possibly the atmosphere contained "whiffs" of oxygen as early as 2.7 Ga, implying that oxidative weathering of the continents (and Mo loss) began before the GOE. Proxies for the average composition of the upper continetal crust (UCC) should reflect this loss. V.M.Goldschmidt suggested that continental glacial till deposits could be such a proxy, and thus we have studied the chemical compositions of Paleozoic to Paleoproterozoic glacial tillites.

Ancients tillites from around the world show systematic changes in Mo abundances with time, regardless of location. Mo abundances for all Paleoproterozoic (2.4-2.2 Ga) samples are comparable to the upper crustal estimate (1.1 ppm) whereas post-Paleoproterozoic samples show depletions in Mo of up to an order in magnitude. This depletion in Mo is especially apparent when compared to elements with similar compatibility in igneous environments (i.e., LREE) and when all samples are corrected for quartz and carbonate dilution when normalized to Y or Al. Relatively undepleted Mo contents in Paleoproterozoic tillites implies insufficient oxygen in the atmosphere at that time to preferentially mobilize Mo during glacial erosion, or for the UCC to have developed an intrinsic oxidative weathering chemical signature. Both hypotheses place limits on the presence of any Neoarchean whiffs of oxygen in the atmosphere. A test of these hypotheses is available in the Mo contents of Quaternary tills derived from exclusively Archean crustal terranes, as an absence of depletion in Mo would be inconsistent with both hypotheses.

Natural hazards and scientific advice: Interactions among scientists, decision makers and the public

PAOLO GASPARINI

Università di Napoli Federico II (paolo.gasparini@na.infn.it)

The death toll of natural hazards has been dramatically increasing for a few decades. This is mainly a consequence of the increase of population density and of the vulnerability of many hazard prone areas. False and missed alarms have been harshly questioned by the population and sometimes by governmental authorities. An extreme case is the first level conviction of seven Italian scientists for the information given to the public before the Mw6.3 earthquake hitting the city of L'Aquila (Italy) and surrounding municipalities on April 6, 2009. Similar and greater disasters occurred after 2009 due to natural hazards, such as the Tohoku exceptionally violent earthquake and tsunami hitting Japan in 2011, the Christchurch earthquake sequence in New Zealand, the large floods covering central and south eastern Europe in 2006 and 2013, the floods triggered by Hurricane Irina in NE USA in 2012 etc. The reactions of public and legal authorities have been different, not reaching the extremes of L'Aquila sentence. The reactions of people and authorities to scientific information appears to be strongly conditioned by the level of risk-awareness and memory of past events. However, all the reactions of public and administrators have a common background: the lack of consciousness that we live in a probabilistic world where all scientific assessments concerning natural hazards and risks have a probabilistic character and a related uncertainty. This concept is missing in the legislation of many countries. The court of L'Aquila sentence had immediate negative consequences, at least in Italy, triggering a strongly defensive attitude in all the actors of crisis management during a natural event, hindering the implementation of innovative methodologies, such as those of early warning, that can save many lives but have inherently significant levels of false and missed alarms. Future scenarios of science - decision making people interactions must consider seriously the pros and cons of the rapidly growing role of social networks in immediate pre or during crisis information. The complexity of future communication scenarios can be approached by a widespread and transparent use of a probabilitic approach in risk governance, an advanced pre-event formation of people and administrators, and the establishment of operational risk reduction guidelines. Finally a reformulation, where necessary, of the legislation on the management of risks should clarify duties and responsibilities and introduce the concept that false and missed alarms may be significant in any risk management method.

Mantle source heterogeneity beneath the Garrotxa Volcanic Field (NE Spain)

D. GASPERINI*[1], G. GISBERT[1], D. GIMENO[1], M.AULINAS[1], P. MACERA[2] AND D. BOSCH[3]

[1]Dep. Geoquímica, Petrologia i Prospecció Geològica, Universitat de Barcelona. 08028 Barcelona, Spain (*correspondence: gasperinidaniela@gmail.com; ggisbert@hotmail.com; domingo.gimeno@ub.edu; meritxellaulinas@ub.edu)

[2]Dip. Scienze della Terra, Universitá di Pisa. 56126 Pisa, Italia (macera@dst.unipi.it)

[3]Earth Science Department, Geosciences Montpellier (CNRS). 34095 Montpellier, France (bosch@gm.univ.montp2.fr)

The Neogene volcanism in NE Spain, which is related to the rift-type extensional tectonics affecting the eastern margin of Iberia since late Oligocene, is well represented in the basalts and basanites from the Garrotxa Volcanic Field (GVF). Geochemistry of the GVF magmas is comparable to that of the Cenozoic Eastern Atlantic and Euro-Mediterranean eruptive centers related to the European Astenospheric Reservoir (EAR). The EAR is thought to have originated by the mixing between plume-like material (carrying a HIMU signature) and the shallower depleted mantle (DMM). The GVF mantle source and the EAR share comparable trace element distribution, enrichment levels and characteristic ranges of trace element ratios (e.g., Ba/La, K/La, Zr/Nb). However, isotope data from the GVF magmas call for the presence of a compositionally heterogeneous mantle source, which is considered to be the result of the mixing between two end-members. While a first end-member presents relatively high $^{143}Nd/^{144}Nd$ and $^{206}Pb/^{204}Pb$ values and shows geochemical features close to average EAR, the second end-member is characterized by relatively lower $^{143}Nd/^{144}Nd$ and $^{206}Pb/^{204}Pb$ and slightly higher $^{87}Sr/^{86}Sr$ ratios that are recurrent in EMI-type magmas. To constrain the isotope features of the GVF magmas, their Sr, Nd and $^{206}Pb/^{204}Pb$ isotopic compositions together with those of worldwide OIB, anorogenic European rocks, and lithosperic and crustal samples from the Pyrenean and Iberian domains were projected into a tethraedron with the four classical mantle end-members (DMM, EMI, EMII, HIMU) as vertices. The three-dimensional perspective indicates that the GVF mantle source isotope characteristics are consistent with a heterogeneous lithosphere, variously metasomatized by both the EAR and EMI components, and strongly related to the local tectonic structure, e.g., crustal thinning.

Calculation of the mixing ratio of wastewater effluents leakage to a pristine water source: The Israeli Experince

G. GASSER[12], I. PANKRATOV[2], H. GLAZMAN[3], G. RESHEF[2], S. ELHANANY[2] AND O. LEV*[1]

[1]Hebrew University of Jerusalem, Israel (ovadia@mail.huji.ac.il)
[2]Israel Water Authority, Bet Dagan, Israel
[3] Israel Nature and Park Authority, Israel

A methodology to estimate of the average percentage of wastewater effluents in an otherwise pristine water site was developed and applied in several vulnerable sites in Israel using mono or multiple effluent indicators. The model takes into account the levels and the uncertainty margins in the evaluation of each of the indicators in the site, in the potential effluent sources and in the uncontaminated surrounding.

Several detailed demonstrative studies exemplify the use of this model by the Israel Water Authority. In these studies we used chloride, acesulfame and carbamazepine as wastewater effluent indicators.

a The Northern Galilee springs: This research concentrated on six nearby perched springs draining upper cretaceous carbonate aquifers with Karst morphology which are influenced to an unknown extent by agricultural communities that still use septic tanks. In this site fecal contamination was found in the past, but since then the two major sources of pollution in the area were collected and diverted to a mechanical biological wastewater treatment systems.

b The Shafdan soil-aquifer treatment site. Leakage from the soil – aquifer treatment system of the Dan municipality (treating some 130 Mm^3 per annum) to the coastal plain aquifer was quantified.

c The contamination of the perched Judea Mountains springs which serve for irrigation and recreation by septic wastes was explored.

In all cases we found good correspondence between the dilution predictions by the two organic tracers, whereas the chloride predictions differed somewhat and exhibited higher level of uncertainty.

Chemical influence on recoil damage annealing and impact on (U-Th)/He age in apatite

C. GAUTHERON[1]*, R. PINNA-JAMME[1], R. KETCHAM[2], J. BARBARAND[1], L. TASSAN-GOT[3], A. CARTER[4] AND M. PAGEL[1]

[1]UMR IDES, UPS, France (* cecile.gautheron@u-psud.fr, rosella.pinna@u-psud.fr, jocelyn.barbarand@u-psud.fr, maurice.pagel@u-psud.fr)

[3]IPN, UPS, France, tassango@ipno.in2p3.fr
[4]IEPS, UCL-Bbk, London, UK; a.carter@ucl.ac.uk

Apatite (U-Th)/He (AHe) age is a function of the production/ejection and diffusion of He particles in a grain of determined size and for a particular time-temperature path. Recent studies have demonstrated that He diffusion is sensitive to the amount of α-recoil damage [1-2]. As a result, new models accounting for α-recoil damage creation and annealing were created to characterize the diffusion behaviour of He in apatite, which are currently utilized in forward and inverse tools for reconstruction of T-t paths [3]. However, although these models are based on the annealing scheme used for apatite fission tracks (AFT), the effect of grain chemistry on annealing rates, shown to be critical for AFT, has not been investigated in the context of He diffusion. For this purpose, we studied the grain chemistry measured by microprobe (EMPA), laser and solution ICPMS on independent AFT dated and He degassed grains. We investigated the behaviour of sedimentary samples from Hercynian origin that shows a wide range in AFT single grain ages due to variable apatite composition (measured by Dpar, EMPA or ICPMS). Our aim was to test if apatite chemistry has an influence on the annealing rate of α-recoil damage. Dispersion of the single grain ages is large for both AFT and AHe datasets although AHe ages are systematically younger (AFT: ~14-208 Ma; N=117; AHe: ~4-76 Ma and one grain at 120 Ma; N=36). Using the thermal history reconstruction from the AFT data, we show that the poor correlation observed between AHe age and eU content can be simply explained by adjusting the annealing law parameter. For slowly exhumed samples we demonstrate that apatite grain chemistry can more easily explain some of the AHe grain age variation. This study reveals that grain chemistry can significantly influence He diffusion, and we conclude that to fully access the thermal history information in AHe ages, the potential for variation in damage annealing kinetics needs to be considered.

Interactions between glassy materials and metallophyte plants: Application to the remediation of polluted soils

A. GAUTHIER AND M. DUBOIS[1]

[1]LGCgE, Lille1 University, SN5 Building, 59655 Villeneuve d'Ascq-France. Arnaud.gauthier@univ-lille1.fr

The contamination of soils by heavy metals has become a really important problem, especially in some highly industrialized areas such as north of France. One of the ways of treatment is the remediation using metallophyte plants able to trap pollutants from soils. The aim of this work was to follow the evolution of a plot of polluted land in the presence of metallophyte plants (*Arabidopsis halleri*) and of a phosphated amendment. This amendment consist of a glassy matrix (Ca-Si-P) in order to increase the phosphorus concentration into the soil. Moreoever the alteration of this glass produces the development of crystallized secondary phases (hydroxyapatite) which can trap heavy metals.

The contents in metals observed in plants after culture are about 2 % for cadmium and of 4 % for lead. Moreover, the contents in metals contained in the superior parts are much more important than those determined in the absence of amendment (5 and 8 % respectively for Cd and Pb). Samplings of ground were besides realized and prepared in order to observe root / soils contacts by ESEM. To try to understand the impact of this amendment on the behaviour of metals contained in the sediment, elementary mappings were made on these polished sections. These observations tend to prove that the zinc seems diffuse and integrated within the root. In the case of a stake in culture in the absence of amendment, we observe a gradient of rather weak concentration with only the presence of a zone more concentrated in periphery. In the presence of amendment, the cartography brings to light a more important concentration, with a gradual increase towards the heart of the root. A very clear border rich in lead is set up in external border, whereas this element is absent in the heart of the root. Besides, the lead distribution on the edge of the root seems to be correlated to the type of substratum of culture. So in the presence of amendment this border appears more continuous and thicker.

This study has permitted to show a great capacity of *A. halleri* to mobilize specifically zinc from solid phases of soil.

Metasomatism in the Dora Maira whiteschists investigated by SHRIMP oxygen isotopes and U-Pb geochronology

LAURE GAUTHIEZ-PUTALLAZ*, DANIELA RUBATTO, AND JOERG HERMANN

Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia (*correspondence: laure.gauthiez-putallaz@anu.edu.au)

The coesite and pyrope-bearing ultra-high pressure (UHP) metamorphic whiteschists from the Dora Maira unit, Western Alps underwent pervasive metasomatism. However, the timing and setting of the metasomatism are still disputed. We analysed U-Pb and oxygen isotopes in zircon and monazite with the SHRIMP ion-microprobe, and trace-elements by Laser-Ablation ICP-MS in the major REE-bearing phases, in order to better constrain the timing of the fluid influx and its relationship to UHP metamorphism.

Zircons cores with oscillatory-zoning are dated at ~265 Ma and have a $\delta^{18}O$ of ~ 9-10 ‰. They are interpreted as magmatic relics recording the age and oxygen signature of the granitic protolith, before metasomatism. Zircon rims and the monazite grains yield an Alpine age (35-34 Ma) and a significantly lower $\delta^{18}O$ of ~ 6-7‰. for a prograde to peak metamorphic temperature of ~700-730°C, the $\delta^{18}O$ of Alpine zircon and monazites indicate equilibrium with the major metamorphic phases [1]. The core-rim $\delta^{18}O$ offset in zircon is interpreted as a shift in bulk-rock $\delta^{18}O$ corresponding to the metasomatic event that altered the granitic protolith. The zircon rims are composed of up to 4 concentric domains, different in CL emission but identical in oxygen composition and age: $\delta^{18}O$ ~6‰ and ~34 Ma. The trace-element patterns of these rims show variations from HREE-rich to HREE-depleted, which mirror the compositional variation in the garnet. This indicates zircon growth before and during progressive garnet growth. A similar record is present in monazite. According to previous petrological studies [2], garnet growth started at 25 to 30 kbar and 650°C and continued until the metamorphic peak at 45 kbar.

Thus, the granitic protolith underwent metasomatism at pressures lower than 25 kbar before the onset of garnet crystallisation, either during seafloor alteration or early prograde subduction. Prograde (25 kbar) to peak (45 kbar) metamorphism occurred over a short time-interval of 1-2 Ma corresponding to minimum burial rates of 3 to 4 cm/y.

In the upper mantle, the abundances of highly siderophile elements (HSE: Os, Ir, Ru, Rh, Pt, Pd, Au, Re) are mainly controlled by Fe-Ni-Cu-bearing sulfides and platinum group element alloys. In order to assess the role of melt migration on the HSE distribution in mantle rocks and to constrain the HSE composition of secondary sulfide melt in mantle rocks, *in situ* LA-ICP-MS and whole rock HSE analyses on pyroxenite samples from the Lanzo (northern Italy) and the Lherz (southern France) peridotite massifs have been obtained.

More than 95% of the analysed sulfides from pyroxenites of both peridotite bodies show a pentlanditic composition with some showing subsolidus exclusions of chalcopyrite. Websterites and Al-rich clinopyroxenites display no systematic differences in HSE compositions of sulfides. Sulfides from both locales are variably depleted in Pt and Au, whereas the bulk rocks are not, indicating the additional presence of Pt-rich alloy phases and presumably native Au. Sulfides from Lanzo pyroxenites show Os, Ir and Ru abundances at 1-10 x CI chondrites, and variable $Pd/Ir_{(CI)}$ of 1-7. Compared to Lanzo, sulfides (and whole rocks) from Lherz pyroxenites are more enriched in Os, Ir and Ru, with $Pd/Ir_{(CI)}$ of 0.5-5. The variations of Pd/Ir in sulfides from the same thin section mostly reflect large variations of Ir abundances (in contrast to grain boundary sulfides in lherzolites, which tend to have variable Pd abundances). The presence of sulfides with suprachondritic Pd/Ir (or Pd/Os) and Re/Os in the same section as sulfides that show chondritic to subchondritic ratios of these elements is indicative of small- scale disequilibrium during magmatic processes. The compositional range of sulfides in some pyroxenites is most easily explained if sulfide melt with chondritic to subchondritic Pd/Ir and Re/Os from peridotite became mobilized during infiltration of sulfur saturated basaltic melt containing sulfide melt with high Pd/Ir and Re/Os.

Cosmogenic Nuclides, River Geochemistry, and Lanforms Reconstruction methods to estimate erosion rates in Reunion Island

E. GAYER[1], P. LOUVAT[1], L. MICHON[1,2], C. ETZOL[1] AND M. KURZ[3]

[1]Institut de Physique du Globe de Paris, Sorbonne Paris Cite´, Univ Paris Diderot, UMR 7154 CNRS, Paris, France
[2]Université de la Réunion, La Réunion, France
[3]WHOI, Woods Hole, MA, USA

Understanding mechanisms that modify landscapes is essential for risk assessment in tropical islands. Because measurements of erosion rates are critical for understanding landform evolution, the use of cosmogenic isotopes in river sediments or the use of river load geochemistry, both to estimate average erosion rates of drainage areas have grown rapidly in recent years.

In this study we aim to estimate erosion rates of highly eroded drainage areas of the Réunion Island and we compare 3 methods of measurment : i) from cosmogenic ^{3}He concentrations [^3He_c], ii) from river geochemistry and iii) from landforms reconstruction.

The first drainage area under invistagation is Cilaos Cirque, located on the south flank of the Piton des Neiges Volcano (PdN). Helium concentrations and isotopic ratios have been measured in olivine rich sands from the Grand Bras River. [^3He_c] have been calculated using: (i) the $^3He/^4He$ ratio measured by crushing and (ii) the ^{3}He and ^{4}He concentrations measured by melting the resulting powder. Dissolved and suspended loads in Grand Bras River have also been analysed for their major and trace elements contents in order to characterise both chemical and mechanical erosion products. Finally, digital elevation model derivatives and K-Ar geochronological data have been used to reconstruct the PdN morphology and calculate the volume of material eroded over the past 70Ka. Initial results indicate average erosion rates of 1.02±0.40 and 0.47±0.16 mm/yr for the cosmogenic and river geochemistry methods respectivly, while erosion rates from PdN morphology reconstruction range from 4 to 12 mm/yr. Cosmogenic and river geochemistry results show a reasonable agreement but their discrepency with the landform reconstruction results suggests 2 questions: are the cosmogenic and river geochemistry methods suitable to quantify fast erosion rates (>>1mm/yr)? does the cosmogenic isotopes method actually provide short-term erosion estimation in fast erosion environment? Further measurments along the Grand Bras River and over other drainage areas will allow to answer these questions.

Sr and Nd isotopes of modern cold seep carbonates from the northern South China Sea

L. GE[1]*, J.S.CHEN[1], S.Y. JIANG[2] AND F T. YANG[2],

[1]Institute of Isotope Hydrology, School of Earth Sciences and Engineering, Hohai University, Nanjing 210098, PR China(*correspondence: gelu211@163.com)
[2]State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, PR China

Methane-derived carbonate precipitation, a well-known phenomenon at hydrocarbon seeps on active and passive continental margins worldwide, forms as a result of microbial oxidation of methane and bacterial sulphate reduction. Seep carbonates are generally well preserved in the sedimentary and geological records, and hence can supply information about fluid compositions, fluid sources, and fluid migration pathways over geologic time. In cold seep related studies, it is important to identify the origin of methane-rich fluids. The determination is generally inferred from stable isotopes and rare earth elements. In addition, isotopic tracers have been used for investigating the origin of fluids in continental margin sediments (Sr, Li, B and I isotopes, e.g.).

In this study, we report the Sr and Nd isotopic compositions on a series of modern cold seep carbonate chimneys from the northern South China Sea. $^{87}Sr/^{86}Sr$ ratios of cold seep carbonates vary from 0.709171 to 0.709269, which are indistinguishable from modern seawater (mean 0.709175), reflecting a shallow marine Sr source.

ε_{Nd} values of cold seep carbonates are between -8.60 and -5.38, which lie within the range of modern sea water and sediments in the northern South China Sea. The Nd isotopic characteristics imply a mixed Nd source from two end members, but different proportions of mixture.

We conclude that the Sr and Nd isotopes can be used to identify the origin of fluids at cold seep sites.

This research is funded by the National Science Foundation of China (Grant No. 41203021) and the Jiangsu Postdoctoral Sustentation Fund, China (Grant No. 1201061C) and the State Key Laboratory for Mineral Deposits Research Fund of China (Grant No. 17-1112-2).

Microbial iron reduction in marine intertidal sediments

JEANINE S. GEELHOED[1]*, HALINA E. TEGETMEYER[12] AND MARC STROUS[1,2]

[1]Max Planck Institute for Marine Microbiology, Bremen, Germany (*correspondence:jgeelhoe@mpi-bremen.de)
[2]Center for Biotechnology, Bielefeld University, Germany

Oxidized iron compounds may be important electron acceptors for anaerobic respiration, in particular in marine intertidal sediments. Tidal cycles generate changes in the position of the chemocline and may drive rapid cycling of iron between oxidized and reduced iron species. The possible mechanisms for iron(III) reduction include microbial iron reduction by respiratory microorganisms, use of iron(III) as electron sink by fermentative microorganisms and the indirect reduction of iron with sulfide that is generated by sulfate-reducing microorganisms. Using geochemical and omics methods we aim to identify the microorganisms responsible for iron(III) reduction and the pathways involved.

We have incubated the microbial community from the surface layer of a marine intertidal flat using medium that contains both iron, as sparingly soluble iron(III) hydroxide, and sulfate as electron acceptors in anaerobic continuous culture with different electron donors. Batch incubations with the enriched microbial community using labelled sulfate were carried out to evaluate the importance of the production of sulfide by sulfate-reducing bacteria for the indirect reduction of iron(III).

The development of the enriched microbial community was analyzed using automated rRNA intergenic spacer analysis (ARISA), and the metagenome of this enriched community was sequenced. Sequences denoting 16S rRNA genes and universal single copy genes were used to analyse the microbial community composition. The metagenome, together with metatranscriptomic and/or metaproteomic analyses, also gives insight into substrate utilization and the pathways involved in the reduction of iron and sulfate. Based on our data, a model for carbon, sulfate and iron(III) utilization in this system is presented.

The role of the Mid-Atlantic Ridge for chemical fluxes in the Atlantic: Clues from Ra and Ac isotopes

WALTER GEIBERT[1], YU-TE HSIEH[23] AND GIDEON M. HENDERSON[2]

[1]School of GeoSciences, University of Edinburgh, Grant Institute, The King's Buildings, West Mains Road Edinburgh EH9 3JW; walter.geibert@ed.ac.uk

[2]Department of Earth Sciences, South Parks Road, Oxford, OX1 3AN, England

[3]now at Dept. of Earth, Atmospheric and Planetary Sciences, MIT, 45 Carleton Street, E25-623, Cambridge, MA 02142, USA,

We present data on the distribution of short-lived radium isotopes ^{223}Ra and ^{224}Ra, as proxies for their parent isotopes ^{227}Ac and ^{228}Th, from the deep South Atlantic (GEOTRACES cruises GA10E and GA10W), together with ^{228}Ra and ^{226}Ra data from the same samples. Samples were collected in-situ using submersible autonomous pumping systems (SAPS) equipped with two MnO_2-coated acrylic fibers in series. We use a new evaluation method to determine Ra adsorption efficiencies of this sampling technique with a Ra delayed coincidence counter (RaDeCC), avoiding the determination of the efficiency based on the decrease of Ra from the 1st to the 2nd absorber (1-B/A). Instead, we have individual efficiencies for each absorber. Efficiencies of the new sampling method are on average 30% (±8%) for two absorbers combined, with an average sample volume of 381 L.

Elevated ^{227}Ac values at ~3000m across the Atlantic basin, with a maximum at the mid-Atlantic Ridge (MAR), suggest a potential effect of the MAR on the distribution of chemical species in various ways: As a source for elements that can be modeled as analogues of ^{227}Ac; as a a barrier between ocean basins; and by enhancing isopycnal mixing with long-distance effects.

Hematite/Water Interfaces Probed by Second Harmonic Generation

FRANZ M. GEIGER[1]

[1]Department of Chemistry, Northwestern University, 2145 Sheridan Road, Evanston, IL, 60208, USA geigerf@chem.northwestern.edu

The Fe(III)/Fe(II) redox couple is a fundamental transformation pathway for iron oxides, however, the study of iron oxide surfaces in aqueous solution by powerful spectroscopic techniques has been limited due to "strong absorber problem". Here, we overome this issue using atomic layer deposition (ALD) of thin films of polycrystalline α-Fe_2O_3 which were analyzed using the Eisenthal chi$^{(3)}$ technique, a variant of second harmonic generation (SHG) that reports on interfacial potentials. The point of zero charge was found to be 5.5 ± 0.3. The interaction of aqueous Fe(II) at pH 4 and in 1 mM NaCl with ALD-prepared hematite was found to be fully reversible and to lead to about 4 times more ferrous iron ions adsorbed per square centimeter than on fused-silica surfaces under the same conditions. The data are consistent with a recently proposed conceptual model for net Fe(II) uptake or release that is underlain by a dynamic equilibrium between Fe(II) adsorbed onto hematite, electron transfer into favorable surface sites with attendant Fe(III) deposition, and electron conduction to favorable remote sites that release and replenish aqueous Fe(II). Additional work carried out under flow conditions at pH 4 with 10 mM NaCl resulted in partially irreversible adsorption of Cr(III), the extent of which was found to depend on Cr(III) concentration, as confirmed by X-ray photoelectron spectroscopy. The interaction of Cr(III) with hematite was compared with the adsorption of Cr(III) to the silica/water interface, which is the substrate for the ALD-prepared hematite films, and found to be fully reversible under the same experimental conditions. The observed binding constant for Cr(III) interacting with the silica surface was found to be 4.0(6) × 10^3 M^{-1}, which corresponds to an adsorption free energy of –30.5(4) kJ/mol when referenced to 55.5 M water. Cr(III) surface coverages were calculated to be 1.0 × 10^{12} ions/cm^2 assuming a +3 charge for chromium. The observed binding constant for Cr(III) interacting reversibly with the hematite surface was calculated to be 2(2) × 10^4 M^{-1} (adsorption free energy of –35(2) kJ/mol). Maximum metal ion surface coverages 8.3 × 10^{11} reversibly bound ions per cm^2, again assuming a +3 charge of chromium. The data also allows us to estimate that about 6.7 × 10^{12} Cr(III) ions are irreversibly bound per cm^2 hematite at saturation coverage. The results of this investigation are discussed in the context of surface passivation in permeable reactive barriers.

Silicon isotope variation in the Buck Reef Chert (Barberton Greenstone Belt) records early Archean basin evolution

S. GEILERT[1]*, M.J. VAN BERGEN[1] AND P.Z. VROON[2]

[1]Utrecht University, 3584 CD Utrecht, Netherlands (*correspondance: s.geilert@uu.nl; m.j.vanbergen@uu.nl)

[2]VU University Amsterdam, 1081 HV Amsterdam, Netherlands (p.z.vroon@vu.nl)

Silicon isotopic signatures of chemical sediments receive growing attention, given their applicability in the search for properties of ancient seawater and the understanding of the environment in which the first live evolved. An important target is the reconstruction of secular changes in surface temperature of the Precambrian Earth, however, interpretations are problematic since controls of the isotopic signals are potentially manifold. Here we report the existence of significant silicon isotope variability in, chemically precipitated chert layers covering a continuous stratigraphic section across the ~3.42 Ga Buck Reef Chert (BRC) in the Barberton Greenstone Belt (South Africa). The δ^{30}Si values range from +0.36‰ for shallow-marine sediments in the lower part of the section to -1.25‰ for deeper water deposits in the upper part. A total shift of 1.6‰ thus accompanied chert formation in a single Archean basin in the course of deepening. Cherts at the base of the section represent silicified felsic volcaniclastic sediments and have exclusively positive δ^{30}Si values between +0.14 and +0.68‰.

Rare earth elements and yttrium patterns confirm the marine origin of the cherts and support the presumed basin evolution, from coastal shallow waters to a deep basin, well-below storm base. From the combined evidence we infer that the δ^{30}Si variations in the BRC reflect changes in the predominant origin of the silica, with terrigenous input supplying positive δ^{30}Si to shallow waters and seafloor hydrothermal sources negative δ^{30}Si to deeper levels. Our findings demonstrate the viability of silicon isotopes of cherts for reconstructing the evolution of ancient marine basins.

Complexation of oxyanions by diatom cells

A. GELABERT[1]*, O.S. POKROVSKY[2], J. SCHOTT[2] AND A. FEURTET-MAZEL[3]

[1]Univ. Paris Diderot, Sorbonne-Paris-Cité, Inst. de Physique du Globe de Paris, UMR CNRS 7154, Paris, France

[2]Lab. Géoscience Environnement Toulouse (GET), UMR CNRS 5563, Toulouse, France

[3]LEESA, UMR CNRS 5805, Univ. Bordeaux 1, France

Diatoms are unicellular algae located at the base of short, energy-efficient food webs. Since they are widespread and exhibit strong amphoteric properties, they are expected to constitute important environmental sorbants for potential or known toxic trace elements such as Cr(VI), Mo(VI) and W(VI). However, most of the studies devoted to these oxyanions underline the lack of information regarding their mobility or their speciation in natural systems. Particularly, their interaction with microorganisms is poorly documented despite the potential control they can exert on trace elements cycling. The main goal of this study is thus to provide a surface complexation model able to describe the sorption of chromate, molybdate and tungstate ions onto diatom surfaces.

Four diatom species (*Navicula minima, Achnanthidium minutissimum, Skeletonema costatum, Thalassiosira weissflogii*) representative of freshwater, estuarine and marine systems were investigated. Cr(VI), Mo(VI) and W(VI) sorption isotherms as a function of pH and oxyanion concentration were collected. Experimental data were modelled assuming a constant capacitance to account for the coulombic interactions in the EDL. Both molybdate and tungstate exhibit a maximum in sorption at acidic pH, with a sorption edge between pH 4.5 and 6.5 depending on the cell/oxyanion ratio. Sorption onto the cell surface differs for these two elements with a stronger complexation constant for tungstate (logK=12.2 for *Thalassiosira weissflogii*) compared to molybdate (logK=10.5). Interestingly, freshwater species display generally a higher affinity for molybdate compared to the marine and estuarine diatoms. Chromate behaves differently, with a sorption edge around pH 7.5, but also with a strong desorption occuring at low pH (around pH 3). No reduction from Cr(VI) to Cr(III) was necessary to model chromate sorption isotherms. For the three oxyanions, the experimental data were best fitted considering monodendate mononuclear complexes with the positively charged amino groups present in the diatom cell wall structure. Because of the rigorous thermodynamic approach used in this study, this work constitutes an important step for the understanding of oxyanions cycling in natural systems.

Pre-Seismic Hydro-Chemical Anomalies in Water of Well Liaogu-1 in Shandong Province, China

JIE GENG

Earthquake Administration of Shandong Province, 5 Weiqi Road, Jinan 250021, China

Since its formal operation in 1981, the Well Liaogu-1 has showed good capability to reflect earthquakes with Ms≥5.0 within certain range around even the pre-seismic abnormal changes of hydro-chemical constituents are quite different for each earthquake. Based on fault dislocation theory and rock mechanics experiments with the data collected more than 30 years, some major results were summarized.

1, the well Liaogu-1 at a special tectonic position with good hydrogeological and borehole conditions is reliable for continuous observation, and a wealth of valuable actual observation data are obtained. Abnormal changes of hydro-chemical constituents reflected well to earthquakes Ms≥5.0 in a range of 500km around the well.

2, The synchronous abnormal changes of multiple hydro-chemical constituents in the well before the Heze Ms5.9 earthquake(1983) were caused by the intensifying activity of the Liaokao fault from random to ordered fracturing, indicating local increase of tensile stress and corresponding pressure reduction around the borehole. The appearance of a complete set of medium-term, short-term and imminent anomalies is a reflection of the preparation process of the source stress field.

3, some single hydrochemical parameter displayed obvious abnormal change before the earthquakes of Datong Ms5.8(1991), Ningjin Ms5.8(1981), South Yellow Sea Ms5.3(1992) and Cangshan Ms5.2(1995), reflecting the intensification of regional tectonic stress field and the response of the tectonic sensitive area where the well Liaogu-1 located in.

4, various field-source seismic precursor characteristics of multiple constituents are of certain prediction significance. The appearance of source precursors means that earthquake with Ms≥5.0 may occur in the near future at some tectonic position on the same active fault. The appearance of field precursors means that the activity of regional stress field is intensifying and earthquake with Ms5.0 may occur in a couple of weeks or months on some other active fault zone. Therefore, to distinguish field precursor and source precursor is greatly important for earthquake forecast and prediction.

Lower continental crust residue in Mesozoic EM1-type basalts from the North China craton

XIAN-LEI GENG, YONG-SHENG LIU* AND SHAN GAO

Faculty of Earth Sciences, China University of Geosciences, Wuhan, 430074, China
(*correspondence: yshliu@hotmail.com)

The origin of Enriched Mantle 1 (EM1) end-member has been in great controversy. In order to investigate the role of the lower continental crust (LCC) in generation of EM1 basalts, the Early Cretaceous (~125 Ma) Yixian and Sihetun basalts (MgO >10%) from the North China craton were collected, and their major, trace element and Sr-Nd-Pb isotopic compositions were measured. These basalts show low $\varepsilon_{Nd}(t)$ (-1.48 to -11.8), low initial $^{206}Pb/^{204}Pb$ ratios (<17.306), and slightly high initial $^{87}Sr/^{86}Sr$ ratios (0.70622 to 0.70679), pointing to an origin of EM1. Enrichment of K, Pb and Sr, and depletion of Nb and Ta are also shown in these basalts. These features can not be explained by recycling of subducted oceanic crust with sediments which was usually regarded as the origin of EM1 OIBs, because dehydration will lead to depletion of K, Pb and Sr and enrichment of Nb, Ta in subducted residue that was shown in global EM1 OIBs. We suggested that involvement of ancient LCC components in the mantle source could be responsible for the generation of the above isotopic and trace element signatures.

High Mg# values (>72), low CaO/Al_2O_3 ratios (<0.65) and high Fe/Mn ratios (56-70) with low CaO (<8.5 wt%) and FeO^T (<9 wt%) contents suggest that these basalts could have been derived from a pyroxenite source produced by hybrid interaction between peridotite and Si-rich melts from subducted MORBs or foundered eclogitic LCC. MORBs have much higher $^{143}Nd/^{144}Nd$ and lower $^{87}Sr/^{86}Sr$ ratios compared to these basalts. Thus, subducted MORBs could not have been the source of the hybridizing melts. Instead, the source of the melts were most likely to be foundered eclogites that originated from ancient lower continental crust of the NCC.

Collectively, recycling of the foundered lower continental crust during the peak (~130Ma) of the lithospheric thinning of the North China craton could have played a significant role in production of the Mesozoic intraplate EM1 magmatism. Such lower continental crust components may be also present for some OIBs, especially those with continent-like trace element compositions (e.g. Aphanasey Nikitin Rise) [1, 2].

Constraining the nature of the western Azores mantle source using Pb-Hf-Os isotope systematics

F.S. GENSKE*[123], C. BEIER[3], S.P. TURNER[2], A. STRACKE[1] AND K.M. HAASE[3]

[1]Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Corrensstrasse 24, 48149 Münster, Germany, felix.genske@uni-muenster.de
[2]Dept. of Earth and Planetary Sciences, Macquarie University, Sydney NSW 2109, Australia
[3]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Schloßgarten 5, D-91054 Erlangen, Germany

Basalts from the Azores islands in the central North-Atlantic provide an opportunity to investigate the composition of the deeper mantle brought to the surface by the Azores plume. Here, we present Hf, Pb and Os isotopes in geochemically well-characterised primitive lavas from the Azores islands. New data are presented from the islands Flores and Corvo, which are situated west of the Mid-Atlantic ridge (MAR), in addition to several submarine lavas from the far west of the Azores plateau.

The location of Flores and Corvo furthest from the inferred Azores plume is geodynamically not well understood. Radiogenic isotopes allow constraining the source composition of the Flores and Corvo lavas and allow comparison with the islands east of the MAR. Their $^{176}Hf/^{177}Hf$ and $^{206}Pb/^{204}Pb$ isotope ratios range from 0.282957 to 0.283069 and from 19.5166 to 19.7799, respectively, whilst $^{187}Os/^{188}Os$ isotope ratios range to subchrondritic ratios, from 0.13970 to 0.12485. We show that, at Corvo and Flores to the west of the MAR, an enriched mantle component is present that is similar to enriched mantle underneath the eastern islands. Yet, the highly enriched, EMII-type component found on São Miguel is absent in the western lavas.

However, simple mixing of a common Azores plume component with the local depleted mantle fails to fully explain the observed isotope-trace element relationships. Differences in Nb/Zr and Ta/Hf between islands east and west of the MAR indicate the presence of an additional mantle component that is largely absent in the east, or, that unusual conditions during partial melting prevail. The latter may promote pronounced fractionation of Zr and Hf from Nb and Ta, respectively. Interestingly, a similar enrichment of Nb-Ta over Zr-Hf has been observed in MORB from the MAR to the south of the Azores plateau [1], suggesting that this signature of the high field strength elements may be a feature of the regional north Atlantic mantle or that conditions during partial melting in ridge and plume-related settings can produce these unusual trace element signatures.

A new insight of the role of the fluids below Victoria Land (Harrow Peaks, Antarctica)

GENTILI S.[1], COMODI P.[1], BONADIMAN C [2], COLTORTI M.[2] BIAGIONI C.[3] AND ZUCCHINI A.[1]

[1]Earth Sciences Dept., University of Perugia, (Italy)
[2]Earth Sciences Dept., University of Ferrara, (Italy)
[3]Earth Sciences Dept., University of Pisa, (Italy)

This contribution presents a mineralogical and petrological study of a new mantle xenoliths population NE of Harrow Peaks (HP, 74 02.785S 164 47.466E, q. 335m). Xenoliths are entrained in Cenozoic alkaline dykes and necks intruding consolidated tufaceous sediments. They are mainly amphibole-bearing spinel harzburgites and lherzolites similar to those found at Baker Rocks [1]. The xenoliths range from protogranular to porphyroclastic and granoblastic in texture with a medium to coarse grain size. Mg [MgO/(MgO+FeO) mol%] of primary olivine and orthopyroxene range from 86.6 to 89.5 and from 87.8 to 90.5 respectively. The high Ni contents of olivine (NiO 0.31-0.46 wt%) associated with low mg values of a few harzburgites and lherzolites would suggest Fe enrichment in this mantle domain. Metasomatic textures are widespread with amphibole and phlogopite as newly formed hydrous (metasomatic) minerals. The former occurred both disseminated and in veins whereas phlogopite is found only as tiny disseminated crystals.

X-ray powder diffraction quantitative analyses by Rietveld method were performed to determine modal composition, including amorphous phases. Moreover a detailed crystal-chemical study was developed on amphibole by means of single crystal X-ray diffraction and in-situ major and trace element (including volatiles) analyses. Among the peridotite phases amphibole is the main volatile acceptor and its study contributes to decipher the role of water circulation during metasomatic process and its effects in controlling the mantle redox conditions. Amphiboles are paragasite in composition, with partial vacancy in A site and M4 site disordered with presence of Ca, Na and Fe^{2+}. Relatively low concentration of Ti (Ti ≤0.35 a.f.u.), as well as structural data of M1 site, testify that amphibole was crystallized in a low aH_2O environment [2]. Taking into account that amphiboles is equilibrated with the anhydrous parageneses (at least for Fe/Mg and Ti), aH_2O will be constrained by the degree of amphiboles dehydrogenation, as well as by the water content in coexisting nominally anhydrous phases (olivines and pyroxenes).

[3]LASIM, , Université Lyon 1, CNRS UMR 5579, Villeurbanne, France

Dust particles acts as a sink for many gases, such as sulfur dioxide. It is well known that SO_2 reacts on dust particle surfaces leading to the production of SO_4^{--}.

It is known that light-driven reactions on dust particles containing TiO_2 or Fe(III) oxides produce OH radicals from water. These radicals can convert SO_2 adsorbed onto the particles into H_2SO_4, which stays on the particles.

Here, we show that OH radicals may leave the dust particles and go on to initiate gas-phase chemistry with gaseous SO_2.

To simulate such conditions, we shone light into a flow tube containing low concentrations of dust, along with water vapor and SO_2, and monitored the particle concentrations inside the tube.

Low dust concentrations are necessary for new particle nucleation; high dust concentrations would provide enough surface area for sulfuric acid to adsorb onto the dust, instead of nucleating aerosol. These findings are supported by recent field observations near Beijing and Lyon.

Adsorption of D-Ribose and inorganic phosphate on clay minerals – molecular stabilization and phosphate condensation

THOMAS GEORGELIN[1], MAGUY JABER[1] AND JEAN-FRANCOIS LAMBERT[1]

[1]Universite Pierre et Marie Curie – UPMC Paris VI, Laboratoire de Reactivite de Surface, CNRS, UMR CNRS 7609, 4 place Jussieu, 75252 Paris Cedex 05, France

Nucleotides and more broadly DNA and RNA play a fundamental role in anabolic metabolism and are considered as "high-energy" compounds. For this reason, their prebiotic formation pose a particular problem since their synthesis is thermodynamically uphill in aqueous solution and therefore forbidden. This is a significant question in the frame of the "RNA world" models, which explain later stages of evolution, but require the previous synthesis of nucleotides and thus phosphorylations. The possible role of mineral surfaces in prebiotic processes has been considered at least since the work of Bernal (1951). This idea has been tested for several prebiotic reactions, especially the condensation of peptide bonds from monomeric amino acids, but also for phosphorylations and phosphate polymerization. Even if such reactions on mineral surfaces have a significant potential for the formation of high-energy coumpounds, there is little consensus as to the fundamental mechanisms that are involved. In this context, the aim of our work is to enlighten the mechanism of adsorption of nucleobases, D-Ribose, nucleosides and inorganic phosphate on different mineral surfaces, mainly clays such as montmorillonite, saponite, hectorite, Laponite (R) and also on high-surface non-porous amorphous silica. The first results obtained by XRD, TGA, ^{31}P and ^{29}Si NMR show that inorganic phosphate ions deposited on these surfaces condense to polyphosphates at considerably lower temperatures than in bulk KH_2PO_4. By co-adsorption of phosphate and a nucleoside, e.g. adenosine, it appears that some surfaces promote the phosphorylation of nucleosides in the same range of temperature. In separate experiments, D-ribose adsorption and stabilization were studied since the lack of stability of ribose is another problem for RNA world scenarii. Our results show a strong stabilisation of ribose by clays and amorphous silica. A similar stabilization has been previously observed with borate minerals, whose presence in prebiotic earth environnement is however open to doubt. Thus, our study shows the first example of ribose stabilization by prebiotic minerals. Phosphorylation of the sugar was also observed.

Date them all: Re-Os ages for Upper Jurassic-Lower Cretaceous shales, ammonite zones and chrons

S.V. GEORGIEV[1], G. XU[1], H.J. STEIN[12], J.L. HANNAH[12], AND H.M. WEISS[3]

[1]AIRIE Program, Colorado State University, USA georgiev@colostate.edu (* presenting author)
[2]CEED Centre of Excellence, University of Oslo, Norway
[3]SINTEF Petroleum Research, 7465 Trondheim, Norway

Numerical ages of Upper Jurassic and Lower Cretaceous stages are derived mostly from correlation of magneto-stratigraphic patterns of Sub-Boreal and Tethyan ammonite zones to the M-sequence marine magnetic anomalies, coupled with constraints from cycle stratigraphy [1]. The ages for Late Jurassic polarity chrons, however, are ultimately based on a model for gradually increasing Pacific spreading rates from ~170 Ma to ~125 Ma that has only a few age constraints [1]. This sequence of correlations with little radiometric age control is further complicated by the extreme faunal provincialism during the late Jurassic.

Here we present Re-Os ages for organic-rich shale from the Upper Jurassic-Lower Cretaceous Hekkingen Formation in the Norwegian Arctic. Three intervals with detailed Boreal biostratigraphy yield isochrons with precision better than 1%, including the ^{187}Re decay constant uncertainty. In the Nordkapp Basin, the base of the section in the *A. serratum* Zone (correlated with the Tethyan *P. bifurcatus* Zone, chron M29r) yields a late Oxfordian age of 157.8 Ma. In the Troms III locality to the SW, an interval in the *A. Subkitchini* Zone (correlated with the Tethyan *S. Platynota* Zone, chron M25) yields a Kimmeridgian age of 154.7 Ma. The top of the section at Troms III is no older than the Sub-Boreal *H. kochi* Zone (correlated with the Tethyan *S. boissieri* Zone, chron M16). Combined with the top of the Nordkapp Basin section, these samples yield a Valanginian age of 137.8 Ma. In addition, shales from the *A. eudoxus* or *A. autissiodorensis* Zones (Tethyan *H. beckeri* or *H. hybonotum* Zones, chron M23 or M22A) yield a less precise Tithonian (?) age of 150.3 Ma. Published Late Jurassic Re-Os ages [4,5] are critically evaluated and integrated with our new ages to refine the time scale for Upper Jurassic-Lower Cretaceous stages.

Funding: CHRONOS project (Lundin Norway AS, Eni Norge AS, and Det Norske ASA) and NRC Petromaks project 180015/S30.

Micromorphology investigations by imaging alteration, supergene and anthropogenic processes in regoliths

MARTINE GÉRARD[1]*, LUCA TROMBINO[2], FLORA BOEKHOUT[1], AISHA KANZARI[1], JEAN CLAUDE PARISOT[3] AND GEORGES STOOPS[4]

[1]IMPMC,,Université P&M Curie, IRD, France, martine.gerard@impmc.upmc.fr, flora.boekhout@impmc.upmc.fr, aisha.kanzari@impmc.upmc.fr (*presenting author)

[4]Ghent University, Belgium, georges.stoops@ugent.be

Micromorphological investigations on undisturbed samples by microscopic and ultramicroscopic techniques allow us to interpret the processes behind the formation of regoliths, sediments and anthropogenic deposits. Keywords are fabric, groundmass composition, microstructures and pedo/biofeatures.

The composition of the micromass represents a record of the processes of alteration leading to regolith formation. The groundmass consists of fine (micromass) to coarse constituents organised with a specific spatial distribution and varying types of preservation history. Investigating the groundmass thus provides clues on the paleoenvironnemental conditions, the different genetic processes behind rock and soil formation (supergene, low T hydrothermal, anthropogenic) and their impact on ecosystems or paleoenvironment.

Improvements in electron microscope imaging technology now permits us to make detailed micromorphological observations up to the nanoscale (previously limited to microscale) : another domain of observations is open in the micromass to the micromorphologists. Optimisation of the microgeochemical mapping technique is another powerful tool to gain insight in chemical migration fronts. Limits concerning homogenisation of the fabric and disapearence of rock fabric may be bypassed. However, if this new detailed information is not linked to petrographic macroscopic evidence and field observations, the analyses may remain ambiguous.

Different petrographic and electronic images of the mineral paragenesis in the micromass associated to their microgeochemical characteristics will be discussed. Examples will be given of the climatic record of different paleosoils, the impact of previous hydrothermal alteration on saprolites, the evolution of the weathering process, and neo-formation of minerals related to weathering and protosoil formation in mining waste rock piles.

He diffusion on apatite viewed by microbeam ERDA and RBS experiments

C. GERIN[1]*, E. OLIVIERO[2], C. BACHELET[2], L. TASSAN-GOT[3] AND C. GAUTHERON[1]*

[1]UMR IDES – CNRS-UPS, Orsay, France (*correspondance: cecile.gautheron@u-psud.fr)
[2]CSNSM-CNRS/UPS (oliviero@csnsm.in2p3.fr, bachelet@csnsm.in2p3.fr)
[3]IPN/CNRS-UPS, Orsay, France (tassango@ipno.in2p3.fr)

The perfect knowledge of the helium diffusion behavior in minerals is a key issue to interpreted thermochronological (U-Th)/He ages. Indeed, He age is the interplay between alpha particle accumulation produced during radioactive decay in a crystal and its diffusional loss by thermally activated diffusion. In apatite, recoil damage accumulation during α-decay is function of their production via the effective U content and their annealing [1,2,3], which depends on the temperature and grain chemistry.

The recoil damaging has been recognized has as playinging an important role in helium diffusion but its annealing rate combined with the grain chemistry need to be explored. For this purpose, dedicated experiments are conducted by using microbeam ERDA (Elastic Recoil detection analysis) coupled to RBS (Rutherford Backscattering (Spectroscopy) analysis on macro apatite crystals of different compositions. He atoms have been implanted ion polished crystal at 15 keV, (mean projected range of 120 nm) deep and fluences of 10^{17} to 10^{16} He/cm^{2}beam intensity., and Tthe He front is plumbed with in the ERDA experiments using a 15°-15° angle after implantation and different annealing temperature heating steps. RBS and ERDA experiments are conducted on the same grain to characterize the possible effect of natural damage, induced irradiation damages and amorphization for the irradiation higher fluencedose.

ERDA and RBS analyses have been validated for apatite by Ouchani *et al* [4], giving us the possibility to extend diffusion studies toward low temperatures which are hardly attained in experiments based on in-vacuum release. In addition, the irradiation effect on the crystal surface is investigated by AFM to characterize possible high damage zones and possible amorphization. Preliminary ERDA results confirm the influence of damage and the grain chemistry on He diffusion.

Hydrothermal exploration of mid-ocean ridges: Where might the largest sulfide deposits occur?

CHRISTIOPHER R GERMAN[1]

[1]Woods Hole Oceanographic Institution, MA 02543, USA (cgerman@whoi.edu)

Hydrothermal activity occurs along all mid-ocean ridges, and in all ocean basins. In this paper I will review what is currently known about worldwide distributions of active venting and how that knowledge has evolved since the first discovery of submarine hydrothermal activity in the late 1970s. I will pay partcular attention to the case of slow spreading ridges and discuss the extent to which the incidence of high-temperature venting along such ridges might appear anomalously high when compared to the available magmatic heat budget and whether this may be attribuatble to a difference in the partitioning of hydrothermal heat fluxes between focussed and diffuse flow, at fast- and slow-spreading ridges. Developing this theme, I will discuss the importance of tectonically-hosted hydrothermal fields on slow spreading ridges as locales at which high-temperature fluid flow and associated polymetallic sulfide deposition can be sustained over thousand year time-scales – significantly longer than the perceived decadal lifetimes of vent-sites along fast-spreading ridges. Finally, I will close with a consideration of ultra-slow spreading ridges where venting is also now known to be widespread but where very few active vent-sites have yet been tracked to source. Surprisingly, on these ultra-slow spreading ridges, our preliminary evidence reveals that even neovolcanically hosted hydrothermal fields can apparently be sustained at any one site over sufficiently long time-scales that large polymetallic sulfide deposits can become established.

Coupled cycling of Fe and C_{org} in submarine hydrothermal systems: an ocean biogeochemistry perspective.

CHRISTOPHER R. GERMAN[1], LOUIS LEGENDRE[23], SYLVIA G. SANDER[4], NADINE LE BRIS[56] AND SCOR WORKING GROUP[135]

[6]CNRS, Observatoire Océanologique de Banyuls sur Mer, France (lebris@obs-banyuls.fr)

Submarine hydrothermal venting was first discovered in the late 1970s. For decades the potential impact that vent-fluxes could have on global ocean budgets was restricted to consideration of processes in hydrothermal plumes in which the majority of chemical species are incorporated into polymetallic sulfide and/or oxyhydroxide particles close to the ridge-crest and sink to the underlying seafloor. This restricted view of the role that hydrothermal systems might play in global-ocean budgets has been challenged, more recently, by the recognition that there might also be a significant flux of *dissolved* Fe from hydrothermal systems to the oceans that is facilitated through organic complexation. In this paper we review field-based and modeling results, including investigations that we have carried out under the auspices of SCOR-InterRidge Working Group 135, that reveal potential relationships between C_{org} and Fe in hydrothermal plumes, and indicate that hydrothermal systems may play significant roles in both the global biogeochemical Fe cycle and the global ocean carbon cycle.

Vulnerability of soil carbon release with increasing temperature in tropical montane forests

F. GERSCHLAUER*, K. BUTTERBACH-BAHL AND R. KIESE

Karlsruhe Institute of Technology, IMK-IFU, 82467 Garmisch-Partenkirchen, Germany (*correspondence: friederike.gerschlauer@kit.edu, klaus.butterbach-bahl@kit.edu, ralf.kiese@kit.edu)

Changes in terrestrial ecosystems due to shifts in climate occur in many dimensions, and include changes in the biogeochemical cycle of carbon (C) amongst others. Tropical montane ecosystems and their supportive ecosystem processes are particularly vulnerable to global warming [1, 2]. Soils from tropical forests are known to have significant effects on the global carbon cycling and climate [3] but data of these feedbacks are still scarce, for Africa in particular.

In a long term incubation experiment we investigated how increasing temperature affects soil carbon release of four different montane forest ecosystems. The Lower montane, *Ocotea*, *Podocarpus* and *Erica* forests are located along an altitudinal gradient at Mt. Kilimanjaro, Tanzania, between 1900 and 3800 m a.s.l. Soils (0-10cm and 10-30cm) of the respective sites were incubated at 15 and 25°C and 60% water holding capacity over a year's period.

Prelimenary results demonstrate that at all sites at both temperatures soil from 0-10cm released more CO_2 than from 10-30cm, with exception of the *Erica* forest where 0-10 and 10-30cm had equal production rates of CO_2 at 15°C. At the first weeks of incubation soils of all sites have been very active and magnitude of cumulative CO_2 release was highest in *Ocotea and Erica,* medium in the Lower montane and lowest at the *Podocarpus* forest. Comparing the release of soil carbon at temperatures approx. 10°C higher than site specific mean annual temperature revealed the same order. This indicats that the *Ocotea* and *Erica* forest are of higher risk in loosing soil carbon due to increasing temperatures with climate change.

Age and matter sources of ophiolites of the Kuznetsk Alatau, SW Siberia: New Sm-Nd isotope data

I.F. GERTNER[1]*, T.B.BAYANOVA[2], T.S. KRASNOVA[1], N.A. DUGAROVA[1], V.V. VRUBLEVSKII[1] AND G.R. SAYADYAN[3]

[1]Tomsk State University, Russia (*labspm@ggf.tsu.ru)
[2]Cola Science center of RAS, Apatity, Russia
[3]Far East Geological Institute of RAS, Vladivostok, Russia

Ophiolites of the Kuznetsky Alatau Ridge are an ancient suture zone formed as a result of the collision of few arc island terrains on the active margin of Siberian continent during the Late Cambrian time (~500 Ma). One of typical ophiolite fragments of this region is the association of ultrabasic and basic rocks of the Barkhatnaya, Zayachiya, Severnaya, and Zelenaya mountain apexes. It is an arc-like structure, where ultrabasites are in the rims and basites are in the core. According to regional geological conclusions, the temporal range of ophiolite forming is from Early Cambrian to Late Riphean time. Our new data of Sm and Nd isotopes for the whole rocks of mantle hyperbasites and ultramafic-mafic rocks are close to the most ancient time of these rocks.

The Sm-Nd isochron based on the four whole rock samples of harzburgite, chromitite and dunite (from the Barchatnaya apex) has a slope corresponding to the age 950±59 Ma at MSWD = 0.968 and εNd (T) = +9,5. The 7-point regression line based on the whole rocks magmatic peridotites and gabbroides of toleitic series is demostrated the closed temporal interval. Its slope corresponds to the age 937±50 Ma at MSWD = 0.966 and εNd (T) = +7,8. The restitic ultrabasites of the Barkhatnaya apex correspond to the characteristics of the strongly depleted backarc basin -type mantle substrate whereas magmatic rocks of internal part are similar to MOR-type crust. Rocks of dike-type complex from the Barkhatnaya apex have a more young age of formation and metamorphism. The slope of Sm-Nd isochron based on the two whole rock samples and two mineral separates of diabasites corresponds to the age 679±34 Ma at MSWD = 1.86 and εNd (T) = +8,2. Harzburgites of the Severnaya and Zelenaya apexes are characterized a wide diapason of Nd-isotope ratios that show a contamination of mantle substrate by crust fluid matter during the recrystalization of these obuction in upper crust. Acording to the rate of syntectonic recrystalization of rocks the range of εNd (T) parameters are changed from +7.96 to -6.51.

This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.1257).

On the origins of Platinum-Group Minerals in ophiolitic chromitites

*F. GERVILLA[1], W.L. GRIFFIN[2], J.M. GONZÁLEZ-JIMÉNEZ[2], J.A. PROENZA[3], SUZANNE.Y. O'REILLY[2] AND N. J. PEARSON[2]

[1]Dpt. Mineralogy & Petrology (UGR-IACT), Granada, Spain (*correspndence: gervilla@ugr.es)
[2]GEMOC ARC National Key Centre, Sydney, Australia. bill.griffin@mq.edu.au; jose.gonzalez@mq.edu.au; sue.oreilly@mq.edu.au; norman.pearson@mq.edu.au
[3]Dpt. Cristallography, Mineralogy & Mineral Deposits (UB), Barcelona, Spain (japroenza@ub.edu)

Platinum-Group Minerals (PGM) commonly occur as solid inclusions in chromitites hosted in the mantle section or the mantle-crust transition of ophiolite complexes. The most widely accepted idea is that PGMs now encased in larger chromite crystals precipitated from melts and were later mechanically trapped by growing chromite. This hypothesis, traditionally accepted by many authors, has been sustained until now on the basis of morphological features of the PGMs in the chromitites. This approach does not provide a satisfactory explanation for the PGMs beyond determining *empirically* the T-fS_2 conditions for their crystallisation from the melts that also precipitated the host chromitite. The key question of how the PGMs form and why they are found in the chromitite remains unresolved.

A major breakthrough in our understanding of the relationships between the chromitites and their enclosed PGM has come in the last few years, through new experimental data and the *in situ* analysis of Os isotopes by laser-ablation ICPMS analysis [1] Integration of these advances, a re-interpretation of the microstructures and the Os-isotope analyses of individual PGMs suggest several different origins for the PGMs in chromitites: (1) most suites of PGMs mainly record crystallisation during mixing of multiple batches of isotopically distinct melts, followed by physical entrapment in chromite; (2) some PGMs in chromitites may have been scavenged from wall-rock peridotites during migration of the parental melts of the chromitites through the mantle; (3) other platinum-group minerals may have precipitated from metasomatic fluid and/or melts that infiltrated existing chromitites. All of these processes may be required to explain the presence in the chromitites of micrometric PGMs with distinct Os-isotope compositions.

Establishing the Magnesium isotope (δ^{26}Mg) signature of early and late diagenetic dolomite types

A. GESKE[1]*, R. GOLDSTEIN[2], D.K. RICHTER[1], D. BUHL[1], T. KLUGE[3], C.M. JOHN[3] AND A. IMMENHAUSER[1]

[1]Ruhr-University Bochum, Institute for Geology, Mineralogy and Geophysics, Universitätsstraße 150, 44801 Bochum, Germany (*correspondence: anna.geske@rub.de)

[2]University of Kansas, Department of Geology, 1450 Jayhawk Blvd., Lawrence, KS 66045, USA

[3]Imperial College London, ESE Department, Prince Consort Road, SW7 2BP London, United Kingdom

The Magnesium isotopic composition has been established as a paleo-climate/paleo-weathering proxy in marine and terrestrial carbonate precipitation environments. Precipitation kinetics of dolomites and dolomite precipitation models, which relate to their diagenetic environments and the commonly complex fluid chemistry, are under debate. Any independent geochemical evidence, such as specific dolomite δ^{26}Mg signatures characterizing specific dolomite formation realms, has the potential to add a valuable additional interpretation tool. This study represents a considerable advance in dolomite Mg isotope research and reviews data from previous research studies. In addition, we took advantage of well-established isotope systems in order to establish a detailed diagenetic history of each sample invested. Proxies included oxygen (δ^{18}O), carbon (δ^{13}C) and strontium (^{87}Sr/^{86}Sr) isotopes as well as main and trace element abundances. Our data indicate that there is no unambiguous Mg isotopic pattern that characterizes specific dolomite types. At present, it seems obvious, that magnesium isotope values of different dolomite types are controlled by a complex array of factors. Burial dolomites display the widest isotope range observed. Obviously, in the burial domain, the temperature of the precipitating fluid is of interest. Therefore, we applied clumped isotope thermometry (Δ_{47}) to burial dolomites displaying end-member Mg isotope values. Our preliminary data set reveals a fair correlation between burial fluid temperature and dolomite Mg isotope signature. As the clumped isotope closure temperature for dolomite is not established yet, this could represent an interesting contrast to recent work [1] documenting that earliest diagenetic sabkha dolomites homogenized under burial temperatures of up to 450ºC. The tentative working hypothesis is that the temperature of the precipitating burial fluid affects, amongst other factors, dolomite δ^{26}Mg signatures.

[5]Systematic Mineralogy, 44, 11th line V.O, apt. 76, Saint-Petersburg 199178, Russia

$BaCa_6[(SiO_4)(PO_4)](PO_4)_2F$ (space group *R*-3*m* (No.166) *a* = 7.09660(10) Å, *c* = 25.7284(3) Å, *Z* = 3), a not yet approved new mineral, has recently been found enclosed in paralavas confined to pyromethamorphic rocks of the Hatrurim formation, Israel.

The structure of it is easiest described as a 1:1 stacking of the two modules (1) $\{Ca_6(T^{4.5+}O_4)_2F\}^{4+}$ and (2) $\{Ba(T^{5+}O_4)_2\}^{4-}$ along the **c**-axis. Module (1) consists of close packed sevenfold coordinated Ca with (SiO_4) and (PO_4) tetrahedra filling the gaps. F is surrounded by 6 Ca atoms forming allmost perfect octahedra. Module (2) is characterized by (PO_4) tetrahedra connected to sixfold coordinated Ba.

The modular stacking of $BaCa_6[(SiO_4)(PO_4)](PO_4)_2F$ presents a new structure type. The only mineral with related structure we are aware of is nabimusaite $K(Ca_{12}(SO_4)_2(SiO_4)_2)O_2F$ (space group *R-3m*, *a* = 7.1905(4), *c* = 41.251(3) Å, *Z* = 3) [1]. The structure of its synthetic analog has been reported before and is characterized by a 2:1 stacking of modules similar to those of $BaCa_6[(SiO_4)(PO_4)](PO_4)_2F$ but with different cations [2].

^{238}U-^{234}U-^{230}Th ^{-226}Ra systematics in fossil scleractinian corals

BASSAM GHALEB[1], SÉBASTIEN HUOT[1] AND CLAUDE HILLAIRE-MARCEL.[1]

[1]GEOTOP and, département de Science de la Terre et de l'Atmosphère, Université du Québec à Montréal, Succ. Centre-Ville, Montréal, QC, H3C 3P8, Canada

The ^{230}Th-U dating method is widely used to date reef and deep-sea scleractinian (aragonitic) corals. The method relies on the assumption is that the sample remained in a closed radioactive system with respect to U and Th isotopes through time. This assumption is usually tested through mineralogical examination of the sample (i.e., through the absence of any diagenetic/secondary calcite) and the comparison of its initial $^{234}U/^{238}U$ activity ratio [$(^{234}U/^{238}U)_0$], with that of the global oceanic $^{234}U/^{238}U$ activity ratio [$(^{234}U/^{238}U)_{marine}$]. However, Pons-Branchu *et al*. [1] have shown that this assumption can be violated when a coral experienced an early diagenetic evolution. This results in slight ^{230}Th ages offsets without significant shifts in the initial $^{234}U/^{238}U$, due to the fact that the early diagenetic and syngenetic U-phases had a nearly similar isotopic signature. More commonly, discrete redistribution of U-series isotopes occur through time. When they result in $(^{234}U/^{238}U)_0$ offsets *vs* [$(^{234}U/^{238}U)_{marine}$, age correction models have been proposed (e.g., U-trend; Thompson *et al*.)[2]. We already proposed to use ^{226}Ra to document the relative closure of radioactive system in the ~ 10-50 ka range, through a $^{226}Ra/^{230}Th$ *vs* $^{230}Th/^{234}U$ pseudo-concordia approach (Hillaire-Marcel *et al*., 2006)[3] . Here we demonstrate that slight disequilibria between $^{226}Ra/^{230}Th$ are generally observed in fossil corals of all ages, notably from the last interglacial and point to some Ra-U mobility in their aragonitic skeleton at least during the last 50 ka, thus likely earlier. We will also examine the impact of such isotopic offsets on the calculated ^{230}Th-U ages and estimate the usefulness/validity of age-corrections based on linear trend intercepts with concordia curves.

Geochemical considerations of the gehlenitic skarns from Valea Crişenilor – Oraviţa (Romania)

C.GHINEŢ[1*], ŞT.MARINCEA[1], E. BILAL[2] AND A.M. IANCU[1]

[1]Department INI, Geological Institute of Romania, 1 Caransebeş Str., RO-012271, Bucharest, Romania (*correspondence: cristina.ghinet@igr.ro)

[2]Centre SPIN, Ecole Nationale Supérieure des Mines de Saint-Etienne, 158, Cours Fauriel, F-42023 Saint-Etienne Cedex 2, France (bilal@emse.fr)

A shallow-level pluton of Late Cretaceous age, belonging to the "banatitic" magmatic and metallogenetic belt, caused extensive contact methamorphism of Cretaceous limestones and marls sequences in the Oraviţa area. In Valea Crişenilor, a small elongate apophysis of this pluton mainly dioritic, with some variations toward quartz diorite and monzonite, intruded a series of calcareous deposits of Crivina Formation deposed in Reşiţa anticlinorum. The intruded formations experienced an extended contact metamorphism with local generation of high-temperature mineral species.

The observed mineral assemblages reflect a wide range of temperature and fluid-composition space. In this respect, the metamorphic peak assemblages in the calcite-saturated rocks include wollastonite, melilite, ellestadite-(OH), titanian grossular and scarce spurrite. The estimated equilibra temperature for this mineral assemblage is about 820-870ºC with a C-rich, internally buffered pore-fluid. The aperence and infiltration of the C-poor fluids, triggering the formation of retrograde mineral assemblages comprising monticellite, vesuvianite, grandite garnets, diopside, clintonite. These assemblages formed probably near 600ºC. A low-temperature retrogression affected the previous mineral paragenesis producing scawtite, hydrogrossular, hibschite, xonotlite, thomsonite.

As it is expected, the intensity of the contact metamorphism decreases from the innermost to the outermost parts of the aureole. In this respect, the mineral reactions involving carbonate and silicate minerals led to the formation of various of Si-poor silicates, but rich in Al and Ti oxides, while the next skarn zone can be circumscribed to a Si- , Mg-rich and Al-poor geochemical system, marked by the formation of gehlenite, vesuvianite ± wollastinite, garnet.

The Ca-Si ratio value is close to that of Mg-Si, suggesting a weak circulation of the fluids and a thermodinamic closed system, followed by the retrograde stage, marked by a high mobility of the chemical elements into an open system.

The future of thermodynamic databases: Community driven data systems fueled by the geoinformatics revolution

M.S. GHIORSO[1]

[1]OFM Research, 7336 24th Ave NE, Seattle, WA 98115, USA (*correspondence: ghiorso@ofm-research.org)

Internally consistent thermodynamic databases are critical community resources that facilitate the calculation of heterogeneous phase equilibria and thereby support geochemical, petrological, and geodynamical modeling. These "databases" are actually derived data/model systems that depend on a diverse suite of physical property measurements, calorimetric data, and experimental phase equilibrium brackets. In addition, such databases are calibrated with the adoption of various models for extrapolation of heat capacities and volumetric equations of state to elevated temperature and pressure conditions. Finally, these databases require specification of models for the mixing properties of solid, liquid, and fluid solutions, which are often rooted in physical theory and, in turn, depend on additional experimental observations. The process of "calibrating" a thermochemical database involves considerable effort and an extensive computational infrastructure. Because of these complexities, the community tends to rely on a limited number of thermochemical databases, generated by a few researchers; these databases are often out-of-date and are universally difficult to maintain. Their longevity is generally linked to that of their creators.

Geoinformatics is poised to alter the manner in which thermodynamic databases are created, maintained, tailored, and applied. By making underlying data resources universally available, and by focusing development on a generalized web-based computing infrastructure that permits a wider community of users to evaluate those data in an internally consistent and thermodynamically rigorous context, the generation of thermodynamic data/model collections can be made more transparent and spontaneous. Through automated generation of web services that standardize the linkage between thermochemical databases and the geochemical, petrological, and geodynamical models they serve, the lag time between generation and evaluation can be shortened and a broader community of users can be empowered to participate in model creation and evaluation. A prototype system that embodies this approach to thermochemical database construction will be demonstrated. Requirements for broad-based application of this geoinformatics architecture will be discussed.

Neoproterozoic granites of Sharm El-Sheikh area, Egypt: Mineralogical and geobarometric variations

MOHAMED FOUAD GHONEIM, BOTHINA TAHA EL DOSUKY, MOHAMED THARWAT HEIKEL, TAMER ABU-ALAM* AND MAHMOUD SHERIF.

[1](ghoneimf@science.tanta.edu.eg)

Sharm El- Sheikh District, south Sinai, includes representative granitic outcrops. Mineral of the hosted granites are analyzed to elucidate geobarometric variation, which could prove their evolution. The amphiboles classified as calcic and alkali amphiboles. The calcic amphiboles are Ferro-edenite while the alkali amphiboles are typically riebeckite. Amphiboles varieties are of magmatic nature. Biotites encountered mostly in monzogranites and syenogranites. They classified as meroxene (Mg-rich varieties). They pertain to metamorphic-metasomatic types. Biotites have calc-alkaline affinity for the syenogranites and monzogranites. Feldspars have albite and orthoclase end-members. Coexisting amphiboles and plagioclase are used to estimate the physicochemical parameters of their crystallizing parent magma. It is clarifies that syenogranites underwent temperature and pressure of formation ranges of 520-730 ^{O}C; <3 kbars. The alkali feldspar granites record 450-830 ^{O}C; <4 kbars. The riebeckite-bearing granites record the lowest temperature condition among all varieties since it estimate formation at 350-650 ^{O}C; <4 kbars.

Spatial dispersion at a watershed scale of some mining-originated metals in various solid materials

S. GHORBEL[1*], A. COURTIN-NOMADE[1], B. POATY[1], C. GROSBOIS[2] AND M. SOUBRAND[1]

[1]Univerity of Limoges, GRESE, FST, 123 avenue A. Thomas, 87060 Limoges Cedex France. (*correspondence : sonda.ghorbel@hotmail.fr, alexandra.courtin@unilim.fr, nedvyp@yahoo.fr, marilyne.soubrand@unilim.fr)

[2]University of Tours, EA 6293 GeoHydrosystemes Continentaux, Parc de Grandmont. 37200 Tours, Fance (cecile.grosbois@univ-tours.fr)

River sediments in the french Massif Central, the largest metallogenic area in France, are ones of the most mining-impacted. The study area belongs to the Loire River basin, the largest french basin. This study deals with a former Ag-Pb mining district (Miodet sub-basin, 30 km long and 100 km^2) located in the upstream part of the Loire catchment. The french Massif Central was the first area for Ag-Pb production in France. Mining activities in the studied district lasted between 1873 and 1901 and generated waste materials which constitute today dumps on ~ 24,600 m^2. Around 6000 t of Pb and 6 t of Ag were extracted during that period. Nowadays 100,000 m^3 of tailings are still exposed to atmospheric conditions, overhanging the Miodet River.

Both tailings, located upstream of the Miodet watershed, and sediments, collected all along the river, have been sampled to evaluate the spatial dispersion of various metals (especially As, Fe, Mn, Pb and Zn) at a basin scale, 100 years after the end of mining activities. In addition, the aim of this study is to evaluate the accumulation and stability of the metal host phases within the Miodet River as well as to estimate how the anthropogenic activities infer on metals dissemination. The use of complementary approaches (Fig. 1) allow determining the partitioning and the post-depositional redistribution (mobilization/sequestration) of metals and metalloids as well as to assess their mobility.

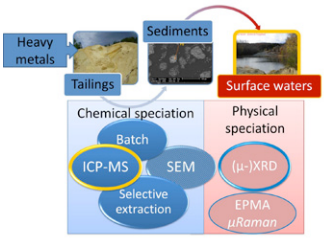

Figure 1: Diagram presenting the applied methodology.

^{34}S enrichment during chemotrophic sulfur oxidation by bacteria

WRIDDHIMAN GHOSH[1], MASRURE ALAM[1] AND ANINDA MAZUMDAR[2]

[1]Bose Institute, Kolkata - 700054, India

[2]National Institute of Oceanography, Goa - 403004, India

The three distinct proteobacteria *Paracoccus pantotrophus* (*Pp*), *Tetrathiobacter kashmirensis* (*Tk*) and *Thiomicrospira crunogena* (*Tc*) unanimously rendered kinetic enrichment of ^{34}S in the end product sulfate (SO_4^{2-}) (overall fractionation ranged between -4.6‰ and +5.8‰) during chemolithotrophic oxidation of thiosulfate ($S_2O_3^{2-}$) or tetrathionate ($S_4O_6^{2-}$). *Pp* uses the Sox multienzyme system to oxidize $S_2O_3^{2-}$ (but not $S_4O_6^{2-}$) to SO_4^{2-} without any intermediate formation. *Tk* oxidizes $S_4O_6^{2-}$ directly to SO_4^{2-}, but its $S_2O_3^{2-}$ oxidation proceeds via $S_4O_6^{2-}$ formation. *Tc*, in its turn, oxidizes $S_2O_3^{2-}$ to SO_4^{2-} by depositing extra-cellular elemental sulfur under low pH and oxygen. Molecular biology of sulfur oxidation in the last two species is ill-defined, even though both of them possess *sox* gene homologs in their genomes. All the studied processes were found to start with +ve Δ^{34}S values, subsequent to which (owing to Rayleigh fractionation) Δ^{34}S approached zero as δ^{34}S of produced SO_4^{2-} came close to δ^{34}S of the substrate $S_2O_3^{2-}/S_4O_6^{2-}$. In *Pp* and *Tc*, as the reactions progressed, $\Delta^{34}S_{thiosulfate\text{-}sulfate}$ values became –ve owing to continued ^{34}S enrichment in SO_4^{2-}. Apparent physiological disparities notwithstanding, all the three bacteria exhibited analogous ^{34}S fractionation kinetics during $S_2O_3^{2-}$ oxidation (and also $S_4O_6^{2-}$ oxidation in case of *Tk*), with ^{34}S enrichment rates observed during their peak sulfate-producing stages being almost identical. This indicated the potential involvement of identical S-S bond-breaking enzymes in all these processes. Concurrent proteomic analyses detected the hydrolase SoxB in the actively sulfate-producing cells of all three species. Inducible expression of *soxB* was also observed during $S_4O_6^{2-}$ oxidation by *Tk*, which was particularly interesting because the established Sox pathway has not yet accommodated $S_4O_6^{2-}$ as a substrate. Notably however, no other Sox protein except SoxB was detected in lithotrophically-growing *Tk* cells even after proteomic scanning of its entire peptide map. Instead, several other redox proteins were found over-expressed during $S_2O_3^{2-}/S_4O_6^{2-}$ dependent growth, thereby indicating that there is more to $S_4O_6^{2-}$oxidation than SoxB alone.

The effects of sulfide and sulfate ions on degradation kinetics of chlorinated organics by nanoscale zero valent iron

S. GHOSHAL * AND C. R. SAI RAJASEKAR

[1]Dept. of Civil Engineering, McGill University, Montreal, QC H3A 2K6, Canada
(*correspondence: subhasis.ghoshal@mcgill.ca)

A promising technology for the clean-up of aquifers contaminated by toxic chlorinated organic compounds is the sub-surface injection of nanoparticles of zero valent iron (NZVI) into the contaminated zones to enable rapid, *in situ* destruction of chlorinated compounds to non-toxic end products via surface-mediated electron transfer and hydrogenation reactions. However, iron oxide shells form readily on the surface of the NZVI which may reduce its reactivity over time. Although several studies have examined the reactivity of NZVI to chlorination aliphatic pollutants, there is limited knowledge on the effects of natural groundwater ions on the surface chemistry and reactivity of NZVI to target pollutants. In this study we show that sulfide and sulfate ions, which are ubiquitous in groundwater environments, may significantly alter the reactivity of NZVI.

Sulfide and sulfate ions readily react with NZVI in solution to form various iron sulfide precipitates on the NZVI surface. An FeS coating NZVI enhances the ability of the NZVI to degrade chlorinated organic compounds due to the creation of a conductive outer layer that efficiently transfers electrons from the electron rich core of the zero valent iron nanoparticle. Our studies show that the reactivity of the NZVI-FeS was distinct from the reactivity of pure FeS. Rapid dechlorination of trichloroethylene (TCE) was observed particularly at lower concentrations of sulfide (~ 2 mM). The first order TCE degradation rate constant increased from 0.013 hr^{-1} for NZVI only to 0.432 hr^{-1} NZVI reacted with sulfide. The surface morphology and chemistry of NZVI reacted with sulfide and sulfate were studied using TEM-EDX and X-ray photoelectron spectroscopy (XPS), and these techniques confirmed the presence of FeS at the surface and provided data on the spatial distribution of FeS. Particle size measurements by nanoparticle tracking analysis showed no observable change in the average hydrodynamic diameter of bare NZVI and NZVI reacted with sulfide and sulfate. Thus increases in reactive surface area cannot be attributed to the increase in reactivity. Rather, the increased efficiency of electron transfer through a thin FeS outer layer on the NZVI enhances NZVI reactivity.

Textural and compositional zoning of plagioclase as archive of magmatic evolution: The Mt. Etna case study

P.P. GIACOMONI[1], M. COLTORTI[1], C. FERLITO[2], C. BONADIMAN[1] AND G. LANZAFAME[2]

[1]Dept. of Physics and Earth Sci., Univ. of Ferrara (*correspondance:pierpaolo.giacomoni@unife.it)
[2]Dept. of Biol. and Earth Sci., Univ. of Catania; (cferlito@unict.it)

Textural and compositional features of plagioclase represent an useful tool to investigate magma chamber processes and changes in physical-chemical conditions of the shallow feeding system. Notwithstanding a coherent and univocal description and classification of plagioclase textural features is still lacking, as well as their link to magmatic processes. The study of more than 130 thin sections from Mt. Etna recent eruptions (2001, 2002-2003, 2004-2005 and 2006) offer a unique opportunity to fill this gap. Classification was developed taking into account different portion of the crystals, rather than simply label a single crystal. This allows to recognize different types of core (euhedral and rounded) and rims (dusty or with melt inclusion alignment) divided by oscillatory zoned overgrowth. Thermobarometric and crystal-melt equilibrium equations have been used to estimate the oxygen fugacity in magmas [1] and the amount of dissolved water content using the hygrometers of [2]. These data were introduced in the MELT's modelling to estimate the plagioclase stability field and to calculate theoretic composition at distinct water content, thus relating each crystal portion to growth or dissolution events occurring at specific P-T-fO_2 conditions and water contents. Results suggest a rather continuous plumbing system, ruling out the hypothesis of significant magma chambers in the Etnean plumbing system. Such system is persistently filled by magmas with quite similar major element composition but different dissolved H_2O, with the initial H_2O content constraining the depth at which plagioclase crystallizes. A small number of phenocrysts nucleate at 14 km whereas most plagioclase nucleates between 7 and 4 km of depth. At this depth, mixing occur between variably H_2O-enriched magmas, causing dusty textures in more albitic plagioclase. On the other hand, volatile loss due to fast ascent decompression promotes undercooling and crystal growth enhancing melt inclusions entrapment at crystal rims.

Petrological study of Cenozoic basic lavas and melt inclusions from Northern Victoria Land (Antarctica)

P.P. GIACOMONI[1*], M. COLTORTI[1], S. MUKASA[2], C. BONADIMAN[1], C. FERLITO[3] AND B. PELOROSSO[1]

[1]Dep. of Physics and Earth Sci., Univ. of Ferrara (*correspondance:pierpaolo.giacomoni@unife.it)
[2]Dep. of Earth Sci., Univ. of New Hampshire (sam.mukasa@unh.edu)
[3]Dep. of Biol. and Earth Sci., Univ. of Catania; (cferlito@unict.it)

This study offers a first view of the petrologic features of basic lavas and melt inclusions (MI) in olivine phenocrysts from Northern Victoria Land (Antartica). Samples were collected during three Italian expeditions with the aim of comparing major element composition and volatile content in the lavas and their mantle sources.

Major elements and volatiles (H_2O, CO_2, S, F and Cl) were analyzed in MI, while major and trace elements were carried out on lavas from three localities, Eldridge Bluff, Shield Nunatak and Handler Ridge.

Lavas are olivine-phyric (up to 15 %vol) with minor clinopyroxene and plagioclase in a glassy to microcristalline plagioclase-dominated groundmass; opaque minerals are mostly magnetites and subordinately ilmenites. The great majority of lavas are basanites (42.20-45.02 wt% SiO_2, with 3.36-4.21 wt% of Na_2O+K_2O) with Mg# (MgO/(MgO+FeO) mol%, Fe_2O_3=0.15FeO) ranging from 44.87 to 60.83. Lavas from Handler Ridge are the most primitive. At similar fractionation degree, however two series can be distinguished based on K_2O and trace element contents (Rb, Ba, La, Nb and Zr).

MI in olivine phenocrysts from Shield Nunatak basanites were analysed. They are comparable to the host lavas but encompasse a wider range in composition (43.68 to 48.73 wt% SiO_2, with 2.81-4.55 wt% of Na_2O+K_2O) and Mg# 49.51 to 74.44). The great majority of olivine in equilibrium with MI are more forsteritic than the enclosing crystal suggesting that MI were trapped from a less evolved magma or, most probaby, that Mg-Fe interdiffusion occurred between olivine and MI after entrapment.

Most of MI have H_2O content ranging from 0.70 wt% to 1.19 wt% and CO_2 from 25 ppm to 341 ppm (H_2O/CO_2~1). At comparable H_2O contents few samples show a remarkable higher CO_2 values (1322 ppm to 3905 ppm) with a H_2O/CO_2 down to 0.8.

Magma migration at Mt. Etna in 2012-2013 detected by gas emissions and plume temperature

S. GIAMMANCO[1], G.G. SALERNO[1], A. LA SPINA[1], L. SPAMPINATO[1], T. CALTABIANO[1], P. BONFANTI[1], F. MURÈ[1], R. MAUGERI[1] AND V. LONGO[1]

[1]Istituto Nazionale di Geofisica e Vulcanologia. Osservatorio Etneo. Catania. Italy (salvatore.giammanco@ct.ingv.it)

In 2012-13 gas emissions from Mt. Etna's summit craters have been continuously observed by the automated UV-scanner network surrounding the volcano, continuous radiometric measurements from a permanent station installed on the SE flank of the volcano, discrete FTIR spectrometry surveys, and soil gas emissions periodically measured in low altitude sites on the SW and E flanks of the volcano. Integration of the parameters derived from the different methodologies allowed tracking of the episodic paroxysms from the New South-East crater (NSEC) and of the sporadic explosive activity at the Bocca Nuova crater (BN). Geochemistry data suggest temporal evolution of gas emissions compatible with a solubility-dependent progressive release of gas species typical of processes of magma migration from depth to surface. In particular, we observed a new phase of degassing that started early in June 2012, two months after the closure of the 2012 paroxysmal eruptive sequence. The new degassing phase was clearly discriminated by all the monitored parameters and firstly detected by soil CO_2 increase. This was followed by increase in SO_2 flux and NSEC volcanic plume temperature in August 2012, and in HCl flux late in October 2012. Whilst soil CO_2 flux described a complete cycle that ended in November 2012, the other geochemical parameters and radiometric data continued increasing and climaxed with the renewal of the NSEC paroxysmal events early in February 2013. The decreasing pattern of the soil CO_2 flux starting from August 2012 contrasting the rising trend of the SO_2 and HCl fluxes and temperature measured at the volcanic plume suggests magma migration from depths less than 7 km to the surface. The low soil CO_2 fluxes recorded since November 2012 seem to indicate that no further magma has been supplied to the volcano shallow feeder system, and that the 2013 eruptive events have been fed by the same magma batch that has started degassing in June 2012.

Geochemistry and petrology of the Khantaishir ophiolite (Central Mongolia)

O. GIANOLA[1], M.W. SCHMIDT[1], O. JAGOUTZ[2] AND S. OYUNGEREL[3]

[1]ETH Zürich, 8092 Zürich, Switzerland (*correspondence: omar.gianola@erdw.ethz.ch) (max.schmidt@erdw.ethz.ch)
[2]MIT, Cambridge, MA 02139-4307, USA (jagoutz@mit.edu)
[3]Mongolian Univ. of Science and Technology, Ulaanbaatar 46, Mongolia (oyunas@must.edu.mn)

Ophiolites are slices of oceanic lithosphere incorporated into continental crust. They often allow, in complete sections, to constrain the petrological and spatial evolution of their constituent lithologies and hence to reconstruct past oceanic basins. Oceanic lithosphere forms after seafloor spreading, which may occur at mid oceanic ridges or in proximity of subduction zones. We present a preliminary petrological and geochemical investigation of the Khantaishir ophiolite, a little studied, ~400 km^2 sized body located in central Mongolia, in the middle of the so called Central Asian Orogenic Belt (CAOB). Aim is to understand its formation history and to reconstruct the tectonic setting where this peculiar ophiolite originated (i.e. mid oceanic ridge or subduction zone). This ophiolite shows a complete crust/mantle transition with a highly refractory mantle composed of harzburgites displaying locally dunitic channels. Towards its top, this mantle is replaced by pyroxenites in discrete zones with a reconstructed sub-horizontal orientation. The igneous crust itself is composed of gabbro, minor gabbronorite (both replaced by pyroxenites in discrete zones), intermediate dykes/sills (but not sheeted dyke complexes) and pillow lavas, capped by a sedimentary cover of cherts and limestones. Major and trace elements of the crustal rocks of the Khantaishir ophiolite are compared with chemical analyses of modern ocean crust-forming localities (i.e. the East Pacific Rise, EPR, the Mariana and the Lau backarc basins). Al_2O_3, TiO_2, MnO, Co, V and Zr vs. X_{Mg} show trends similar to those observed for the Mariana and the Lau backarc basins, rather than to that displayed by the EPR. Dykes/sills and pillow lavas of the Khantaishir ophiolitic complex are generally basaltic-andesitic to andesitic in composition (average SiO_2 of ~57%). Their low TiO_2 (<1.2%) and Ti/V ratio of ~10 contrast with MOR suites, which are basaltic (average SiO_2 ~50%) with TiO_2 values >1.2% and a Ti/V ratio between 20 and 50. This evidence suggests that the igneous crustal rocks of the Khantaishir ophiolite were originated from a mantle source modified by a subduction component.

New insights into the size of atoms from electron density distributions

G.V. GIBBS[1*], N.L. ROSS[1] AND B.B. IVERSEN[2]

[1]Department of Geosciences, Virginia Tech, Blacksburg, VA 24061, USA (*correspondence: ggibbs@vt.edu)
[2]Department of Chemistry and iNANO, Aarhus University, DK-8000, Aarhus, Denmark

V.M. Goldschmidt recognized that one of the key variables controlling trace element partitioning is the size of the trace ion relative to the size of the site in the crystal structure in which it partitions. To date, ionic radii have been used in lattice strain models to predict partitioning behavior [1]. However traditional strategies used to determine ionic radii, based on a rigid oxygen with a fixed radius, are flawed. Analysis of electron density distributions (EDD) of over 50 oxides and silicates show that the EDD of oxygen is not spherical and displays as many different bonded radii as it has bonded interactions [2]. As a result, the bonded radius of oxygen is not fixed: it decreases systematically from 1.40 Å when bonded to an electropositive atom like K to 0.65 Å when bonded to a highly electronegative atom like N. The observation that the bonded radius of oxygen depends on the polarizing impact of the bonded atoms has profound implications for trace element partitioning. Furthermore, models that incorporate bonded radii derived from EDD's may also be useful in predicting trace element partitioning in more intractable systems such as sulphides.

A half million years of suborbital variability from the Cariaco Basin: A proxy for Greenland "ice core" records?

K.A. GIBSON[12]* AND L.C. PETERSON[1]

[1]University of Miami, RSMAS, 4600 Rickenbacker Cswy, Miami, FL 33149 (lpeterson@rsmas.miami.edu)
[2]Now at , University of South Carolina, 701 Sumter St, EWS 617, Columbia, SC 29208
(*correspondence: kgibson@geol.sc.edu)

It is becoming increasingly apparent that rapid climate change on suborbital timescales is a persistent feature of Pleistocene climate. The best-studied archives of rapid climate change are Greenland ice cores, the longest of which presently available extends back to Marine Isotope Stage (MIS) 5e. The Cariaco Basin, located in the southern Caribbean, is a location that holds the potential to extend our understanding of suborbital scale climate variability. The basin is in a region sensitive to changes in the migration of the Intertropical Convergence Zone (ITCZ), has high sedimentation rates (≥30 cm/kyr) and excellent preservation due to periodic deep-water anoxia. The tight linkage between proxies for productivity in Cariaco and $\delta^{18}O$ records in Greenland has been well established [1,2], suggesting the basin could serve as a proxy for conditions in Greenland prior to MIS 5e.

We present a half-million year long scanning X-Ray Fluorescence (XRF) record of sedimentary Molybdenum (Mo) from Ocean Drilling Program (ODP) Hole 1002C in the Cariaco Basin. The Mo record appears to serve as a reasonable proxy for high latitude conditions over the last ~500 kyr. Greenland ice core $\delta^{18}O$ and Cariaco Mo records can be mechanistically linked by changes in the position of the ITCZ during the last glacial period. In earlier glacial periods, Mo enrichments covary with peaks in CH_4 from Epica Dome C and depletions in planktonic $\delta^{18}O$ from Hole 1002C, giving confidence that they record interstadial-like conditions over the full ~500 kyr studied here. The distribution of millennial-scale variability during the last six glacial periods is not consistent, and coupled with evidence for millennial-scale variability during interglacial periods, suggests that ice volume is not the only control on its occurrence. Alternative mechanisms for triggering periods of millennial-scale variability include the influence of precession on high-latitude insolation and the distribution of sea ice, or the influence of precession (and semi-precessional cycles) on the insolation and hydrologic cycle of the tropics.

Experimental investigations on halogen-rich agpaitic phase equilibria

CHRISTOPHER GIEHL*, MICHAEL MARKS AND MARCUS NOWAK

Eberhard Karls Universität Tübingen, Germany,
(*correspondence: christopher.giehl@uni-tuebingen.de)

High concentrations of Cl and F are known to affect phase relations in magmatic rocks. In this study, we present phase equilibrium experiments investigating an iron-rich peralkaline phonolitic composition with variable Cl and F content. The starting material resembles a potential parental melt composition of the peralkaline Ilímaussaq plutonic complex/South Greenland [1].

Nominally dry experiments were performed at 100 MPa, 1000 – 650 °C and low oxygen fugacity adjusted with graphite-lined gold capsules in an internally heated argon pressure vessel and in hydrothermal rapid-quench cold seal pressure vessels. To cover the large *T* interval of crystallization we applied a two-step fractional crystallization strategy. The synthesized mineral phases are titano magnetite, fayalitic olivine, clinopyroxene, alkali feldspar, nepheline and aenigmatite (± native iron). Increased Cl and F concentrations additionally stabilize fluorite (CaF_2), hiortdahlite ($(Ca,Na)_6(Zr,Ti)_2Si_4O_{14}F_4$), Cl-bearing sodalite ($Na_8Al_6Si_6O_{24}Cl_2$) and, characteristic for agpaitic rocks, eudialyte ($Na_4Ca_2(Fe,Mn)ZrSi_8O_{22}(Cl,OH)_2$). ZrO_2 melt concentrations necessary to stabilize hiortdahlite and eudialyte are different (0.9 and ~1.2 wt%, respectively). Thus early hiortdahlite saturation shifts eudialyte saturation to lower *T*.

In the Ilímaussaq rocks, magmatic clinopyroxene shows a gap between Ca-rich and Na-rich compositions, common in evolved peralkaline rocks [2]. This gap may be induced by Ca-rich hiortdahlite and fluorite at the expense of Ca-rich clinopyroxene by reason of increasing F content in the residual melt. Na-rich clinopyroxene, not influenced by Ca-F phases, may then be stabilized coexisting with a more evolved melt at lower *T*. Both the Cl/OH ratio in eudialyte and Fe/Mn partition coefficients between clinopyroxene and eudialyte/aenigmatite decrease systematically with *T*. The comparison with existing data indicates that these ratios may have the potential for geothermometers, rarely available for agpaitic phase assemblages.

[2]Umweltmedizin, Universitätsklinik Freiburg, Germany
[3]Lufthygiene, Deutscher Wetterdienst, Freiburg, Germany
[4]Université de Haute-Alsace, Mulhouse, France
[5]ASPA, Schiltigheim, France
[6]Max-Planck-Institut für Chemie, Mainz, Germany
[7]Holcim (Schweiz) AG, Würenlingen, Switzerland

BIOCOMBUST is a large-scale international research project on health aspects of biomass combustion. Funded by the European Union through its Funds for Regional Development (INTERREG IV Upper Rhine program), it is a cross-border collaboration between several research teams with widely differing expertise, including: mineralogy; geochemistry; pharmaceutical science; environmental medicine; combustion science; aerosol science; human biometeorology; and cement manufacturing.

The research explores the impacts of particulate emissions from biomass combustion on air quality and health. To evaluate these effects, various experiments are performed, including: biomass combustion in the laboratory, district heating facilities, and power plants; chemical, mineralogical, and structural characterization of biomass, particulate emissions, and ashes; optimization of combustion conditions; determination of ash and particulate-emission properties in relation to type of biomass, firing conditions and cooling path; identifying and tracking of particulate plumes as well as collection of emitted particulates around industrial biomass-combustion facilities; determination of cytotoxic, genotoxic, and proinflammatory effects in human lung cells as a result of particulate exposure; determination of the potential of particles to generate reactive oxygen species in human lung cells; investigation of the molecular mechanisms underlying the cell responses to particulate exposure.

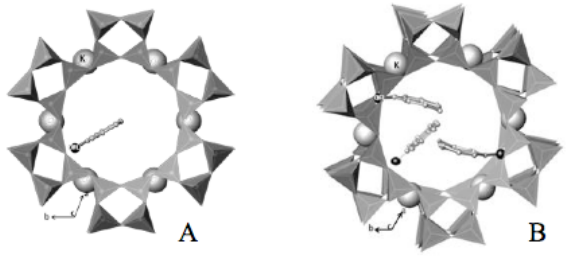
The expected results will provide a basis for technical and economic applications, which eventually will lead to an improvement of both environmental and living conditions. In addition, the results will give an important boost to the sustainable expansion of the biomass industry and to the potential use of the associated ashes as secondary raw materials for the cement industry.

Fluorenone dye- zeolite L hybrid: a novel optical material

GIGLI L[1]., ARLETTI R[2]., QUARTIERI S[3]., VEZZALINI G[1].

[1]Department of chemical and Geological Sciences, University of Modena and Reggio Emilia, Italy,
[2]Department of Earth Sciences, University of Torino, Italy
Department of Earth Sciences- University of Messina, Italy

A major challenge facing humanity is developing renewable source of energy. Following the biological blueprint of the natural photosynthesis is possible design synthetic systems for converting light into stored energy: the so called artificial antenna systems. The encapsulation of ordered chromophore molecules into one dimensional zeolite channel systems results in host-guest compounds suitable for the development of novel optical materials such as lenses, infrared light-emitting diodes (used in telecommunications) or dye nanostructured materials for optical data storage [1]. X-ray powder diffraction study of zeolite K-L loaded with 0.5, 1, 1.5, 2 fluorenone-dye (FL) molecules per unit cell (ZL/FL hybrid) [2], was carried out to understand the functionality of these host-guest systems from the structural point of view. These data evidenced a significant change of the unit cell parameters due to the embedding of FL into the ZL 12-membered channels. The Rietveld refinements revealed that the maximum loading is 1.5 FL molecules per unit cell. A strong interaction between FL carbonyl group and two



extraframework potassium cations is proved by the short bond distances which make this composite very stable.

Fig.1 Projection along *c* axis of the ZL/FL (1 molecule) (A) and ZL/FL (1.5 molecules) composites (B) .

Properties and processing of organic aerosol in the Po valley

S. GILARDONI[1], M. RINALDI[1], M. PAGLIONE[1], S. DECESARI[1], L. POULAIN[2], S. CARBONE[3], R. HILLAMO[3], L. M. RUSSELL[4], P. MASSOLI[5], V. POLUZZI[6] AND M. C. FACCHINI[1]

[1]ISAC-CNR Bologna Italy s.gilardoni@isac.cnr.it; [2]IFT Leibniz Germany; [3]FMI Helsinki, Finland; [4]SCRIPPS San Diego, CA; [5]Aerodyne Research Billerica, MA; [6]ARPA ER Bologna, Italy.

The chemical and microphysical properties of submicron organic aerosol (OA) strongly depend on sources and atmospheric processing.

OA properties were investigated in the framework of ARPA-ER Supersite project and Pegasos project. Observations were performed at an urban site (Bologna) and a rural location (San Pietro Capofiume) in fall 2011, summer 2012, fall 2013, and winter 2013. The suite of deployed measurement techniques included High Resolution Time of Flight Aerosol Mass Spectrometry (HR-TOF-AMS), Hydrogen Nuclear Magnetic Resonance (H-NMR), Fourier Transform Infrared Spectrometry (FTIR), together with thermo and thermo-optical analysis.

At both sites, OA represented about 50% of submicron particle mass during the colder seasons (winter and fall), and about 60% in summer. The oxygen to carbon ratio (O:C), an index of the oxidation level of OA, showed a clear seasonality with higher values in summer at the rural site. Different organic aerosol processing mechanisms characterized different areas and seasons. Photochemical processing was more relevant during summer. Fog processing was significant during fall experiments in the rural site, where frequent and prolonged fog events occurred. Van Krevelen diagram (H:C vs O:C) suggested that different processing mechanisms took place through different chemical oxidation pathways. We also present results from positive matrix factorization (PMF) analysis performed on the datasets collected at both sites.

Ultrafast Pump-Probe Studies of Geochemical Reactions

BENJAMIN GILBERT[1]

[1]Lawrence Berkeley National Laboratory, 1 Cyclotron Road, Berkeley, CA 94720, USA

Time-resolved spectroscopic methods provide new opportunities for understanding reaction mechanisms in all areas of the chemical sciences. In essence, ultrafast spectroscopy using the pump-probe approach can measure the rates of elementary reaction steps that occur on subnanosecond timescales, and provide chemical characterization of reaction intermediates with as much information content as conventional methods. Time-resolved versions of UV-vis, infrared, Raman, X-ray absorption and electron paramagnetic spectroscopy are now available. This presentation will give an introduction to ultrafast pump-probe studies of geochemical reactions, particularly discussing the opportunities and challenges of time-resolved X-ray absorption spectroscopy. TR-XAS is a major focus for all current and planned X-ray sources, and currently undergoing to a rapid growth in facility availability and data quality.

The pump-probe method achieves very high time resolution only when a reaction of interest can be initiated by a fast trigger pulse (the “pump”), typically a laser pulse. Thus, photochemical reactions, such as the photolysis of ferrioxalate or mineral photoreductive dissolution, are naturally suited for ultrafast studies. In addition, the photoreduction or photooxidation of organic and inorganic adsorbates at semiconductor mineral surfaces are also now being studied by ultrafast spectroscopic techniques. However, most geochemical reactions are not naturally light driven, and a major challenge is the development of strategies for reaction initiation. Photoactive dye molecules can be used to efficiently transfer electrons to iron and manganese oxide minerals, and may also permit the study of metal redox reactions in homogeneous solution.

Interpretation of spectroscopic signatures from reaction intermediates can be difficult because their nature precludes the preparation of stable reference species. Thus, simulation can play an important role in the interpretation of TR-XAS. For example, model calculations of the XAS of iron(II) sites in iron(III) oxides revealed that both valence state change and lengthening of the iron-oxygen bond length contributed to the spectral changes observed at the near-edge, confirming the polaronic nature of this reactive site.

A disordered whole-nanoparticle model for 6-line ferrihydrite

BENJAMIN GILBERT[1], J. ERBS[2], R. L. PENN[2], V. PETKOV[3] AND G. A. WAYCHUNAS[1]

[1]Lawrence Berkeley National Laboratory, 1 Cyclotron Road, Berkeley, CA 94720, USA
[2]Department of Chemistry, University of Minnesota, Minneapolis, MN 55455, U.S.A
[3]Department of Physics, Central Michigan University, Mt. Pleasant, Michigan 48859, USA

Ferrihydrite is a probably the most widespread and environmentally important natural inorganic nanoparticle, composed of defective nanocrystals of hydrous iron(III) oxide. Recently, Michel *et al*. (2007, 2010) proposed a structural model for ferrihydrite in place of the long-accepted model by Drits *et al*. (1993). The *Drits* and *Michel* models each achieve arbitrarily good agreement with, respectively, XRD and PDF data, but not with both. Because X-ray scattering methods have a growing role in structural studies of nanoscale materials, it is essential to understand the origin of this apparent paradox. Here we present a novel structural analysis of total X-ray scattering data acquired from 6-line ferrihydrite. We generated candidate whole-nanoparticle models of ferrihydrite composed of a two-phase *Drits* model, the *Michel* model, or a *hybrid* phase based on a single-phase *Drits* model that incorporated tetrahedral Fe sites, creating a lattice in which the *Michel* model was one of many possible topologies. We implemented a reverse Monte Carlo (RMC) approach to explore alternative configurations of iron occupancies plus structural disorder, and to refine the nanoparticle structure using both the reciprocal and real-space forms of the X-ray scattering data.

Nanoparticles based upon the *hybrid* structure converged to give better agreement to the experimental total scattering data than was attained for nanoparticles based upon either the *Michel* or *Drits* models. RMC models that incorporated tetrahedrally coordinated iron sites achieved better matches to the data than RMC models with face-sharing octahedra. Long-range vacancy disorder was essential for optimum fits to the scattering data, highlighting the advantage of whole-nanoparticle models in place of unit cell models. The RMC-derived structures do not satisfy all experimental constraints, but our results suggest a route to achieving better descriptions of this, and other, defective nanomaterials.

We will show data from 20nm-resolution synchrotron photoelectron spectromicroscopy and microcalorimetry, demonstrating that in sea urchin biominerals the first mineral deposited is hydrated amorphous calcium carbonate (ACCH2O), which rapidly transforms into ACC, which slowly transforms into calcite [1]. The same process occurs abiotically, but it takes seconds to crystallize, whereas in the animal it takes days, hence the above phase transitions are highly bio-regulated. The energetics [2], spatial distribution of phases, and time-evolution [3] of this complex process will be presented, with particular emphasis on the role of SM50 [3], a protein that appears to stabilize ACCH2O in vitro, and may have this function in vivo [4].

Matrix dependance for the quantification of sulphur in sulphide minerals by LA-ICP-MS

S.E. GILBERT*, L.V. DANYUSHEVSKY AND S. MEFFRE

CODES, Univarsity of Tamania, Hobart, Tasmania, Australia, 7000 (*correspondence: sgilbert@utas.edu.au)

Matrix effects due to differencs in ablation characteristics can be significant between minerals during LA-ICP-MS analyses [1, 2]. In this study we investigate the degree of matrix dependance on the quantification of sulphur between a range of sulphide minerals including pyrite, phrrhotite, bornite, chalcopyrite, sphalerite and pentlandite.

The major element yeilds (sensitivity per ppm) for these sulphide minerals were compared on three laser ablation systems: a 213 nm and 193 nm Nd:YAG lasers and a 193 nm Excimer laser. Sulphur fractionation was significant for some minerals. For example, for both pyrrhotite ($Fe_{1-x}S$) and bornite (Cu_5FeS_4) S yields relative to Fe are consistently high on all laser systems, by up to 12 and 40 % respectively, compared to pyrite (FeS_2). In comparison no fractionation is seen between Cu and Fe [3].

These observation can in part be explained by examining the amount of melt within, and adjacent to, the laser ablation crater. The degree of melting is mineral specific and dependant on the physical properties of the mineral (ie heat capacity), as melting occurs even at low energy close to the ablation threshhold. The degree of melting in each sulphide mineral was assessed with SEM imaging, by inspecting the morphology of the crater rim and deposited material adjacent to the ablation site. Very little melting occurs during pyrite ablation in contrast to pyrrhotite and bornite, which show evidence of liquid melt within and around the ablation crater.

We propose that the high yileds of S relative to Fe and Cu in these minerals is due to the high volatility of S. The implications for the quantification of S in sulphide minerals, and the factors that influence the liberation of S, such as melting during ablation, are discussed.

Evolution of AFM mineral assemblages in the Jálama granitic pluton

GIL-CRESPO P.P.[1], TORRES-RUIZ J.[2], PESQUERA A.[1] AND RODA-ROBLES E[1].

[1]Departamento de Mineralogía-Petrología, Universidad del País Vasco, PO Box 644, E-48080 Bilbao, Spain

[2]Departamento de Mineralogía-Petrología, Universidad de Granada, Campus Fuentenueva, E-18002 Granada, Spain

The Jálama pluton crops out in the Central Iberian Zone (Spain). It intrudes into low-grade metasedimentary rocks from the Schist-Greywacke Complex, and includes two main units: (1) the central unit, which consists of an inhomogeneous sillimanite-bearing monzogranite with hypidiomorphic seriate texture containing mainly quartz, alkali feldspar, plagioclase, muscovite and biotite. (2) the external unit, which comprises (i) a coarse-grained monzogranite with hypidiomorphic seriate to porphyritic texture including quartz, K-feldspar, plagioclase, biotite, muscovite ± tourmaline, the tourmaline being relatively abundant in places, (ii) an equigranular granite with a mineral association similar to the monzogranite, but muscovite being more abundant than biotite, and (iii) a fine- to medium-grained leucogranite containing quartz, alkali feldspar, plagioclase, muscovite and tourmaline as essential components. Based on textural relationships, mineral compositions, and AFM liquidus topologies, the sequence of AFM mineral reactions in the Jálama pluton may have evolved from L_1 = Bt + Ms + L_2, through L_2 = Bt + Ms + Tur + L_3 to L_4 = Ms + Tur. Biotite would react with a B-bearing melt (L_3) to produce further tourmaline during crystallization to lower temperatures, and subsequent crystallization of the residual melt (L_4) gave rise to the muscovite + tourmaline facies. The $FeMg_{-1}$ exchange operator involving the crystallization of biotite and tourmaline, with an average K_D value ((Mg/Fe)tur/(Mg/Fe)bt) ~ 2.0, covers a wide range of Fe/(Fe+Mg) in the AFM topology. The restricted accesibility to the three-phase Tur-Bt-Mus field of most granitic melts, nevertheless, would account for the separation of biotite + muscovite assemblages from tourmaline-bearing assemblages. The three-phase assemblage displaces toward higher Fe/(Fe+Mg) values with decreasing temperature based on the AFM liquidus topology. This suggests a solidus temperature for the biotite-muscovite assemblage higher than for the tourmaline-muscovite assemblage. This is consistent with the emplacement of the pluton under epizonal conditions (~200-300 MPa) at temperatures in the range of 650-800ºC using the zircon saturation thermometry.

Geochemical tracing of methane from unconventional gas production

STUART M.V. GILFILLAN[1], R. STUART HASZELDINE[1], FINLAY M. STUART[2] AND SUSAN WALDRON[3]

[1]School of GeoSciences, University of Edinburgh, UK (*correspondance: stuart.gilfillan@ed.ac.uk
[2]Isotope Geosciences Unit, SUERC, East Kilbride, UK
[3]School of Geographical and Earth Sciences, University of Glasgow, UK.

There is significant public concern surrounding the exploitation of unconventional gas resources. Many of these concerns relate to potential methane contamination of potable water supplies in shallow aquifers. Public apprehension is predominantly linked to experiences of unconventional gas extraction in the USA where there is strong and growing public dispute around the "fracking" process. Evidence of groundwater contamination by produced gas is equivocal. Some studies have found no direct causality between fracturing and groundwater contamination. However, there is a developing group of work in the USA by individual researchers [1] and by the Environmental Protection Agency [2], which suggests that a degree of contamination of groundwater has occurred.

In such a commercially active sector, a strong suite of evidence is needed to unequivocally detect contamination and allow successful remediation litigation. Simple documentation of elevated methane content in groundwater is not sufficient to enable a legally secure diagnosis. Rival claims can be made that the methane present in the groundwater is from drilling operations which predate shale gas exploration, or that observations of hydrocarbon content, including methane gas, in shallow aquifers are due to natural processes unconnected with unconventional gas exploration. For these reasons, an extremely robust identification of methane source, or multiple methane sources, is needed. In this study we focus on providing the means to make that identification.

Using existing data, we will show how C and H isotopes, radiocarbon (^{14}C) and noble gases (He Ne Ar Kr Xe) can be used to geochemically "fingerprint" produced gas from coal bed methane and shale gas deposits. This clear "fingerprint" can be used to distinguish any produced gas from from other gas sources and provide a robust means for identifying produced methane contamination of shallow groundwaters.

Volcanostratigraphic controls on the occurrence of massive sulfide (VMS) deposits in the Oman Ophiolite

S. GILGEN*, L. W. DIAMOND AND I. MERCOLLI

Rock–Water Interaction, Institute of Geological Sciences, University of Bern, Switzerland (*correspondence: gilgen@geo.unibe.ch)

The Semail ophiolite in northern Oman is capped by up to 2 km of basaltic–andesitic lavas that host copper-dominant, Cyprus-type, volcanogenic massive sulfide (VMS) deposits. This study identifies the multiple volcanostratigraphic horizons on which the deposits are situated, based on characterization of footwall and hanging-wall lavas from 16 deposits or deposit clusters. Comparison of their field and petrographic features, compositions of igneous clinopyroxenes and whole-rock geochemical signatures permits their classification within a modified version of the established regional volcanostratigraphy.

Four extrusive units host VMS deposits: Geotimes (earliest), Lasail, Alley and Boninitic Alley (latest). The latter was known only at a few localities but the present study reveals its regional extent and significance as a host for VMS deposits. The new results show that VMS deposits sit on or near the Geotimes/Lasail and Geotimes/Alley contacts as well as entirely within the Lasail, Alley and Boninitic Alley Units. The Geotimes and Lasail Units represent Late Cretaceous, ocean spreading ridge and related off-axis volcanic environments respectively. Highest Cu grades tend to occur in deposits lying on or within the Geotimes. The Alley and Boninitic Alley Units represent younger, subduction-related volcanism prior to Coniacian–Santonian obduction of the ophiolite. Highest Au grades occur in deposits within the Boninitic Alley.

In contrast to earlier studies, the new results show that essentially every horizon that marks a hiatus in lava deposition in the Semail ophiolite, i.e. contacts between the four major eruptive units, and umbers and sedimentary chert layers within the units, has exploration potential for Cu–Au VMS deposits.

[8]Dept. of Earth Sciences, University of California, Riverside, CA, USA

The evolution of Earth's oceans on geologic timescales has included episodes when basinal waters were anoxic and sulfidic (euxinic). The expansion of sulfidic bottom waters has the potential to drive significant chemical and biological changes in benthic environments. Considerable interest exists to develop tools that can be used to identify these conditions. Sulfur isotope analyses ($^{33}S/^{32}S$, $^{34}S/^{32}S$ and $^{36}/^{32}S$) in combination with other geochemical indicators show promise in studies of dynamic bottom-water conditions in low oxygen settings. Here, we present multiple sulfur isotope analyses of sulfate, dissolved sulfide, and sedimentary sulfides (AVS and pyrite) from diverse settings in the modern Black Sea to address basin-wide sulfur cycling. Within this well constrained depositional and environmental context, we describe variations in $\delta^{34}S$, $\Delta^{33}S$ and $\Delta^{36}S$ that, along with other geochemical proxies such as iron geochemistry, track the historical shoaling of sulfidic deep waters. Multiple sulfur isotope approaches are especially sensitive to oxidative and reductive pathways of microbial S metabolisms that vary in phase with changes in bottom-water redox. The processes that control the sulfur isotopic signatures are ultimately related to the interplay of rates of pyrite formation, sulfide oxidation, and diffusion of sulfide and dissolved iron in the sediments. By extrapolation, we argue that the sulfur isotope signatures may provide a tool for identifying chemocline shoaling events and ecological changes in the biologic S cycle in the geologic past.

Kinetic of H_2O_2 generation and decay during pyrite-water reactions

C. GIL LOZANO*[1], E.L. ADAMS[1], A.F. DAVILA[2], A.G. FAIREN[3] AND L.G. DUPORT[1]

[1]Universidad de Vigo. 36200 Vigo. Spain. (corresponding author*: karolina_gil@uvigo.es)
[2]SETI Institute, Mountain View, CA 94043, USA.
[3]Cornell University. Ithaca, 14853 New York, United States

The oxidative dissolution of pyrite is driven by a complex mechanism that involves the transient formation of H_2O_2 and other reactive oxygen species [1], however, a kinetic analysis dealing with the time evolution of these species is presently lacking. In this work, we measured the real-time generation and decomposition of H_2O_2 on pyrite surfaces under different boundary conditions with amperometric biosensors. In addition, simultaneous measurement of the O_2, Fe(II), together with Fe(III) generated as a byproduct of Fenton reaction, were done with Clark sensors, and UV-VIS spectroscopy. The observed general pathway for H_2O_2 time evolution consisted of an S-shaped stretched exponential profile, with a first stage marked by an increasing generation of H_2O_2 until a critical concentration value of peroxide was reached. From this moment on, the measured amount of H_2O_2 in solution decreased towards a nearly stationary value. Further, experiments were performed to assess the reversibility of the process and to evaluate the possible role of pyrite-generated H_2O_2 and other ROS in the long-term redox evolution in natural environments. A new kinetic model based the coupling between H_2O_2 and Fenton reaction in aqueous solution was performed to fit the experimental data. Results showed that the observed amount of peroxide at each instant can be closely related to the supply rate of Fe^{+2} resulting from pyrite dissolution, which progressively degrades H_2O_2 inducing the continuous generation of secondary ROS in solution. Thus, it can be speculated that the mineral pyrite may act as a Fenton-like reagent, able to induce long-term oxidation through the geological realm.

A great number of medieval religious buildings in Europe contain stained glass windows. A number of original glass fragments (i.e. with original medieval lead framework) coming from restoration projects (Girona, Tarragona, Pedralbes Monastery at Barcelona (Spain); the Siena Cathedral, the San Petronio Basilica and the San Giacomo Maggiore church in Bologna (Italy)) have been analyzed in term of major, minor and trace elements. In contrast to the coeval glass windows of central Europe, most of the studied glass fragments are soda-glass of Mediterranean origin, whereas the imported K-glass were used only to realize some colors in the windows (in most of cases red ruby plaque glass). Concerning the technological aspects, these glass were realized starting from the colorless base glass, to which metal-transition elements were added to obtain the different colors. A first conclusion is that some elements, singularly REE associated to Nb and other trace elements characterize the source of silica, that is quartz sand or quartz cobbles. This allows to the identification of homogeneous sets of colored and colorless glass (i.e., original medieval glass) in the same windows and sites, even in the cases of subsequent widespread reposition of glass fragments over the centuries. Total content in Sr provides information on the calcium carbonate source (limestone or aragonitic shells).The different shades of the green color were obtained by using a Fe-Cu association. The study of green glass fragments by ICP-MS and laser ablation HR-ICP-MS allows to characterize different mineral salts taking into account the associated trace element metal associations. We acknowledge the technical support of the CCiT of the Universitat de Barcelona and the ICTJA-CSIC labGEOTOP, infrastructure co-funded by ERDF-EU (Ref. CSIC08-4E-001). This work has been carried out in the framework of the research group PEGEFA SGR2009 972 (Generalitat de Catalunya).

Perturbing a field diffusion experiment: First results of the DR-A test in the Mont Terri Rock Laboratory (Switzerland)

T. GIMMI[12], O.X. LEUPIN[3], J.M SOLER[4] AND L.R. VAN LOON[2]

[3]Nagra, CH-5430 Wettingen, Switzerland

[4]IDAEA-CSIC, E-08034 Barcelona, Spain

Clay-rich formations have repeatedly been shown to provide an appropriate environment to safely retain harmful solutes. However, a thorough understanding of diffusion of anions, cations and uncharged tracers through clay is fundamental to assess any long-term transport properties. A field diffusion experiment (DR-A) was recently started in the Mont Terri Underground Rock Laboratory (Switzerland). The aim of this experiment is to provide insights on coupled transport and sorption processes that are of central importance in clays, notably anion exclusion, competing sorption by cation exchange, anion and cation diffusion, and to test the predictive capability of transport codes.

The experimental design is based on established setups (DI-A1 and DI-A2 [1,2]) with a traced artificial pore water (APW) that should match the local geochemical conditions and which is circulated through a 1-m injection interval. The tracers included HTO, I^-, Br^-, Cs^+, 85-Sr^{2+}, 60-Co^{2+} and Eu^{3+}. However, unlike earlier experiments, the traced APW was exchanged after 6 months by a non-matching solution (~3 times higher ionic strength, strongly increased in K content compared to the original APW) still containing the tracers. This geochemical perturbation was expected to provoke responses that can be observed in the circulated solution.

The increase of the ionic strength and the K content led to a release of Cs from the exchanger and back-diffusion into the circulated solution. So far, no clear effect on anion exclusion was observed. The data will be interpreted by several modelling groups (IDAEA-CSIC, PSI, Univ. Bern, Univ. British Columbia, Lawrence Berkeley Natl. Lab.) using codes with different representations of the coupling between ionic strength and the transport and sorption properties.

Understanding Long-Term Variability of Dust in Different Parts of the World

GINOUX P, MALYSHEV S AND SHEVLIAKOVA E

paul.ginoux@noaa.gov

Over the last decade dust modeling has made large progress and satisfactory dust forecasting is now being provided operationally by several modeling groups. However, unsatisfactory comparison with observations, especially long-term datasets, indicates limiting factors of dust modeling. One of these factors is related to the dynamic variation of dust sources, which can be observed from satellite data. This is particularly problematic to study dust effects on climate, and feedbacks.

In this presentation, after summarizing the most prominent changes of dust concentration observed in different parts of the world, we will review several modeling approaches which were used to simulate decadal variations of dust. The recent implementation of a dust module within a dynamic land model, which is coupled with atmosphere/ocean/ice models, will be used to understand observed dust variability over the last 60 years and to evaluate the contribution of sea-surface temperature, vegetation and landuse changes to long-term variability of dust. Finally, some additional factors which may affect aeolian dust in the future will be presented.

CCN Relevant Properties of Biomass Burning Aerosol

M. GIORODANO AND AKUA ASA-AWUKU[1*]

[1]University of California, Riverside, Riverside, CA 92521, USA (correspondence akua@engr.ucr.edu)

Biomass burning contributes upto 2-3 Pg C per year to the atmosphere, of which the composition and phase are not well characterized. The oxidation of these emissions can produce additional aerosol downwind from sources that can directly and indirectly modify climate. Controlled burns were conducted at UC-Riverside's CE-CERT facility to understand the influence of aged wood smoke for aerosol cloud formation process. The emissions were diluted and injected into a 12 m3 Teflon environmental chamber. The smoke was allowed to mix in the chamber, and a suite of instrumentation measured changes in aerosol phase chemical and physical properties. The smoke is photochemically active; ultraviolet lights age the wood smoke over a 6-8 hour period and cloud condensation nuclei (CCN) properties are transient. This presentation focuses on the changes in CCN activity due to key factors that are used to quantify and predict hygroscopcity. The kappa-hygroscopicity varies significantly with photochemical age and supersaturation. A high resolution time-of-flight aerosol mass spectrometer is used to analyze aerosol chemical composition. Size distribution and CCN activity are determined with a SMPS and CCN counter.

A combined sedimentological and biomarker record across the Neoproterozoic Bitter Springs Excursion

MARTINO GIORGIONI[1]*, AMBER JARRETT[1], MARTIN KENNEDY[2] AND JOCHEN BROCKS[1]

[1] Research School of Earth Sciences, Australian National University. Canberra, ACT 0200, Australia (*correspondence: martino.giorgioni@anu.edu.au)

[2] School of Earth and Environmental Science, University of Adelaide. Adelaide SA 5005, Australia

Isotopic records from carbonate carbon of the Neoproterozoic (1000 – 542 Ma) display extremely large negative excursions, with $\delta^{13}C$ values shifting from 5‰ to 8‰ down to –4‰, –6‰, or even –12‰. The origin of such large amplitude variations is still enigmatic because they do not occur in any other geological period, except in diagenetically altered carbonate platforms [1].

In this work we focus on the Bitter Springs Excursion (BSE), which is the oldest (~800 Ma) and the least extreme in the Neoproterozoic, with $\delta^{13}C$ values shifting from 6‰ to –4‰. In respect to the other large excursions this is the only one not preceeding nor followed by a large glacial event, and it is the only case in which the negative excursion is recorded both in carbonate and in organic $\delta^{13}C$ [2].

We present sedimentological and geochemical data from a new core drilled through the Bitter Springs Formation of the Amadeus Basin in Central Australia. The lower part of this unit consists of a thick succession of carbonate and evaporitic facies (Loves Creek member), whereas the upper part is dominated by red silty marlstones alternating with gray, more carbonatic facies (Jonnys Creek member). Bulk carbonate $\delta^{13}C$ is between –4‰ and –2‰ within the Loves Creek member, corresponding to the upper part of the BSE. The base of the Jonnys Creek member coincides with the end of the excursion, with $\delta^{13}C$ increasing up to 6‰. However, the $\delta^{13}C$ pattern is continuous indicating that there is no significant hiatus at the boundary between the two members.

We also present the first detailed record of indigenous [3, 4] biomarkers from within and above the BSE. Shifts in facies as well as in biomarker assemblages suggest significant ecological changes at the end of the BSE within the Amadeus Basin.

Enrichment of Pb, Se, As, U and Cs in commercial cosmetic clays

K. GIOURI*, A. PAPADOPOULOS, A. BOURLIVA, E.TZAMOS, L. PAPADOPOULOU, K. NTOUANOGLOU AND A. FILIPPIDIS

Aristotle University of Thessaloniki, School of Geology, Department of Mineralogy-Petrology-Economic Geology, Thessaloniki 54124, Greece (*correspondance:agiouri@geo.auth.gr)

Three samples, representing different commercial types of cosmetic clays (white, green and red) were analyzed for 29 trace elements (Ag, As, Ba, Be, Cd, Ce, Co, Cr, Cs, Cu, Ga, Hf, Hg, La, Mo, Ni, Pb, Rb, Sb, Sc, Se, Sr, Th, Tl, U, V, Y, Zn and Zr).

According to EC regulation [1] the presence of As, Be, Cd, Cr, Hg, Ni, P, Pb, Sb, Se, Te, Tl, Zr and their compounds is prohibited in cosmetics. However, for 16 trace elements (As, Ba, Ce, Cr, Cs, Cu, La, Ni, Pb, Rb, Sr, Th, V, Y, Zn and Zr), concentrations ranging from 10 ppm to 410 ppm have been detected in the studied clays.

Compared to the average concentration of elements in shales (average shale) [2] (Fig. 1), white clay (WC) is enriched in Pb (11.0 times), Cs (2.0 times) and U (2.0 times), green clay (GC) is enriched in As (3.3 times) and U (2.1 times), while the red clay (RC) is enriched in Se (9 times).

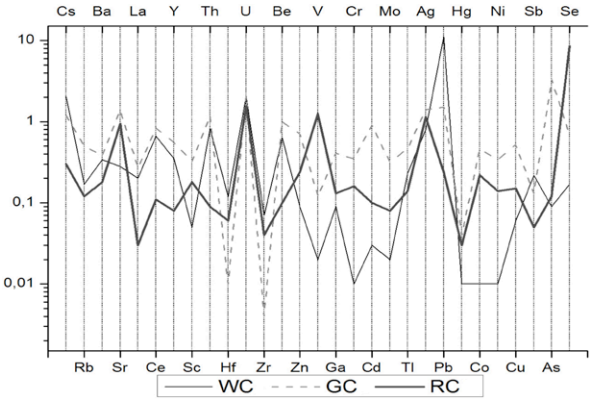

Figure 1: Average shale-normalized trace element spider diagram patterns of the studied samples; elements sorted according to their electronegativity values.

U-Pb and Hf isotopes in zircons from mantle chromitites of the Finero Peridotite (Ivrea Verbano Zone)

T. GIOVANARDI[12], A. ZANETTI[3*], M. MAZZUCCHELLI[2], M. TIEPOLO[3], F.-W. WU[4], A. LANGONE[2] AND R. VANNUCCI[1]

[1]Dip. Scienze della. Terra e Ambiente, Univ. di Pavia, Pavia, Italy

[3] Istituto di Geoscienze e Georisorse, CNR, Pavia, Italy
[4]IGG, Chinese Academy of Sciences, Beijing, China
(*correspondence: zanetti@crystal.unipv.it)

The Finero Phlogopite Peridotite unit (hereafter Ph-Pd. Ivrea-Verbano Zone, IVZ: Southern Alps) is the unique worldwide example of orogenic mantle massif completely constituted by phlogopite-bearing ultramafics (mainly harzburgites, websterites and dunites) after pervasive to channelled melt migration events. A precious opportunity to provide further constraints on the petrologic and geodynamic evolution of such a mantle sequence is given by the occurrence of zircons in chromitites usually composed by Chromite+Orthopyroxene±Clinopyroxene±Amphibole.

Zircons show low CL emission and are generally homogeneous. Few grains display cores slightly darker than the rims. Zircons have up to 1420 and 800 ppm of U and Th, respectively, with Th/U ratio up to 1.6. U-Pb LA-ICP-HRMS analyses yield most concordant Lower Jurassic dates with a weighted average $^{206}Pb/^{238}U$ age at 187±2 Ma. A few darker cores yield Middle Triassic concordant $^{206}Pb/^{238}U$ ages from 242±7 Ma to 229±7 Ma. Zircons also show $^{176}Hf/^{177}Hf$ ratios in the range of 0.282486-0.282610, which give sub-chondrititic $\varepsilon Hf_{(188)}$ (-6.0 to -1.6). The relatively high U and Th contents and the large Th/U ratios are the evidence that the chromitite zircons crystallised from a melt, which, according to the low $\varepsilon Hf_{(188)}$ values, had a marked crustal signature. This melt is analogous to that at the origin of the phlogopite harzburgites and websterites. The absence of internal zoning in zircon is interpreted as the result of homogenisation after a prolonged residence at high temperature mantle conditions. In this frame, the Lower Jurassic ages are proposed to date the cooling of the mantle sequence during exhumation for the opening of the Alpine Tethys. Conversely, the few Middle Triassic dates could represent the age of mantle metasomatism. As a whole, our data strongly support that the Finero area experienced a different geodynamic evolution with respect to the rest of IVZ.

Use of whole rock geochemistry for ignimbritic unit recognition: An example from the Sulcis area (SW Sardinia, Italy)

G. GISBERT AND D. GIMENO

Facultat de Geologia, Universitat de Barcelona, C/ Martí i Franquès s/n, 08028 Barcelona, Spain. (ggisbertp@hotmail.com, d.gimeno.torrente@gmail.com)

In the Sulcis area (SW Sardinia, Italy) a thick Oligo-Miocene volcanic sequence formed during the drifting and rotation of Sardinia from the European continental margin to its current position. These volcanics originated by the combined effect of oceanic crust subduction under the Corsica-Sardinia microplate and increased extensional tectonics after 18 Ma. The volcanic deposits are over 600 m thick and cover an area more than 40 km in diameter which includes part of the mainland and two minor islands. This volcanic sequence consists of two differentiated halves: a lower one formed by andesitic lava domes and flows, and an upper one formed by a pile of trachytic and rhyolitic up to comenditic ignimbritic mantles, some of which cover the whole studied area. This ignimbritic sequence has been divided over the years into 18 units. The similarities between the various ignimbritic units, both macro- and microscopically in many cases, combined with the large facies variability some units may present, make the correct identification of units and correlation between zones and outcrops difficult in such a wide area, which is divided, moreover, by the sea. To solve this problem a thorough study of the ignimbritic suite was carried out involving the volcanostratographic revision and the whole rock geochemical characterisation of each unit. Whole rock geochemistry was analysed by means of XRF, ICP-MS and ICP-OES. A protocol was developed which allows the identification of the ignimbritic units in the Miocene Sulcis ignimbritic pile based on whole rock geochemistry. It works by projecting geochemical data of problem samples into specially-designed binary diagrams. This tool for the recognition of units using only its whole rock geochemistry has allowed us to solve many cartographic and stratigraphic doubts in the study area, proving its usefulness. From now on it can be also used by other researchers working in the area. Moreover, the methodology followed to elaborate this protocol can be applied elsewhere.

This study has been funded by the spanish project CGL2011-28022.

The long-term security of geologic carbon storage is critical to its success and public acceptance. Much of the security risk associated with geologic carbon storage stems from its buoyancy. Gaseous and supercritical CO_2 are less dense than formation waters providing a driving force for it to escape back to the surface via fractures, or abandoned wells. This buoyancy can be eradicated by the dissolution of CO_2 into water prior to, or during its injection into the subsurface. The dissolution will further enhance mineral storage of CO_2 especially if injected into silicate rocks rich in divalent metal cations such as basalts and ultra-mafic rocks.

We have demonstrated the dissolution of CO_2 into water during its injection into a rock formation leading to its geologic solubility storage in less than 5 minutes. This process was verified via the successful injection of over 170 tons of dissolved CO_2 into porous basaltic rocks located 400-800 m below the surface at the CarbFix [1,2,3] field injection site in SW Iceland. Rock dissolution, dilution, and dispersion, caused the pH and alkalinity of the injected water to increase. Concomitantly, the concentration of most dissolved elements increased and carbonate minerals became saturated. Conservative tracers and ^{14}C labelled CO_2 were mixed into the injected gas and water stream to monitor the subsurface transport and to assess the degree of subsurface carbonation.

Dating mantle metasomatism: A new tool (U/Pb LIMA titanate) and an impostor ($^{40}Ar/^{39}Ar$ phlogopite)

A. GIULIANI[1], D. PHILLIPS[1], M.K. KENDRICK[1], R. MAAS[1], A. GREIG[1], R. ARMSTRONG[2], M.R. FELGATE[1] AND V.S. KAMENETSKY[3]

[1]School of Earth Sciences, The University of Melbourne, Australia (*corresp: a.giuliani@student.unimelb.edu.au)
[2]Research School of Earth Sciences, Australian National University, ACT, Australia
[3]School of Earth Sciences, University of Tasmania, Australia

Precise dating of fluid processes in the Earth's mantle remains a major challenge for geoscientists. The U/Pb and Ar/Ar dating techniques have both been used in an attempt to constrain the timing of mantle metasomatic events; however, the Ar/Ar results have proven contentious [1]. Here we compare the $^{40}Ar/^{39}Ar$ ages obtained for large phlogopite grains from 7 mantle xenoliths from the 84 Ma Bultfontein kimberlite (Kimberley, South Africa), with U/Pb ages from metasomatic zircon and LIMA minerals coeval with phlogopite.

LIMAs are unusual titanates that occur in phlogopite-rich metasomatised peridotites [2]. LIMA minerals are enriched in incompatible elements (e.g., LILE, LREE, HFSE), with high U (250-400 ppm) and Pb (200-700 ppm) contents. U/Pb geochronology on LIMA minerals is limited by the low U/Pb ratios and high common Pb. In this study, the U, Th and Pb isotopes of LIMA minerals from three mantle xenoliths were measured by *in-situ* LA-ICP-MS. Common Pb values were determined from isotope dilution MC-ICP-MS measurements of coeval clinopyroxene grains. LIMA U/Pb ages are ~ 170-180 Ma, in agreement with a U/Pb age of 184±2 Ma obtained for a single zircon from one of the LIMA-bearing xenoliths. These results suggest a link between mantle metasomatism and Karoo magmatism in southern Africa [3].

Ar/Ar step-heating analyses of phlogopite grains were conducted using a new generation ARGUSVI multi-collector mass spectrometer. All the phlogopite samples yielded much older $^{40}Ar/^{39}Ar$ ages (up to 780 Ma) than coexisting zircon and/or LIMA minerals. We attribute these anomalously old Ar/Ar ages to the presence of excess ^{40}Ar in the metasomatic fluid that crystallised phlogopite [4]. We conclude that the $^{40}Ar/^{39}Ar$ phlogopite technique cannot be used to date mantle metasomatism.

Textural evolution of a basaltic melt in function of cooling rate

[1]L. GIULIANI, [1]F. CAUTI, [12]G. IEZZI, [13]F. VETERE, [12]B.T. POE, [2]A. CAVALLO, [2]V. MISITI, [2]G. VENTURA[2], S. MOLLO AND H. BEHRENS

[2]Istituto Nazionale di Geofisica e Vulcanologia, Via di Vigna Murata 605 00143 Rome, Italy

[3]Institute for Mineralogy, Leibniz University of Hannover, Callinstr. 3, Hannover, D-30167, Germany

The evolution of textures has been quantified in run-products of basaltic composition solidified at 0.0167, 0.117, 1, 3, 30 and 150 °C/min from superliquidus to 800 °C. Three of these six cooling rates were run two times. At cooling rates ≤1 °C/min and ≥3 °C/min crystals are faceted and dendritic, respectively. Crystals and dendrites have been analyzed by image analysis, to obtain the proportion (area%), length and width (μm), aspect ratio, orientation of maximum axis (°) and phase density (n/area) of objects.

As the cooling rate increases crystal and plagioclase contents monotonically decrease, whereas clinopyroxene content shows an asymmetric Gaussian-like trend; the amount of spinel is instead always < 6 area%.

The strength of the fabric (preferred orientation of crystals) is low, except for one experiment at 0.0167 and 150 °C/min due to the likely presence of a thermal gradient.

The aspect ratio of plagioclase and spinel smoothly decreases with decreasing cooling rate; conversely, the shape of clinopyroxene does not show a specific trend.

As the cooling rate increases, the abundance of tiny crystals progressively and exponentially increases. In general, the number of crystals per area, which reflects nucleation, exponentially increases as the cooling rate increases, except at 150 °C/min.

At 150 °C/min this basaltic melt is virtually glassy (< 2 area%), indicating that 150 °C/min is close to the critical cooling rate (*R*c) for this melt.

Finally, run-products from three duplicated experiments show crystal content differences < 1, 4 and 18 area% under 0.0167, 1 and 30 °C/min, respectively.

The evolution of textural parameters experimentally observed here allows us to calibrate geo-speedometers and design new glass-ceramics.

Experimental determination of chlorine isotope fractionation in Cl_2-Cl^-_{aq} and $ClOH_{aq}$-Cl^-_{aq}

THOMAS GIUNTA*, JABRANE LABIDI HANS AND G.M. EGGENKAMP

Laboratoire de Géochimie des Isotopes Stables, IPGP, 1 rue Jussieu, 75238 Paris Cedex 05, France. (*correspondence: giunta@ipgp.fr)

In nature, the most common oxidation state of chlorine is -I (Cl^-). However, in some extreme environments such as hydrothermal systems, atmosphere or Martian soils, occurrences of other oxidized form of chlorine have been recognized. *Redox* reactions are known to produce large isotopic fractionations, that have been theoretically estimated for chlorine stable isotopes at equilibrium [1].

In order to explore both the chemistry and the isotopic effects of some of these redox processes, we designed a chloride oxidation experiment. In our apparatus, liquid HCl is mixed at ~ 20°C with H_2O_2, a powerful oxidant. Under a highly complex reaction pathway, this mixture ultimately leads to the formation of Cl_2 gas. The new forming gas is directly flushed out and trapped in a KOH solution, where it disproportionates into Cl^- and ClOH. In the oxidation reaction, the maximum production of Cl_2 is about 20% of the initial HCl. This experiment allows us to explore the isotope fractionation associated with three reactions: i) the oxidation of Cl^-_{aq} into Cl_2, ii) Cl_2 degassing, iii) Cl_2 disproportionation into Cl^-_{aq} and $ClOH_{aq}$.

The lack of fractionation during degassing implies that $\alpha(Cl_{2gas}\text{-}Cl_{2aq})$? 1.000. Assuming batch equilibrium, we can therefore determine the fractionation factors as follows:

$10^3 \ln \alpha(Cl_{2gas}\text{-}Cl^-_{aq}) = 3.72 \pm 0.25$ ‰ at ~ 20°C, and

$10^3 \ln \alpha(ClOH_{aq}\text{-}Cl^-_{aq}) = 3.04 \pm 0.20$ ‰ at ~ 20°C.

These two values are slightly lower than the theoretically calculated values [1][2]. We will discuss the likely hypothesis to explain these discrepancies.

Dating metamorphic stages in HP-terranes: Case study in the Sesia Zone (NW-Alps, Italy)

FRANCESCO GIUNTOLI, MARTIN ENGI AND AFIFÉ EL KORH

[1]Institut für Geologie, University of Bern, Baltzerstrasse 1+3, CH-3012 Bern, Switzerland (francesco.giuntoli@geo.unibe.ch)

The dynamics of assembly of HP-terranes is of major geotectonic significance. We report on a field-based study in the Sesia Zone, a HP-terrane formed during Alpine convergence. The three main parts of the Sesia Zone essentially derive from the rifted NW-margin of the Adriatic continent.

Micaschists showing a HP foliation (eclogite to blueschist facies) and weak (greenschist facies) retrogression were studied in detail. Assemblages comprise multiple generations of phengite, garnet, glaucophane (±early omphacite) and allanite, plus quartz, epidote, chlorite, and titanite rimming rutile. Microstructural and mineral-chemical data indicate that growth zones in garnet and allanite correspond to distinct HP stages. In some cases, these can be related to discrete phases of deformation (D1/D2, D3).

Garnet cores are strongly porphyroclastic, with at least two overgrowth phases. Allanite composite grains have a LREE-rich metamorphic core believed to be stable with early grt plus first generation phen (Si-rich), gln, and rutile. Allanite rims (one or more) show lower LREE and seem to be stable with second generation phen, gln and probably grt. Thermobarometry for each stage is in progress.

Preliminary Th-Pb age data for aln were obtained by *in situ* LA-ICP-MS analysis: 80-74 Ma for cores and 68-62 Ma for rims (imprecise owing to small volumes). These ages compare well with the two HP stages (HP1: ~75 Ma; HP2: ~65 Ma) Regis *et al*. (2013) found in several samples of the Fondo slice of the Sesia Zone, from which pressure cycling was inferred (Rubatto *et al*. 2011). Taken together with their data, the present sample suite indicates that YoYo tectonics may have operated in one (or more?) slices, which span at least 16 km along strike of the Sesia Zone.

Field-based research continues to define the size and geometry of tectonic slices that constitute the Sesia HP terrane. Kinematic constraints quantifying the relative mobility of such fragments are sorely needed, as the scale of mixing within subduction channels is poorly known. Understanding the overall processes in subduction channels requires that results from numerical models and field data be combined.

Inferring a West Antarctica firn temperature history from a shallow ice core using a new proxy.

V. GKINIS[12], T. JONES[1], J. WHITE[1], B. VAUGHN[1], E. STEIG[3], B. MARKLE[3] AND S. SCHOENEMANN[3]

[1] Institute for Arctic and Alpine Research, University of Colorado, Boulder, CO 80309, (v.gkinis@nbi.ku.dk)

[2]Center for Ice and Climate, University of Copenhagen, Copenhagen DK 2100

[3]Earth and Space Sciences, University of Washington, Seattle, WA 98195, USA, steig@uw.edu

The isotopic composition of polar ice has traditionally been used as a proxy for the temperature of the precipitation site. The validity of the method has however been challenged over the years, mainly due to apparent artifacts related to the seasonality of the precipitation, shifts in moisture source areas and others. Water isotope diffusion in firn is a process that can be used to infer past temperatures without the common problems of the traditional slope method. The method exploits the spectral information contained in the water isotopic composition time series and thus requires data sets of high resolution measured with high precision. Here we describe the method of firn water isotope diffusion and present ways to extract the firn temperature signal from high resolution $\delta^{18}O$ and δD time series. We apply this method on a 300 m shallow core from WAIS divide Antarctica (WDC2005A), sampled at a resolution of 3.3 cm and extending back to 1200 years b2k. We discuss on the findings of our temperature reconstruction and compare it to the temperature inferred with the traditional slope as well as with recent borehole temperature studies.

Metal micronutrients for anaerobic oxidation of methane

JENNIFER B. GLASS[1*], JOSHUA A. STEELE[1], KATHERINE S. DAWSON[1], SHAWN E. MCGLYNN[1], CHRISTOPHER T. REINHARD[1] AND VICTORIA J. ORPHAN[1]

[1]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA 91125; (jglass@caltech.edu)(*presenting author)

Methane is produced and consumed by microbes via metabolic pathways that involve metalloenzymes [1]. Our focus is trace metal requirements for anaerobic oxidation of methane (AOM) performed by microbial consortia of sulfate-reducing bacteria (SRB) and anaerobic methanotrophic euryarcheota (ANME) in marine methane seep sediments, where porewaters are highly sulfidic (up to 25 mM HS^-) and scavenging by sulfide mineral precipitation may reduce the availability of bioessential metals.

Using both metagenomic and metaproteomic data, we are characterizing the "metallome" of ANME/SRB consortia enriched from methane seep sediments. Iron-sulfur and heme-containing proteins are involved in reverse methanogenesis, sulfate reduction and the Wood-Ljungdahl carbon fixation pathway. Iron is likely transported by ferrous iron transporters in both symbiotic partners. Cobalt as vitamin B_{12} is present in enzymes involved in reverse methanogenesis, carbon fixation and methionine synthesis. Genes for high-affinity cobalt uptake and vitamin B_{12} biosynthesis are present in both symbiotic partners. Nickel as the tetrapyrrole cofactor F_{430} and as Ni-Fe-S clusters is involved in reverse methanogenesis and carbon fixation, respectively. Molybdenum-iron nitrogenases [2] and molybdate (MoO_4^{2-}) transporters are found in both partners, and a Mo or tungsten-containing enzyme is also involved in reverse methanogenesis.

Measurements of dissolved metal concentrations in methane seep sediment porewaters revealed that Co, Ni and Fe levels were below those required for optimal growth of cultured methanogens [1]. In contrast, dissolved Mo concentrations were generally high (~1 μM), suggesting that thiomolybdates (MoS_4^{2-}) are soluble in these porewaters. The similarity in size and charge between MoS_4^{2-} and MoO_4^{2-} may allow anaerobes to transport both species through the same transporters. Results from incubation experiments using sediment with a well-characterized ANME/SRB population and low dissolved metals, designed to test if Fe, Co and Ni additions stimulate AOM activity and/or ANME/SRB growth, will also be presented.

A role for liquid immiscibility in granites and granodiorites

ALLEN F. GLAZNER[1] AND JOHN M. BARTLEY[2]

[1]Dept. of Geological Sciences, Univ. of North Carolina, Chapel Hill, NC 27599, USA (afg@unc.edu)

[2]Dept. of Geology and Geophysics, Univ. of Utah, Salt Lake City, UT 84112 (john.bartley@utah.edu)

Mafic segregations in granodioritic and granitic bodies, such as layered granodiorites (LGs) and ladder dikes (LDs), are typically interpreted to have formed by separation of mafic minerals from a more silicic magma body via processes such as gravitational settling and shear flow. In the Sierra Nevada of California and other examples, the whole-rock geochemistry and mineral chemistry of the mafic layers rule out such an interpretation and instead suggest that these layers are the heavily recrystallized products of liquid immiscibility.

LGs and LDs consist of high concentrations of biotite, hornblende, magnetite, titanite, apatite, and zircon, leading to extreme enrichments in REE, Fe, Zr, P, and Ti; $Fe_2O_3^t$ in some LD mafic layers approaches 35 wt%, and La 1000x chondrite. LGs and LDs also have low Al and low Mg numbers (Fig. 1). These features require that the minerals in the layers were not derived from the surrounding pluton by crystal-liquid separation. Instead, they are consistent with crystallization from an Fe-rich immiscible liquid exsolved from high-silica liquid during the latter stages of crystallization. Although immiscibility is obscured in plutonic rocks owing to crystallization of the immiscible liquids, it has been proposed for several layered mafic complexes, and we suggest that it is a minor but widespread process in the late-stage evolution of granitic systems.

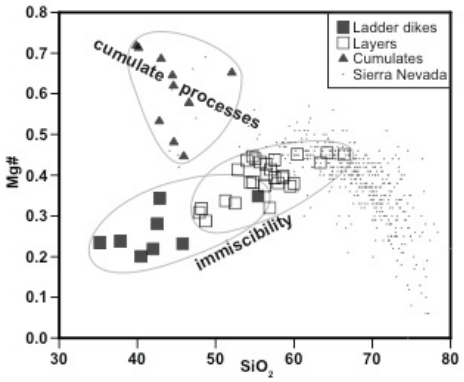

Figure 1: Mg number vs. SiO_2 for the Sierra Nevada batholith and occurrences of cumulate rocks, LDs, and LGs therein. LDs and LGs have much lower Mg numbers than cumulate rocks, consistent with immiscibility.

Heme *b* in particulate material from the Atlantic and Southern Oceans

M. GLEDHILL*[1], D.J. HONEY [1], M.J. RIJKENBERG[12] M.N. NIELSDOTTIR[1] AND E.P. ACHTERBERG[1]

[1]Ocean and Earth Science, University of Southampton, National Oceanography Centre Southampton, UK (martha@soton.ac.uk)

[2]Department of Biological Oceanography, Royal Netherlands Institute of Sea Research, Texel, The Netherlands (*correspondence: martha@soton.ac.uk)

Heme *b* is the iron containing prosthetic group of hemoproteins, which include *b* type cytochromes, peroxidases and catalases. We determined the heme *b* abundance in particulate material on three cruises in the Atlantic and Southern Oceans. Analysis of phytoplankton cultures indicated that we recovered approximately 18% of the total cellular iron pool in marine phytoplankton as heme *b* [1, 2]. We show that particulate heme *b* concentrations are depleted relative to particulate carbon and chlorophyll *a* in samples from the Southern Ocean and high latitude North Atlantic when compared to samples from the tropical North Atlantic Ocean. The phytoplankton communities in the Southern Ocean and high latitude North Atlantic are iron stressed during at least part of the growing season, whereas the iron supply to the tropical North Atlantic is high due to aerosol inputs. The observed lower heme *b* to carbon ratios are consistent with the patterns of iron supply and suggest a reduced capacity for photosynthetic and respiratory electron transport in high latitude phytoplankton populations. However, comparison with primary productivity determined on the same cruises showed that heme *b* use efficiency, defined as the amount of heme *b* required to fix a mole of carbon per second, was enhanced at high latitudes compared to the tropical North Atlantic. We discuss the implications of our results for phytoplankton iron requirements in the Atlantic Ocean.

Regional urban geochemical baseline for heavy metals and persistent organic pollutants in Dublin, Ireland (SURGE Project)

GLENNON, M.M[1]., SCANLON, R.P[1]* .,O'CONNOR, P. J[2]., HARRIS, P[3]. AND OTTESEN, R.T[4].

[1]Geological Survey of Ireland, Beggar's Bush, Haddington Road, Dublin 4, Ireland. (*ray.scanlon@gsi.ie).

[2]Independent Consultant, Dublin, Ireland.

[3]National University of Ireland, Maynooth, Ireland.

[4]Norges Geologiske Undersøkelse, Trondheim, Norway.

The Dublin SURGE (Soil Urban Geochemistry) Project establishes a baseline for inorganic elements and persistent organic pollutants in topsoils in Dublin, Ireland for the first time. Topsoil samples (n=1058) of 0-10 cm depth from the greater Dublin area (430 km^2) were analysed for 31 inorganic elements by ICP-AES. A subset of 194 samples was analysed for polycyclic aromatic hydrocarbons (PAHs) and polychlorinated bipheyls by GC-MS and GC-ECD respectively.

Exploratory data analysis was carried out on the analytical results using bedrock, soil type and land use zones data to reveal natural and anthropogenic influences on soil geochemical concentrations. Box plots, histograms and cumulative probability curves indicate that concentrations of Pb, Cu, Zn, Hg and PAHs are strongly influenced by human activities in the docklands, the inner city and heavy industry areas of Dublin. Historical industry, domestic coal burning, reuse of contaminated soil and traffic emissions are likely sources.

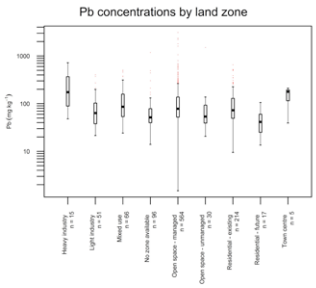

Figure 1. Box plots for Pb in topsoil showing higher median concentrations (mg/kg) in heavy industry and town centre zones.

To better understand historical anthopogenic sources of contaminants, historical industry locations were compiled and employed in a preliminary multivariate spatial analysis which demonstrates strong spatial correlations between key contaminants and certain historical industries. The project provides systematic, regional baseline data for urban soils relevant to the protection of human health, compliance with environmental legislation and urban regeneration.

Oxygen dynamics in marine sediments: From microbial to global Scale

RONNIE N GLUD[123]

[1]University of Southern Denmark
[2]Scottish Association of Marine Science
[3]University of Aarhus

Oxygen availability and dynamic are key factors regulating the biological and biogeochemical functioning of marine sediments. On microscale in has in recent years become evident that marine sediments are much more dynamic than previously anticipated. Micro scale topography, particulate sedimentation, short and long term changes in hydrodynamic are all factors that induce temporal and spatial variations in the oxygen distribution. Furthermore, macro and meio fauna activity constantly affect the distribution of microbial microniches. The intense dynamic affect the microbial interactions and ecology, putting high demands on metabolic versatility and/or mobility of microbes in a constantly changing environment. Also on meso- and regional scale the awareness on the importance of spatial and temporal dynamics is increasing. The benthic seascape and its interaction with large scale hydrodynamic features lead to highly uneven deposition of organic material and thereby in large scale distribution of benthic communities and biogeochemical process rates. The presentation will – on the basis of a number of case studies, using state of the art technology – discuss and challenge our conceptual understanding on benthic O_2 dynamics and sediment functioning.

Hydrogeochemical and Isotopic Investigation around the Manisa

GÜLER GÖÇMEZ[1] AND ERKAN HAFIZOĞLU[2]

[1]Selcuk University, Geological Engineering Department, Konya, Turkey
(correspondence: gulergoçmez@selcuk.edu.tr)
[2]Celal Bayar Universty Vocational High School
(ehafızoğlu@hotmail.com)

Investigated area, include Manisa country, Saruhanlı district on northeast of Manisa, Karaoğlanlı district on southeast Muradiye on north and Akgedik on west. Study area contains approximately 350 km^2 area.

The basement of the investigation area is made up Upper Cretaceous-Paleocene aged Bornova melange which contains metasandstone, metamudstone and this units lateral and vertical transition gray coloured micritic limestones,white coloured tuff. This basement is overlaid unconformably by lower Miocene aged. Yeniköy formation including red coloured conglomerate gravelly sandstone and sandstone. This formation is overlaid conformably by Lower-Middle Miocene aged Zeytindağ formation, which contains conglomerate, sandstone, claystone, marl, shale, limestone of clay, tuff. Zeytindağ formation is overlaid unconformably by Upper Miocene aged Yamanlar volcanites that is made up andesite, dacite gravel blocks and aglomerates.Yamanlar volcanites is overlaid unconformably by Upper Miocene – Pliocene aged Aliağa formation which consist of sometimes tuff alloyed, claystone, siltstone, white - yellow coloured lacustrine limestones. All these formations are unformably is overlaid by Quaternary aged the Alluvium and slope deposits.

Investigation area, to be found in the very important structure İzmir Ankara suture zone, paleotectonic era geography of the Anatolia. According the Schoeller diagram of waters of wells in study area lines combining the anions and rations are approximately parallel. Most ions in waters Ca, Mg and HCO_3. Statics level in the drill wells is 0,26-93,5 meters. Dynamics levels 1,22-94 meters and debit is in between 15-95 lt/sn. According to physicochemical analysis of the wells in investigation area drillings which have close value run from the same area. According to isotope analysis results of the waters in this drilling.^{18}O values are (-6,46)-(-7,84),^{2}H values are (-34,95)- (-45,41) and ^{3}H values are 0,90-3,55 . In isotopic studies, points belong to waters were nearly parallel and close to meteoric water line. So the waters have meteoric origin

Geochemistry of Fast-spreading Lower Crust: Results from IODP Expedition 345 at the Hess Deep Rift

M. GODARD[1], R. MEYER[2], A. SAHA[3], K. M. GILLIS[4], J.E. SNOW[5], A. KLAUS[6] AND IODP EXPEDITION 345 SHIPBOARD SCIENTIFIC PARTY

[1]Géosciences, CNRS-Université Montpellier 2, France; (Marguerite.Godard@um2.fr)
[2]University of Bergen, Norway
[3]Indian Institute of Science, Bangalore, India
[4]University of Victoria, B.C., Canada
[5]University of Houston, Houston TX, USA
[6]Texas A&M University, College Station TX, USA

We report preliminary results of IODP Expedition 345 (Site U1415, Dec. 2012-Feb. 2013) to the Hess Deep Rift where propagation of the Cocos Nazca Ridge into young, fast-spreading East Pacific Rise crust exposes a dismembered, but nearly complete lower crustal section, with extensive exposures of the plutonic crust. Reasonable recovery for hard rock expeditions (15%–30%) was achieved in three holes (35–110 m below seafloor), despite water depths of more than 4500 m and challenging drilling conditions.

Olivine gabbro and troctolite are the dominant plutonic rock types at Site U1415, with minor gabbro, clinopyroxene oikocryst-bearing troctolite, clinopyroxene oikocryst-bearing gabbro, and gabbronorite. All recovered gabbroic rocks have primitive compositions except for one gabbronorite sampled in the upper rubble zone at Hole U1415E, that is similar in composition to the evolved shallow gabbros previously sampled at Hess Deep. Site U1415 olivine gabbros, gabbros and gabbronorites overlap in composition : they have high Mg# (79-87), high Ni (130-570 ppm) and low TiO_2 (0.1-0.3 wt.%). Troctolites have high Mg# (81-89), Ni (260-1500 ppm) and Cr (365- 1100 ppm) and low TiO_2 (<0.1 wt.%). The main geochemical characteristics of Site U1415 gabbroic rocks are consistent with formation as a cumulate sequence from a common parental MORB melt, troctolites representing the most primitive end-member of this sequence. They overlap in composition with the most primitive of slow and fast spread crust gabbroic rocks. These primitive geochemical signatures seem however contradictory with orthopyroxene (up to 5%) in the primary mineral assemblage of the olivine gabbros. In MORB crystallization series, orthopyroxene is expected to crystallize from evolved melts. The presence of orthopyroxene in the primitive gabbroic sequence sampled at Site U1415 suggests that it was formed in a more complex magmatic system, with possible mixing with melts in equilibrium with mantle orthopyroxene.

Rates of consumption of atmospheric CO_2 through the weathering of loess during the next 100 years of climate change

YVES GODDÉRIS[1], SUSAN L. BRANTLEY[2], LOUIS M. FRANÇOIS[3], JACQUES SCHOTT[1], DAVID POLLARD[2], MICHEL DÉQUÉ[4] AND MARIE DURY[3]

[1]Géoscience Environnement Toulouse, CNRS, France
[2]Earth and Environmental Systems Institue, PennState, USA
[3]IAG, Université de Liège, Belgium
[4]Météo-France/CNRM, CNRS/GAME, Toulouse, France

We investigate how weathering of the Mississippi Valley loess will respond over the next 100 years of climate change along a North-South transect. Using a cascade of numerical models for climate (ARPEGE), vegetation (CARAIB) and weathering (WITCH), we explore the effect of an increase in CO_2 of 315 ppmv (1950) to 700 ppmv (2100 projection). Our simulations predict that temperature increasing in the next 100 years causes the weathering rates of the silicates to increase into the future. In contrast, the weathering rate of dolomite – which consumes most of the CO_2 – decreases in both end members (South and North) of the transect due to its retrograde solubility. We thus infer slower rates of advance of the dolomite reaction front into the subsurface, and faster rates of advance of the silicate reaction front. However, additional simulations for 9 pedons located along the North-South transect show that the dolomite weathering advance rate will increase in the central part of the Mississippi Valley, owing to a maximum in the response of vertical drainage to the ongoing climate change.

The carbonate reaction front can be likened to a terrestrial lysocline because it represents a depth interval over which carbonate dissolution rates increase drastically. However, in contrast to the lower pH and shallower lysocline expected in the oceans with increasing atmospheric CO_2, we predict a deeper lysocline in future soils. In the central Mississippi Valley, soil lysocline deepening accelerates but in the South and North the deepening rate slows. This result illustrates the complex behavior of carbonate weathering facing short term global climate change. Predicting the global response of terrestrial weathering to increased atmospheric CO_2 in the future will mostly depend upon our ability to make precise assessments of which areas of the globe increase or decrease in precipitation and soil drainage.

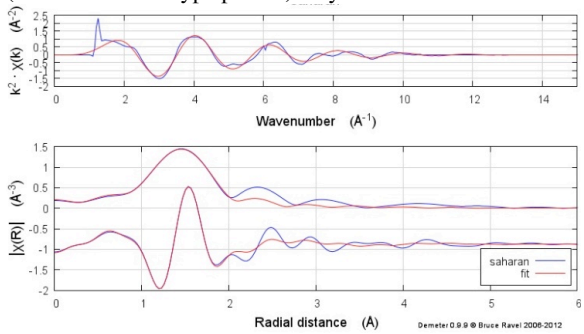
New insights into iron mineralogy and geochemistry in Saharan dust precipitated over Greece

A. GODELITSAS[1]*, P. NASTOS[1], T.J. MERTZIMEKIS[1], N. CHATZIKONSTANTINOU[1], A. DOUVALIS[2], K. TOLI[3], J. GÖTTLICHER[4], R. STEININGER[4] AND R. SIMON[4]

[1]School of Science, University of Athens, Greece
[2]Dept. of Physics, University of Ioannina, Greece
[3]GWP Mediterranean, Athens, Greece
[4]ANKA Synchrotron Radiation Fac. KIT, Karlsruhe, Germany

The Saharan dust samples were collected on membrane filters after intense "red rain" episodes over the Greek megacity Athens. Characterization by means of bulk powder-XRD and SEM-EDS showed quartz, calcite and dolomite, as major crystalline phases and minor phyllosilicates (mostly clays). Detailed Synchrotron μ-XRF study proved that many trace elements are intercorrelated with Fe in microparticles of potential anthropogenic origin (e.g. Fe-Mn-V-Cu), as well as the presence of very hazardous elements such as Pb and As. Moreover, it was concluded that Fe also forms individual Fe-oxide and/or oxyhydroxy phases (sole Fe spots in μ-XRF maps) and besides it is frequently associated to Ca-containing phases and particularly carbonates (frequent Ca-Fe overalp in μ-XRF maps without Si or any other metal). However, Synchrotron μ-XRD study gave no clear evidence of crystalline Fe-oxides and/or -oxyhydroxides. Subsequent Mössbauer spectroscopic study showed abundant Fe^{3+}-containing constituents and minor Fe^{2+}-phases (ca. 5% paramagnetic component having Mössbauer parameters characteristic of a Fe^{2+} state). The investigation of the μ-XANES and -EXAFS (Figure below) indicated that Fe^{3+} most probably corresponds to ferrihydrite-type -XRD-"amorphous"- phases, but structural units from other Fe-oxydroxides, like akaganeite, and Fe^{3+}-oxyhydroxy-sulphates (schwertmannite-type phases) may also contribute.



Sequential leaching experiments, using appropriate acids and ICP-MS analyses, revealed a significant percentage of extractable Fe (and also Zn, Mn and Pb), fundamentally due to carbonate phases comprising ~60% of the material according to bulk XRD. It is herein stated that Fe in Saharan dust precipitated over eastern Mediterranean, and particularly Greece, is predominantly related to Fe^{3+}-oxyhydroxy (most probably ferrihydrite-type) phases, and to a lesser extent to Ca-(Mg)-carbonates hosting possibly the Mössbauer-detected minor Fe^{2+} component.

Direct observations of structures developed on fluorite surfaces after contact with an aqueous solution

J.R.A. GODINHO[1], C.V. PUTNIS[2] AND S. PIAZOLO[3]

[1]Department of geological sciences, Stockholm University, 10691 Stockholm, Sweden;(jose.godinho@geo.su.se)
[2]Institut für mineralogie, University of Münster, 48149 Münster, Germany; putnisc@uni-muenster.de
[3]GEMOC ARC National key center, Department of earth and planetary sciences, Macquarie University, Australia; (sandra.piazolo@mq.edu.au)

In this study we used an atomic force microscope equipped with a fluid cell to observe the surface dynamics during the first minutes of contact between a solution and polished fluorite surfaces with orientations (115), (334), (104), (110) or (102). 3-D confocal profilometry was used to analyze the surface topography developed on the same surfaces for dissolution times up to 3200 hours.

The surfaces studied, with an initially high density of defects, showed fast changes during the first seconds in contact with solution. Different types of structures were observed on the surface depending on its initial orientation and the solution composition. These structures dissolved slower than the main surface persisting for at least 1620 hours of continuous dissolution. The inhibition of dissolution on the areas of the surface where the structures developed induced the growth of crystallographically controlled topography, which was linked to a variation of the surface reactivity and measured dissolution rate.

A new interpretation of traditional kinetic and thermodynamic models of dissolution applied to surfaces with high density of defects is proposed to explain the observations. It is proposed that the structures developing rapidly during the first contact with the fluid are a fluorite phase more stable than the initial surface. A new dissolution model is suggested to include the following steps: a) fast initial dissolution at defect sites; b) formation of a fluid boundary layer at the interface mineral-solution enriched in the dissolving ions; c) precipitation of a stable phase on surface defects. This model highlights the importance of considering surface defects for advancing our understanding of processes happening at the interface mineral-solution and for developing more accurate kinetic dissolution models essential in Earth and material sciences.

The pH of the Dead Sea brine: Calibrating the combination electrode measurements

R. GOLAN[12], I. GAVRIELI[2], B. LAZAR[3] AND J. GANOR[1]

[1]Geological and Environmental Sciences, Ben Gurion University of the Negev, Beer Sheva, 84105, Israel
[2]Geological Survey of Israel, Jerusalem, 95501, Israel
[3]Institute of Earth Sciences, The Hebrew University of Jerusalem, 91904, Israel

While the pH is a major variable controlling the carbonate system speciation and the saturation state of carbonate minerals in aqueous systems, it's measurement in hypersaline brines is not trivial. In such media, a problem with liquid junction potential may arise when employing standard pH measurements using a combination pH glass electrode.

The hypersaline Dead Sea and its predecessor, Late Pleistocene Lake Lisan, precipitated sequences of seasonal aragonite laminae during most of their geological history. The seasonality in aragonite deposition from the Ca-chloride brines was attributed to supersaturation induced by mixing of the inflowing high bicarbonate fresh runoff water in the Ca-rich lake brine [1]. This study evaluates and verifies the pH measurements in Dead Sea brine and its mixtures with deionized water using a liquid-junction-free cell [2], consisting of a pH glass electrode (Orion 81-01) and Cl^- ion selective electrode, ISE (Orion 9417).

The voltage of the ISEs cell is proportional to the log activities product of H^+ and Cl^-. A calibration curve was prepared by measuring the ISEs cell voltage per incremental addition of 32% HCl to the brine. Cl^- activity was calculated based on the Pitzer data base and MacInnes convention using the PHREEQc software [3]. The pH values of the unknown brines were derived from the calibration curve by measuring the cell voltage and its major ion composition.

Simultaneous pH measurements by the ISEs and a standard combination pH glass electrode (Orion 81-03, calibrated with low ionic strength buffers) were conducted for comparison. It was found that the pH difference between the measurements by the two electrode system was linearly correlated with ionic strength. Hence, by applying appropriate correction factor it is possible to use a standard combination pH electrode to measure pH of very high ionic strength solutions. The pH of the surface brine of the Dead Sea was determined to be 6.28.

Syn-Variscan anorogenic volcanism in northern Gondwana: SIMS U-Pb ages and REE patterns of zircon from deep borehole in coastal Israel

T. GOLAN[1], Y. KATZIR[1] AND M.A. COBLE[2]

[1]Ben Gurion University of the Negev, Beer Sheva 84105, Israel (tzahig@post.bgu.ac.il)
[2]Stanford University, SHRIMP-RG lab, CA 94305, USA

The Helez Deep 1A borehole (southern coastal Israel) penetrated a 200 m thick (5977-5767 m depth interval) felsic volcanic section, the Gevim quartz porphyry, overlying Precambrian basement rocks and overlain by Triassic shales. Previous Rb-Sr and K-Ar dating of these volcanics yielded Permian and Jurassic ages, respectively, considered as recording rifting-related magmatism in the Levant margins of the NeoTethys. We present SIMS U-Pb dating of zircons separated from rock-cuttings recovered from 4 different depths within the volcanic unit (~10 zircon grains each), which yield Early Carboniferous crystallization age for the Gevim quartz porphyry. Zircons of the two deeper samples yield calculated concordia ages of 353 ± 3 and 345 ± 2 Ma (2σ), whereas for the two shallower samples 350 ± 10 and 355 ± 15 Ma discordia intercept ages were calculated. While separated zircon is fresh and idiomorphic, feldspar and micas, the major Rb and K carriers in felsic igneous rocks, are heavily altered to clay. The Rb-Sr and K-Ar clocks were thus reset by hydrothermal alteration. This is the first discovery of Early Carboniferous volcanism in northern Africa and Arabia. It closely follows uplift and erosion of several regional 'Geanticlines' and coeval with steep crustal thermal gradients in the Levant. Zircon REE patterns measured by SIMS indicate within plate 'A-type' granite affinity. The geodynamic setting of volcanism is thus extensional rather than of Variscan compression, possibly related to rifting and detachment of Gondwanan terranes that were eventually incorporated to the Variscan orogeny.

Molybdenum drawdown during the Cretaceous OAE 2

T. GOLDBERG[1*], S.W. POULTON[2], T. WAGNER[3], AND M. REHKÄMPER[1]

[1]Imperial College London, London SW7 2AZ, UK, (*t.goldberg@imperial.ac.uk)
[2] University of Leeds, Leeds, LS2 9JT, UK
[3]Newcastle University, NE1 7RU, Newcastle upon Tyne, UK

During the Cretaceous greenhouse, globally occurring events of black shale deposition were associated with widespread ocean deoxygenation. Possibly the most pronounced of these oceanic anoxic events (OAE's) was the Cenomanian-Turonian OAE2 (~94 Ma). However, although certain redox sensitive trace metals tend to be preferentially sequestered in sediments deposited under anoxic conditions, with Mo drawdown being specifically prone to euxinic settings, these elements are generally somewhat depleted in sediments deposited during OAE2. To understand the driving factors responsible for this depleted trace metal drawdown, we have studied a low latitude section from the proto-North Atlantic Ocean in high-resolution, where existing biomarker and iron-sulphur data point to a dominantly euxinic water column, with periodic transitions to ferruginous water column conditions.

We utilised a variety of redox proxies (Fe-speciation, redox sensitive trace metals and Mo isotopes), which, in combination, allows us to evaluate the detailed nature of ocean redox conditions and hence controls on trace metal drawdown. Our data suggest that very low Mo/TOC ratios at Tarfaya and elsewhere in the proto-North Atlantic may have been result of partial restriction of deep-water exchange with other ocean basins. However, the low and possibly heterogeneous δ^{98}Mo values inferred for seawater, together with low Mo/TOC ratios, point to a large decrease in the size of the oceanic Mo reservoir during OAE2 due to a major increase in Mo drawdown under euxinic conditions.

Future gas through bioconversion of stranded coals

S.D. GOLDING[1]*, S.K.. HAMILTON[1], K.A. BAUBLYS[1], J.S. ESTERLE[1], G. TYSON[1], S. ROBBINS[1], V. RUDOLPH[1], H. ZHENG[1], P.C. GILCREASE[2] AND S.L. PAPENDICK[2]

[1]The University of Queensland, QLD 4072, Australia (*correspondence: s.golding1@uq.edu.au)
[2]South Dakota School of Mines and Technology, Rapid City, SD 57701, USA (Patrick.Gilcrease@sdsmt.edu)

The biology of methanogenesis in deep subsurface environments is not well understood, and there has been only limited work on microbial processes in coal seams despite the fact that they may support a large subsurface ecosystem potentially capable of replenishing gas depleted by coal seam gas production. To carry out field scale stimulation of microbial methane production from coal, we need to determine what makes a coal favorable for microbial methane generation, which native microorganisms are essential for the stepwise conversion of coal to methane, what fraction of coal is convertible to microbial methane and whether there are chemical or physical stimulation methods that can enhance the rates of conversion. Many of these questions are best addressed in the laboratory through enrichment experiments using coal bed formation water as the source of microbes and coal as the sole substrate [1]. However, implementation of microbially enhanced coal bed methane will necessarily involve the identification of conceptual exploration targets, which requires not only understanding of the geological history of the coal basin but also the development of ancient analogue models for microbial methane generation.

In eastern Australia, the chemical and stable isotope compositions of coal seam gases and related production waters vary systematically with depth, which reflects mixing between shallow biogenic gas and deeper thermogenic gas in higher rank uplifted coals and variations in openness of the microbial system in low rank coals. In the northern Bowen Basin, methane carbon isotope compositions become less negative with depth and highest gas production occurs at intermediate levels where the gas is of mixed origins [2]. The higher gas production is a function of saturation and permeability. Individual wells in the Surat Basin also commonly show a positively parabolic trend in gas content with depth [3], which is interpreted to reflect enhanced methanogenesis linked to hydrology. Lateral variability in gas content is less well understood and requires further research.

The $^{238}U/^{235}U$ of the Earth and the Solar System

A. GOLDMANN[1], G. BRENNECKA[2], J. NOORDMANN[1], S.WEYER[1] AND M. WADHWA[2]

[1]Leibniz Universität Hannover, Institut für Mineralogie, Callinstr. 3, 30167 Hannover, Germany (correspondence: s.weyer@mineralogie.uni-hannover.de)
[2]Arizona State University, School of Earth & Space Exploration, Tempe, AZ 85287, USA

For this study we performed high precision $^{238}U/^{235}U$ isotope analyses of 27 bulk meteorites (carbonaceous and ordinary chondrites as well as achondrites) and 12 terrestrial basalts. Additionally, we compiled high precision $^{238}U/^{235}U$ data on bulk meteorites from the recent literature in order to constrain the distribution of U isotopic heterogeneities and to determine an average $^{238}U/^{235}U$ for the solar system.

Most meteorites overlap with the U isotope composition observed for terrestrial basalts (137.78 – 137.81, [1] and this study). The most prominent exceptions are among the ordinary chondrites (Richardton H5 = 137.711 and Elenovka L5 = 137.891). Likely, different processes are responsible for the observed U isotope variations on the bulk meteorite scale, including the decay of extant ^{247}Cm [2], evaporation/condensation [3], redox processes or nucleosynthetic heterogeneities, as indicated by different relationships of $^{238}U/^{235}U$ and Nd/U for different meteorites or meteorite components.

All meteorite samples considered here (in total 45) have $^{238}U/^{235}U$ values that define a Gausian distribution with an average value of 137.79 ± 0.03 (at 95% confidence level). The uncertainty of this value is dominated by that of the used U double spike (± 0.16‰ [4]). Notably, the average values for each of the investigated meteorite groups and that of terrestrial basalts define a narrow range between 137.787 and 137.795, which overlaps with the average value for all bulk meteorites taken together. We thus consider the average value obtained from this study ($^{238}U/^{235}U$ = 137.79) to be representative for the Earth and the Solar System, consistent with earlier estimates [3, 5, 6]. We recommend using it for Pb-Pb dating if the precise $^{238}U/^{235}U$ of the sample cannot be obtained. Compared to the Pb-Pb ages based on the previously assumed $^{238}U/^{235}U$ (137.88), the new value of this study results in 0.9 Ma younger ages.

In-situ determination of Fe Isotopes in Kamacite-, Taenite- and Troilite-Phases of Ordinary Chondrites

A. GOLDMANN AND S. WEYER

Leibniz Universität Hannover, Institut für Mineralogie, Callinstr. 3, 30167 Hannover, Germany

In this study we investigated the Fe isotopic composition of metal and sulphide grains in ordinary chondrites. Recent studies [1], [2] found variations in $\delta^{56}Fe$ of up to 0.8‰ in bulk grains or grain fractions, which were manually extracted and dissolved. Here we represent the first in-situ Fe isotope analyses conducted by femtosecond laser ablation-ICP-MS. Instrumental mass bias was monitored with a Ni standard solution, which was simultaneously aspirated during laser ablation. With this method a reproducibility for replicate analyses of homogeneous standards of 0.04 to 0.06 (2 SD) for $\delta^{56}Fe$ was achieved with spot-sizes as low as 30 μm. Prior to isotope analyses metal and sulfide grains were characterized with microprobe analyses.

The analyses of over 100 metal and sulphide grains in H- and L-chondrites revealed $\delta^{56}Fe$ values with a total variation of 1.6‰, ranging from -0.8‰ to +0.8‰, relative to IRMM-014. The analyzed sulphide grains (all troilite), revealed an average $\delta^{56}Fe$ of -0.47‰. Metal grains contained 80% - 90% kamacite with an average $\delta^{56}Fe$ of 0.05‰ and 10% - 20% taenite with an average $\delta^{56}Fe$ of +0.49‰.

These first results show that the abundance of taenite in ordinary chondrites may affect the Fe isotope composition of the bulk metal and that previously observed variations in $\delta^{56}Fe$ may be the result of variations in the sampling of taenite. Larger exolutions of kamacite and taenite were generally isotopically homogeneous, i.e. did not show any diffusive exchange of Fe isotopes.The large $\Delta^{56}Fe_{metal\text{-}FeS}$ of 0.6‰ – 0.8 ‰ in ordinary chondrites (compared to ~0.5‰ observed for iron meteorites [3]) indicates a very low troilite-metal equilibration temperature of <300°C (calculated after [1] using data from [4] for troilite).

The ICDP Dead Sea Deep Drill Core: Chronology and implications for Levant climate change

S.L. GOLDSTEIN[1*], A. TORFSTEIN[1], M. STEIN[2] AND H. KITAGAWA[3]

[1]Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY 10964, USA (steveg@ldeo.columbia.edu)
[2]Geological Survey of Israel, 95501 Jerusalem, ISR
[3]Nagoya University, Nagoya, JPN

The ICDP Dead Sea Deep Drilling Project recovered the longest paleoclimate record in the Middle East, including a ~450m long core in the deepest basin, and extending to MIS 7, based on the overall glacial vs interglacial lithology. Here we report the detailed chronology from ^{14}C of organic material, stable isotopes and U-series of aragonite, changing lithology, stratigraphic correlation with subaerial deposits, XRF-scanning, and layer counting.

The Levant climate conditions are recorded in detail in the sediment layering. During wetter climate intervals varve-like alternating aragonite and detritus (aad) reflect summer and winter seasons, respectively. Less runoff means less aragonite (more mud). Gypsum layers indicate more arid climate, and halite indicates hyper-aridity.

The new chronology shows that major lithological changes coincide with the timing of MIS boundaries; for example, at MIS 2/1 there is substantial gypsum interval (during Heinrich 1) is followed by halite, and interestingly, MIS 6/5 shows a similar transition. Throughout the core, the lithological sequence in detail strongly reflects changes observed in marine and polar records. For example, full glacials (MIS 2, 4, 6) are reflected by thicker aad sequences, while strong interglacial intervals show substantial halite, gypsum, and mud, but little aad. Halite and gypsum are prominent during the warmer intervals of MIS 5 (5e,c,a), while the cooler intervals (5d,b) are characterized by mud and even aad. Short unstable intervals such as the MIS 3 D-O cycles are reflected by short sequences of aad, mud, gypsum.

The most dramatic discovery is a major desiccation event, more extreme than anything during the Holocene, now constrained to occur during MIS 5c, and indicated by an interval of rounded pebbles resembling on-shore beach deposits, overlying ~45 meters of mainly salt. The obvious question arises, why did it happen during MIS 5c rather than 5e? Possible explanations include a more intense southern monsoon during 5e that contributed runoff in the basin, or low enough P/E during both 5e and 5c. In any case, its occurrence has implications for the water-starved Middle East today, with GCM models indicating a more arid future.

Multi-element pedogeochemical prospecting in the Agrochão-Murçós area (NE Portugal)

M. ELISA P. GOMES[12]* AND PAULO J.C. FAVAS[13]

[1]Department of Geology, University of Trás-os-Montes e Alto Douro, 5001-801 Vila Real, Portugal; *correspondence: mgomes@utad.pt
[2]Geosciences Centre, University of Coimbra
[3]IMAR-CMA Marine and Environmental Research Centre, University of Coimbra

Total concentrations of chemical elements in soils of the Agrochão-Murçós area (NE Portugal) were determined in order to define potential spatial anomalies which have economic value based on a multivariate analysis and a geostatistical approach. In the area networks of quartz veins mineralized with scheelite, wolframite and rare cassiterite cut metamorphosed silurian rocks near the ceiling of small apophyses of biotite granodiorite and granite.

Soil samples were collected at 421 locations (20–30 cm depth from the surface) and were taken at intervals of 50 m within parallel sampling lines and spaced 500 m. The total concentrations were determined in each sample after being disaggregated and sieved in a 180 mesh sieve. The solutions were analysed by ICP-OES for a suite of 45 elements.

Principal component analysis and factorial kriging analysis were used to map the spatial distribution of chemical elements in soil. The analysis of the plane of the first three principal components revealed three groups of elements. A group showed a positive correlation with the first principal component and included Al, Na, Ca, Li, Ga, P, Zr, Rb, Sr, Th, U and Rare Earth Elements (REE- Y, La, Ce), while a second group of 11 elements (Fe, Sc, V, Co, Ni, Ti, Cr, Nb, Mn, Ba and Zn) showed a positive correlation with the second component. The third group included As, Cu, W and Pb. Sulfur, K and Sn are better explained isolated respectively by the axes 4, 5 and 7.

Then, the elements were analyzed separately by factorial kriging analysis. In the study area, six anomalies of W, Sn and REE were defined. Tungsten anomalies are spread across an area which coincides not only with the Rebordelo granitic massif but also to some extent with other smaller granite outcrops to the east and the surrounding metasediments. In addition there is a clear correlation with the calculated anomalies and several old Sn/W concessions in the area. The Sn distribution is such that most of the samples fall below percentile 95 and only scattered samples show small concentrations of Sn. The Sn anomaly is restricted and even this represents values of approximately 100 ppm only.

The preservation of sulfur isotope signals in low sulfate systems: How low is low?

M. GOMES[1*] AND M.T. HURTGEN[1]

[1]Department of Earth and Planetary Sciences, Northwestern University, Evanston, IL, USA (*correspondence: maya@earth.northwestern.edu)

The sulfur (S) isotope difference between sulfates and sulfides preserved in sedimentary rocks ($\Delta^{34}S$) has been utilized to reconstruct ancient marine sulfate levels and oxygenation of the early Earth. Many modern lake systems have low sulfate levels (<1mM) and thus serve as useful analogs to low sulfate oceans of the early Earth. In these low sulfate systems, the preserved $\Delta^{34}S$ is typically lower than the magnitude of S isotope fractionation due to microbial S cycling (ε_{SR}) because $\Delta^{34}S$ is quantified as the S isotope difference between S phases (sulfate and pyrite) formed in different portions of the water column/sediment. This is a result of the reservoir effect where, at low sulfate levels, the S isotope composition of the sulfate reservoir becomes enriched in the heavy isotope of S (^{34}S) as microbial sulfate reduction occurs in anoxic portions of the water column/sediment. In turn, dissolved sulfide becomes enriched in ^{34}S with depth as it is formed from a ^{34}S-enriched sulfate reservoir. The result of this effect, which follows Rayleigh distillation theory, is that the S isotope composition of pyrite formed from ^{34}S-enriched sulfide is close to the surface water sulfate S isotope composition and $\Delta^{34}S$ is low. The reservoir effect is particularly important at low sulfate levels because the sulfate reservoir becomes enriched in ^{34}S more rapidly when the sulfate reservoir is small. However, it is not clear how low sulfate levels must be for the reservoir effect to place constraints on $\Delta^{34}S$ values. We use a combined reactive transport and Rayleigh distillation model to assess when the size of the sulfate reservoir affects $\Delta^{34}S$ values. We then compare this model to modern euxinic systems in order to better constrain how $\Delta^{34}S$ values can be used to interpret marine sulfate levels in the past.

Testing of Ce and Eu anomalies in natural zircon as a sensor of oxygen fugacity for Archean magmas

A. GONCHAROV[1,2] AND N. KOROLEV[2]

[1]St. Petersburg State University, Faculty of Geology, Russia (a.goncharov@spbu.ru)

[2]Insitute of Precambrian Geology and Geochronology RAS, St. Petersburg, Russia

The recent experimental calibrations of cerium and europium partitioning between melts and zircons [1, 2] allow calculating Ce and Eu anomalies in magmatic zircons as a function of oxygen fugacity. We ran testing on current database of natural zircons from Precambrian complexes (~3500 - 2000 Ma) of the Voronezh Crystalline Massif (Eastern-European platform) to estimate redox conditions in parental magma sources.

The initial limitation was that CHUR normalized Ce and Eu anomalies in studied zircon cores show a wide variation in complex as well as in the sample, apparently due to the different origin. To separate zircon material in basic and silicic rocks produced by metamorphic or other endogenic process and identify captured or inherited zircons from ones with magmatic genesis has been used recently developed Hf-Nd isotopic systematics [3].

A study of Ce and Eu in selected zircon minerals has allowed an assessment of the redox conditions in magmas source that prevailed in the upper mantle during the formation of ancient basement on Eastern-European platform. The obtained oxygen fugacity value varies from –1 to +2 ΔFMQ for most of basic complexes at temperature range: 800-1000°C and from 0 to +4 ΔFMQ at 700-900°C. Unfortunately, we did not find any correlations between ages and oxygen fugacity values in same complex, the only correlation observed is evolution of redox condition through time due to the different geodynamic settings of magma source.

Relationship between leaf C, N and soil C, N: A case study of degraded grassland in western Jilin Province

H.Y.GONG, Y.F.LI*, D.Y.WANG, S.WAN AND Y.Y.ZHAO

College of Earth Sciences, Jilin University, Changchun 130061, China, (yfli@jlu.edu.cn* presenting author)

Carbon (C) and nitrogen (N) are crucial chemical elements to plant and soil, they play important roles in plants growth and various physiological regulation mechanism. At present it is generally believed that the loss of soil nutrients(C, N etc) is accompanied with land degradation process, and plant nutrients are the dominant source to soil C and N. Therefore, the relationship between plant leaf C, N, C/N and soil C, N, C/N has been one of the hotly-discussed issues in the ecological stoichiometry. However, the C, N stoichiometry in the leaves of Leymus chinensis and soil conditions from the grassland in Chang'ling county in western Jilin Province, NE China, provides insights for the above issue. Our objective is to determine how and to what extent soil organic C(SOC), total N (STN) and C/N(S-C/N) influence leaf total C(LTC), total N (LTN) and C/N(L-C/N) in the study region.

This paper reports the SOC and STN contents of 18 surface soil samples(0-20cm) and the LTC and LTN contents of 18 Leymus chinensis samples.The results indicate that the average content of LTC (457.07mg·g^{-1}) is lower than the global average content (464mg·g^{-1}), however, the LTN content(22.37mg·g^{-1}) is higher than the global average content (20.6mg·g^{-1}), however, the C/N ratio in Leymus chinensis leaf (21.59) is higher than the global average value (16.0). Moreover, the contents of SOC and STN are 10.35mg·g^{-1} and 1.11mg·kg^{-1}, respectively. The research results of Bohn *et al* indicated that the average S-C/N ratio was about 12 in the grassland of almost no land degradation, however, the S-C/N ratio of the study region is 9.44, it is lower than 12. In addition, Pearson correlations analyses done by SPSS software indicate that LTC does not exhibit evidently correlations with SOC (r=-0.19, n=18) and STN (r=-0.16, n=18). The LTN also has no significant correlation with SOC (r=0.11, n=18) and STN (r=0.132, n=18). While the LTN has a very significant negtive correlation with L-C/N ratio(r=-0.918, n=18). The SOC has a very significant positive correlation with STN(r=0.981, n=18). Taken together, the ratio of S-C/N is considerably lower than the global average, while L-C/N ratio is higher than the global average. The variation laws of soil C, N and C/N are inconsistent with plant leaf C, N and C/N. It is suggested that plant leaf C, N and C/N can influence soil C, N and C/N, but be not necessarily leading factor.

Therefore, we conclude that high plant C, N and C/N ratio does not necessarily lead to the high regional soil C, N and C/N ratio correspondingly, they are likely caused by other factors such as soil microbial activity, the decomposition degree of plant residues, soil texture, and external environment and so on.

This work was supported by Natural Science Foundation Project of Jilin Province (201215017).

Distribution and sources of organic matter (OM) in a tropical intertidal mud bank of French Guiana

S. GONTHARET[1*], O. MATHIEU[2], J. LEVEQUE[2], M.-J. MILLOUX[2], S. LESOURD[3], S. PHILIPPE[1], J. CAILLAUD[1] AND A. GARDEL[1]

[3]M2C, CNRS UMR 6143, Université de Caen-Basse Normandie, 24 rue des tilleuls, 14000 Caen, France (Sandric.Lesourd@unicaen.fr)

The 1600km-long coast of South America between the mouths of the Amazon and the Orinoco is characterized by the occurrence of Amazon-derived mud banks. These mud banks are highly unstable structures due to a combination of sedimentary processes (erosion, re-suspension, re-deposition). Depending on their elevation and tidal cycles, they can be temporally emerged, resulting to their rapid colonization and stabilization by microphytobenthos and opportunistic mangroves (i.e. *Avicennia germinans*).

Due to their rapid colonization by vegetation and their strong hydrodynamics features, mud banks represent preferential sites for accumulation and intense remineralization of organic matter (OM). The objectives of this study are **(1)** to characterize the distribution of sedimentary OM and **(2)** to identify the OM sources of sediments sampled during the 2008 Equinoctial spring tide on the landward face of the Macouria mud bank (French Guiana). Elemental and stable carbon and nitrogen isotopic compositions were measured for sediments and potential OM sources (*Avicennia germinans* leaves, microphytobenthos and suspended particulate matter (SPM)). Lower TOC and TN contents are observed, indicating either low terrestrial OM inputs and/or extensive remineralization induced by important and repeated remobilization of mud deposits. The relative contributions of mangrove plants, SPM and microphytobenthos have been estimated using the atomic TN/TOC ratio and the $\delta^{13}C$ values. OM preserved in the sediments is mostly controlled by the SPM associated with minor amounts of OM derived from mangrove plants and microphytobenthos.

Insight into the use of U- and Th-series nuclides for soil-production rates determination

A. GONTIER*[1], S. RIHS[1], E. PELT[1], M-P. TURPAULT[2], D. LEMARCHAND[1] AND F. CHABAUX[1]

[1]LHyGeS/CNRS, Université de Strasbourg, France - (*correspondence: adrien.gontier@etu.unistra.fr; rihs@unistra.fr)

[2]Laboratory of Biogeochemistry of Forest Ecosystems, INRA, Champenoux, France - turpault@nancy.inra.fr

Over the last decades, the U- and Th-series isotopes were used to determine weathering rates in various environments (e.g.,1-5), but some concerns may arise about the use of these chronometers in soil profiles. The objective of this study was to address two of these concerns: the impact of a land cover change and the bedrock characteristics on these chronometers. This study was carried out in the Breuil-Chenue experimental forest site (Morvan, France) developed by INRA-BEF. In 1976, the native forest was partially clear-felled and replaced by monospecific plantations (oak, Douglas and spruce). The site is separated in two adjacent blocks which distinguished by different grain-sizes of the same granite bedrock. Three podzolic soil profiles developed on the coarse grain-size granite were sampled under the native forest, replanted oak and Douglas stands respectively and one soil profile was sampled under the native forest developed on the fine grain-size granite. Some selective extractions were performed in order to investigate the distribution of U and Th among different soil phases, including the cation exchangeable fraction, Fe-Mn amorphous oxides (ammonium-oxalate extraction) and silicate minerals.

No significant amount of U and Th was detected in the exchangeable fraction, but the oxalate-extracted phase (mainly amorphous Fe-Mn oxides and organics) holds up to 25 % of these elements, with clear pedogenic redistribution through all the profiles. In all the four different soil profiles the activity ratios of the U-series nuclides vary within a narrow range of values: from 0.94 to 0.95 for ($^{234}U/^{238}U$) and from 1.19 to 1.22 for ($^{230}Th/^{234}U$), but our results demonstrate that the podzolic pedogenic processes may significantly impact the shallowest soil layers (0-40cm), making these horizons unsuitable for U-series dating. In contrast, the deepest soil layers do not show observable vegetation-derived or grain-size effects on the U-Th series. The soil production rate can therefore be calculated from these latter.

Metal adsorption on mosses: Towards a universal adsorption model

A. G. GONZÁLEZ AND O. S. POKROVSKY

Geosciences Environment Toulouse (GET), CNRS, UMR 5563, Observatoire Midi-Pyrénées, 14 Avenue Edouard Belin, 31400 Toulouse, France

Physico-chemical characterization was performed for four moss species (*Hypnum sp*., *Sphagnum sp*., *P. purum* and *B. rutabulum*) and five metals (Cu^{2+}, Cd^{2+}, Ni^{2+}, Pb^{2+} and Zn^{2+}). Chemical composition of mosses showed that all 4 mosses exhibit similar concentration of Cu and Zn. For Pb and Cd, *Sphagnum sp*. is the most enriched.. The amount of metal released as a function of time for each moss allow to classify the moss species in the following order. For Cu^{2+}, Ni^{2+} and Pb^{2+}: *B. rutabulum* > *P. purum* > *Sphagnum sp*. ≥ *Hypnum sp*.. For Cd^{2+}, *P. purum* > *B. rutabulum* > *Hypnum sp*. ≥ *Sphagnum sp*.. For Zn^{2+}, this sequence is *P. purum* > *B. rutabulum* > *Sphagnum sp*. ≈ *Hypnum sp*.. During this experiment, the DOC amount measurements showed that *Sphagnum sp*. released the lower DOC concentration. The acid-base surface titration of moss species from pH 3 to 11 indicated that *Sphagnum sp*. was species with more negative excess of charge. The pH of point zero charge (pH_{PZC}) was computed as 5.01 ± 0.13, 4.64 ± 0.1, 4.96 ± 0.14 and 6.23 ± 0.25 for *Hypnum sp*., *Sphagnum sp*., *P. purum* and *B. rutabulum* respectively. The adsorption of metal as a function of pH showed different pattern depending on the metal and allow to classify them as following: for Cu^{2+}, *P. purum* > *B. rutabulum* > *Hypnum sp*. > *Sphagnum sp*.. For Cd^{2+} and Zn^{2+}, *B. rutabulum* > *Sphagnum sp*. > *P. purum* > *Hypnum sp*.. For Ni^{2+} and Pb^{2+}, *B. rutabulum* > *P. purum* > *Hypnum sp*. > *Sphagnum sp*. The metal adsorption on moss surfaces as a function of aqueous metal concentration showed a close relationship between moss species for each individual metal. The adsorption order can be expressed by following. For Cu^{2+}, *P. purum* ≈ *Sphagnum sp*. ≈ *B. rutabulum* > *Hypnum sp*.. For Cd^{2+}, *Sphagnum sp*. > *B. rutabulum* > *Hypnum sp*. > *P. purum*. For Ni^{2+}, *Sphagnum sp*. ≈ *Hypnum sp*. ≈ *P. purum* ≈ *B. rutabulum*. For Pb^{2+}, *B. rutabulum* > *Hypnum sp*. > *Sphagnum sp*. > *P. purum*. For Zn^{2+}, *B. rutabulum* ≈ *Sphagnum sp*. ≈ *Hypnum sp*. > *P. purum*. Eventually, a Linear Programming Modeling was applied for experimental data in order to compute the pK_s, pK_m and pK_a.

Simultaneous Laser Ablation Molecular Isotopic Spectrometry (LAMIS), Laser-Induced Breakdown Spectroscopy (LIBS) and Laser Ablation Inductively Coupled Plasma Spectrometry (LA-ICP-MS) for elemental analysis of geological samples

JHANIS J. GONZALEZ[12], JOSE R. CHIRINOS[1], MEIRONG DONG[1], DAYANA OROPEZA[1], XIANGLEI MAO[1], ALEXANDER BOLSHAKOV[2], JONG YOO[2], PAUL SYLVESTER[3], KATE SOUDERS[3], HENRY LONGERICH[3], AND RICHARD E. RUSSO[12]*

[1]Lawrence Berkeley National Laboratory, Berkeley, CA, USA (Correspondence: rerusso@lbl.gov)
[2]Applied Spectra, Inc., Fremont, CA, USA
[3]Memorial University of Newfoundland, St. John's, Newfoundland, Canada

A system that combines the capabilities and analytical benefits of LIBS, LAMIS and LA-ICP-MS was demonstrated for the analysis of samples of geological interest. The system consists of a Nd:YAG laser operated at 213 nm, for the LIBS and LAMIS measurements with a switchable spectrometer-detector system (Czerny-turner spectrograph with ICCD detection and a six channel spectrograph with CCD detection). For ICP-MS measurements a choice between a Quadrupole based system and Time-Of-Flight based system was made depending on the application. The data will show simultaneous determination of major elements such Si, Ca, Mg, C, Al, etc. with LIBS, carbon and boron isotopes determination by LAMIS, with trace composition (i.e., REE's) information from these geological samples by ICP-MS. The data are presented in the form of elemental distribution maps of major and trace elements with lateral resolution on the order of 50 μm.

The effect of Copper in the oxidation of Fe(II) in seawater

MELCHOR GONZÁLEZ-DÁVILA, J. MAGDALENA SANTANA-CASIANO, ARIDANE G. GONZÁLEZ, NORMA PÉREZ-ALMEIDA AND GUILLERMO SAMPERIO

Universidad de Las Palmas de Gran Canaria. Departamento de Química. Facultdad de Ciencias del Mar. 35017, Tafira. Las Palmas de G.C. Spain. Email: (mgonzalez@dqui.ulpgc.es)

The competition between Fe(II) and copper species has been studied in seawater at different initial Cu(II) and Cu(I) concentration (0-200nM). In addition, the effect of pH (6.2-8.5), bicarbonate concentration (2-9mM) and hydrogen peroxide concentration (0-500nM) on the Fe(II) rate constant were also studied. The Cu(II) added in solution was rapidly reduced to Cu(I), at the first 1-2 min, and it remained in solution after 40 min when Fe(II) was added. The initial copper additions increase the oxidation rate of Fe(II) under the different experimental conditions. The rate constant of Fe(II) was a second order pH dependent function at pH over 7.5 and a first order function for lower pH values. In the presence of Cu(II), a first-order pH dependence was always observed. Thus, $FeOH^+$, $FeCO_3$ and probably $FeHCO_3^+$ are involved in the process. In addition, Fe(II) oxidation rate was increased only when both carbonate and Cu(II) concentrations was over 6mM and 100nM, respectively. The effect of H_2O_2 concentrations was also function of the initial Cu(II) additions, but the oxidation rate was equally affected by H_2O_2, thus the observed effect must be only due to the presence of copper species in solution.

Evaluation of heavy metals in sediments of Chapala Lake

M. J. González Guadarrama[1*], R. E. Villanueva Estrada[2] and R. M. Prol Ledesma[2]

[1]Posgrado en Ciencias del Mar y Limnología, Universidad Nacional Autónoma de México, 04510, México D. F (*correspondence: chuy41284@yahoo.com.mx).
[2]Instituto de Geofísica, Universidad Nacional Autónoma de México, 04510, México, D.F.

The Chapala Lake is the largest and most important water body in Mexico, from a geological, chemical and ecological point of view [1, 2, 3]. In this work a relationship between size grain and heavy metals is presented.

Area	Granulometry				Chemical analyzes	
	Mz (Φ)	σ (Φ)	SK	K_G	$\%CO_3^{-2}$	%organic matter
Bank	6.9	2.1	0.1	1.4	4.2	1.0
Center	5.1	1.7	0.0	0.9	4.4	1.1
Lerma River	5.3	1.6	0.0	0.8	2.5	0.6

Table 1 Size grain and chemical analyzes of carbonate and organic matter in the sediments.

Area	Geoaccumulation index					
	Ba	Cr	Cu	Ni	Zn	Pb
Bank	-0.0	0.9	0.2	0.2	0.2	-0.4
Center	-1.1	0.5	0.6	0.5	0.8	-0.1
Lerma River	-1.0	0.6	0.8	0.2	1.0	-0.1

Table 2 Geoaccumulation index calculated [4] for different areas in the Chapala Lake.

According to the calculation of geoaccumulation index and the scale given by Ramos *et al* (1990), no contamination by heavy metals in surface sediments was observed. The size grain is fine; the sediment is poorly sorted, near symmetrical and leptokurtic and the mineralogical analyses show the predominance of clays. The delta of the River Lerma generates organic matter and carbonates migrate to others areas in the lake.

Neo-Archean domains in the Mediterranean and their implications

*J.M. González-Jiménez[1], C. Villaseca[2], W.L. Griffin[1], E. Belousova[1], Z. Konc[3], E. Ancochea[2], Suzanne Y. O'Reilly[1], N. J. Pearson[1], C. J. Garrido[3] and F. Gervilla[3,4]

[1]CCFS Centre of Excellence and GEMOC, Macquarie University, Sydney, Australia. (*Correspondence:jose.gonzalez@mq.edu.au
[2]Dpt. Mineralogía y Geoquímica and Instituto de Geosciencias, Madrid, Spain
[3]Instituto Andaluz de Ciencias de la Tierra (CSIC-UGR), Granada, Spain
[4]Dpt. Mineralogía y Petrología (UGR), Granada, Spain

Mantle-derived rocks, including xenoliths and peridotite massifs, are widesrread thorough the Mediterranean region. A synthesis of Re-depletion model ages (T_{RD}) for both whole-rock samples and *in situ*-analysed of individual sulfides from these mantle-derived rocks reveal mantle domains of different ages across the Mediterranean region.

A maximum T_{RD} age of 1.8 Ga is common to sulfides in xenoliths sampling the the mantle beneath Western Europe (Calatrava Volcanic Field, Spain; Languedoc and Massif Central, France) and of whole-rock samples from Azrou (North Africa) and the Pyrenees (France). A maximum at <1.4-1.3 Ga observed in whole-rock samples from Central Europe (Bohemian and Rhenish Massifs). In contrast, Os-bearing phases in xenoliths (sulfides) and in peridotite massifs (sulfides and platinum-group minerals) from the inner Mediterranean region (Hyblean Plateau in Sicily and Kraubath Massif in Austria) all show an oldest T_{RD} peak at ~ 2.3 Ga, equivalent to the oldest whole-rock T_{MA} of 2.2 Ga for rocks of Beni Boussera in northern Morocco and the 2.4 Ga peak in sulfides from peridotites of the internal Ligurides (Italy). A peak at 2.6 Ga is defined by sulfides in mantle xenoliths from the Tallante volcanic Field in southern Spain.

These data cleary identify the existence of a common Paleo-Proterozoic (~ 1.8 Ga) mantle on both sides of the Mediterranean realm, and an older (~2.2.-2.6 Ga) lithospheric mantle domain within the more recent Maghrebide-Appenine-Betic front generated during the Alpine-Betic orogeny. The Mediterranean basin may contain several buoyant Archean microplates, which could have impeded the northward movement of Africa and contributed to complex tectonics in the Mediterannean basin.

Crystallization of hydroxide cobalt carbonate $Co_2CO_3(OH)_2$, precursor of Co_3O_4, at room temperature

JORGE GONZÁLEZ-LÓPEZ[1*], ÁNGELES FERNÁNDEZ-GONZÁLEZ[1] AND AMALIA JIMÉNEZ[1]

[1]Departament of Geology. Universidad de Oviedo (Spain) jgonzalez@geol.uniovi.es

The crystallization of cobalt carbonate $CoCO_3$, cobalt hydroxide carbonate $Co_2CO_3(OH)_2$ and its hydrated phases $Co_2CO_3(OH)_2 \bullet nH_2O$ have been subject of interest in the scientific literature because they can be precursors of the so-called low-dimensional cobalt oxide-based nanomaterials. Various cobalt salts can be precursors of Co_3O_4, but carbonates and hydroxide carbonates are the most desirable because they are readily available and because no toxic product gases are produced during their calcination. In most cases, the physical properties and applications of the oxide-based nanomaterials are in linked with specific morphologies and hence, a number of works are focused on different experimental methods to achieve these morphologies. In most of the reported experimental works the cobalt carbonate phases have been synthetized by hydrothermal methods and their transformation into cobalt oxides occurs by calcination.

At room temperature, the crystallization behaviour of Co-carbonates seems to be complex and needs to be studied in depth. Under these conditions, the precipitation of crystalline cobalt carbonates or hydroxycarbonates from soluble salt of Co^{2+} and CO_3^{2-} is prevented by the formation of Co^{2+} aqueous complexes. Therefore the obtained phases by direct precipitation in aqueous solution are amorphous. In this experimental work we have aged this amorphous phase in the remaining aqueous solution for two months. We have observed its progressive transformation into a crystalline phase with rosasite-type crystal structure $Co_2CO_3(OH)_2$. The evolution of the morphology and chemical composition of the solids whit aging time, have been examined by X-ray Powder diffraction, scanning electron microscopy, transmission electron microscopy an infra-red spectroscopy.

The final $Co_2CO_3(OH)_2$ crystals grown by aging at room temperature show platelet morphology and are transformed into Co_3O_4 by calcination in a similar way as the crystals of this substance grown by hydrothermal methods do. Moreover, the layered crystal structure of the precursor $Ca_2CO_3(OH)_2$ favors the development of lamellar morphology that, after a topotactic transformation, is approximately maintained in the cobalt oxide new phase.

Nano iron sulfides for carbon dioxide reduction

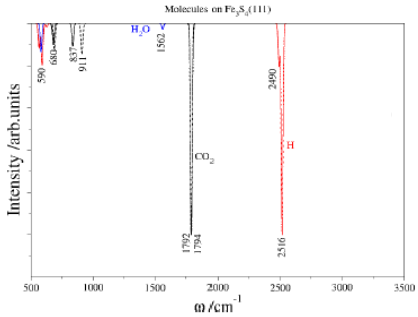
JOSIE GOODALL[1]*, NATHAN HOLLINGSWORTH[1], ANNA ROFFEY[1], KATHERINE B. HOLT[1], GRAEME HOGARTH[1] AND JAWWAD A. DARR[1]

[1]University College London, London, UK *j.goodall@ucl.ac.uk

Despite the high thermodynamic stability of CO_2, biological systems are capable of converting it into a range of organic molecules, under moderate conditions. Iron sulfide membranes formed in the warm, alkaline springs on the ocean floor are increasingly considered to be early catalysts involved the emergence of life. These anaerobic reactions are thought to have been catalyzed by small (Fe,Ni)S clusters similar to the surfaces of present day sulfide minerals.[1]

We have synthesised iron sulfide nanomaterials using a novel methods based on continuous hydrothermal synthesis, where aqueous flows of of iron and sulfide ions are brought into contact with a flow of superheated water (at 450 ºC). The conditions and processes occurring during synthesis can be compared to those that might occur in hydrothermal vents.[2,3] The electrochemical properties of these materials and their stability and activity towards CO_2 and their selectivity to products can be evaluated.

Figure 1: Simulated (solid) and experimental (dotted) IR spectra of



Greigite nanoparticles after CO_2 has been bubbled over the surface

Based on comprehensive computational investigations, a number of iron and iron-nickel sulphide nanoparticles have been designed, synthesised, tested, characterised, and evaluated for the activation and chemical modification of CO_2 at low voltages (obtainable from solar energy)and ambient conditions. Structures including greigite show evidence of interacting with CO_2 (figure 1). The electroduction of CO_2 on iron sulfide surface has been shown to produce small organic molecules including formic acid

Mesoproterozoic and Paleoproterozoic igneous crust of central East Antarctica: Age and origins revealed from glacial clasts

J. W. GOODGE[1]*, C. M. FANNING[2], J. D. VERVOORT[3] AND C. FISHER[3]

[1]Dept. of Geological Sciences, Univ. of Minnesota, Duluth, MN 55812 USA (correspondence: jgoodge@d.umn.edu)
[2]Res. School of Earth Sci., Australian Nat. Univ., Canberra, ACT 0200 Australia, (mark.fanning@anu.edu.au)
[3]Dept. of Earth Sciences, School of the Environment, Washington State Univ., Pullman, WA 99164, USA (vervoort@wsu.edu, chris.fisher@wsu.edu)

New SHRIMP U-Pb zircon ages from a large suite of granitoid clasts collected from glacial catchments draining central East Antarctica show that the crust in this ice-covered region was formed by a series of magmatic events at 2.00-1.90, 1.88-1.85, 1.80-1.79, 1.57, 1.48-1.43, and 1.20-1.10 Ga. The dominant granitoid populations are 1.85, 1.45 and 1.18 Ga, with some showing metamorphic overprinting at 1.18-1.15 Ga. Together, these clast ages indicate the presence in cratonic East Antarctica of a large, composite Proterozoic igneous province that reflects crustal growth across central East Gondwana. Further, they provide direct geologic support for the SWEAT reconstruction of Rodinia by correlation with Laurentia. Abundant ~1.1 Ga igneous and metamorphic clasts indicate the presence of Grenvillian orogenic belts in the interior that may reflect Rodinia assembly, and may sample crust underlying the Gamburtsev Subglacial Mountains.

In addition to U-Pb ages, we determined zircon Hf and O isotopic compositions in order to evaluate crustal history. Hf-isotope compositions were determined simultaneously with U-Pb by LA-ICP/MS in split-stream mode (LASS); O-isotope compositions were measured on SHRIMP-II in negative ion mode. Among the granitoid age populations, the following trends emerge: (1) a general pattern of increasing $\delta^{18}O$ with decreasing εHf, both corresponding with increasing age; (2) granitoids of ~2.0 Ga age have weakly evolved Hf compositions (εHf = +1 to +4) and mantle $\delta^{18}O$; (3) rocks of ~1.57, ~1.79 and ~1.88-1.85 Ga age show evolved crustal compositions with εHf = +5 to -8, and $\delta^{18}O$ = 5.8-8.3 ‰, and the ~1.88-1.79 Ga granitoids require some involvement of Archean crust; (4) rocks of 1.50-1.45 Ga age have mantle signatures with εHf = +5 to +11; and (5) rocks of ~1.2 Ga age have crustal $\delta^{18}O$ signatures and εHf = +2 to +5. Together, these age and isotopic data provide the first glimpse of crustal growth in central East Antarctica and suggest a varied history of relatively juvenile Proterozoic magmatism.

^{54}Cr isotope anomalies and Mn/Cr chronology in chondrites

C. GÖPEL[1]*, J.- L. BIRCK[1], J. ZIPFEL[2], A. GALY[3] AND B. ZANDA[4]

[1]IPGP, 75238 Paris, France (*correspondance: gopel@ipgp.fr), (birck@ipgp.fr)
[3]Senkenberg Institute, 60325 Frankfurt, Germany (jzipfel@senckenberg.de)
[2]Dept. of Earth Sciences, University of Cambridge, UK (ajbg2@cam.ac.uk)
[4]MNHN, 75005 Paris, France (zanda@mnhn.fr)

In order for Cr to be used as a chronometer, the initial homogeneity of its isotopic composition in the solar system has to be verified. Today we have clear evidence for anomalies of ^{54}Cr in different meteorites whereas evidence for heterogeneity of ^{53}Mn and ^{53}Cr is less obvious [1-4].

In order to assess this problem we have performed detailed internal isotopic and mineralogical investigations of recently discovered equilibrated meteorites related to CR chondrites (Tafassasset, NWA 6901), the carbonaceous chondrite (NWA 5958) and of Acapulco. We exploit the double information provided by the Mn/Cr system: dating with ^{53}Mn/^{53}Cr and information on the nucleosynthetically distinct components witnessed by ^{54}Cr.

The bulk rocks of Tafassasset, NWA 6901 and NWA 5958 show positive ^{54}Cr values (1.333 ± 0.126, 1.007 ± 0.188, 0.973 ± 0.153) that are typical for carbonaceous chondrites. In contrast the Acapulco bulk rock exhibits a negative ^{54}Cr anomaly, similar to that observed in achondrites. The mineral phases in Tafassasset (chromite, olivine) exhibit an identical ^{54}Cr excess, while the ^{54}Cr anomaly is variable in different minerals (clinopyroxene, chromite, olivine) of Acapulco. In the ^{55}Mn/^{52}Cr versus ε^{53}Cr diagram the samples of both meteorites fall on linear trends implying variable ^{53}Mn/^{55}Mn ratios that are consistent with well-established chronological information [5, 6].

We will discuss the significance of such internal Mn-Cr isochrons, compare them to age information obtained from other systems and evaluate the new data in respect to the initial heterogeneity of ^{53}Cr and ^{54}Cr of the solar system.

Experimental study of melting, texture, and phase relations of basalt (eclogite)-peridotite-fluid system at sub- and supercritical P-T

N.S. GORBACHEV*, A.N. NEKRASOV, A.V. KOSTYUK, AND D.M. SULTANOV

Institute of Experimental Mineralogy RAS, Academica Osipyana 4, Chernogolovka, Russia (correspondence*: gor@iem.ac.ru)

Fluids have an effective influence on the phase relations and melting of the mantle. Depending on the P-T conditions fluid-bearing silicate systems can be in the subcritical and supercritical conditions. Melting, textures, phase relations at sub - and supercritical P-T are studied experimentally in the system basalt (eclogite)-peridotite-H_2O, H_2O+(Na, K)$_2CO_3$ fluid.

Experiments were carried out in piston-cylinder and anvil-with-hole apparatus by a quenching technique in the range P=2-4 GPa, T=1100-1400°C. Different texture and phase relations of quenched samples served as test that the system goes into a supercritical state. Two experimental techniques were used: Pt-Pt-peridotite ampoules at T=1350-1400ºC and direct melting peridotite in Au and Au-Pd ampoules at T=1100-1200ºC.

At subcritical P-T conditions quenching samples have a massive texture, due to the fact that the massive silicate glass cements solid liquidus phases. At supercritical P-T conditions observed full miscibility between melt and fluid, and in the second critical end point – between minerals, melts, and fluid. The disintegration of the experimental samples observed during quenching supercritical phase. Samples characterized by clastic-like or fragmental-like textures regardless of the composition and technique of experiments. They consist of a mixture of fritted, rolled-like relicts of Ol, Opx from peridotite, reactionary minerals, and products quenching of supercritical phase - microlits of silicate minerals and their joints needle- or dendrite-like forms, microglobules Al-Si glasses, carbonates. Separate fragments remind of “breccia”-relicts of Ol, Opx cement of reactionary Grt, Cpx. Solubility of minerals peridotite, reactionary relation between relict and neogenic reactionary minerals testify to high reactionary ability supercritical phase.

Intra-plate tectonics and magmatisim as a consequence of mantle lithosphere delamination

WERONIKA GORCZYK [1], KATHARINA VOGT [2] AND BRUCE HOBBS [1, 3]

[1]Center for Exploration and Targeting, University of Western Australia,
[2]Swiss Federal Institute of Technology, Switzerlad
[3]Commonwealth and Industrlal Research Organization, Australia

Most of intra-plate melting is associated with interaction of deep mantle plume with mantle lithosphere. Vast amount of mafic/felsic intra-plate intrusions are located along post-collisional lines, where for longer periods time regional tectonic conditions are more likely to be (weakly) compressional to transpressional, and more rarely extensional. Arrival of the asthenosphere-derived plume would suggest initiation of extension along the weak/post-collision zone (craton boundary). Alternatively, in compressional regime a surprisingly large range of instabilities can develop that lead to melting of the lower crust and mantle lithosphere. Unexpected structural complexity arises which is quite sensitive to the geometry and rheological properties. This has dramatic effects on melting and devolatilisation within the lithosphere and hence in the localisation of and melt emplacement. Melts extracted in theses circumstances lead to emplacement of all variety of melts: mafic, intermediate and felsic, from wide range of PT conditions.

In order to investigate theses intra-plate sites of deformation, melt production and crustal growth in relation to cratonic post-collisional contacts we performed a series of 2D numerical experiments by using a coupled petrological–thermomechanical numerical model. The model includes, stable mineralogy, aqueous fluid transport, partial melting, melt extraction and melt emplacement in form of extrusive volcanics and intrusive plutons.

As a case studdy we will present Musgrave Orogeny in Central Australia.

Hydrogeochemical characteristics in the basin area of the ”Rovni” accumulation - influence of the natural radionuclides

[1]V. GORDANIĆ, [1]M. VIDOVIĆ, [2]V. SPASIĆ-JOKIĆ, [3]D. JOVANOVIĆ AND [4]A. SEKE

[1]University of Belgrade, IHTM (gordanicv@gmail.com, mivibgd@yahoo.com)
[2] University of Novi Sad, Faculty of Technical Science (svesna@uns.ac.rs)
[3]Geological Survey of Serbia (dragan.jovanovic@gzs.gov.rs)
[4]University of Belgrade, RGF (anaseke@gmail.com)

The hydrogeochemical prospecting covered 110 km^2 of basin surface area of ”Rovni” accumulation. Among the water flows the most significant rivers are Sušica and Jablanica, which are mostly cut in into the limestones of Mesozoic in age. The area incoporated in the eco-geochemical research is built of Palaeozoic and Mesozoic sediments, and Quaternary material. According to geological-structural characteristics of the terrain, of special significance is the presence of pyroclastic material (tuff, volcanic breccia) as well as limestones (T_2^2) and bauxite ore bodies within. Average values of natural radionuclides content in bauxite are: 2.24 g/t for ^{238}U, 14.82 g/t for ^{232}Th and 0.14% for ^{40}K [1]. Hydrogeochemical research of radioactive elements in bauxite were conducted for all four seasons. Average uranium content for all four seasons varies within the interval 0.21-0.26 μg/l; Ra <0.05-0.09 Bq/l and Rn 0.1-4.7 Bq/l [1] Regarding the presence of Sb, Cu ore occurences, Fe, Cu mineralization (pyritization, limonitization) in the basin area, natural radionuclide contents were determined as well as pH, Eh, Ep, microelements, gases, mineralization and anion-cation composition. Presence of natural radionuclides in water is negligible and it doesn't affect the quality of water in the future accumulation [1]. All results are presented in tables, charts and geochemical maps. Geoecological map of the basin area presents the geoecological state in the living environment before the dam construction, and it also enables making a base for evaluation of accumulation degradation during a multiyear period of exploitation.

Early detection of osteolytic lesions in multiple myeloma using natural Ca isotopes

G.W. GORDON[1]*, J.L. SKULAN[12], M. CHANNON[1], R. FONSECA[3] AND A.D. ANBAR[12]

[1]School of Earth and Space Exploration, Arizona State University, Tempe, AZ, 85287-1404 (*correspondance: Gwyneth.Gordon@asu.edu)
[2]Department of Chemistry and Biochemistry, Arizona State University, Tempe, AZ 85287-1604 (anbar@asu.edu)
[3]Mayo Clinic of Arizona, (fonseca.rafael@mayo.com)

Real time monitoring of bone metabolism in multiple myeloma (MM) would help clinicians detect MM onset earlier than is currently possible. A biomarker detecting incipient or asymptomatic bone destruction would help evaluate the efficacy, timing, and duration of bone-specific therapies. Naturally occurring Ca isotope ratios in serum may be such a biomarker.

Natural changes in the Ca isotope composition of blood provide quantitative information on short-term changes in net bone mineral balance (BMB), information unavailable from conventional biochemical measures of bone metabolism. Net bone gain or loss cause blood and urine to be respectively enriched or depleted in light Ca isotopes. Based on studies of bed-rest induced bone loss [1,2], a net bone mineral loss rate of about <4%/year is detectable.

Osteolytic lesions occur in >80% of MM patients and should cause negative shifts in BMB detectable by Ca isotopes. Patients with MGUS (Monoclonal Gammopathy of Undetermined Significance) progress to MM at a rate of 1-2% per year, often with the onset of osteolytic lesions. In a pilot study, Ca of blood from patients with MGUS was isotopically heavier than Ca in blood of patients with MM (n=19, p=0.01, Mann-Whitney test). This difference is consistent with osteolytic lesions in MM patients. Ca isotopes may be used in the clinic to detect bone disease early, monitor its progression, and evaluate which patients are at highest risk for rapid deterioration.

Split-stream ICPMS migmatite geochemistry: significance for the rheologic evolution of the Western Gneiss Region, Norway

S.M. GORDON[1], D.L. WHITNEY[2], C. TEYSSIER[2], H. FOSSEN[3] AND J. DESORMEAU[1]

[1]Geological Sciences, U of Nevada, Reno, NV, USA, staciag@unr.edu
[2]Earth Sciences, U of Minnesota, Minneapolis, MN, USA
[3]Earth Science, U of Bergen, Bergen, Norway

Exhumed ultrahigh-pressure (UHP) terranes document the subduction of crustal material to mantle depths and its return to the Earth's surface. The Western Gneiss Region (WGR), Norway, is one of the two largest UHP terranes on Earth and consists of a UHP eclogite terrain and a HP granulite terrain that may represent overprinted eclogite; these are separated by a major strike-slip shear zone. To evaluate the geochemical and age relationships of migmatite and mafic pods in both regions, we obtained LA-ICP-MS U-Pb dates and trace-element analyses for zircon from a variety of textural types of leucosome associated with mafic pods. Five leucosomes within highly deformed migmatite in the HP granulite terrain reveal U-Pb lower-intercept ages from ca. 405 to 409 Ma and upper-intercept Proterozoic dates. The Caledonian zircons all have flat Eu anomalies and weakly steep HREE patterns, suggesting HP crystallization. Similar results were obtained from zircon rims extracted from the UHP terrain, with garnet-present ± plagioclase-absent REE patterns and dates as old as 410–406 Ma. The new U-Pb dates suggest a similar melt crystallization history that was coeval with previously determined ages of (U)HP metamorphism of WGR eclogite. Results are consistent with the presence of partially molten crust in a large part of the WGR at HP or UHP conditions. The decreased viscosity and increased buoyancy and strain weakening induced by partial melting may have assisted rapid ascent of HP/UHP rocks from mantle to crustal depths.

Formation mechanisms of reaction zones in Mélange zones: Evidence for mechanical mixing

J.K. GORMAN[1*], S. PENNISTON-DORLAND[1], R.J. WALKER[1], AND H. MARSCHALL[2]

[1]Department of Geology, University of Marlyand, College Park, MD 20742, (*email: jgorman1@umd.edu)
[2]Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, MA 02543

Three mechanisms have been proposed to operate within mélange zones to form metasomatic reaction zones between mafic rock and adjacent peridotite. These mechanisms are: 1) mass transfer by fluid flux, likely parallel to reaction zone contacts, 2) mass transfer by diffusion through an intergranular fluid perpendicular to reaction zone contacts, and 3) mechanical mixing of adjacent lithologies. This study utilizes the broad concentration ranges of highly siderophile elements (HSE) across lithologic contacts to elucidate peridotitic contributions to reaction zones. Ultimately this data can help determine the extent of mechanical mixing contribution to reaction zone formation.

Rinds from two amphibolite grade traverses from the Catalina Schist (CA) are enriched in Os, Ir, and Ru relative to the block. Initial $^{187}Os/^{188}Os$ ratios are distinctly lower in the rinds (0.13–0.18) compared to the blocks (0.43–2.23). Lower grade lawsonite-blueschist facies rinds have similar HSE systematics with high $^{187}Os/^{188}Os$ ratios (0.24–0.33) for mafic block cores and lower ratios (0.12) for the rinds. Similar to the Catalina traverses, the Stavros traverse (Syros, Greece) has very high $^{187}Os/^{188}Os$ ratios for the block (4.1–16.6), a low ratio for serpentinite (0.12) and an intermediate ratio for the reaction zone (0.29). $^{187}Os/^{188}Os$ ratios for the Lia Beach traverse (Syros, Greece) are high in the metabasalt (0.32), whereas the nearby serpentinite has the lowest ratio (0.13). The blackwall zone (thought to be formed by diffusion through an intergranular fluid) has variable ratios (0.16–0.80). Concentrations of Os in the blackwall are lower than both the core and serpentinite.

In order to produce the elemental and isotopic variations seen in the rind in the Catalina traverses and the outermost rind of the Stavros traverse, we suggest initial mechanical mixing of block and peridotite to create rind-like material on the edges of the block. The Lia Beach traverse Os data may indicate initial mechanical mixing as well as a combination of metasomatic flux parallel to the contact and diffusion across the contact. In all traverses, concentrations of other elements suggest a later-stage infiltration of fluids after peak metamorphism.

[3]Laboratoire de Glaciologie et Géophysique de l'Environnement (UMR 5183 CNRS-UJF), 38402 Grenoble, France (jerome@lgge.obs.ujf-grenoble.fr)

In the context of a globally warming climate it is crucial to study the climate variability in the past in order to understand which natural feedbacks can be expected on the atmospheric CO_2 concentration in a future warmer world. The composition of gas from bubbles in polar ice presents a paleo-climate archive that provides a powerful means to study the mechanisms involved in the ~40% increase in atmospheric CO_2 between glacial and interglacial climates. The source of the CO_2 released into the atmosphere during previous deglaciations can be constrained from isotopic measurements. Unfortunately, such studies have been seriously hampered by the experimental difficulty of extracting the CO_2 without contamination or fractionation, and measuring the isotope signal off-line on an isotope ratio mass spectrometer (IRMS).

Here we present an alternative method that leverages the extreme sensitivity afforded by Optical Feedback Cavity Enhanced Absorption Spectroscopy (OF-CEAS) in the Mid-Infrared. This region of the spectrum is accessed by a custom-developed Quantum Cascade Laser operating near 4.35 μm. The feedback to the laser of light that has been spectrally filtered by a high-finesse enhancement cavity has the effect of spectrally narrowing the laser emission and to auto-lock the laser frequency to one of the cavity's longitudinal modes, with clear advantages in terms of acquisition time and signal-to-noise ratio of the measurement. The line strengths in this region are about 5 orders of magnitude higher than in the more easily accessible NIR region near 1.6 μm. A small cavity volume of ~20 mL, this enables the analysis of nmol-sized samples with high precision (< 0.05‰) in a fraction of the time required by the conventional IRMS-based technique. We will show an instrument characterization and preliminary results.

Redox characterization of Fe-bearing clay minerals using electrochemical and spectroscopic techniques

CHRISTOPHER A. GORSKI[12]*, LAURA E. KLÜPFEL[23], ANDREAS VOEGELIN[2], MICHAEL SANDER[3] AND THOMAS B. HOFSTETTER[23]

[1]Pennsylvania State University, University Park, PA, USA * (Correspondence: gorski@psu.edu)

[3]Institute of Biogeochemistry and Pollutant Dynamics (IBP), Swiss Federal Institute of Technology, ETH Zurich, Switzerland

Fe-bearing clay minerals serve as important redox buffers in natural and engineered environments, where they readily undergo electron transfer reactions with bacteria, nutrients, and contaminants. Despite much interest, modeling the extent and kinetics of these interfacial redox reactions has proven to be challenging due to the inability to describe clay mineral redox properties in terms of reduction potential (E_H) values. Such values have been difficult to obtain experimentally because of sluggish electron transfer rates and redox equilibration between clay minerals and electrodes.

Recently, we demonstrated that this challenge can be overcome using mediated electrochemical analyses, in which soluble redox mediator compounds facilitate rapid mineral-electrode electron transfer and redox equilibration [1]. In this approach, the oxidation state of the structural Fe is measured across a series of applied E_H values. In the current study, we applied this technique to four natural Fe-bearing smectites having varied structural Fe-contents, layer charges, elemental compositions, and redox histories to determine how clay mineral redox properties deviate as a function of these variables. X-ray absorption spectroscopy complimented these experiments to determine how structural molecular-scale variations influenced macroscopic redox properties.

All four smectites displayed complex redox behavior; high Fe-content smectites exhibited metastable states during redox cycling and all the smectites were redox-active over a wide range of of E_H values spanning an array of redox regimes, ranging from methanogenesis to aerobic respiration. These results indicate that smectites likely play important roles in determing the fate of contaminants and biological nutrients under a variety of redox conditions.

Noise in Heat Flow Data

WILLIAM GOSNOLD[123]

[1]Harold Hamm School of Geology and Geological Engineering, University of North Dakota, Grand Forks, ND 58202

Temperature disturbances due to a variety of heat transport phenomena in the upper few km of the crust and the inclusion of unconventional heat flow determinations, i.e., use of bottom hole temperatures from petroleum exploration, alter the geothermal gradient and lead to inaccurate heat flow determinations. These data can be problematic in assessing the geoneutrinos flux due to radiogenic heat production because they have been included in the global heat flow database without correction. Careful analysis of heat flow data is particularly important on a local scale where inaccurate determination of surface heat flow can lead to miscalculation of radiogenic and mantle heat flow components and thus to erroneous estimation of the local background geoneutrino flux at sites where observatories could be installed. For example, high and low heat flow anomalies within a 140,000 km^2 area close to the Black Hills are due to gravity-driven regional groundwater flow in confined aquifers. Heat flow determined by conventional methods in Minnesota, Manitoba and Ontario has a long-period transient from ground warming after retreat of the Pleistocene ice sheet that causes under estimation of heat flow by 25 to 40 percent. We present a range of heat flow and heat production models to explore the end members of these conditions.

Nitrogen isotopic fractionation during enzymatic transamination of glutamic acid to form aspartic acid

AKIKO S. GOTO[1*], KASUMI MIURA[2] AND YOSHITO CHIKARAISHI[3]

[1]Institute of Science and Engineering, Kanazawa University, Kanazawa, JAPAN (akigoto@staff.kanazawa-u.ac.jp)
[2]Tokyo Metropolitan University, Tokyo, JAPAN
[3]Japan Agency for Marine-Earth Science and Technology, Yokosuka, JAPAN (ychikaraishi@jamstec.go.jp)

The trophic enrichment of ^{15}N on amino acids from diets to consumers has recently been employed as a potential useful tool for characterizing the trophic position of organisms in ecological food webs (Popp *et al*., 2007; Chikaraishi *et al*., 2009). Amino acids are the basic subunit of biomass protein and major pool of nitrogen in organisms. These facts enhance our motivation to understand nitrogen flux and associated change in the isotopic composition of amino acids in animal metabolisms.

Glutamic acid generally has a significant ^{15}N-enrichment with increase of trophic position (~8‰/each), probably due to the isotopic fractionation associated with its enzymatic deamination or transamination. To evaluate this hypothesis, we estimated the isotopic fractionation factor (α) associated with an *in vitro* enzymatic transamination of glutamic acid to oxaloacetic acid (i.e., to form aspartic acid).

The α value is estimated to be 0.9958 based on change in the observed $\delta^{15}N$ value and abundance data of glutamic acid between before and after transamination. These results are almost consistent with the α estimation in the previous study (Macko *et al*. 1986: α=0.9923) within an analytical error. Also, the α value roughly account for that 86% of glutamic acid (which derived from diets) is deaminated and the remaining only 14% is used to configure biomass protein, when the 8‰ trophic enrichment occurs on glutamic acid from diets to consumers. These values may correspond closely to the "Ten percent law" for the transfer of energy from one trophic level to the next. Thus, we conclude that the transamination is a likely process to explain the observed trophic enrichment of ^{15}N on amino acids.

A study of combustion aerosols in Japan using a nonhydrostatic icosahedral atmospheric model

D. GOTO[1]*, K. SUZUKI[2] AND SALSA PROJECT TEAM[3]

[1]National Institute for Environmental Studies, Ibaraki 305-8506, Japan (*correspondence: goto.daisuke@nies.go.jp)
[2]JPL/CalTech, California (Kentaro.Suzuki@jpl.nasa.gov)
[3]REsearch program on Climate Change Adaptation (RECCA) / development of Seamless chemical AssimiLation System and its Application for atmospheric environmental materials (SALSA project), Japan

An aerosol-coupled global cloud-resolving model, NICAM-SPRINTARS, developed by [1] based on the aerosol module of Spectral Radiation-Transport Model for Aerosol Species (SPRINTARS; [2]) and the global cloud-resolving model of Nonhydrostatic Icosahedral Atmospheric Model (NICAM; [3,4]) is capable to simulate the aerosol processes and distributions not only in the whole globe but also over specific regions using a stretched grid system developed by [5] as a 'seamless' model. In the present study, we develop the seamless aerosol-transport model with the spatial resolution of about 10 km to simulate aerosols around Japan, especially the Kanto region including Megacity Tokyo.

Although in some cities near mountains the present model does not always reproduce both the meteorological and aerosol fields mainly due to large spatial resolution, around the center of Tokyo it can sucessfully simulate meteorological and aerosol fields such as sulfate (Figure). In the presentation, we will discuss the performance of the newly developed aerosol model.

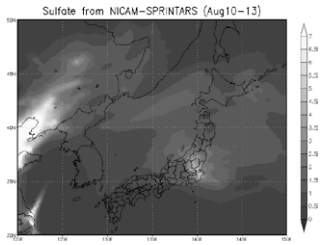

Figure 1: Simulated sulfate around Japan in unit of μg/m^3.

Thermodynamics of solid solutions: the Margules equation and beyond

M. GOTTSCHALK*

GeoForschungsZentrum Potsdam, 14473 Potsdam, Germany, (*correspondence: gottschalk@gfz-potsdam.de)

For the thermodynamic treatment of phase equilibria the knowledge of *Gibbs free energy G* of solid solutions are essential. The thermodynamic models used for solid solutions are mostly the *regular solution*, the *Margules-*, and the *Guggenheim-equation*. The calibration of the involved parameters involves the results from phase equilibria studies. Alternatively, the lattice energy is calculated on the atomistic scale by using empirical force potentials or ab-initio calculations. Cluster expansion and applying statistical mechanics e.g. *Monte Carlo* methods are then used to evaluate *G*. For thermodynamic calculations parameterization of *the Gibbs free energy* rely then on the same models as for the thermodynamic approach.

The *regular solutions* and the *Margules equation* originate from fluid mixtures. A general approach can be applied to solids considering, that the molar mixing energy u depends on x_i and the occupancy x_j of neighboring adjacent or more distant sites. For *one* neighbor of the same site, u is:

$$u = \sum_{i=1}^{c}\sum_{j=1}^{c} x_i x_j u_{ij} \quad \text{with} \quad \Delta U_{ij} = 2u_{ij} - u_{ii} - u_{jj}$$

which gives us the *regular solution*:

$$u = \sum_{i=1}^{c} x_i u_{ii} + \frac{1}{2}\sum_{i=1}^{c}\sum_{j=1}^{c} x_i x_j \Delta U_{ij}$$

If the energy depends on *two* neighboring sites

$$u = \sum_{i=1}^{c}\sum_{j=1}^{c}\sum_{k=1}^{c} x_i x_j x_k u_{ijk} \quad \text{with} \quad \Delta U_{ijk} = 3u_{ijk} - u_{iii} - u_{jjj} - u_{kkk}$$

results in the *Margules equation* including a ternary term:

$$u = \sum_{i=1}^{c} x_i u_{iii} + \sum_{i=1}^{c}\sum_{j=i+1}^{c} x_i x_j \left(x_i \Delta U_{ij} + x_j \Delta U_{ijj}\right) + 2\sum_{i=1}^{c}\sum_{j=i+1}^{c}\sum_{k=j+1}^{c} x_i x_j x_k \Delta U_{ijk}$$

The above equation can also be written in the form:

$$u = \sum_{i=1}^{c} x_i u_{iii} + \frac{1}{3}\sum_{i=1}^{c}\sum_{j=1}^{c}\sum_{k=1}^{c} x_i x_j x_k \Delta U_{ijk}$$

This procedure can be extended to more complex interactions. If the energy of the site depends on the occupancy of *four* of the same site and *two* of a neighboring site:

$$U = \sum_{i=1}^{c_A}\sum_{m=1}^{c_B} x_i^A x_m^B u_{(iiii)(mm)} + \frac{1}{8}\sum_{i=1}^{c_A}\sum_{j=1}^{c_A}\sum_{k=1}^{c_A}\sum_{l=1}^{c_A}\sum_{m=1}^{c_B}\sum_{n=1}^{c_B} x_i^A x_j^A x_k^A x_l^A x_m^B x_n^B \Delta U_{(ijkl)(mn)}$$

It is important to note that these types of equations always split in a term for the *mechanical mixture* and one involving only parameters ΔU based on energy differences, which can be acquired by theoretical calculations for complex and arbitrary system.

In situ monitoring of reaction band formation using synchrotron radiation

L.C. GÖTZE[1*], R. MILKE[1], S. SCHORR[1], R. DOHMEN[2] AND R. WIRTH[3]

[1]Free University of Berlin, Institute of Geological Sciences, Berlin, Germany (*correspondence: lutz.c.goetze@fu-berlin.de)
[2]Ruhr University Bochum, Institute for Geology, Mineralogy & Geophysics, Bochum, Germany
[3] GFZ German Research Centre for Geosciences, Potsdam, Germany

Diffusion reaction couple experiments are an essential tool in order to understand corona microstructures and underlying processes in metamorphosed and igneous natural rocks. By employing a heating attachment and synchrotron radiation we monitored the initial and transient stages of an *in situ* reaction rim formation at the nanoscale. Additionally, by miniaturising the experimental setup using thin films we could lower the temperatures and test durations that are usually applied in diffusion couple experiments.

As a model system the reaction between corundum (Al_2O_3) and periclase (MgO) that forms spinel ($MgAl_2O_4$) was chosen. The diffusion couples consisted of single crystal substrates of either (0001) oriented corundum with an amorphous MgO thin film on top or (111) oriented periclase which reacted with an Al_2O_3 thin film. Thin films were produced by laser ablation, and their thickness was always less than 300 nm. Experimental temperatures were varied from 700 to 1000 °C, and test durations ranged from 5 minutes to 3 hours. The texture of the *in-situ* grown spinel, i.e. the crystallographic relationship between substrate and thin film, was subsequently analysed using a four-circle diffractometer to obtain pole figures. As complementary methods to the X-ray diffraction techniques transmission electron microscopy (TEM) and atomic force microscopy (AFM) were employed.

At 700 and 800 °C no spinel formation could be observed, but the reaction layers crystallise oriented on the substrate. Spinel formation occurs at a moderate rate at 900 °C, and is rapid at 1000 °C. The time series conducted at 1000 °C points to an interface-controlled reaction regime, i.e. the thickness of spinel grows linearly with time. Microstructures within the spinel, as revealed by TEM, suggest 'counter-diffusion of the cations' as the diffusion mechanism. Diffraction spectra and pole figures show that the spinel crystallises and grows epitactically on and into the substrates.

Delayed response in sedimentary discharge from the Himalaya to the ocean at Milankovitch periods

A.T. GOURLAN[1*], C. VOISIN[1], C. CHAUVEL[1] AND J. BRAUN[1]

[1]ISTerre, Université Joseph Fourier, CNRS, BP 53, 38041 Grenoble CEDEX 9, France (* correspondence: alexandra.gourlan@ujf-grenoble.fr)

The neodymium isotopic composition of marine sediments (ε_{Nd}) is often used as a proxy for past climate changes in paleoceanography studies. However, in some parts of the world ocean, the origin of ε_{Nd} variations in seawater over the last Glacial/Interglacial cycles remains unclear. This is particularly true in the Indian Ocean because of its connections with the Atlantic and the Pacific Ocean waters, and because of the huge Himalayan sedimentary discharge that brings low ε_{Nd} into the ocean. The ε_{Nd} variations could result of changes in the global oceanic circulation or be due to changes in the continental input controlled by continental rainfalls. Here we present a simple technique to discriminate these two interpretations at a given site, based on the correlation of $\delta^{18}O$ and ε_{Nd} seawater signals. We show in-phase records at site SK129-CR2 [1] (Arabian Sea) and out-of phase records at site ODP-758 [2] (Bay of Bengal), suggesting that the two sites have recorded different phenomena through time. Arabian Site fluctuations were interpreted as changes of the thermohaline circulation and Bay of Bengal Site fluctuations as changes on the Himalayan input. As Himalayan rivers input is linked to the Earth's climate variability, we filtered the time series of $\delta^{18}O$ and ε_{Nd} at Site ODP 758 around the three periods related to the three main orbital parameters. We show that the time lag between $\delta^{18}O$ and ε_{Nd}, increases from 1000 to 2000 and then to 7000 years for the 23 ky, 41 ky, and 100 ky filtered signals. To explain the delays between temperature changes recorded by $\delta^{18}O$ and ε_{Nd}, two models were proposed: diffusive [3] and erosion [4] models of Himalayans. For the first time, we demonstrate that a geochemical dataset can record and thus constrain the time lag in the erosional response of an active mountain belt to climate change.

Relevance of model complexity for assessing contaminant leaching from a fractured degrading concrete structure

JOAN GOVAERTS, JANEZ PERKO, DIEDERIK JACQUES, AND SURESH C. SEETHARAM[1]

[1]Institute for Environment, Health and Safety, Belgian Nuclear Research Centre (SCK•CEN), Belgium, jgovaert@sckcen.be

Cementitious materials such as concrete, used in near-surface disposal facilities for radioactive waste, play a crucial role in ensuring the waste retention capabilities within the repository. During the lifetime of the facility, the concrete is in permanent contact with infiltrating rain or soil water, which is not in the equilibrium with the cement pore water. Chemical degradation of concrete affects several properties and consequently could accelerate the leaching of contaminants from the disposal system. One important degradation process is leaching of calcium. The effect of calcium leaching encompasses loss of material's mechanical strength, change of physical properties such as porosity, permeability and change of retention capacity for contaminants.

A small-scale representation of a concrete waste container wall with a fracture going through the middle is modeled in a simplified 2D geometry. The geochemical degradation reactions are solved using iPhreeqc, which is then linked to the finite element software COMSOL Multiphysics. By taking advantage of COMSOL's unique capability of treating fracture flow and transport as an implicit 1D-boundary, the computational burden of the problem is drastically reduced.

In a stepwise manner, both the chemical and physical complexity of the model are increased. Along the way, different concrete minerals are added to the geochemical system, starting from system based solely on portlandite and ending up with a state-of-the-art description with inclusion of different C-S-H minerals. By then linking the chemical degradation to the hydraulic and diffusive properties of the concrete, several levels of complexity are again added. It is then evaluated which additions add enough safety-relevant information in order to justify the increase in computational demands. This is done by comparing Ca leaching rates and the evolution of safety relevant properties such as the total water flux through the system or the pH (which influences the mobility of contaminants). On the basis of these analyses, recommendations are made for the safety assessment modelling of large-scale disposal facilities.

Geochemical baseline mapping in India using top and bottom soil samples for environmental management

PRADIP K. GOVIL

National Geophysical Research Institute, Hyderabad, India. (govilpk@gmail.com)

As a part of IUGS/IAGC Global Baselines Program, National Geophysical Research Institute (NGRI), Hyderabad has carried out studies leading to the preparation of geochemical maps of India for top and bottom soil for 25 elements. India is devided into 122 GRNs, out of which 118 cells of 160 x 160 sq. Km have been sampled and analysed by using X-ray fluorescence spectrometer at NGRI, Hyderabad.

Samples were collected by using the field manual (Green Book) prepared by Geological Survey of Finland. All the data is compiled and plotted by using a software SURFER to prepare the baseline maps. The data was interpreted with the underlying geology of the area. Baseline studies are useful to define the natural abundance and the spatial distribution of chemical elements in the earth's surface to which changes caused by human activities can be compared.

Geochemical maps have been interpreted and spatial correlation was found between the underlying geology and elemental abundances in the sampled media. The hot spots for the toxic metals can be seen at a glance for the whole country, which will help in taking suitable remedial measures. Mean, median, maximum, minimum and average concentrations were calculated and presented in this paper for chromium, copper, nickel, arsenic, cobalt, strontium, rubidium along with some major oxides like aluminium, iron, titanium, manganese, sulphur, calcium, magnesium, sodium, potassium and silica. Geochemical map of chromium is shown below:

Microbial uptake of phosphate during anaerobic oxidation of methane

J.S. GRAF*, J. MILUCKA, T.G. FERDELMAN AND M.M.M. KUYPERS

Max Planck Institute for Marine Microbiology, Celsiusstrasse 1, 28359 Bremen, Germany (*correspondence: jgraf@mpi-bremen.de)

Sulfate-coupled anaerobic oxidation of methane (AOM) in sediments is considered a major sink of methane in the ocean and plays an important role in sedimentary biogeochemical cycling of carbon and sulfur [1]. The *Deltaproteobacteria* (DSS) associated with the methanotrophic archaea (ANME) mediating AOM are capable of polysulfide disproportionation and couple the carbon and sulfur cycles during AOM [2].

Investigations using transmission electron microscopy/energy-dispersive X-ray analysis showed amorphous particles, enriched in iron and phosphorus, only present in the cytoplasm of the *Deltaproteobacteria* bacterial partner [2]. The function of these particles is yet unknown. We investigated the microbial uptake of phosphate during AOM using $^{33}P_i$ radiotracer experiments. In our studies we used highly enriched AOM cultures originating from sediments of the Mediterranean mud volcano Isis. These sediments were enriched during 9 years of continuous cultivation and consist mainly (>95%) of ANME-2 and DSS cells as determined by CARD-FISH [3].

Radiotracer incubations on our AOM cultures lasting seven days showed an accumulation of $^{33}P_i$ tracer in the biomass and a decrease of tracer in the medium in the presence methane. In controls without methane $^{33}P_i$ uptake was minimal. In methane amended samples there was a linear correlation between sulfate reduction and the disappearance of $^{33}P_i$ radiotracer in the medium. The specific activity of $^{33}P_i$ in the medium decreased (phosphate concentration remained constant) suggesting phosphorus turnover at a significant rate of ~ 3% of the sulfate reduction rate.

Nuclear Waste disposal: from geosciences to multigenerational safety and society

BERND GRAMBOW[1] AND SOPHIE BRETESCHE[2]

[1]SUBATECH, UMR 6457 Ecole des Mines, Université de Nantes, IN2P3, 4 rue Alfred Kastler, 44307 Nantes

[2]Dept. Science Social et Gestion, Ecole des Mines de Nantes, 4 rue Alfred Kastler, 44307 Nantes

A very large quantity of highly radiotoxic nuclear waste has been accumulated worldwide in the last 30 years constituing health risks for many thousands of generations. Isolation in futur deep geological disposal facilities is considered today by national and European legislation, by governmental commissions international agencies and large parts of the scientific community as the best strategy to reduce the long term risk. Nevertheless, serious doubts remain in the public and by NGOs.

Scientific proof for the safety of long term waste isolation is provided in particular by the geosciences by detailed site characterisation, comparaison of disposal concepts to natural analogues and by ellucidating detailed process understanding for mineral dissolution, mass transfer resistance for exemple of clays, geomechanics, hydraulics of site evolution etc.

Using examples from waste form dissolution in confined space, from the geochemistry of radionuclide migration and from water transport in clays, the paper presents how scenarios for potential radionuclide release to biosphere and potential doses to future generations can be obtained. Safety analyses generally show that doses will remain always (up to millions of years) lower than today legal limits. The validity and credibility of such analyses can be increased by qualitative lines of evidence, demonstrating the safety case.

From a societal point of view there are however a certain number of questions:

1) The focus on the long term risk is based on the fact that most analyses show zero risk for the first 1000 of years. However in case of reversible disposal, the repository will remain open for more than hundreds of years, with associated risks for todays generations similar to that of typical nuclear installations. Incorrect repository closure after the end of reversibility period may increase the long term risk.
2) The meaning of risk of very low doses to thousands of generations is chalanged the societal debate on low doses in particular after the Chernobyl desaster.
3) The horizon of responsibility for thousands of generations has no paralel in any human ethics

Long-term fate and transport of fission products and actinides in geosphere

BERND GRAMBOW, G. MONTAVON, A. ABDELOUAS AND T. SUZUKI[1]

[1]SUBATECH, UMR 6457 Ecole des Mines, Université de Nantes, IN2P3, 4 rue Alfred Kastler, 44307 Nantes

Global natural distribution pattern of radionuclides and homologues elements between fluids and rock formations allow a certain classification of mobility with respect to charge/valence when considering the fate of radionuclides in geological formations.

Ion exchange and surface complexation allow prediction of mobility influencing environmental parameters for Se, Cs and I. Diffusion rates in compact clay are very low since the clay rock pores are so small that electrostatic repulsion limits the available space for anion diffusion and even certain of these “mobile” nuclides may show significant retardation. However, in much less compact systems like aquifers, fixation of sparingly soluble radionuclides on mobile clay particles provides additional transport vectors. In a shallow waste disposal site a complex relationships between the clay /radionuclide/solution system, influence of transportable organic matter, the colloid loads, size distribution and the hydrodynamics of the aquifer was observed.

An important issue is whether redox states or organic/inorganic speciation change along transport path.. In deep geologic conditions like those foreseen for high level nuclear waste disposal, very anoxic to reducing conditions are often attaint assuring very slow migration rates of actinides, Tc(IV), Se(0) etc. but even in soils, in close vicinity to the atmosphere, microbial activity may lead to fixation of low redox states of elements like Tc.

The complex interplay between radionuclide mobility influencing factors has recently been studied for Selenium in soil type environments: competition and synergies between reactivity of different mineral surfaces (clay, quartz, calcite iron hydroxide) solution composition, microbes and their influence on bioavailability.

A factor often overlooked in assessing long term radionuclide mobility is the potential irreversible entrapment of radionuclides by slow mineral/water reactions. At solid/solution equilibrium the dynamics of dissolution and precipitation is still ongoing, allowing not only adsorption on stable surfaces but as well incorporation in the sub-surface of the mineral, protecting it from release by sorption/desorption equilibrium.

Definition of a clean energy system for decontamination of acid mine waters and recovering their metal load

J.A., GRANDE[1*], M.L. DE LA TORRE[1], J.M. ANDÚJAR[1], T. VALENTE[21] AND M. SANTISTEBÁN[2]

[1]Centro de Investigación para la Ingeniería en Minería Sostenible (CIPIMS). Escuela Técnica Superior de Ingeniería. University of Huelva. Ctra. Palos de la Frontera s/n, 21819, Huelva, Spain, (*correspondence: grangil@uhu.es)

[2]CIG-R (PEst-OE/CTE/UI0697/2011) – Centro de Investigação Geológica, Ordenamento e Valorização de Recursos, Universidade do Minho, Campus de Gualtar, 4710-057 Braga, Portugal, teresav@dct.uminho.pt

Acid mine drainage (AMD) is one of the largest hydrochemical problem resulting from anthropic activity, with consequences worldwide. For this reason is understandable the importance of innovative measures for recovering rivers affected AMD. Taken in account the substantial changes in terms of European legislation on water quality, under the framework of Directive 2000/60/EC (Water Framework Directive, WFD), the proposal of remediation measures for streams affected by AMD in the period marked by the standard has become even more relevant.

The most common techniques, applying corrective measures to mitigate the process, have high costs of installation and maintenance, or poor performance. On the other hand, the cheaper approaches often cause undesirable discharges of pollutants.

The aim of the system presented in this study is to neutralise acid mine waters and recover their metal load, using energy obtained from renewable sources. With this approach, the treated water is produced without releasing emissions into the atmosphere, without using fossil fuels and at an acceptable cost. At the same time, it allows the Cu dissolved in the waters to be separated from the rest of the metal load and sulphates. Therefore, it makes possible the metal´s recovery, transforming an environmental passive into an industrial income, in an economic context in which the price of Cu reaches around 7300 US$/ton.

[2]CIG-R (PEst-OE/CTE/UI0697/2011) – Centro de Investigação Geológica, Ordenamento e Valorização de Recursos, Universidade do Minho, Campus de Gualtar, 4710-057 Braga, Portugal (teresav@dct.uminho.pt)

[3]University of Oviedo, Hydrogeophysics and NDT modeling Unit. Oviedo. Spain (pauli@uniovi.es)

The present study was performed in the Marismillas water dam, in the Iberian Pyrite Belt, SW Spain. This reservoir receives water from the Tinto River, known by its historical high levels of contamination by AMD. Additionally to soluble pollutants, sulfates and metals in the form of particulate matter have been transported for decades. Consequently, today, Marismillas is clogged by the accumulation of sulfide-rich material from the RioTinto mines.

An integrated sampling campaign was accomplished with the following objectives: i) to characterize the input waters; ii) to reveal horizons for preferential accumulation of metals, and iii) to propose a model of the clogging process.

The samples were collected in three drill cores, from the surface to the bottom. Geochemical and mineralogical analyses were performed each 10 cm.

The results indicate high average concentrations of metals and metaloids (Cu, Zn, Pb, and As > 1200 ppm). A strong accumulation of these elements (> 2000 ppm) was detected at depth 1-2 m. Geochemical trends indicate strong correlation between major elements mobilized from the source materials (sulfides and felsic host rocks). So, Fe and Al, as well as Cu and Zn are clearly associated in the sediments. Regarding mineralogy, in addition to clay minerals, the finest fraction (<2μm) is dominated by jarosite and goethite. Therefore, combining geochemistry and mineralogy allowed mapping the properties of dam, identifying major mineralogical hosts of environmental, but also economic relevant elements, such as REE.

A Second Lunar Magma Ocean?

MARION GRANGE*AND ALEXANDER NEMCHIN.

Curtin University, Department of Applied Geology, GPO box U1987, WA 6845, Perth, Australia.
*(correspondence: m.grange@curtin.edu.au)

The Lunar Magma Ocean (LMO) model is one of the key concepts in the current understanding of lunar evolution. It is used to explain a range of geological, mineralogical and chemical characteristics of the Moon, such as the presence of anorthositic crust, a reservoir enriched in incompatible elements and mare basalts. The LMO model suggests that the lunar crust, made up of Ferroan-Anorthosite (FAN), formed by segregation and floatation of plagioclase from the magma ocean, after ~75% of the initial liquid has crystallised as mafic cumulates. After ~95% solidification, the remaining liquid is enriched in incompatible elements (e.g. K, REE, P, U, Th, Zr…) and constitutes the KREEP reservoir. Although this reservoir has never been sampled as such, its existence is indicated by incompatible elements enrichment in some plutonic rocks, which are interpreted to be emplaced into the FAN crust. These rocks are also enriched in Mg and are referred to as Mg-suite. The presence of a KREEP component in this suite and the associated enrichment in incompatible elements also results in a widespread crystallisation of zircon in these rocks.

Very specific sequence of crystallisation predicted by the LMO model demands particular timing relationships between FAN, KREEP reservoir and Mg-suite rocks. However, absolute dating of FAN and Mg-suite samples reveals a significant overlap in ages that is inconsistent with the LMO model. In particular, the contradiction is highlighted by the recently obtained precise ages of (i) the oldest lunar zircon at 4417 ± 6 Ma [1], which must represent the youngest possible limit for the formation of KREEP reservoir and (ii) a sample of FAN at 4360 ± 3 Ma [2], which suggests the oldest limit for the lunar crust crystallisation.

The only way to resolve the controversy posed by chronological data is to accept the possibility of a second magma ocean on the Moon at ~4360 Ma, resulting from a massive impact and probably restricted to the near site of the Moon.

Contribution and effects of the volcanic carbon dioxide over the urban area of Naples

D. GRANIERI[1*], A. COSTA[2], G. MACEDONIO[3], M. BISSON[1] AND G. CHIODINI[3]

[1]INGV, Sezione di Pisa, Via della Faggiola 32, 56126 Pisa, Italy (*granieri@pi.ingv.it, bisson@pi.ingv.it)
[2]INGV, Sezione di Bologna, via Donato Creti 12, 40128 Bologna, Italy (antonio.costa@bo.ingv.it)
[3]INGV, Sezione di Napoli, via Diocleziano 328, 80124 Napoli, Italy (macedon@ov.ingv.it, giovanni.chiodini@ov.ingv.it)

The city of Naples is nearest to the Solfatara crater (Campi Flegrei caldera) that is a prodigious source of natural CO_2 [1]. In this study, the CO_2 plume dispersion is simulated using the DisGas code [2], under the most significant local-scale wind and hydrodynamic conditions of the atmosphere. Results showed that the western quarters of the city, as well as the inhabited area around the Solfatara, are mantled by the volcanic plume when atmospheric circulatory patterns are dominated by the common winds blowing from the sea. Under these conditions the CO_2 content in the air increases above normal values, reaching more than one thousand ppm in proximity to the Solfatara crater to a few tens of ppm several kilometres from the source (Figure 1). Simulated values satisfactory agreed with CO_2 concentrations measured by two stations inside the crater. A complete discussion of these results is presented elsewhere [3].

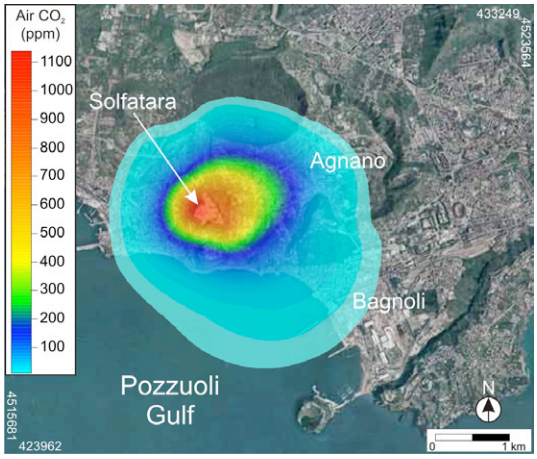

Figure 1: CO_2 plume dispersion over Naples. The concentration is expressed as values in excess of background CO_2 level.

The kinetic effects of H_2O in metasomatic and xenolith breakdown reactions

TOM GRANT[12], RALF MILKE[1], BERND WUNDER[2], LUIZ MORALES[2] AND RICHARD WIRTH[2]

[1]Campus Lankwitz, Freie Universität Berlin, Berlin 12249, Germany (tomgrant.gfz.fu@googlemail.com)
[2]GFZ, Helmholtz Centre Potsdam, Potsdam, Germany

The role of fluids, specifically water, in mineral replacement reactions has long been noted. Water is a vital catalyst as it lowers activation energies for reactions and increases solubilities of components for transport. The kinetic effects of fluids have been studied for solid-solid and solid-fluid reactions applicable to metamorphism but little attention has been paid to solid-melt reactions involved in metasomatism and xenolith breakdown in parent melts. We take the natural examples of olivine xenocryst breakdown in phonolite melt to form phlogopite rims and re-create these experimentally. Rim growth is parabolic with time, indicating diffusion limited reaction rates. No diffusion profiles are observed in the olivines or the melt suggesting transport via grain boundaries is rate limiting.

As the total water content is below the saturation threshold of the melt there should be no fluid phase in the system. However, addition of water to the melt significantly increases rates of reaction. This could be linked to changing transport porperties of rim grain boundaries at different levels of fluid saturation. We use Dual Beam (FIB + SEM) serial sectioning to observe 3D microstructures of the rims as well as TEM to determine the presence of pores in the reaction rims. The results of this show that free fluid forms in localized regions at the micron to submicron scale and that these are not well connected. The correspondence of water content in the melt with rim growth kinetics suggests that the grain boundaries become increasingly hydrated but not completely fluid saturated. This increases the transport of components through the rims, allowing faster growth rates.

The amount of fluid present in reactions of this kind will affect the rates of xenolith breakdown which are commonly used to assess residence times and ascent rates of magmas. The kinetic and transport properties of grain boundaries during melt infiltration and reaction during metasomatism will also be strongly influenced by the levels of fluid saturation, even if the bulk melt remains water-undersaturated. Understanding the affects of fluid saturation in grain boundaries is therefore vital.

Cycling of silicic acid and nitrate in the Eastern Equatorial Pacific: Insights from stable silicon and nitrogen isotopes

PATRICIA GRASSE[1]*, EVGENIA RYABENKO[1], MARK A. ALTABET[2] AND MARTIN FRANK[1]

[1]GEOMAR, Helmholtz Centre for Ocean Research, Kiel, Germany
[2]School for Marine Science and Technology, University of Massachusetts Dartmouth
(*correspondence: pgrasse@geomar.de)

We present the first direct comparison between dissolved stable silicon ($\delta^{30}Si(OH)_4$) and nitrogen ($\delta^{15}NO_3^-$) isotopes in the upwelling area off Peru to investigate the biogeochemical processes controlling nutrient cycling in one of the globally largest Oxygen Minimum Zones (OMZs). Nitrate is a generally important source of new nitrogen for phytplankton, whereas silicic acid is a key nutrient for diatoms, which dominate the phytoplankton assemblages in upwelling areas. Silicon and nitrogen isotopes in the euphotic zone of the upwelling area are mainly controlled by biological utilization during which the lighter isotopes are preferentially incorporated into the organisms. Silicon isotopes are subject to a relatively simple cycling only influenced by utilization and subsequent dissolution of diatoms. In contrast, there are additional processes exerting control the N isotope composition of dissolved nitrate including anoxic ammonium oxidation (anammox) and/or denitrification within the OMZ. Given that the water masses feeding the coastal upwelling cells originate from the suboxic zone, the surface waters near the shelf show low $\delta^{30}Si(OH)_4$ values (2‰) under strong upwelling conditions corresponding to high $\delta^{15}NO_3^-$ values (14‰). During the cruise a large mesoscale eddy was present in the study area and clearly influenced the nutrient stable isotope composition, as well as the phytoplankton community. Pronounced silicic acid limitation in the center of the eddy structure is indicated by high NO_3^-:$Si(OH)^4$ ratios (~15) leading to the highest $\delta^{30}Si(OH)_4$ values (3.7‰) accompanied by high $\delta^{15}NO_3^-$ values (16‰). The results show that both water mass mixing and remineralization processes influence the dissolved nitrogen and silicon isotope composition. Due to grazing of zooplankton and/or microbial remineralization a larger fraction of the nitrogen is recycled within the upper water column compared to silicic acid, which is more efficiently transferred to the deep waters. This is indicated by a smaller degree of utilization for nitrate in comparison to silicic acid in the study area. The combination of $\delta^{30}Si(OH)_4$ and $\delta^{15}NO_3^-$ helps to disentangle utilization and N-loss processes and better understand paleo records and.

Determination of microbial consortia and its adaptation to environmental changes in the Neo-Archaean

NATHALIE V. GRASSINEAU[1] AND EUAN G. NISBET[1]

[1]Earth Sciences Department, Royal Holloway, University of London, Egham, TW20 0EX, UK
(nathalie@gl.rhul.ac.uk)

Isotopic fingerprints in Archaean sediments track metabolic processes, and are often the best evidence of biological activity. However poor and limited preservation make reconstitution of Archaean environments from rock records very challenging. Studying multiple localities around the world for one specific period helps to create a better picture of Archaean environments for this time window, but it is still a succession of snapshots, and such models can be misleading.

This work uses three cores and coexisting stromatolitic deposits from proximal but spatially different localities to reconstitute contemporary but sedimentologically varied Archaean environments. Well preserved 2.7 to 2.65 Ga sediments from the Belingwe Greenstone Belt (Zimbabwe) have been studied. The Manjeri and Cheshire Fms, laid down in a continental basin, consist of carbon- and sulphur-rich cherts and dark shales, as well as shallow-water limestones. In carbon-rich sections in cores from the Shavi and Jimmy Members, Manjeri Fm, and stromatolite surface outcrops, the overall 39‰ range for $\delta^{13}C_{red}$ and the overall 40‰ range for $\delta^{34}S$, plus $\Delta^{33}S$, molybdenum and iron isotopic information, suggest a wide spectrum of bacterial consortia, showing adaptations to environmental changes. This allows us to map out a wide sequence of microbial/sedimentary facies in coexisting microbial consortia in evolving prokaryotic communities.

Assessment of river water quality in catchments: Impact of urbanization on particle bound pollutant fluxes

PETER GRATHWOHL*[1], MARC SCHWIENTEK[2], HERMANN RÜGNER[3] AND MICHAEL RODE[4]

[1]Eberhard Karls University of Tübingen, Hölderlinstr. 12, 72074 Tübingen, Germany. (*correspondence: grathwohl@uni-tuebingen.de)
[2]Water Earth System Science (WESS), Keplerstr. 17, 72074 Tübingen, Germany. (marc.schwientek@uni-tuebingen.de)
[3]Water Earth System Science (WESS), Keplerstr. 17, 72074 Tübingen, Germany. (h.ruegner@uni-tuebingen.de)
[4]Helmholtz Centre for Environmental Research-UFZ, Brückstr. 3a, 39114 Magdeburg, Germany. (michael.rode@ufz.de)

Transport of many urban pollutants in rivers is coupled to transport of suspended particles, potentially dominated by storm water overflows and mobilization of legacy contamination of sediments. Concentration of these pollutants depends on the mixture of “polluted” urban and “clean” background particles. In the current study, the total concentration of polycyclic aromatic hydrocarbons (PAHs), the amount of total suspended solids (TSS) and turbidity were measured on a monthly basis in water samples from 5 catchments with contrasting land use in Southwest Germany and 3 catchments in the Bode Basin in Eastern Germany over up to 1.5 years. In addition, single flood events with large changes in turbidity were sampled at high temporal resolution. Linear correlations of turbidity and TSS where obtained over all catchments investigated. From linear regressions of turbidity vs. total PAH concentrations in water, concentrations of PAHs on suspended particles were obtained. These values comprise a robust measure of the average sediment quality in a river network and may be correlated to the degree of urbanization represented by the number of inhabitants per total flux of suspended particles. The findings are promising for other particle-bound contaminant fluxes (PCBs, phosphorus, etc.) and in terms of on-line monitoring of turbidity as a proxy for pollution.

Origin of REE patterns in AMD-impacted areas

A. GRAWUNDER[1]*, S. MEISSNER[1], D. MERTEN[1], S. PAŠALIĆ[1], S. KARLSSON[2], B. ALLARD[2] AND G. BÜCHEL[1]

[1]Friedrich-Schiller-University, Jena, Germany (*correspondence: anja.grawunder@uni-jena.de)
[2]Örebro University, Örebro, Sweden

Rare earth elements (REE; La-Lu) are a group of elements with a high potential as process indicators in the system rock/soil and water. Acid mine drainage (AMD)-impacted areas often have high concentrations of REE due to low pH. Moreover, they feature with a pronounced enrichment of middle REE (MREE) a very common phenomenon which is still under debate. Different AMD-impacted sites in Europe were investigated for REE patterns and their origins. Three of them showed the typical MREE-enrichment (Fig. 1) despite different geology (shales, volcanic rocks) and water source (lake, creek, groundwater). Based on a series of pyrite samples, it was found with H_2SO_4 - batch tests that one source for MREE enrichment is the release from pyrite under acidic conditions (Fig. 1), assuming complexation with a metastable S-species [2]. An exception was Ljusnarsberg, a former Swedish Cu mining area. For this site the REE patterns were rather enriched in light REE (LREE, Fig. 1). Saturated column experiments with heap material (pH 2.6-2.7) in combination with H_2SO_4 - batch tests of abundant minerals showed that release from a biotite group member controls the REE pattern in the open pit water to a large part (Fig. 1). Concluding, these results give a new view on REE pattern development in AMD-impacted areas.

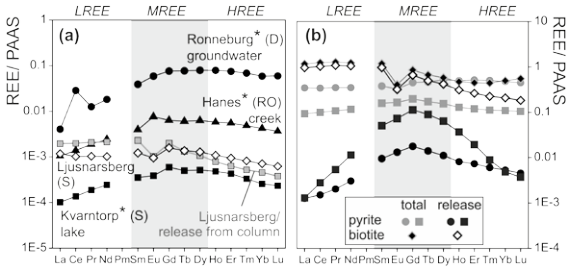

Figure 1: Examples for PAAS [1] normalised REE patterns of **(a)** AMD-impacted water (* from [2]) and effluent of column experiments with heap material of an AMD-impacted area; **(b)** total and released REE of pyrite samples [2] and biotite.

Mercury transport along the Tiber River basin (Central Italy)

J.E. GRAY[1]*, V. RIMONDI[2], P. COSTAGLIOLA[2], P. LATTANZI[3], O. VASELLI[2] AND G. PATTELLI[2]

[1]US Geological Survey, MS 973 Federal Center, Denver, USA (*correspondence: jgray@usgs.gov)
[2]Dipartimento Scienze della Terra, Università di Firenze, 50121 Firenze
[3]Dipartimento di Scienze Chimiche e Geologiche, Università di Cagliari, 09127 Cagliari

The Mt. Amiata Hg district (MAMD) was an area of significant Hg mining up to the 1980s, with a total Hg production exceeding 102,000 tons. High concentrations of Hg were found in rivers, such as the Paglia River, which drains the NE part of the MAMD. In this study, stream sediment, stream water and fish were collected from the Tiber River and its tributaries to evaluate long distance Hg transport downstream from the MAMD. Along the Tiber River, samples were collected both upstream and downstream from the confluence with Paglia River to determine any adverse affects of Hg to the Tiber River.

The highest Hg concentrations in stream sediment, water and fish were found along the Paglia River, which is most proximal to Hg mines, and along the Tiber River just below the confluence with the Paglia River. Overall, Hg generally decreased with increasing distance from the MAMD, suggesting dispersion and dilution of Hg with increasing distance from mined areas. Five sediment samples exceed the probable effect concentration for Hg of 1.06 µg/g, above which harmful effects are likely to be observed in sediment-dwelling organisms. Concentrations of stream water Hg generally correlated with sediment Hg indicating that Hg is dominantly transported as particulates. The Alviano dam, located along the Tiber River, acts as a sink for Hg, where Hg contaminated sediment is deposited.

Of the fish muscle samples collected, 17% exceeded the 0.30 μg/g (wet weight, methyl-Hg) USEPA fish muscle Hg guideline recommended to protect human health. Fish with the highest Hg concentrations were collected from the Paglia River, whereas no fish collected from the Tiber River contained Hg beyond the USEPA guideline. Lower Hg concentrations in fish in the Tiber River are a result of dispersion and dilution of Hg with increasing distance from mined areas, as well as generally low methylation of Hg on the Tiber River.

Controls on the uptake of Mg, Sr and Li in benthic foraminifera *Uvigerina peregrina*

WILLIAM R. GRAY[1*], MARIËTTE WOLTHERS[23] AND JONATHAN A. HOLMES[1]

[1]Department of Geography, University College London, UK; william.gray.09@ucl.ac.uk (*corresponding author) (j.holmes@ucl.ac.uk)
[2]Department of Chemistry, University College London, UK; (m.wolthers@ucl.ac.uk)
[3]Department of Earth Sciences-Geochemistry, Utrecht University, the Netherlands

The uptake of trace elements into benthic foraminiferal calcite is controlled by the temperature and carbonate ion saturation (ΔCO_3^{2-}) of the water in which calcification occurs. Trace element/Calcium ratios can potentially be used to elucidate past changes in bottom water temperature (BWT) and ΔCO_3^{2-}, providing the relationships between trace element uptake and environmental variables can be accurately constrained. Current *Uvigerina peregrina* trace element/Ca calibrations are predominantly based on the super-saturated waters of the North Atlantic. In order to constrain the effects of temperature and ΔCO_3^{2-} on trace element uptake, and assess the fidelity of trace element-temperature/ΔCO_3^{2-} relationships in under-saturated waters we present new core top *Uvigerina peregrina* trace element/Ca data with a focus on the under-saturated waters of the North Pacific.

Core top *Uvigerina peregrina* samples were obtained from the Bering Sea, Cascadia Basin, Gulf of California and Okhotsk Sea in the North Pacific, and the Florida Straits in the North Atlantic. The core top sites were chosen to cover a wide range of bottom water temperatures (2 to 17 ^{o}C) and carbonate ion saturation states (-10 to 135 µmol kg^{-1}). Trace element/Ca ratios were analysed by quadrupole ICP-MS. Our results reveal a significant negative relationship between test size and both Li/Ca, and Sr/Ca ratios, demonstrating an ontogenetic control on trace element uptake, possibly related to changing calcification rate. Mg/Ca, Sr/Ca, and Li/Ca ratios are significantly correlated to both BWT and ΔCO_3^{2-}, however the relationship between trace element/Ca ratios and BWT/ΔCO_3^{2-} differs in under-saturated and super-saturated waters, with Li uptake displaying a higher sensitivity to ΔCO_3^{2-} in under-saturated waters.

Magmatic and linked hydrothermal processes fractionate Mo isotopes

NICOLAS D. GREBER[1]*, ANDREA R. VOEGELIN[2], THOMAS PETTKE[1] AND THOMAS F. NÄGLER[1]

[1]Institute of Geological Sciences, University of Bern, Switzerland (*correspondence: greber@geo.unibe.ch)
[2]Departement of Geosciences and Natural Resource Management, University of Copenhagen, Denmark (andrea.voegelin@geo.ku.dk)

Molybdenum isotope ratios in the marine sedimentary record are a valuable tool for reconstructing the evolution of atmospheric oxygen and paleo-redox conditions of the oceans. However, mass-balance models are highly dependent on the characterization of the (terrestrial) Mo sources. Recent results on the Mo isotope composition of terrestrial igneous rocks [1] and molybdenites [2] show a Mo isotope variability that is larger than previously suspected for crustal rocks and minerals. Therefore, two geochemically well-understood systems, the Kos Island Arc volcano (Greece) and the porphyry Questa Mo deposit (New Mexico, USA), were investigated systematically. The magmatic evolution of the igneous rock suite from Kos was predominantly controlled by fractional crystallization. The molybdenites from the porphyry Questa Mo deposit were produced during two distinct mineralization stages, related to two hydrothermal fluid exsolutions from an increasingly fractionated magma [3].

The magma evolution from basalt to dacite on Kos is characterized by increasing δ^{98}Mo (total δ^{98}Mo range = 0.3‰) along with increasing Mo concentrations, as expected for a highly incompatible element. The δ^{98}Mo of the molybdenites from the Questa deposit ranges from -0.48‰ to +0.40‰, with a median at -0.06‰. The median δ^{98}Mo increases from first stage (-0.17‰) to late stage molybdenites (0.21‰). Based on these results we recognize three different processes that produce systematic Mo isotope fractionation between 700 and 350°C in igneous and hydrothermal environments: (a) fractional crystallization, (b) magmatic-hydrothermal fluid exsolution and (c) molybdenite precipitation.

All these processes lead to the enrichment of heavy Mo isotopes in the more evolved magma or fluid phase. This indicates that the mean Mo isotope composition of all molybdenites (δ^{98}Mo ≈ 0.4‰; [2]) reflects a maximum value for Earth`s upper crustal signature.

Multiple generations of TTG gneisses host Eoarchean supracrustals in the Innukjuak domain (Québec, Canada)

J. C. GREER[1], N. L. CATES[1], G. CARO[2] AND S. J. MOJZSIS[134*]

[1]University of Colorado, Geol. Sciences, Boulder, CO, USA
[2]CRPG- CNRS and Université de Lorraine, Nancy, France
[3]Laboratoire de Géologie de Lyon, ENS & UCBL1, France
[4]MTK, Institute for Geological and Geochemical Research, Budapest, Hungary *mojzsis@colorado.edu

The ca. 3750-3780 Ma Nuvvuagittuq supracrustal belt (NSB) in northern Québec is the best known of a dozen or so km-scale supracrustal belts (or “enclaves”) which are part of the Innukjuak domain of the northwest Superior province in Canada [1,2]. Dominantly (mafic) amphibolites and minor paragneisses in these supracrustal belts are surrounded and intruded by several generations of tonalite-trondhjemite-granodiorite (TTG) gneisses; these imparted metamorphic overprints on the enclaves beginning at ca. 3750 Ma. Previous work also documented a ca. 3650 Ma tonalitic gneiss in the core of the NSB fold belt [2; referred to here as the central tonalitic gneiss (CTG)] as well as rocks of the “Boizard suite” (Aboi), a terrane of ca. 2700 Ma granitoid gneisses that volumetrically dominate the Innukjuak domain [3]. New geochemical and U-Pb zircon geochronological data are presented for these gneisses coupled with data from a previously undated but locally significant pale granodioritic gneiss enveloping the NSB, the “Voizel suite” (Avoi; [2]).

We find that most Aboi zircons are up to ca. 3700 Ma inherited cores from multiple generations with ca. 2700 Ma igneous overgrowths. The CTG hosts mainly ca. 3650 Ma igneous cores with narrow rims. Younger zircons typically have spongy textures attributable to hydrothermal growth. Outside the NSB, Avoi rocks are the principal host for various Innukjuak domain supracrustal enclaves. Most Avoi igneous zircon cores from these localities cluster about 3550 Ma with younger metamorphic rims. Younger Avoi ages tend to be discordant. A tonalitic gniess cross-cutting amphibolites from a supracrustal belt northeast of the NSB, and within Avoi, yielded a maximum concordant zircon age of 3653±8 Ma; it may be cogenetic with the CTG. The previously unrecognized 3550 Ma Avoi igneous event is recorded as metamorphic zircon growth within many of the NSB lithologies [4], particularly in metasedimentary units and the CTG.

The oxygen isotope excess $\Delta(^{17}O)$ of marine nitrous oxide

IMKE GREFE AND JAN KAISER

University of East Anglia, School of Environmental Sciences, NR4 9TJ Norwich, UK (i.grefe@uea.ac.uk, j.kaiser@uea.ac.uk)

The small ^{17}O isotope excess $\Delta(^{17}O)$ of atmospheric nitrous oxide (N_2O) of (0.9±0.1) ‰ (vs. VSMOW) is regarded to be mainly a result of chemical in-situ production in the troposphere and the stratosphere. These mechanisms only have a negligible contribution to the global N_2O mass budget, but do significantly affect the ^{17}O excess of atmospheric N_2O because of the high ^{17}O excess of the species involved (NO_y, O_3).

However, Kaiser *et al*. (2004) suggested that the main biological N_2O sources (denitrification, nitrification) can also have an influence on the $\Delta(^{17}O)$ value of atmospheric N_2O. Therefore, soils and ocean should also be considered as a source of the ^{17}O excess in atmospheric N_2O.

We present depth-resolved measurements of the ^{17}O excess in dissolved N_2O from the Atlantic Ocean, the Scotia Sea and the Weddell Sea. In the temperate, subtropical and tropical surface Atlantic Ocean, we observed $\Delta(^{17}O)$ values of up to 1.5 ‰ relative to N_20 in air. Values above the tropospheric mean value of 0.9 ‰ were observed down to 300 m depth. This means that oceanic N_2O from these regions contributes to the atmospheric ^{17}O excess. In polar regions and in the deep Atlantic Ocean, the isotope excess was between 0 and 0.9 ‰. Irrespective of the oceanic net N_2O mass flux, this would lead to a net reduction of the atmospheric ^{17}O excess.

These results show that oceanic N_2O emissions need to be taken into account for tropospheric N_2O isotope budget calculations. However, further measurements in other ocean regions are needed before the net effect of oceanic N_2O on the ^{17}O excess can be established.

A 100% renewable power system in Europe – let the weather decide!

MARTIN O.W. GREINER[1], GORM ANDRESEN[1], ROLANDO RODRIGUEZ[1], SARAH BECKER[1], ANDERS SONDERGAARD[1], TUE JENSEN[1] AND TIMO ZEYER[1]

[1]Department of Engineering and Department of Mathematics, Aarhus University, Ny Munkegard 120, DK-8000 Aarhus, Denmark, (greiner@imf.au.dk)

Todays overall macro energy system based on fossil and nuclear resources will transform into a future system dominantly relying on fluctuating renewable resources. At the moment it is not really clear what will be the best transitional pathway between the current and the future energy system. In this respect it makes sense to think backwards, which means in a first step to get a good functional understanding of fully renewable energy systems and then in a second step bridge from there to todays energy system. Based on state-of-the-art high-resolution meteorological and electrical load data, simple spatio-temporal modelling, time-series analysis and the physics of complex networks, fundamental properties of a fully renewable pan-European power system are determined. Amongst such characteristics are the optimal mix of wind and solar power generation, the optimal combination of storage and balancing, the optimal extension of the transmission network, as well as the optimal ramp down of fossil and nuclear power generation during the transitional phase. These results indicate that the pathways into future energy systems will be driven by an optimal systemic combination of technologies, and that economy and markets have to follow technology

A-type granites of Prydz Bay, Antarctica: Products of melting of a two-component granulite crust?

E.S. GREW[1]*, R. MAAS[2], A.G. CHRISTY[3], C.J. CARSON[4], M.G. YATES[1] AND S.D. BOGER[2]

[1]School of Earth and Climate Sciences, Univ Maine, Orono, ME 04469, USA (correspondence: esgrew@maine.edu)
[2]School of Earth Sciences, Univ Melbourne, Parkville, 3010, Australia (maasr@unimelb.edu.au)
[3]Centre for Advanced Microscopy, Australian National University, Canberra, 0200, Australia
[4]Geoscience Australia, PO Box 378, Canberra, 2601, Australia (chris.carson@ga.gov.au)

Cambrian (519-494 Ma) A-type granites, cropping out over ~130 km along the Prydz Bay coast are structurally, texturally and mineralogically diverse. Intrusions in the SW carry hornblende, chevkinite-perrierite, allanite and titanite; those in the NE carry garnet and monazite. Fluorite is widespread; oxides include magnetite, hercynite, ilmenite and, locally, högbomite and hematite. The granites (SiO_2 59.8-77.7%, ASI 0.95-1.19) are high in Fe, alkalis and K_2O/Na_2O (1.1-5.2), Ga/Al, HFSE and REE, with remarkably high Zr (322-1625 ppm), LREE (Ce 107-2101 ppm) and Th (up to 878 ppm Th; Th/U = 28-142). REE fractionation is strong (La_N/Yb_N 36-454), being more pronounced in the NE. Sr-Nd-Hf isotope ratios ($^{87}Sr/^{86}Sr$ 0.708- 0.726, ε_{Nd} –8 to –13, ε_{Hf} –4 to –14) and Nd-Hf model ages are consistent with magma sources in equivalents of the exposed Neoproterozoic ortho- and paragneisses. High $^{207}Pb/^{204}Pb_t$ (15.71-15.77) and low $^{206}Pb/^{204}Pb_t$ (17.7-18.16) indicate Pb isotope evolution in a high-μ reservoir since ~2.5 Ga, followed by a low-μ stage for several 100 Ma prior to granite formation. A ~1 Ga granulite-facies event recorded in Prydz Bay gneisses could explain the drop in U/Pb. Co-variation of REE-Y and Sr-Nd isotopes in the granites suggests at least two crustal components in the magma source. Component 1 (ε_{Nd} ~ –13, $^{87}Sr/^{86}Sr$ >0.72) produced melts with strong HREE fractionation and Y depletion (major residual garnet), represented by 3 of the 4 NE intrusions. Component 2 (ε_{Nd} –7 to –10, $^{87}Sr/^{86}Sr$ 0.708-0.714) produced melts with lower Gd_N/Yb_N (less residual garnet), represented by the SW intrusions. Both components contain the high-207/low-206 isotope signature inferred to be linked to the regional ~ 1 Ga granulite-facies gneisses. Since these source rocks are residual, dehydrated gneisses, it is inferred that temperatures well above the wet solidus were required for melting at ~0.5 Ga, a condition we suggest was inherited from the pre-collision thermal structure of the lithosphere in Prydz Bay.

'Kimberlitic' zircons from Paleproterozoic Kimozero kimberlites (Karelia): Mineralogy, geochemistry and U-Pb geochronology

J.G. GRIBAN[12]*, A.V. SAMSONOV[1], E.B. SALNIKOVA[3], AND E. N. LEPEHINA[4]

[1]IGEM RAS, Moscow, Russia, (*correspondence: julie.griban@gmail.com)
[2]Lomonosov Moscow State University, Russia,
[3]IPGG RAS, St. Petersberg, Russia,
[4]VSEGEI RAS, St. Petersberg, Russia

The origin of xenocrystic zircons from the Paleoproterozoic Kimozero kimberlite is in discussion. The kimberlite is located in the Eastern part of the Karelian craton among the Middle Paleoproterozoic (2.1-2.0 Ga) Zaonezhskaya supracrustal sequence of the Onega trough.

Most zircons separated from the kimberlitic breccias are large (up to 1000 μm) isometric, soccer-ball shape crystals and correspond to the description of kimberlitic zircons [1]. There are two general types of inner structure of the zircons: homogenous and oscillatory zoned.

Oscillatory zoned zircons represented as cores in zircon grains. They have U-Pb isotopic age around 2.4 Ga. Their geochemical characteristics suggesting they are relicts of magmatic zircons formed from depleted, possibly, basaltic source.

The two genetic groups of homogenous zircons from Kimozero kimberlites were revealed. The zircons of Ist group are extremely depleted by all trace elements such as REE, U, Th, P, Ti, Li and have the age of 1986±4 Ma. Their geochemical characteristics are comparable with kimberlitic zircon megacrysts described for various kimberlites all over the world. Thus, the zircons are thought to be engaged from a mantle Kimozero kimberlite source. The obtained age for the Kimozero kimberlitic zircons is very close to the age of the alkaline-ultrabasic carbonatite magmatism in the North-Western part of the Karelian craton 1999 ± 5 Ma [2]. The zircons of IInd group are also depleted by U, Th, REE, but they are enriched in Hf, P, Li, Ti and have an older U-Pb age of 2406±6 Ma. Geochemical features of the zircons of IInd group are typical for lower crustal xenoliths [3]. Their crystallization was probably related with granulite metamorphism occurring 2.4-2.5 Ga ago as part of large-scale intense thermal reworking of lower crust by rising plume under the eastern part of the Baltic shield.

Diamonds have been reported from the mantle parts of ophiolites for ≥30 years, but have been widely dismissed as contaminants, because their morphology (octahedral + planar cubic faces) and isotopically light C ($\delta^{13}C$ to -27) are unlike kimberlitic diamonds. However, diamonds have now been found *in situ* in the chromitites and peridotites of many ophiolites in Tibet (Yarlung-Zangbo suture) and the Polar Urals [1]. LA-ICPMS analyses of the diamonds show LREE-enriched trace-element patterns parallel to those of kimberlitic fibrous diamonds. The patterns are distinct from those of synthetic diamonds, and the ophiolitic diamonds thus appear to be natural. However, there are also striking differences from cratonic diamonds: strong negative anomalies in Sr, Sm, Eu and Yb; extremely low Fe; high Ta and Mn-Ni-Co (present as alloy microinclusions). The diamonds are accompanied by a range of alloys, native metals, carbides and silicides; these and the low Sm-Eu imply very low fO_2. High-Si rutile and coesite pseudomorphs after stishovite suggest pressures ≥10 GPa. Finally, some peridotites yield whole-rock Re-Os T_{RD} ages back to 3.4 Ga [2]. The presence of these super-reducing ultra-high pressure (SuR-UHP) assemblages in large ultramafic massifs raises important questions: Are the SuR-UHP rocks widespread at depth, and brought up along sutures, or are they related to the subduction process? Do the old T_{RD} ages indicate an origin as subducted SCLM, or does such ancient depleted material exist in the "convecting mantle"? How did the massifs come up rapidly enough to avoid graphitizing the diamonds? These SuR-UHP massifs carry unique information on the tectonics of collision zones, mantle convection processes, and the physical and chemical makeup of the deep mantle.

Micro-scale carbonation of single facets of Portlandite

GRAHAM GRIFFITHS[1], DAVID CHERNS[2], RICHARD BALL[3], GEOFF ALLEN AND ADEL EL-TURKI

[1]g.griffiths@bristol.ac.uk
[2]D.Cherns@bristol.ac.uk
[3]R.J.Ball@bath.ac.uk

The carbonation of portlandite to calcite is considered a key adhesive process in almost all historic mortars, right up until the beginning of the 20th century. Even in the present day, so-called "high-calcium cements", which rely on this reaction, are still widely used for cosmetic and conservation purposes. While the precursor hydroxide and the consequent carbonate have previously been extensively characterized, a subject of much current interest is the physical manifestation of the conversion between the two, i.e. by what mechanism does the reaction get from crystalline portlandite to crystalline calcite?

To study this reaction in-situ and at very early stages, it is necessary to generate pristine calcium hydroxide surfaces on which to perform subsequent reactions; crystalline facets of portlandite as a reactive substrate is key to isolating the reaction path of carbonation and any intermediates that may occur. To provide these facets, artificial specimens of portlandite were generated by precipitation from aqueous solution by way of a novel nitrogen-drying cell. Following exposures to pure CO_2 lasting from 1 to 48 hours, a new phase was seen growing on the portlandite surfaces, characterized using scanning electron microscopy. This was subsequently identified as highly voluminous calcium carbonate "nodules" using transmission electron microscopy, small angle electron diffraction and Raman spectroscopy. While the carbonate Raman spectra ultimately tended towards calcite, spectra taken with the first one to three hours were closer to that of an amorphous phase of calcium carbonate. In addition to its low crystallinity, this new phase was seen, using TEM, to be highly expansive; generating large volumes of carbonate with the consumption of relatively little hydroxide. This is believed to be a consequence of the sequestration of water within the rapidly formed nodules, which would then gradually stabilize to calcite with time or heating.

Simulated exposure of crude oil to sunlight and characterization using atmospheric pressure photoionization fourier transform ion cyclotron resonance mass spectrometry

MATTHEW T. GRIFFITHS[1], RAFFAELLO DA CAMPO[1], PETER B. O'CONNOR[1] AND MARK P. BARROW[1]*

[1]Department of Chemistry, University of Warwick, Coventry, CV4 7AL, United Kingdom (*correspondence: M.P.Barrow@warwick.ac.uk)

Petroleum is a vital resource and is likely to remain so for the foreseeable future, providing the primary basis of most transportation energy and being the precursor for many materials. Due to its finite availability, production of petroleum is in decline, although worldwide consumption continues to increase. Lower quality sources of crude oil have become increasingly exploited as a result. Releases of petroleum into the environment can occur, whether arising from natural seepage or from human activity, and it is known that natural processes can influence the chemical composition of these complex mixtures. The effects of solar radiation have been targeted for the following study.

A crude oil sample was divided into three allocations: one sample was exposed to ultraviolet light, the second sample was exposed to light from a SoLux lamp which mimics sunlight, and a third sample served as a control. After more than a month of exposure, the chemical compositions were determined and compared using a 12 T Fourier transform ion cyclotron resonance mass spectrometer.

Atmospheric pressure photoionization was selected as the ionization method due to its suitability for studying less polar components which may be present within crude oils, such as sulfur-containing compounds and hydrocarbons which do not incorporate any heteroatoms. The thousands of components observed were categorized according to heteroatom content, carbon number, and double bond equivalents, and profiles for each sample could be created. It was found that specific heteroatom classes more readily degraded, accompanied by an increase in oxygen-containing compound classes. The findings contribute to a better understanding of changes to the chemical composition of crude oil in the environment and possible changes in toxicity.

The behaviour of submicron inclusions during host deformation

T. A GRIFFITHS[1]*, G. HABLER[1], R. ABART[1] AND D. RHEDE[2]

[1]University of Vienna, Althanstrasse 14, 1090 Vienna, Austria (*correspondence: th.griffiths@univie.ac.at)

[2]GFZ Potsdam, Telegrafenberg C 121, D-14473 Potsdam, Germany (rhede@gfz-potsdam.de)

Both brittle and plastic deformation strongly influence the location, rates and mechanisms of material transport in the earth's interior. Mineral reactions and diffusion can be controlled by deformation, but in turn contribute to its localisation. We investigate the mechanisms of interaction between deformation and chemical reaction in the context of re-equilibration of inclusions in a deforming host mineral.

Permian pegmatite garnets from the Koralpe, eastern Alps, contain numerous submicron sized inclusions. The pegmatitic assemblage was affected by deformation under eclogite facies conditions during the Cretaceous tectono-metamorphic event. The meta-pegmatite garnet deformed crystal-plastically at this metamorphic stage [1].

Trails of inclusions crosscutting the garnet have a coarser grain size (1-10μm Ø) than inclusions outside the trails. In 10-40μm wide zones flanking the inclusion trails the original $\leq$ 1μm sized inclusions are absent, defining bleaching zones.

FEG-microprobe data showed that it is possible to form the microstructure isochemically. However, some trails were also found where inclusions have coarsened non-isochemically. In both cases no change in garnet major element composition was observed.

From their microstructural characteristics it is inferred that the trails formed at sites of healed brittle cracks. Garnet deformation has been mapped using EBSD and correlates with re-equilibration microstructures. Bleaching zones are associated with systematic very low angle lattice rotations of garnet. Additionally, lattice rotations of up to 10° occurred adjacent to already coarsened inclusions.

The new microstructural, microchemical and textural data document several different interactions between material transport, crystallization and deformation processes which contribute to the final microstructure. TEM investigations provide the opportunity to examine the types of defects present in order to help determine the mechanisms through which chemical and mechanical processes have interacted on the nanoscale.

First investigations of IO, BrO, and NO_2 summer atmospheric levels at a coastal East Antarctic site using mode-locked cavity enhanced absorption spectroscopy

ROBERTO GRILLI[1], GUILLAUME MÉJEAN[1], MICHEL LEGRAND[2], SUZANNE PREUNKERT[2] AND DANIELE ROMANINI[1]

[1]Laboratoire Interdisciplinaire de Physique (LIPhy) UMR 5588, Grenoble, France.

[2]Laboratoire de Glaciologie et Géophysique de l'Environnement (LGGE) UMR 5183, Grenoble, France.

The detection of highly chemical reactive halogenated species, such as BrO and IO represents a challenge for analytical techniques due to their short lifetime and very low abundance. The ability to take part to oxidative processes, such as the oxidation of dimethyl sulfide (DMS) and Mercury, increases the interest of the atmospheric community to better understand their role in the atmosphere and mainly in the Antarctica boundary layer where information from the polar ice cores, unique archive of climate proxies, can be retrieved. Detection of part per trillion (pptv, $1{:}10^{12}$) levels of BrO and IO radicals can be performed by probing rotationally structured electronic transitions in the near-UV employing mode-locked cavity-enhanced absorption spectroscopy (ML-CEAS). The technique is based on the injection of a broadband femtosecond laser into an optical resonator. The robust and transportable spectrometer provides shot-noise limited measurements for as long as 10 minutes, reaching detection limits of 0.04, 2, 10 and 200 ppt (2σ) for IO, BrO, NO_2 and H_2CO, respectively. The results of a field campaign at Dumont d'Urville Station in Antarctica during the austral summer 2011/12 highlight the differences in the oxidative capacity of the atmospheric boundary layer at coastal Antarctic sites, with the halogen chemistry being promoted to the West and the OH and NO_x chemistry on the East (Grilli *et al*, GRL, 40, 1-6, 2013).

Inclusions in halite – evidence of mixing of evaporite xenoliths and kimberlites of Udachnaya-East pipe (Siberia)

S.N. GRISHINA

V.S. Sobolev Institute of Geology and Mineralogy, 630090 Novosibirsk, Russia (correspondence: grishina@igm.nsc.ru)

Unknown compositional features of kimberlite magma, notably highly elevated alkalies and chlorine (up to 6 wt.%) have been declared in Udachnaya-East kimberlites [1]. These data are controversial and one question of debates is origin of chloride-carbonate segregations in unserprntinized kimberlite. It was supposed, that segregations represent pools of residual liquids and thus provide a new insights into composition of the kimberlite magma. Crustal assimilation is the alternative hypothesis and was considered theoretically [2]. We tried to use inclusion data as a new approach to clarify the origin of chloride-bearing segregations and the reasons for high chlorine content of kimberlites.

Part of chloride xenoliths in Udachnaya-East kimberlites are disagregated and extensively altered to chloride-carbonate composition along the fractures and xenoliths boundaries. Transition from pervasive to no alteration xenoliths is correspondent to carbonate-rich and carbonate-free ones. Texture and inclusions of carbonate-free xenoliths are similar to pyrometamorphic evaporates [3]. Chloride-carbonate zones have distinctive textural features indicative of partial melting. The interaction between chlorides and kimberlites reveals by occurence of natrocarbonatite-bearing inclusions along the fractures and boundaries both inside xenoliths and in kimberlite groundmass.

Chloride-carbonate segregations formed as a result of crystallisation of contaminated kimberlite magma in disagregated chloride xenoliths. High chlorine content of studied kimberlites reflect syn-eruptive contamination.

Emerald mineralization at the Anuri prospect, Nunavut, Canada

L.A. GROAT[1], A.A. BRAND[1] AND P. KLEESPIES[2]

[1]University of British Columbia, Vancouver BC V6T 1Z4, Canada (*correspondence: groat@mail.ubc.ca)
[2]North Country Gold Corp., Edmonton AB T6E 5V8, Canada

Emerald has been identified in 7 intervals from 3 drill holes at the Anuri Au and Ag prospect which is located ~410 km N of Rankin Inlet in Nunavut. The prospect is within the Committee Bay Greenstone Belt, which forms part of the Rae domain of the western Churchill province. The emerald occurs in rocks of the Neoarchean volcano-sedimentary Prince Albert Group, primarily in an altered komatiite with a texturally and mineralogically variable matrix of biotite, actinolite, plagioclase, pyrite and occasional quartz, calcite, and accessory minerals such as apatite, titanite, rutile, chalcopyrite and molybdenite. The emerald (and colorless beryl) can occur in quartz veins, at contacts, and potentially as a hydrothermal overprint. Electron probe microanalysis shows that the dominant chromophore is Cr (with essentially no V), with a maximum content of 2.62 wt% Cr_2O_3 or 0.20 Cr *pfu*. The emerald also contains unusually high concentrations of Na (maximum 2.66 wt.% Na_2O, or 0.49 Na *pfu*), Mg (to 3.41 wt.% MgO, or 0.48 Mg *pfu*), and Fe (up to 1.99 wt.% FeO, or 0.16 Fe *pfu*). The source of the Be is likely a nearby 2718 Ma tonalite [1] which intrudes the komatiites.

Long range transport of volcanic aerosols: The Eyjafjallajökull plume 2010

B.GROBETY[1]*, M. MEIER[1], C. BOTTER[1], K. WEBER[2], C. FISCHER[2], A. VOGEL[2], E. GOLDENBERG[3] AND R. GIERE[3]

[1]Department of Geosciences, Univ. of Fribourg, Switzerland (*correspondence: bernard.grobety@unifr.ch)
[2]Laboratory for Environmental Measurement Techniques, University of Applied Sciences, Duesseldorf, Germany
[3]Institute of Geosciences, Univ. of Freiburg, Germany

The plume of the Eyjafjallajökull 2010 and its transport into European airspace gave the possibility to study how the physico-chemical properties of a volcanic aerosol are affected by long-range transport. We compared the mineralogical composition and the morphology of particles of samples of resuspended ash collected in Iceland with samples taken from an airplane, which crossed the plume over the Dutch-German border and ground samples from the town of Freiburg im Breisgau and the Vosges Mountains. A clear change in mineralogy and morphology could be observed between airborne samples taken close to the volcano and after long range transport. The ground and airborne samples taken in and over Germany are impoverished in olivine, clinopyroxene and plagioclase phaenocrysts compared with Icelandic samples. The loss of these phaenocrysts is a consequence of the difference in density between the volcanic glass and the mafic crystals. The aspect ratio of the particles changes also during transport. Particles with high aspect ratio (>2.5) are almost absent in the plume over Europe. Possible explanation is the higher specific surface of such particles, which will enhance the tendency of aggregation. Average physical properties (melting point, hardness) of the plume particles relevant for air traffic security after prolonged transport are thus clearly different from the one close to the emission point. When assessing the societal and environmental impact of a volcanic plume these continuous physico-chemical changes will ultimately have to be taken into account.

The role of crustal assimilation on the oxidation state of arc magmas

S.B. GROCKE[12]*, E. COTTRELL[1], S.L. DE SILVA[2], B.J. ANDREWS[1] AND K.A. KELLEY[3]

[1]Smithsonian Institution, NMNH, DC 20560, USA (*correspondence: grockes@geo.oregonstate.edu)
[2]College of Earth, Ocean, and Atmospheric Sciences, Oregon State University, OR 97331, USA
[3]Graduate School of Oceanography, University of Rhode Island, Narragansett Bay Campus, RI 20882, USA

Oxygen fugacity (fO_2) governs magmatic evolution, phase assemblage, and gas speciation. Magmas erupted in volcanic arcs tend to be several orders of magnitude more oxidized than those at mid-ocean ridges, however the processes that lead to oxidation have not been identified. Here, we explore two mechanisms that may influence the fO_2 recorded by subduction-related volcanic rocks: 1) post- or syn-eruptive alteration, and 2) assimilation of continental crust. We use several proxies to estimate the fO_2 recorded by lavas, pumice and scoria erupted from the Central Volcanic Zone of the Andes: 1) whole rock $Fe^{3+}/\Sigma Fe$ ratios, 2) $Fe^{3+}/\Sigma Fe$ ratios in quartz- and olivine-hosted melt inclusions using micro X-ray absorption near-edge structure (XANES) spectroscopy, and 3) magnetite-ilmenite oxybarometry. Samples span a range of crustal contribution, as indicated by their radiogenic isotope compositions ($^{87}Sr/^{86}Sr$ = 0.705-0.712), and cover the full suite of magma compositions erupted during the Neogene history of the arc (52 - 74 wt.% SiO_2). $Fe^{3+}/\Sigma Fe$ ratios range from 20-80% in these samples. This full range is observed for all stages of magmatic differentiation (basaltic andesites to rhyolites), all extents of crustal assimilation (30-100%), and all types of eruptive product (lavas, pumice and scoria). Comparison of the fO_2 calculated from bulk $Fe^{3+}/\Sigma Fe$ ratios (post-eruptive) versus that calculated from Fe-Ti oxides or melt inclusion $Fe^{3+}/\Sigma Fe$ ratios (pre-eruptive), enables us to quantify the effect of post- or syn-eruptive alteration. Some sample suites show excellent agreement between the three techniques employed in this study. In other cases, where pumices show evidence of alteration in hand-sample, the fO_2 recorded by bulk $Fe^{3+}/\Sigma Fe$ ratios is two orders of magnitude more oxidized than corresponding ratios from melt inclusions or oxybarometry, suggesting modification of whole rock $Fe^{3+}/\Sigma Fe$ ratios by post-eruptive processes. Our work demonstrates that care must be taken when exclusively relying on bulk techniques to determine magmatic fO_2, as whole rock may be subjected to post-emplacement oxidation. Moreover, our results show that neither crustal assimilation nor crystal fractionation systematically oxidize bulk continental arc magmas.

Fluid-mineral interactions of CO_2/O_2, NaCl-brines and siderite-ankerite-mixtures at geological CO_2-storage conditions

J. GRÖGER-TRAMPE[1*], S. WALDMANN[1], T. NOWAK[1] AND C. OSTERTAG-HENNING[1]

[1]Federal Institute for Geosciences and Natural Resources (BGR), D-30655 Hannover, Germany (*correspondence: jgroeger@uni-bremen.de)

An option considered for the geological storage of CO_2 in Germany is the injection into deep saline aquifers. The geochemical effects triggered by impurities or so called incidental associated substances in CO_2 streams are an issue for mineral trapping of CO_2. The carbonates siderite and ankerite are possible sequestration products of mineral trapping of CO_2 or can already initially occur in the target formations.

In the presented set of experiments the effect of O_2 in the CO_2 stream on siderite-ankerite-mixtures will be investigated. These experiments are conducted in static Au-Ti-cells at 20 MPa and 353 K with CO_2 containing 4 mol% O_2. Saline groundwater is simulated by using a 2.7 mol/kgW NaCl-brine. Solution sampling during the the experiment is performed to monitor changes in the solution composition and thus mineral dissolution and precipitation reactions. First results of a reference experiment without the addition of O_2 (to be compared with the experiment containing O_2) show the expected dissolution of the siderite-ankerite-mixture (release of Ca, Mg, Fe and Mn). During the further course of the experiment a decrease of Fe- und Mn-concentrations indicates the formation of a new mineral phase, e.g. a Mn-rich siderite. Scanning-electron-microscopy (SEM) supported this assumption by revealing Fe- and Mn-rich precipitates on the mineral surfaces which were likely formed during the experiment. This and other assumptions will be further tested by deploying isotopically labeled CO_2 in upcoming experiments.

"Garnet signature" systematics and the structure of oceanic lithosphere

CHRISTOPHER J. GROSE[1] AND JUAN C. AFONSO[1]

[1]Department of Earth and Planetary Sciences, CCFS/GEMOC, Macquarie University, North Ryde, Sydney, NSW 2109, Australia.

Humphreys and Niu [1] showed that a geochemical database of 115 volcanic islands revealed trends in elemental systematics following the thickness of oceanic lithosphere. After performing corrections to lithospheric age estimates for volcanic islands we find that the trend with age is substantially more apparent. Specifically, we focus on La/Sm and Sm/Yb systematics, elevated values of which are thought to be a function of the presence of garnet in the melt source. The trend is not a simple function of lithospheric thickness. Values of these ratios are low for young ages (<15 Ma) and abruptly jump to a higher value which is constant over older seafloor.

To explain this structure, we combining a new thermal plate model of the oceanic lithosphere with a thermodynamic assessment of garnet stability to estimate relative values of La/Sm and Sm/Yb as a function of lithospheric age. We hypothesize that the transition to high La/Sm and Sm/Yb at ~15 Ma occurs because the LAB intersects the garnet stability field at ~50 km depth at this age. Models are in excellent agreement with observations.

Effects of nutrients on compound specific carbon fixation in phytoplankton

J. GROSSE[1*] AND H.T.S. BOSCHKER[1]

[1]Royal Netherlands Institute for Sea Research, PO Box 40, Yerseke, The Netherlands. julia.grosse@nioz.nl
([*]presenting author)

The coastal waters of the North Sea have been affected by eutrophication over the past decades and subsequent efforts to reduce riverine nutrient loads resulted in a major shift in N:P:Si nutrient ratios. The consequent changes in the limiting resource can alter the biochemical composition of phytoplankton and translate through the food web, affecting its structure, functioning, and consequently the carrying capacity of an ecosystem.

Stable isotope tracers are widely used to estimate primary production in many ecosystems. However, beyond total carbon uptake rates limited emphasis is given to investigate into which of the major cellular compounds (amino acids, fatty acids, carbohydrates and DNA/RNA) the fixed carbon is allocated. Since all these compounds have different C:N:P requirements resource limitations should affect their biosynthesis differently.

We combine GC-c-IRMS and LC-IRMS approaches to trace stable isotope incorporation into major cellular components, such as amino acids, fatty acids and carbohydrates, and determine their concentrations and biosynthesis rates. We applied these methods to stations in the North Sea, where different nutrients are limiting.

The contributions of macromolecules to total biomass as well as their synthesis rates differ substantially between stations and the phytoplankton communities respond differently to nutrient additions by re-allocating fixed carbon to other macromolecules on short timescales (24 hours). Though still preliminary, we hope that this work will allow us to infer changes in phytoplankton stoichiometry and consequent food web changes.

Geochemistry of organic matter from Lower Ordovician Dictyonema Shale (Podlasie Depression, NE Poland)

IZABELLA GROTEK, EWA KLIMUSZKO, STANISŁAW WOLKOWICZ* AND JERZY MIECZNIK.

PGI-NRI, 4 Rakowiecka, 00-975 Warsaw, Poland (stanisław.wolkowicz@pgi.gov.pl)

Lower Ordovician Dictyonema Shale occur in the Podlasie Depression (NE Poland). The succession comprises from about a dozen cm to 4.0 m (2.7 m at the average) of black claystones passing gradually upwards into the brownish ones. The rocks display U-V-Mo mineralization (black shale type).

20 samples were covered by geochemical studies, including TOC, bitumen fractions, saturated hydrocarbons, aromatic hydrocarbons. Moreover, vitrinite reflectance measurements and maturity calculations were made on vitrinite-like matter.

TOC content ranges from 3,86 do 11,5% which shows shale samples also show good to very good hydrocarbon generating potential of the studied samples. This is confirmed by generation of significant amounts of hydrocarbons, ranging from 450 do 2,860 ppm. The share of hydrocarbons in bitumens ranges from 11% to 36,6%, being lower than that of asphaltenes and resins. The amounts of aromatic hydrocarbons predominate over those of the saturated ones. The coefficient of migration is low (from 0.002 to 0.013), showing that labile components are syngenetic with sediment. Analysis of n-alkanes indicated that the organic matter is here of the sapropel type. Detailed analysis of compounds of the terpane group showed low level of maturation of organic matter. This is confirmed by results of measurements of thermal maturation of authigenic organic components. Average vitrinite reflectance values range from 0,46 to 0,61% Ro, being not related to depth of burial of these rocks. The obtained data indicate low temperature diagenesis (of the order of 50-800C at the most).

Lower Ordovician Dictyonema Shale series are rich in solid organic matter and may be treated as very good parent rocks for hydrocarbon generation. At the same time they are rich in labile components. The organic matter is of marine origin and represents products of decay of algae and bacteria. Degree of its alteration is low, corresponding to early stage of oil window. Therefore, these rocks and the overlaying ones do not appear promising as a target in search for shale gas reserves.

Resolving the gap between laboratory and field rates of weathering

GRUBER, C.[1], ZHU, C.[2], GEORG, B.R.[3] AND GANOR, J.[1]

[1]Department of Geological and Environmental Sciences, Ben-Gurion University of the Negev, Israel, (*correspondence: chengrub@post.bgu.ac.il)
[2]Department of Geological Sciences, Indiana University, USA
[3]Water Quality center, Trent University, Canda

The rate of minerals' weathering is a key factor in many environmental problems such as the relationship between silicate weathering and global climate over geological timescales, the availability of inorganic nutrients in soils, geological carbon sequestration, global geochemical cycles, and the distribution of porosity and permeability in hydrocarbon reservoir rocks [1]. Weathering rates of silicate minerals observed in the lab are up to five orders of magnitude higher than those inferred from field studies. The many differences between experimental conditions in the lab and natural conditions in the field have been thoroughly discussed in previous studies, but the gap was not fully resolved.

This study is using a novel method to determine dissolution rates in a single point batch experiment by measuring the change of silicon stable isotopes ratio of a spiked solution with time. The silicon isotope ratio method is used in the present study to measure weathering rates of feldspar under ambient temperature and circum neutral pH [2]. It is for the first time that albite dissolution rate (or any silicate mineral) is described as a function of deviation from equilibrium under ambient temperature and circum neutral pH. The new experimental data confirm the extrapolation of high temperature data and numerical modeling exercise [3,4,5], and fully resolve the gap between lab measurements and field estimates. The agreement between the confirmed rate law and the field data indicates that the extensive debate on the gap reflects the so far inability to measure the dissolution rates under typical field conditions, using standard laboratory experiments.

Linkage between gold mineralization and hydrocarbon accumulation in the Youjiang basin, South China: Petrographic evidence

X.X. GU[1], Y.M. ZHANG[1], C.Y. WU[1], B.H. LI[2], S.Y. DONG[2] AND C.J. XUE[1]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing 100083, P.R. China (bzzym@163.com)

[2]College of Earth Sciences, Chengdu University of Technology, China

The Carlin-type gold deposits and paleo-oil reservoirs in the Youjiang basin, South China spatially show close association, suggesting a genetic linkage between gold mineralization and hydrocarbon accumulation. Petrographic studies show that bitumen in the gold deposits is commonly present as a migrated hydrocarbon product in mineralized rocks but is absent in barren sedimentary host rocks. Bitumen dispersed in ores is closely associated and/or intergrown with ore-stage hydrothermal minerals. Bitumen occurring in hydrothermal veins and veinlets is paragenetically associated with pre-, syn-, and post-ore stage mineral assemblages. These observations suggest an intimate relationship between bitumen precipitation and gold mineralization. In the paleo-oil reservoirs, bitumen occurring with calcite is typically concentrated along pore/vein centers and along the wall of pores and fractures, indicating approximately coeval precipitation. Fluid inclusion studies show that aqueous inclusions, hydrocarbon- and CO_2-rich inclusions are dominant in the syn- and post-ore stage quartz and calcite, indicating that the ore fluid consisted of an aqueous solution and an immiscible hydrocarbon phase. In the paleo-oil reservoirs, similar types of inclusions including liquid C_2H_6, vapor CH_4, CH_4-H_2O, and aqueous inclusions occur in diagenetic pore- and fissure-filling calcite associated with bitumen. The close association of gold deposits and paleo-oil reservoirs, the paragenetic coexistence of bitumens with ore-stage minerals, and the presence of abundant hydrocarbons in the ore fluids all suggest that the gold originated, migrated and precipitated along with the hydrocarbons in an immiscible, gold- and hydrocarbon-bearing, basinal fluid system.

The research was funded by the National Natural Science Foundation of China under grants of 40930423.

Geochemical Characteristics and Tectonic Environment of Basement Granite in Weiyuan Structure, Sichuan Basin, Southwest China

GU ZHIDONG, ZHAI XIUFEN AND WANG ZECHENG

Research Institute of Petroleum Exploration and Development, PetroChina, China

(* correspondance: guzhidong@petrochina.com.cn)

Based on the deep wells drilled into the basement in Weiyuan structure, and aeromagnetic negative anomalies, the basement of Weiyuan structure in Sichuan Basin of Southwest China, is proved to be composed of granitoids.

Well core observation and thin section identification results show that syenogranite is the main rock type. The features of major elements include high Si content, high alkali value, high K_2O/Na_2O ratio, high K content but low Na content, suggesting that it belongs to high-K calc-alkaline and metaluminous - weakly peraluminous series. The LREE is rich, with HREE loss and intensely negative Eu abnormality, while the chondrite-normalized distribution shows right tilting seagull-like patterns. High field strength elements Th, U, Pb, Nd, Sm and large ion lithophile elements Cs, Rb are rich, while high field strength elements Nb, Eu, Ti, Sc and large ion lithophile elements Ba, Sr are depleted(Fig.1).

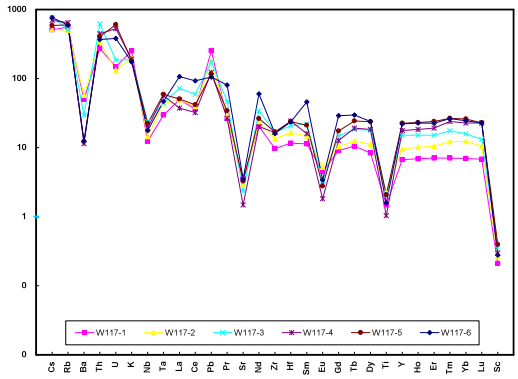

Fig.1 Spider diagram of primitive mantle normalized trace elements of basal granite in W117 well

The genetic type is A_2 granite, probably formed by highly fractional crystallization of crust molten magma mixing with a small amount of mantle magma. This type of granite is deduced to have developed from extensional rifting tectonic environment which may be related to Rodinia supercontinent break-up event in Neoproterozoic.

[4]DiSAT, Università dell'Insubria, I-22100 Como, Italy.

Nanoscaled crystals (NCs) and the processes governing their nucleation and growth play a fundamental role in relevant, and diverse, fields, such as (to mention a few) geochemical cycling, mining and biomineralization. The limited coherence length of NCs, the presence of compositional and structural defects and the interaction with organic components make these systems highly complex, with a *short-range order only*. In the diffraction space, these features turn into diffuse scattering, falling between and below the Bragg peaks. The Debye equation [1] is a *Total Scattering* approach treating Bragg and diffuse scattering on an equal basis and, therefore, is able to use the *entire* information present in the experimental diffraction pattern. Conversely, conventional single-crystal and powder X-ray and neutron diffraction methods deal with Bragg intensies only. Recently, we have proposed a new, original and computationally efficient implementation of the Debye Function Analysis [2], which enabled us to *quantitatively* characterize, in terms of structure, size and shape distributions, different kinds of nanocrystalline materials [3]. Among these, citrate-controlled biomimetic apatites [4], very similar in size, shape and composition to bone apatites, have been for the first time characterized by DFA. Combining DFA and AFM, we were able to unravel the mechanism forming platy-shaped NCs from an amorphous calcium phosphate precursor. A major role of citrate in controlling the growth mechanism of the apatitic mineral clearly emerges.

High-silica rhyolites and granites: Products of the shallow crust

GUILHERME A. R. GUALDA[1] AND MARK S. GHIORSO[2]

[1]Earth & Environmental Sciences, Vanderbilt University, Nashville, TN 37235, USA; (g.gualda@vanderbilt.edu)
[2]OFM Research - West, Seattle, WA 98115, USA; (ghiorso@ofm-research.org)

High-silica rhyolites and granites (>75 wt. % SiO_2, anhydrous) are common features of the crust, as part of both the volcanic and plutonic records. While low crystallization pressure (<250 MPa) is typically inferred, it has been suggested that they form via polybaric evolution, with initial crystallization at relatively high pressures (> 500 MPa).

We use glass compositions derived from the EarthChem portal, selected natural examples from the literature, and rhyolite-MELTS calculations to probe the depth at which different magma compositions can form within the crust.

We demonstrate that the phase relations in the Qz-Ab-Or ternary dictate the silica content of silicic melts and cause silica content to increase with decreasing pressure. Our analysis has profound implications for the origin of silicic melts and magmas within the continental crust, specifically:

(a) *Silicic magmas are expected to show stratification in silica contents within the crust*. Melts within the crust will show a gradient in maximum silica content; while dacites can occur over much of the crust, high-silica rhyolites are confined to the shallow levels of the crust.

(b) *High-silica rhyolite glass can only form at low P, requiring crystallization in the shallow crust*. Polybaric evolution of magmas is confined to their possible range of occurrences. While dacites can evolve via decompression-driven crystallization over a large range of pressures (as recorded in glass inclusions), high-silica rhyolites are confined to the shallow crust (consistent with narrow range of silica contents in glass inclusions).

(c) *The existence of high-silica pumice requires fractionation or melting at low pressure*. Whole-pumice with high-silica rhyolite composition requires melting or fractionation in the shallow crust, which precludes direct derivation of high-silica magmas from high pressures without substantial fractionation at low pressure, and shows that high-silica rhyolites and granites are intrinsic to the shallow crust.

(d) *Low-pressure cumulates or melting residues must exist in the shallow crust*. If shallow-level fractionation is required, then crystal cumulates or partial melting residues must be present within the upper crust. The crystal cumulates necessary to form high-silica rhyolites are to be found within upper crustal granitoid plutons.

The concept of end of waste in view of developing sustainable secondary geo-materials

A.F. GUALTIERI[1*], A.VIANI[2] AND S. POLLASTRI[1]

[1]Dipartimento di Scienze Chimiche e Geologiche, Università di Modena e Reggio Emilia, 41121 Modena, Italy (*correspondence: alessandro.gualtieri@unimore.it)

[2]Institute of Theoretical and Applied Mechanics AS, Prague and Centrum Excelence Telč, 588024 Czech Republic.

The concept of *end of waste*, adopted by the European Commission on December 2005, regards under which conditions a waste could cease to be waste and could be regarded as a non-waste material. This is a revolutionary way to think of wastes not just as refuse to be dismissed but as secondary raw material to be exploited, with an enormous social and economic impact. In this scenario, the creativity of *materials* scientists is highly stimulated and the key to success is the development of innovative and sustainable means to transform a waste into a secondary raw material of potential economic value. To this aim, stimulus comes from the so called geo-inspiring materials. This contribution presents the results of a long-term project aimed to recycle asbestos containing materials (ACMs), into secondary raw materials for various industrial applications. The high temperature product of transformation of ACM can be successfully recycled in clay bricks, rock-wool, glass–ceramics, ceramic pigments [1], geopolymers [2], concrete [3], and recently also for innovative formulations of calcium sulfoaluminate cement clinkers [4] and magnesium phosphate cements [5].

We present the maps of K, eU, and eTh radioelement abundances of Elba Island (Italy) realized by means of a geostatistical interpolation of airborne γ-ray data, performed with a module of four NaI(Tl) crystals of 16 L mounted on an autogyro. We applied the Collocated Cokriging (CCoK) multivariate estimator in a non-conventional way for interpolating the under-sampled airborne gamma-ray data using the geologic map as constraining ancillary variable. An arbitrary number has been assigned to each geological formation and used in the algorithm for estimating the radioelement abundances: the independence from the random assignment process has been tested for three distinct models. The spatial variability shows well-defined structures for the linear coregionalization models. The abundance maps indicate a distinct correlation between the geological formation and radioactivity content. High K, eU and eTh abundances were estimated in the intrusive granitic complex of Mt. Capanne and low abundances in the geological formations in the N-E sector of Elba Island. However, a clear anomaly of high K content in the Mt. Calamita promontory confirms the presence of felsic dykes and hydrothermal veins not reported in geological map of Tuscany Region at scale 1:10000. This result confirms that the internal variability of the radiometric data is not biased by the multivariate interpolation.

Dissolution rates of plagioclase feldspars at 22 °C as a function of pH and plagioclase composition

S. GUDBRANDSSON[12*], D. WOLFF-BOENISCH[1], S.R. GISLASON[1] AND E. H. OELKERS[12]

[1]Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavik, Iceland (*snorgud@hi.is),(boenisch@hi.is), (sigrg@hi.is)

[2]GET/CNRS, 14 Avenue Edouard Belin, 31400 Toulouse, France (eric.oelkers@get.obs-mip.fr)

Feldspars are the most abundant mineral in the Earth's crust and thus play an integral role in the plethora of natural geochemical processes including global element cycling. Moreover, as a major reservoir of silicate mineral bound Ca, plagioclase dissolution may serve as an important source of the divalent cations required for mineral carbonation [1]. Our ability, however, to model such processes is currently confounded by inconsistencies among plagioclase rate data measured in distinct laboratories; corresponding rates reported in the literature vary by as much as 3 orders of magnitude. In addition there is a nearly complete lack of measured dissolution rates for the Ca-rich feldspars at alkali conditions. This laboratory study has been designed to overcome some of these ambiguities.

The steady state, far-from-equilibrium dissolution rates of 5 distinct plagioclases ranging in composition from albite (An8.9) to anorthite (An88.8) were measured in mixed flow reactors at 22±2° C and pH from 2 to 11. The dissolution rates of all plagioclases based on silica release rates show a common U-shaped behaviour as a function of pH where rates decrease with increasing pH at acid condition but increase with increasing pH at alkaline conditions. As previously observed, constant pH plagioclase dissolution rates increase with increasing anorthite content at acid conditions; measured anorthite dissolution rates are ~2.5 orders of magniture faster than those of albite at pH~2. Perhaps more significantly plagioclase dissolution rates are independent of plagioclase composition at alkaline conditions. Preliminary interpertation and data fitting suggests that plagiocalse dissolution rates are consistent with their control by the detachement of Si-rich activated complexes formed by the removal of Al from the mineral framework. Taking account of this mechanism and transition state theory yields a robust equation that describes plagioclase dissolution rates as a function of the compostion of both the mineral and fluid phase over the full range of pH found in natural systems.

Ferromanganese crusts as proxies for deep water Ni, Cu, Zn and Fe isotope variations

BLEUENN GUEGUEN[12*], OLIVIER ROUXEL[2] AND YVES FOUQUET[2]

[1]IFREMER, Centre de Brest, Unité Géosciences Marines, 29280 Plouzané, France (*bleuenn.gueguen@univ-brest.fr)

[2]Institut Universitaire Européen de la Mer, UMR 6538, Laboratoire Domaines Océaniques, Université de Bretagne Occidentale, BP 80 F- 29280 Plouzané, France (olivier.rouxel@ifremer.fr; yves.fouquet@ifremer.fr)

While ferromanganese (Fe-Mn) crusts have long been characterized by elevated concentrations of Ni, Co, and Cu arising from their very slow growth rates (1-6 mm/Ma), the sources of metals in hydrogenous seafloor deposits and their record of evolving deep sea metal fluxes remain strikingly unresolved. Temporal geochemical variations in Fe-Mn crusts were mostly investigated for paleoceanographic studies of oceanic circulation and climate variations with radiogenic isotope (Pb, Nd, Os). Since transition metals are actively involved in key biogeochemical processes, it is crucial to understand how metal oceanic sources and internal cycling responded to major oceanic perturbations in the past. As a result, unlocking the history of trace metals using transition metal isotopes is now receiving growing interest.

Here, we report high resolution Ni-Cu-Zn-Fe isotope profiles in two Fe-Mn crusts collected in the North Pacific Ocean (Apuupuu seamount, south of Hawaii). This record provide a compehensive view of the last 6 Ma. Results show that Ni, Cu and Zn isotope variabilities are restricted with $\delta^{60/58}Ni_{SRM986}$ = +1.73 ±0.03‰, $\delta^{65/63}Cu_{SRM976}$ = +0.64 ±0.04‰ and $\delta^{66/64}Zn_{SRM3168a}$ = +2.12 ±0.06‰. In contrast, $\delta^{56/54}Fe$ values range from -0.04 to -0.68‰ and differ between both crusts, albeit showing concomitant kink of Fe isotopes at ~2-2.5 Ma correlating with Pb isotope ratios. Overall, Ni, Cu, and Zn isotope records in Fe-Mn crusts are consistent with their modern oceanic values, after consideration of potential isotope fractionation during incorporation in Fe-Mn oxides, while Fe isotope record is strongly affected by local effects due to short residence time and local halmyrolitic and/or hydrothermal sources.

[2]Commissariat à l'Energie Atomique, DEN DPC, F-91191 Gif Sur Yvette, France

The precise Nd isotopic composition is of major interest in nuclear (determination of nuclear fuel burn-up, …) [1] or geosciences applications (paleoceanography, …) [2]. Direct determination of Nd isotopic ratios in sample is hampered by isobaric interferences and chemical separation before isotopic measurements is required.

In this study, the separation of lanthanides was performed by high-performance liquid chromatography using analytical column with strong cation exchange (SCX) groups bounded to the silica surface. A gradient elution mode was used with the mobile phase containing the organic acid HMB (2-hydroxy 2-methylbutyric acid).

For this study, a *JNdi-1* standard solution was used. The Nd peak was collected in various fractions for isotope ratio measurements by MC-ICP-MS (Neptune Plus, Thermo Scientific), to evaluate Nd isotopic fractionation during elution. Raw ratios were corrected for mass bias using Nd reference values obtained by the flash evaporation method in Thermal Ionisation Mass Spectrometry [3,4].

The range of variation observed along the elution peak is about 2‰/amu, which is significant considering an external reproducibility obtained by sample standard bracketing method on the *JNdi-1* isotopic standard lower than 0.03‰ for all isotopic ratios. This trend indicates a preferential elution of heavy isotopes. This phenomenon imposes to collect the total Nd elution peak in order to determine the true isotopic ratios. The potential consequences of this behaviour on the accuracy of the measurement will be presented. This result is essential for future on-line experiments with HPLC hyphenated with MC ICPMS in order to measure accurate Nd isotopic ratios.

A new radiation damage based model for He diffusion in zircon

W.R GUENTHNER[1*], P.W. REINERS[1], R.A. KETCHAM[2], L. NASADALA[3] AND G. GIESTER[3]

[1]University of Arizona, Tucson, Arizona 85721 USA (*correspondence: wrg@email.arizona.edu)

[2]University of Texas, Austin, Texas 78712 USA

[3]University of Vienna, Althanstr. 14, 1090, Vienna, Austria

A key assumption in zircon and apatite (U-Th)/He dating has traditionally been that the diffusion kinetics of ^{4}He in the mineral of interest are constant across a broad spectrum of chemical compositions. Increasingly, practitioners of the technique are discovering that a "one-size-fits-all" approach to these kinetics is inadequate and are developing more grain-specific diffusion models to both explain data complexities, and to better constrain time-temperature histories. Here we present diffusion measurements that show how a zircon's alpha dose, which we interpret to correlate with radiation damage, influences its He diffusivity. Results from step-heating experiments on pairs of crystallographically oriented slabs of zircon are as follows: from 1.2×10^{16} α/g to 1.4×10^{18} α/g, the frequency factor measured parallel to the c-axis decreases by ~4 orders of magnitude, causing He diffusivity to decrease (e.g. by ~3 orders of magnitude at between 140 and 220 °C). Above ~2×10^{18} α/g, activation energy decreases by a factor of two, and diffusivity increases by ~9 orders of magnitude by 8.2×10^{18} α/g. We attribute these trends to two separate, though related, mechanisms. Initially, progressive damage in-growth leads to greater tortuosity of diffusion pathways, decreasing He diffusivity. As in-growth continues, damage zones become interconnected, shrinking the effective diffusion domain size and increasing the crystal's bulk He diffusivity. We parameterize the damage-diffusivity relationship and couple it to a model describing damage annealing as a function of time and temperature (as in the RDAAM of Flowers *et al*. (2009)). This new model describes the coevolution of damage, He diffusivity, and (U-Th)/He date of a zircon.

[3]LCPME UMR 7564 CNRS-Université de Lorraine – 405 rue de Vandoeuvre 54601 Villers-lès-Nancy

Nitrate is a common contaminant causing eutrophication, particularly in agricultural areas, such as in Brittany (France). In this region, natural green-rust phases (fougerite) significantly contribute to the bluish color of hydromorphic soils. These minerals are thought to form upon reduction of Fe(III)-minerals by bacterial activity under anoxic conditions [1,2]. Since synthetic green rusts phases are known to reduce NO_3^- to NH_4^+ [3], potential for *in situ* denitrification involving bacterial metabolism and abiotic reduction by biogenic green-rust has been raised.

In the present study, biogenic hydroxycarbonate green-rusts, GR(CO_3), were produced in the laboratory from the reduction of either lepidocrocite or ferric oxyhydroxycarbonate [4] by *Shewanella putrefaciens* strain ATCC 12099. These biogenic Fe(II,III)-containing minerals were characterized by XRD, TEM and transmission Mössbauer spectroscopy, and their interactions with nitrite were studied. Results show that kinetics of reduction by biogenic GR(CO_3) differ from those reported for synthetic analogues [5]. In addition, XRD and EXAFS analysis of time-series samples help to elucidate the chemical mechanisms involved when green rusts get oxidized.

An integrated geochemical, hydrological and hydrodynamic approach to model arsenic at a fluvial confluence

PAULA GUERRA[1*], CRISTIAN ESCAURIAZA[1], CHRISTIAN GONZALEZ[1], VERONICA MORALES[1], GONZALO PIZARRO[1] AND PABLO PASTEN[1]

[1]Pontificia Universidad Catolica de Chile, Santiago, Chile. (pguerra@ing.puc.cl)(* presenting author)

Fluvial confluences are natural reactors where geochemistry, hydrology and hydrodynamics can interact in complex ways to determine the fate of contaminants in a watershed. Seasonal and diurnal changes in flow, chemical composition and the non-uniform, impermanent, three dimensional field of velocities induce relevant deviations from simplified models. This is particularly relevant in watersheds receiving acid mine drainage (AMD), where confluences are primary producers of highly reactive solid phases like hydrous iron oxides (HFOs) and hydrous aluminum oxides (HAOs). We used geochemical-hydrodynamic modeling, field measurements, and laboratory experiments to study a model confluence. Our field scale model is the Azufre River (pH<2, E.C>10000μS/cm, $[Fe]_{Total}$~60mg/L, $[Al]_{Total}$~65mg/L, $[As]_{Total}$~2 mg/L)-Caracarani River (pH~8.6, E.C~1500μS/cm) confluence, located in the Chilean Altiplano. We performed geochemical simulations for the mixing ratio $C_{Azufre}=Q_{Azufre}/Q_{Total}$ (L/L) in a range of 0 to 0.5 and coupled them to 3D numerical simulations of flow. Heterogenous spatial/temporal profiles of pH-induced HFOs and HAOs and a downstream buffer is achieved at pH~2.8-3.2, where As concentration is not only diluted by mixing, but also sorbed onto the assemblage of the amorphous phases (up to 30%). Experimental mixtures of natural waters in the laboratory and field measurements were consistent with our simulations. Despite the assumptions and limitations of geochemical modeling, this integrative approach allows the study of critical scenarios and highlights the importance of evaluating kinetic and equilibrium assumptions. Our study improves the knowledge on the fate of As in surface waters, vital for the design of treatment systems or monitoring programs in extreme environments such as the Altiplano.

Unraveling cryptic high-temperature polymetamorphism: An Alpine example

V.E. GUEVARA *[1] AND M.J. CADDICK[1]

[1]Dept. of Geosciences, Virginia Tech, Blacksburg, VA 24061, USA *(correspondence: vguevara@vt.edu)

Distinguishing between mineral phases which record evidence of distinct metamorphic events in high-grade polymetamorphosed rocks is one of the most difficult tasks facing metamorphic petrologists. This is particularly challenging when attempted on rocks that have experienced partial melting in at least one of these events. Resetting of mineral equilibrium compopsitions during metamorphic overprinting and an evolving bulk-rock composition during partial melting or late-stage fluid fluxing mean that both conventional thermobarometry and quantitative *P-T* modeling can be ineffective or easily misinterpreted. Here, we aim to elucidate the nature of potentially polymetamorphic granulites from the Gruf Complex, Central Alps, through integration of trace element thermometry, *in-situ* geochronology, and pressure-temperature (*P-T*) pseudosection modeling of carefully chosen textural domains. The Gruf Complex contains ultrahigh temperature (UHT) granulites and remains one of the most enigmatic features within the Alpine orogenic belt. Some studies suggest that UHT conditions record peak *T* during the Eocene Alpine orogen [1], whilst others invoke UHT conditions during Permian rifting overprinted by upper amphibolite facies migmatisation during Alpine orogenesis [2, 3].

Zr in rutile (rtl) and Ti in quartz (qtz) thermometry on grains in several textural domains of a single hand sample help to resolve ambiguity regarding the phases and textures that record different stages of the rock's history. Results suggest the presence of two distinct generations of biotite (bt), recording dramatically different *T*. Rtl grains within highly resorbed, high-Ti bt yield 710–780 °C. Textural association with high-*T* opx + grt ± sill assemblages suggests that they may record prograde heating leading to incomplete bt dehydration melting, and resultant formation of porphyroblastic opx with rtl inclusions that yield 810–880 °C. Rtl grains in texturally equilibrated, low-Ti bt or in matrix cordierite clearly record a later stage, low *T* recrystalization. Qtz and rtl grains in grt yield *T* of 800-850 °C, suggesting possible grt growth coeval with opx.

Reconstruction of nutrient redox cycling in the Early Neoproterozoic

ROMAIN GUILBAUD[1*] AND SIMON W. POULTON[1]

[1]School of Earth and Environment, University of Leeds, Leeds LS2 9JT, UK ([*]correspondance: r.j.guilbaud@leeds.ac.uk)

A significant body of evidence suggests that the deep ocean remained anoxic until the terminal Neoproterozoic. Recent studies on mid-Proterozoic [1] and later Neoproterozoic [2,3] (<750 Ma) marine sediments indicate that water masses beneath the oxic surface ocean were dominantly ferruginous, with sulphidic conditions restricted to the continental margins. However, in contrast to the Mesoproterozoic, sulphidic continental margin conditions appear to be particularly sparse in the later Neoproterozoic, while little is known about the nature of ocean chemistry in the early Neoproterozoic. This is particularly significant since the bioavailability and the redox cycling of nutrients are prone to change dramatically when shifting from sulphidic to ferruginous conditions. Thus, the biogeochemistry of the ocean preceeding the onset of the first Neoproterozoic glaciation is poorly constrained. Here, we reconstruct the evolution of coupled redox-nutrient cycling throughout a succession capturing pre- (>800 Ma) to syn-glacial sediments. Our focus is on a succession of deeper and shallower marine deposits from the Huainan region, northern China. The transect constitutes a potential archive of the biogeochemical response to linked changes in ocean redox conditions and nutrient feedbacks during the run-up to extreme climate change. Our data document the links between phosphorous cycling and ferruginous waters, under conditions characterised by low sulphate and apparent low productivity.

Optimization of LA-ICP-MS for U-Pb dating of young zircons

M. GUILLONG[1*], O. BACHMANN[1] AND A. VON QUADT[1]

[1]ETH Zurich · Inst. for Geochemistry and Petrology, Clausiusstrasse 25, 8092 Zürich, Switzerland *guillong@erdw.ethz.ch

Laser ablation ICP-MS is a powerful method to determine the age of rocks by measuring U/Th/Pb isotopes. The method is fast, cheap and for many applications precise and accurate enough when using robust corrections and reference materials [1]. In this work we show the optimization of a laser ablation system equipped with a 2nd generation 2 volume constant geometry ablation cell (Resonetics: S-155LR) in combination with a high sensitivity sector filed ICP-MS (Thermo: Element XR). Investigated parameters includes laser crater size, repetition rate and energy density, as well as signal length, gas flows and ICP-MS parameters with respect to, precision, accuracy, sample throughput and resolution. Results for different zircon standard reference material are shown and observations including down hole fractionation, low count rates, and the importance of integration interval settings are discussed.

The optimized instrumentation is used to determine the age of young zircons from Kos Plateau Tuff with a known eruption age of 160 ky. Due to the high sensitivity, it is possible to date these zircons using a 30 μm spot and 5Hz ablation rate with a precision similar to SHRIMP [2]. Several challenges dating zircons of this age range are addressed: Due to the low count rates on the Pb isotopes the mean of ratios is different than the ratio of the mean. For accurate dating of young zircons a U-Th disequilibrium correction is necessary, for which a precise Th/U ratio is needed, both in the individual zircons as well as in the magma. Due to the relatively fast drilling of laser ablation (~0.1 μm/pulse) we often observe inherited cores resulting in mixed signals which makes the setting of integration intervals important but can give indication about the pre-eruptive magmatic history of zircons [3].

On the filtering of dust by planetesimals and its consequences for the compositions of planetary systems

TRISTAN GUILLOT[12*] AND SHIGERU IDA[2]

[1]Université de Nice-Sophia Antipolis, Observatoire de la Côte d'Azur, CNRS, Nice, France (tristan.guillot@oca.eu)

[2]Tokyo Institute of Technology, Tokyo, Japan (ida@geo.titech.ac.jp)

The inner solar system, and in particular Mercury, Venus, the Earth and Mars contains very little water. Asteroids between Mars and Jupiter are known to be progressively more water-rich as they orbit further to the Sun. Yet, we know that protoplanetary disks contain vast amounts of water ice, and that the ice line (i.e. the distance at which water vaporizes) moves progressively inside of 1 AU before gas photoevaporation takes place. Ice grains could thus potentially deliver significant amounts of water there, in disagreement with the evidence in our Solar System.

We show that the inside-out formation of planetesimals can effectively filter dust and prevent icy grains from reaching the inner regions of the system. This occurs when the mass in planetesimals exceeds a threshold well below that obtained from adding the mass of solids present in the present-day Solar System. This thus explains why the inner Solar System is dry, but potentially also why other planetary systems may lead to the formation of wet, low-density planets. The potentially high solid-to-gas ratio obtained in the late phases would also help to understand the very large masses in heavy elements derived in giant planets observed by transit surveys including CoRoT and Kepler.

Magmatic evolution and intensive parameters of the Santa Maria Rhyolites, Paraná Magmatic Province, Brazil, as inferred from whole rock and mineral geochemistry

GUIMARÃES, L.F.[1], POLO, L.A[1] AND JANASI, V.A.[1]

[1]University of São Paulo

The Santa Maria rhyolites correspond to a sequence of effusive glassy to hipocrystalline rocks occurring as lava-domes and flows in the southern portion of the Paraná Magmatic Province, south Brazil. Detailed field work in the Soledade-Gramado Xavier region has shown that they correspond to the uppermost sequence of the low-Ti magmatism, which is characterized by a succession of pahoehoe basalt-aa basalt-dacite-rhyolite.

The rhyolite magmas have some unusual characteristics such as high magma temperatures (up to 1,000oC, as indicated by apatite saturation and two-pyroxene thermometry), high H2O contents (2.5-3.5 wt%, estimated from the plagioclase geohygrometer), and consequently lower viscosities (~104 Pa.s) compared to typical rhyolites, what could in part respond for the dominantly effusive mode of emplacement.

The rhyolites are chemically homogeneous, with 71-73 wt% SiO2, 0.65-0.70 wt% TiO2 and enriched in K2O (4-5 wt%) and other incompatible elements (210–300 ppm Rb; 680–930 ppm Ba; ~350 ppm Zr and □ REE ~300 ppm) compared to the associated dacite units.

The scarce (~3-5 vol.%) 0.5-1.5 mm plagioclase phenocrysts have homogeneous cores with compositions varying from An46 to An54; resorption surfaces present in some crystals may be mantled by a thin, more calcic (An57-60) rim. Trace-element contents determined by LA-ICPMS are also relatively homogeneous; results of inverse modeling for Ba, Sr, Rb and LREE using Kds from literature are broadly consistent with crystallization from the host melts.

An increase in the temperature of the magmas suggested by resorption textures and inverse zoning of plagioclase may have occurred immediately prior to eruption, as a result of heating by latent heat of crystallization or, more probably, was due to injections of hotter magma, as evidenced by the occurrence of scattered dm-sized ball-shaped dacitic enclaves.

Lu-Hf isotope systematics of the ca. 3.92-3.96 Ga Acasta Gneiss Complex (NWT, Canada)

M. GUITREAU[123*], J. BLICHERT-TOFT[12], S.J. MOJZSIS[1245], A.S.G. ROTH[6], B. BOURDON[12], N.L. CATES[4] AND W. BLEEKER[7]

The Acasta Gneiss Complex (AGC) is a remnant Hadean (pre-3900 Ma) ancient crust composed of strongly deformed, polyphase mafic to felsic gneisses that preserve a protracted multi-stage history of magmatic emplacement, inheritance, and subsequent tectono-thermal modifications that induced generalized migmatization. The complexities observed in these ancient gneisses have been documented in previous geochronological studies of the AGC (e.g. U-Pb, ^{147}Sm-^{143}Nd), and are evident also in the Lu-Hf isotope systematics. Here, we report new whole-rock Lu-Hf isotope measurements which show that some AGC gneisses have been disturbed by metamorphic garnet growth and/or migmatization and mineral segregation, while others have preserved their Lu-Hf isotope systematics relatively intact. Results reveal identifiable Hadean and later (Eo- to Paleoarchean) magmatic events at around 3960 Ma and again at 3600 Ma, with a major metamorphic episode of the complex at ca. 3730 Ma. The oldest and least contaminated gneisses yield a mean Lu-Hf regression age of 3945 ± 91 Ma, which is in good agreement with U-Pb zircon geochronology [1]. The role of yet older crust (4000-4200 Ma) in the formation of the AGC is also evident, but this crust was not ubiquitous. Assimilation calculations show that the mantle source of the least contaminated samples in the oldest age group had Hf isotope compositions near that of the chondritic uniform reservoir (CHUR) 3960 My ago.

Geochemical Characteristic of Felsic Dykes Within the Karakaya (Kaymaz) Granite Eskişehir, Turkey

B.GULLU[1], Y.K.KADIOGLU[25], O.ZOROGLU[3], T.KORALAY[4], K.DENIZ[5] AND C.O.KILIC[5]

[1]Aksaray Uni. Dept of. Geol. Eng., Aksaray, Turkey (*correspondance: bgullu@aksaray.edu.tr)
[2]Ankara Uni. Earth. Sci. App&Res. Center, Ankara
[3]General Directorate of Min. Res. And Exp., Ankara
[4]Pamukkale Uni. Dept. of. Geol. Eng., Denizli
[5]Ankara Uni. Dept. of Geol. Eng., Ankara

Karakaya (Kaymaz) granite is exposed to the east of Eskişehir City within the Sakarya Continent at eastern part of northwest of Anatolia. Karakaya granite has holocrystalline granular texture and mainly composed of quartz, orthoclase, oligoclase, biotite, tourmaline, ± allanite, ± zircon [1]. Karakaya granite covers an area of 16 km^2 as NW-SE trending semi elliptical shaped and cut by felsic dykes with direction of N10-35W [2].

Felsic dykes have myrmekitic and graphic textures are in composition of alkali feldspar granite and granophyr. Evolution of geochemistry of host rocks and felsic dykes indicates continuous trend between felsic dykes and their host rocks. This trend suggested the differentiation products of same magma resource for felsic dykes and host rocks.

ORG normalized elemental patterns of felsic dykes reveal enrichment with Large Ione Lithophile Elements with respect to High Field Strength Elements. Besides, chondrite normalized elemental patterns of Rare Earth Elements show prominent enrichment of Light Rare Earth Elements with respect to Heavy Rare Earth Elements.

REE characteristics of felsic dykes are calculated as $(La/Yb)_N$: 17.47–17.51, $(Eu/Eu^*)_N$: 0.63–0.77, $(La/Sm)_N$: 11.85–12.41 and $(Sm/Yb)_N$: 1.413–1.47.

High LREE/HREE values and all the field geology, petrography and geochemical data reveal that the felsic dykes are the residual melts of the mixed felsic and mafic products of mantle signature crustal source magma.

The authors wish to thank DPT (dpt-2012K120440) and Ankara University (BAP 09B4343016) for supporting Project.

Water Geochemistry of the Thermal Waters in the Eastern Black Sea Section (Ordu, Rize and Artvin), Turkey

F. GULTEKIN[1*] E. HATIPOGLU[1] AND A. FIRAT ERSOY[1]

[1]Karadeniz Technical University, 61080 Trabzon, Turkey*(correspondence: fatma@ktu.edu.tr) (hatipogluesra@gmail.com, arzufirat@gmail.com)

Eastern Black Sea Section is characterized by a magmatic arc developed in the Cretaceous- Tertiary. Thrust faults, strike-slip faults and normal faults are formed in the region. Accordingly, in the area strike-slip faults, trending NE-SW direction, creates lines for thermal water outlets. Sarmaşık (Fatsa-Ordu), Ayder (Çamlıhemşin- Rize), Ilıcaköy (İkizdere-Rize) and Ilıca (Şavşat- Artvin) thermal waters, discharging from along these faults and fractures, are located in the region.

Temperature of Sarmaşık and Ilıca thermal springs, discharging from basaltic and andesitic rocks are 48°C and 38°C respectively. Thermal well waters temperature in the Ayder and İkizdere areas are 57°C and 63°C respectively. In the study area pH values are between 6.32- 8.92, EC values are between 200- 8463 μS/cm, TDS values are between 130-5500 mg/l. The Na-HCO_3 thermal waters of Ayder, İkizdere and Ilıca are Peripheral waters. Sarmaşık thermal waters, which is classified as Na-Ca-Mg-SO_4 are Steam heated waters. While thermal waters of Ayder and İkizdere are Immature Waters, Sarmaşık and Ilıca thermal waters are Partially Mature Waters. The thermal waters of Ayder and Sarmaşık are undersaturated with respect to gypsum, amorphous silica, calcite, aragonite and dolomite, but İkizdere and Ilıca thermal waters are oversaturated with respect to calcite, aragonite and dolomite.

The concentration values of trace element Rb, Cs and Li vary in thermal waters of four regions. Ilıca thermal waters has the highest trace element concentration. Ayder thermal water are not affected by water-rock chemistry, compared with rare elements of rock and waters. In the Sarmaşık, İkizdere and Ilıca area water chemistry is similar to the rock chemistry according to rare elements content. Based on their stable isotope contents waters are meteoric in origin. Ilıica and İkizdere thermal waters have a more positive values of $\delta^{18}O$ due to water-rock interaction.

(*correspondence: guenther@inorg.chem.ethz.ch)

Non-matrix matched calibration is one of the most widely applied strategies for quantification in laser ablation-inductively coupled plasma mass spectrometry. It relies on the assumption that sensitivities obtained for the elements in standards and samples are identical in relation to the internal standards used. Based on the observation that vaporization of the elements inside the ICP was found to be significantly affected by the matrix composition, various imaging techniques were applied to study vaporization of laser-generated aerosols within the ICP for different matrices. The results obtained indicate that vaporization points of particles in the plasma are species dependent (e.g. CaO, Ca, Na_2O, Na). Therefore, the efficiency of sampling different elements is affected by their respective diffusion rates in the plasma. It will also be shown that optimization of gas flow, ICP Rf-power adjustment or optimization of the sampling position cannot overcome these matrix problems. Additionally, data acquisition at high time resolution, using an ICP-TOF-MS (Tofwerk AG, Thun, Switzerland) allows studying the signal structure in greater detail and variations in the vaporization of different elements will be discussed.

Finally, various mix gas additions to the carrier gas were tested to stimulate a more uniform vaporization process of laser-generated aerosols within the ICP and some of these results will be presented and discussed in detail.

Crust–mantle interaction of Late Jurassic Qianlishan granites in South China: Constraints from geochemistry and in-situ analyses of zircon U–Pb–Hf–O isotopes

CHUN-LI GUO[1]*, BING YIN[2] AND YI-MING XU[3]

[1]MLR Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, 100037, PR China
[2]Hu'nan Shizhuyuan Nonferrous Metals Liability Co. Ltd., Chenzhou, 423037, PR China
[3]Southern Hu'nan Iinstitute of Geology and Survey, Chenzhou, 423000, PR China

The Qianlishan granitic pluton is closely related to the Shizhuyuan superlarge W–Sn–Mo–Bi polymetallic deposit. It is composed of two phases, porphyritic biotite granite and equigranular biotite granite. Representative samples from each phase were analyzed using SIMS zircon U–Pb technique, and results were 155–153 Ma and 153–152 Ma (2σ) respectively. The granitic rocks have high SiO_2 contents (73.2–77.7 wt%) and total alkali (7.27–9.36 wt%). For example, ASI (aluminum saturation index) values of two phases are 0.91–1.01 and 1.01–1.27 respectively. K_2O/Na_2O ratios of two phases are 1.29–2.82 and 0.86–1.36 respectively. LREE/HREE ratios are 3.95–6.80 and 1.10–2.12 respectively. The second phase has more obvious Eu negative anomaly (Eu/Eu*=0.01–0.02) than the first one (Eu/Eu*=0.13–0.28) and the second one has more conspicuous Sr, P, Zr and Ti depletion than the first one. P_2O_5 vs SiO_2, Zr saturation thermometer, whole rock Sr–Nd and zircon $\delta^{18}O$ values proved the Qianlishan granites are belong to a high evolved I–type. Whole rock $\varepsilon_{Nd}(t)$, zircon $\varepsilon_{Hf}(t)$ and $\delta^{18}O$ values fall into the ranges –9.3 to –6.4, –8.0 to –1.0, and 5.24‰–7.45‰ respectively, and combined with zircon Hf two-stage model ages (T_{DM2}) of 1.45Ga–1.73Ga. Trace–element geochemistry and isotope systematics further imply that the Qianlishan granitic magmas were most probably derived by partial melting of Palaeo– to Mesoproterozoic metamorphic lower crustal rocks and there were obvious mantle materials participating in during the granite formed. Combined previous researches, it is inferred that the Qianlishan granite was produced in an extensional structual setting, which reulting in the lithosphere thinning and an influx of asthenophere.

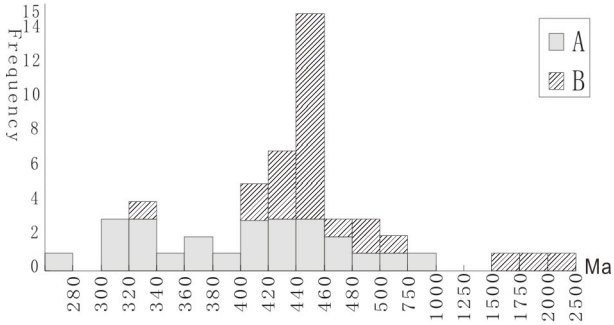
The characteristics of metamorphic basement for the Bogda late Paleozoic rift through, eastern Tianshan mountains, China

JUNFENG GUO[1*] AND YONG LI[1]

[1]College of Earth Science and Land Resourses,Chang'an University,Xi'an 710054,China
(*correspondence:guojunfeng540@gmail.com)

East tianshan mountains bogda rift trough located in the binding site between junggar and turpan-hami precambrian blocks,the tectonic setting is an upper paleozoic continental rift zone.Detrital zircon dating of newly discovered on the bogda orogenic northe rim tectonic quartz schist shows that two sampling points apart 20meters reflects a remarkable difference about the origin and the reformation of the metamorphic basement.the rifting from the early carboniferous,the deposition is characterized by a set of basalt and rhyolite bimodal volcanic and clastic rocks;the late carboniferous rift closed.magmatism occurred in the tensional environment.

A sampling point on 25 zircon LA-ICP MS U-pb age analysis showed that the sample material composition,source formed in a wide range of geological time(figure 1,A sample data).B sampling point 30 zircon LA-ICP MS U-pb age analysis shows that 22 zircon of which given the relative concentration of the age of information,the weighted age of 450.3±4.3(MSWD=1.7).batch of these zircon was short columnar or long columnar euhedral,the subhedral structure,with zircon shock rings clear,which indicate the source mass came from the magmatic,and the metamorphic protolith main diagenetic's late cambrian;sampled twice by a total of six zircon older than 540 million years,and the distribution of dating was scattered.bathc of these zircon was rounded,the weaker reflected light intensity,indicating that the metamorphic protolith old crystalline basement(fig.1 B sample data).



Analysis of characteristics on different components of hydrocarbons in organo-clay complexes

MIN GUO[1], JINGONG CAI[1]*, TIANZHU LEI[2] AND FEI DING[1]

[1]State Key Laboratory of Marine Geology, Tongji University, Shanghai 200092, China
(*correspondence: jgcai@tongji.edu.cn)
[2]Key Laboratory of Petroleum Resources Research, Institute of Geology and Geophysics, Chinese Academy of Sciences, Lanzhou 730000,China

To investigate the characteristics of hydrocarbons with different occurrence states in clay minerals, samples of clay fraction (<2μm) were separated from argillaceous source rocks in Palaeogene of Dongying Sag in Jiyang Depression. The clay fractions were sequentially treated with Soxhlet extraction, alkaline hydrolysis, acid hydrolysis and mixed acid (10% HF and 10% HCl) processing, then the quantitative detection of GC-MS was employed to the organic components. The results show that there were great variations in the contents and the composition distribution characteristics of hydrocarbons with different treatments, a) the content of free hydrocarbons obtained by Soxhlet extraction was maximum (603.74μg/g), while the second part was the hydrocarbons obtained by mixed acid processing, and the hydrocarbons from alkaline and acid hydrolysis were the least part (23.51μg/g, 12.73μg/g, respectively); b) the free hydrocarbons from Soxhlet extraction were mainly consisted of heavy components (C_{15}^{+}), ranged 52%~94%, 80% on average; and the hydrocarbons from alkaline and acid treatments were chiefly composed of light components (C_1-C_{14}), mainly ranged C_7-C_{11}, and the contents of light components were 73%, 77%, 65%, respectively. Through the contrastive analysis on the content of hydrocarbons in different burial depth, it can be found that the hydrocarbons were dominated with light components above 2000m, with the content more than 70%, and were dominated with heavy components below 2000m, with the content much more than 70%.

The organo-clay complexes are the main carrier of organic matter and hydrocarbons in argillaceous source rocks. It is of great significance to study the geochemical characteristics of petroleum based on different treatments in clay fractions for the migration study of petroleum and the resource evaluation of unconventional petroleum.

REE and trace element patterns across the Ediacaran-Cambrian transition, South China

QINGJUN GUO[1*], YINAN DENG[1], HARALD STRAUSS[2], DOROTHEE HIPPLER[3], GERHARD FRANZ[3] AND GUANGXU ZHU[1]

[1]Inst. of Geographic Sci. and Nat. Res. Research, Chinese Academy of Sciences, Beijing 100101, China (guoqj@igsnrr.ac.cn)
[2]Westfälische Wilhelms-Universität Münster, Corrensstr. 24, 48149 Münster, Germany
[3]Technical University Berlin, Inst. of Applied Geosciences, Ackerstr. 76, 13355 Berlin, Germany

The Ediacaran and Cambrian interval belong to the most important periods in Earth's history. Deposits from the early Cambrian of the Yangtze Platform in South China represent a valuable source of information for the reconstruction of the evolution of marine palaeo-environments. Concentrations of REE and trace elements in kerogen as well as in bulk rocks from different depositional environments of the Yangtze platform indicate oxic conditions for shallow-water environments, and euxinic conditions in the deeper sea. The oxygenation of the water column of shallow-marine environments is manifested in two oxygenation events, one occurring in the upper Meishucunian and the second in the lower Qiongzhusian. Particularly the second oxygenation event resulted in the change of benthic redox conditions form anoxic to (sub-) oxic, which likely had an impact on the Cambrian explosion of life.

The early Cambrian Ni-Mo-PGE polymetallic ore layer, which occurs in most sections of the Yangtze Platform, shows a considerable enrichment of certain trace elements and coincides with negative $\delta^{13}C_{org}$ values. It is used as a marker for stratigraphic correlation separating the Meishucunian and the Qiongzhusian. Trace metal enrichment in associated black shales further indicates widespread euxinic conditions , although the extreme enrichment of some metals may originally come from hydrothermal plumes associated with spreading ridge volcanism. The results of this study thus provide valuable information about palaeo-environmental changes in the oceans during the Ediacaran-Cambrian transition,which may be used for the stratigraphic division of the Lower Cambrian.

Magmatic digestion of the crust and the origin of silicic magmas in Iceland: Insights from partially melted crustal xenoliths

A.A. GURENKO[1,2]*, I.N. BINDEMAN[3] AND I.A. SIGURDSSON[4]

[1]CRPG/CNRS, BP 20, 54501 Vandoeuvre-lès-Nancy, France (*correspondence: agurenko@crpg.cnrs-nancy.fr)
[2]Geology & Geophysics, Woods Hole Oceanographic Institution, Woods Hole, USA
[3]Geological Sciences, University of Oregon, Eugene, OR 97403, USA
[4]South Iceland Nature Centre, 900 Vestmannaeyjar, Iceland

Silicic magmas play a fundamental role in the origin of the continental crust. Whether silicic magmas predominantly result from extensive fractionation of the parental basaltic melts or they originate during partial melting of the older metamorphosed oceanic crust is still a subject of debate.

We studied partially melted, glass-bearing granite to syenite xenoliths from the Tindfjallajökull Pleistocene volcanic complex, SW Iceland. EPMA and LA ICP-MS were used for analysis of major and trace elements, SIMS and single grain laser fluorination methods were applied for zircon dating and O isotope analysis of minerals and glasses. The xenoliths consist of strongly resorbed, partially melted relicts of anorthitic plagioclase and K-rich feldspar (Fsp; Ab_{21-80} An_{1-37} Or_{1-78}, $\delta^{18}O$ = 5.3-6.2‰ given in permil relative to SMOW standard) and rounded quartz (Qz; 5.9-6.8‰) in the mingling colorless (5.5-6.2‰) through pale or light brownish (5.1-5.9‰) to dark-brown magnetic (4.0-5.0‰) interstitial glass matrix. Spongy aggregates and elongated crystals of orthopyroxene (mg# = 62-75, Wo_{1-10} En_{58-77} Fs_{20-36}) and clinopyroxene (mg# = 52-68, Wo_{34-43} En_{31-46} Fs_{16-27}) are common. They probably have crystallized during reaction of hot mafic magmas with surrounding crustal (plagiogranitic?) rocks at T = 800-1100° C. Magnetite (Spl_{1-9} Mag_{58-84} Usp_{14-37}) and rare ilmenite often form clusters with zircon and chevkinite, and together with apatite represent the accessory mineral association.

Many Icelandic lavas have systematically lower in $\delta^{18}O$ (i.e., <5.2-5.6‰) due to their interaction with the upper-crustal rocks altered by meteoric water, but they may contain strongly $\delta^{18}O$-diverse olivines and zircons [1,2]. The important result of this work is that although the studied xenoliths are not low-$\delta^{18}O$, suggesting no interaction with meteoric water, they also contain low- to high-$\delta^{18}O$ (2.2-6.3‰) young zircons (0.18-0.25 ± 0.03 Ma, 2 SD). This may suggest *in-situ* crystallization of the high-$\delta^{18}O$ zircons from the "minute" partial melts under local isotopic equilibrium. On the other hand, part of the zircon cores representing the lower end of the $\delta^{18}O$ range and being out of equilibrium with the interstitial melts could be inherited from the adjacent hydrothermally-altered crustal rocks having low $\delta^{18}O$ values.

Chromium(III) and bismuth(III) complexation to organic matter: EXAFS spectroscopy and equilibrium modelling

J.P. GUSTAFSSON[1*], A.G. OROMIEH[1], C. SJÖSTEDT[2], I. PERSSON[1] AND D.B. KLEJA[13]

[1]Swedish University of Agricultural Sciences, Uppsala, Sweden; *(correspondence: jon-petter.gustafsson@slu.se)
[2]Department of Chemistry, KTH Royal Institute of Technology, Stockholm, Sweden
[3]Swedish Geotechnical Institute, Stockholm, Sweden; Dan.Berggren.(Kleja@swedgeo.se)

The complexation of chromium(III) and bismuth(III) to mor layer material was investigated. Characterization of the products was made at MAX-Lab, Lund, Sweden, using Cr *K*-edge and Bi L_3-edge EXAFS spectroscopy.

The EXAFS results showed a predominance of monomeric organic complexes for chromium(III). The sorption of chromium(III) was pH-dependent. Chromium(III) complexation was found to be very slow at pH < 4, and equilibration times of three months or longer were required to reach equilibrium. For bismuth(III), complexation was quicker and found to be very strong, with more than 94 % bound at pH 1.2 also at a high bismuth(III) loading. EXAFS spectroscopy showed that the bound bismuth(III) ion is strongly distorted and interacts with a second bismuth(III) ion at ~4 Å. The complexation of bismuth(III) remained essentially unchanged even in the presence of a potent competitor such as iron(III).

The results from the spectroscopic investigation and from the quantitative solution data were used to calibrate new and improved complexation models for the Stockholm Humic (SHM) and the NICA-Donnan models. Similarities and differences in the organic complexation of the four trivalent metals chromium(III), bismuth(III), iron(III) and aluminium(III) will be discussed.

The study of Hg transformation in the Au recovery plant tailing area using thermal release technique with atomic absorption detection

M.A. GUSTAYTIS[1*], O.V. SHUVAEVA[2], I.N. MYAGKAYA[1]AND E.V. LAZAREVA[1].

[1]Institute of Geology and Mineralogy SB RAS, Koptyug Pr. 3, Novosibirsk 630090, Russia (*goustaitis_m@mail.ru)
[2]Institute of Inorganic chemistry SB RAS, Acad. Lavrentiev Pr., 3, Novosibirsk, 630090, Russia

It is known that gold mining is one of the most powerfull sources of mercury emission into environment. A present investigation was focuses on the Ursk tailings located in Kemerovo region (southwestern Siberia, Russia), that contains waste material produced by the cyanidation of the primary gold polymetallic ores and ores of the oxidation zone with elevated level of mercury and consisting of sand, sand-silt, silt and organic (peat mounds and buried peat).

As a result of the study it has been shown that in tailing shed wastes matereals mercury is presented as HgX_2, HgS and methylmercury at the predominance of $HgCH_3^+$ and $Hg^{2+,}$ and also as impurities in pyrite and barite. Herewith in sand matter mercury is contained as oxidizing species (49-54 μg/g) and CH_3HgX (9-60 μg/g); in sand-silt - as HgX_2 (~15 μg/g), CH_3HgX(~15 μg/g) and HgS (~3 μg/g); in silt - as oxidized species (12-43 μg/g), merthylmercury (9-21 μg/g) and HgS (3-13 μg/g). In organic matter close to waste methylmercury prevails (up 25 to 2 μg/g), but in organic matter of perennially wet zone mercury exists as cinnabar and mercury selenide (Hg_{total}=2350 g/t).

It can be assumed that Hg^{2+}-compounds are formed under the interaction of the shed wastes material with the components of the environment while methylmercury appears due to the presence of organic carbon in the pore solution as in the solid its concentration is negligible. As for organic carbon it may originate from the substances of peat mounds and buried peat. Mercury content in pyrite and barite does't generally exceed 10% of the total one.

On the base of the results of the present study and the published data as well the scheme of mercury transformation was proposed.

The study was supported by Grant 11-05-01020 from RFBR and an 2012-2013 OPTEC grant for young scientists, and was run as part of SB RAS Integration Project #94.

With an estimated 2,000 to 12,000 Gt of carbon released over ≤10 ka, the Paleocene-Eocene Thermal Maximum (PETM) is an excellent analogue for understanding the long-term effects of present-day fossil fuel carbon combustion. The carbon cycle perturbation during the PETM was initiated at ~ 56 Ma and lasted for less than 200 kyr. Temperature reconstructions indicate warming averaging ~5°C. However, to date, no constraints exist for the response of surface water *p*H through this fossil carbon release event. If the injection of several thousand Gt of carbon occurred sufficiently rapidly relative to the mixing time of the oceans, it should have resulted in a significant drop in surface water *p*H that subsequently recovered to near pre-event values. The existence of such a perturbation of surface water *p*H can be resolved by means of the boron isotopic composition of marine carbonates.

Here the first MC-ICP-MS based boron isotope record from both mixed-layer and thermocline dwelling foraminiferal species across the PETM from DSDP Site 401 in the North Atlantic will be presented. These results are complemented by elemental records and new carbon and oxygen isotope data generated from the same samples. Although we find perturbations in our various elemental and isotopic records across the PETM-related carbon isotope excursion (CIE), the degree of ocean acidification and, hence, inferred carbon release, is surprisingly small. Carbon cycle modelling using our new boron isotope records suggests that this comparatively small degree of ocean acidification during the CIE was driven by a methanogenic source of carbon.

CO_2: Waste or resource ? The role of mineral/water interfaces

F. GUYOT

IMPMC, Université Paris Diderot, IPGP, CNRS, UPMC, Paris, France (guyot@impmc.upmc.fr)

In the context of the anthropogenic destabilization of the carbon cycle, the CO_2 molecule is often considered as a waste to be captured and stored as far away as possible. Both nature and chemistry suggest, however, that, in some specific conditions, CO_2 can be turned into a useful resource. In this talk, I will examine how mineral/water interfaces present in several geological systems could possibly contribute to that purpose. Solid carbonates and hydrocarbonates produced by CO_2 carbonation of basic and ultrabasic minerals can sometimes be valuable materials. Their characteristics mostly depend on interfacial layers that develop at the surface of the primary minerals. Results of observations by focused ion beam coupled to transmission electron microscopy, in different contexts between 25°C and 180°C, will be given; the role of iron on their passivating properties will be shown. Abiotic hydrogen production and CO_2 reduction, a way of converting CO_2 into energetic resources, but also into strong greenhouse species, will be demonstrated at mineral/water interfaces by contrast with the fact that no such processes occur in pure aqueous phase. The actions of magnetite and of iron carbonate (siderite), will be investigated. The production yields of different organics ranging from formic acid to methanol and to methane in presence of iron-bearing mineral surfaces will be given and modeled. High resolution transmission electron microscopy of magnetite and siderite surfaces will be shown and discussed with respect to this question. Finally, recent intringuing mineral preferences concerning biological CO_2 reduction in the oceanic sub seafloor will also be examined. A tentative geomicrobiological and thermodynamic model will be proposed for understanding different routes of CO_2 reduction at those mineral/water interfaces.

The ultra-high pressure phase diagrams of SiO_2 and $MgSiO_3$

F. GUYOT[1*], A. BENUZZI-MOUNAIX[2], S. MAZEVET[34] AND T. TSUCHIYA[4]

[1]IMPMC, Université Paris Diderot, IPGP, CNRS, UPMC, Paris, France ([*] correspondence : guyot@impmc.upmc.fr)

[3]LUTH Observatoire de Paris, CNRS, UPD, Paris, France
[4]CEA-DAM-DIF, Arpajon, France
[5]Geodynamics Research Center, Ehime University, Matsuyama, Ehime, Japan

As a result of condensation sequences in protostellar nebulae and subsequent metal/silicate differentiation, planetary mantles are to first order close to an average $MgSiO_3$ composition. Indeed, large uncertainties exist about the Mg/Si ratios but in all cases, the question of the dissociation of $MgSiO_3$ or Mg_2SiO_4 into MgO and SiO_2 is crucial for understanding the mantles of terrestrial planets, the putative rocky cores of giant planets and possibly the early Earth. In this study, we have investigated the ultra high pressure phase diagram of SiO_2 using ab initio quantum calculations. We have observed an increase with pressure of the average effective Si-O coordinence from 4 to 9 in both solid and liquid phases. We have calculated the melting line and extracted elementary thermodynamic parameters for the solid and liquid phases which were then used to infer dissociation pressures and temperatures of $MgSiO_3$. The ab initio calculated electrical conductivity of the SiO_2 liquid phase allowed us to determine the position of liquid metallic SiO_2 in the phase diagram. The thermodynamic connections between SiO_2 metallization and $MgSiO_3$ dissociation and the implications for rocky cores of giant planets and early terrestrial mantle will be discussed. Finally, all these results from theory will be compared with experimental results acquired at ultra high pressures in dynamical compressions, including very recent ones.

Prebiotic Simulations of Shallow Sea Hydrothermal Vents: Photochemical Reduction of CO_2 on Sphalerite

MARCELO I. GUZMAN* AND RUIXIN ZHOU

Department of Chemistry, University of Kentucky, Lexington, KY 40506, USA (marcelo.guzman@uky.edu)

A key requirement to understand the origin of life is to explain how early metabolism could have emerged. In the model of central universal metabolism [1], all carbon fixation pathways used by living organisms share at least one common intermediate [2], implying that all carbon fixation mechanisms are linked, and that a prebiotic mechanism should have used key organic compounds from present anabolic cycles. Photoelectrochemical reactions on semiconductor mineral surfaces have been proposed to play a central role in this scenario.

In this study sphalerite (ZnS) semiconductor mineral is used as a model catalyst to explore prebiotic reactions occurring in a shallow sea hydrothermal vent [3]. Sunlight free energy drives otherwise unviable reactions in the prescence of ZnS mineral produced *in situ*. The material and photoelectrochemical characterization of the ZnS colloidal suspensions and comparison to commercial samples includes powder X-ray diffraction, transmission electron microscopy, energy dispersive spectroscopy, and dynamic light scattering.

Experimental sesults show the photoreduction of dissolved carbon dioxide (C+IV) and the coevolution of species produced from sulphide hole scavenger. The photoreduction reaction proceeds to generate formate as the main initial photoproduct. The quantum efficiency of formate production (Φ) in the ultraviolet spectrum at pH relevant to the early ocean waters ($7 < pH < 9$) follows a dependence on wavelengths described by the equation: Φ (%) = 10.730 - 0.031 × λ (nm), with a coefficient of correlation $r^2 = 0.991$. The quantum efficiency does not depend on temperature between 283 and 328 K. The mechanism provides a way to capture energy from the environment while producing carbon feedstock useful in anabolism. The results of this study suggest that central metabolites could have participated in a viable enzyme-free cycle for carbon fixation in a shallow sea hydrothermal vent, where light, sulfide minerals, carbon dioxide, and other organic compounds interacted on the prebiotic Earth to generate an autonomous chemical cycle [1].

Trace element partitioning between immsicible silicate and carbonate melts, based on natural melt inclusions from Kerimasi volcano, Tanzania

TIBOR GUZMICS[1] AND ZOLTÁN ZAJACZ[2]

[1]Lithophere Fluid Research Lab, Department of Petrology and Geochemistry, Eötvös University Budapest, Hungary
[2]Department of Earth Sciences, Institute of Geochemistry and Petrology, ETH Zürich, Switzerland

Although trace element partitioning between immiscible silicate and carbonate melts has been studied experimentally [1, 2], the reason for enrichment of calciocarbonatites in HFSE (=high field strength elements), REE (=rare earth elements) and Y is still controversial.

We have carried out LA-ICP-MS analyses of silicate and carbonate melt inclusions as well as rock forming minerals from two plutonic rocks (afrikandite and calciocarbonatite) from Kerimasi volcano. Melt inclusions show that immiscibility between silicate and carbonate melts occurred from a parental carbonated nephelinite magma. During liquid immiscibility Li, Na, Pb, Ca, Sr, Ba, B, REE, Y, U, V, Nb, P, Mo, W and S are partitioned into the carbonate melt whereas, Mg, Mn, Fe, Co, Ni, Cu, Zn, Al, Sc, Si, Ti, Hf, Zr and Th are partitioned into the silicate melt. Potassium, Rb, Cs, and Ta show almost no preferential partitioning. Strong distribution of sulfur (as SO_4^{2-}) and P (as PO_4^{3-}) into the carbonate melt (relative to silicate melt) could result in partitioning of Nb, Pb and all REE into the same melt. In perovskites compatibility of MREE, LREE, Ti, Zr, Nb, Ta and U increases; in magnetite that of Nb and Zn also increases during evolution of carbonate melts from afrikandite to calciocarbonatite.

We demonstrate that enrichment of calciocarbonatite rocks in LREE, Nb, Zr, Zn, Th and U is determined by both the fractionation of elements during silicate-carbonate liquid immiscibility prior to formation of these rocks and the significant changes in $D_{\text{MINERAL-CARBONATE MELT}}$ values during subsequent evolution of the physically separated carbonate melt.

Effects of volcanic CO_2 vents on a freshwater environment, the Laacher See

S. GWOSDZ[1], I. MÖLLER[1], H. H. RICHNOW[2] AND M. KRÜGER[1]

[1] Federal Institute for Geosciences and Natural Resources (BGR), 30655 Hannover, Germany
[2] Helmholtz Centre for Environmental Research (UFZ), 04318 Leipzig, Germany

The Laacher See volcanic centre, located in the middle of the East Eifel volcanic field (Germany) discharges about 5 000 t of CO_2 per year. The CO_2 is released from multiple gas vents at the bottom of the lake. Natural CO_2 sources like Laacher See allow the determination of CO_2-induced biogeochemical alterations of ecosystems.

Therefore, biogeochemical parameters as well as microbial metabolisms, abundance and diversity were studied to assess potential effects of elevated CO_2 concentrations on that freshwater sediment ecosystem.

CO_2 seeps at the lake bottom and reference areas were localised using different hydroacoustic measurements. The flux rates and the composition of seeping gases were verified with divers and a small remotely operated vehicle (ROV). For the investigation of active metabolic pathways, cultivation experiments under aerobic and anaerobic conditions were conducted and the formation of e.g. CO_2 and CH_4 was analyzed by gas chromatography. The microbial population was characterized using quantitative real time PCR (qPCR) for 16S rRNA and functional genes, TRFLP and sequencing.

Dissolved CO_2 in bottom water as well as in sediment pore water samples had a carbon isotopic signature close to that in the gas bubbles, both confirming a magmatic origin of the gas. Analysis of water samples collected close to intensive CO_2 seeps showed a low pH and an increase of dissolved CO_2. Furthermore, geochemical and microbiological analyses of deep sediment cores from CO_2-affected and reference sites showed alterations in the carbon isotopic signature, pH, microbial activity and populations. 16S rRNA gene copy numbers of Bacteria and Archaea from CO_2 induced and reference sites varied by four orders of magnitude. Similar results could be detected for the analyzed microbial CO_2 and CH_4 turnover. Our results illustrate a CO_2 impact on the geochemistry, microbial activity and community composition caused by the increasingly anaerobic and acidic environmental conditions.

U–Pb chronology and REE geochemistry of large zircons in Estherville mesosiderite

MAKIKO K. HABA[1]*, AKIRA YAMAGUCHI[2], HIROYUKI KAGI[1], KEISUKE NAGAO[1] AND HIROSHI HIDAKA[3]

[1]Geochemical Research Center, University of Tokyo, Bunkyo-ku, Tokyo 113-0033, Japan (correspondence: kikuchi@eqchem.s.u-tokyo.ac.jp)

[2]Antarctic Meteorite Research Center, National Institute of Polar Research, Tachikawa, Tokyo 190-8518, Japan

[3]Department of Earth and Planetary Systems Science, Higashi-Hiroshima, Hiroshima 739-8526, Japan

Mesosiderites are breccias composed of almost equal proportions of silicates and Fe-Ni metal. The oxygen isotopic compositions of the silicate parts of mesosiderites and HED (howardite, eucrite, and diogenite) meteorites indicate that their parent bodies are same or located in the same region [1]. However, an origin and formation histories of mesosiderites are still enigmatic, because they have experienced complex metamorphism [2]. In this study, we report results of *in situ* analyses of large zircons found in Estherville mesosiderite.

An electron probe micro-analyser was used to identify a zircon by elemental mappings of Zr and Si and for quantitative analysis of major elements. Crystallinity and structure of zircons were evaluated by Raman spectra and cathodoluminecence (CL) images, respectively. U–Pb isotopes and rare earth elements (REE) contents were analyzed using a sensitive high resolution ion micro-probe (SHRIMP).

Two large zircons, 30 × 100 μm and 100 × 300 μm, were found. The CL images and Raman spectra indicate that the larger zircon consists of several domains. U and REE contents of the most part of the zircons are quite low compared with those in basaltic eucrites [3, 4]. However, the larger zircon has U- and REE-enriched area where U and REE contents are well consistent with those in basaltic eucrites. The ^{207}Pb–^{206}Pb age of the U- and REE-enriched area is 4520 ± 14 Ma (2σ, n = 3), which is younger than zircons in basaltic eucrites [3] and Vaca Muerta (mesosiderite) [5]. These results suggest that the original zircons in Estherville were similar to those in basaltic eucrites and could have recrystallized and overgrown during the metal-silicate mixing event.

Oxygen transfer across the capillary fringe: Impact of transient flow conditions and coarse-material lenses

C.M. HABERER[1]*, M. ROLLE[1,2], O.A. CIRPKA[1] AND P. GRATHWOHL[1]

[1]Department of Geosciences, University of Tübingen, Hölderlinstraße 12, 72074 Tübingen, Germany (*correspondence: christina.haberer@uni-tuebingen.de)

[2]Department of Civil & Environmental Engineering, Stanford University, 473 Via Ortega, Stanford, CA 94305, USA.

We performed quasi 2-D flow-through experiments at the laboratory bench-scale to investigate the impact of transient flow conditions and a coarse-material inclusion on oxygen transfer from the unsaturated zone, across the capillary fringe (CF), to anoxic water. The experimental setup consists of a flow-through chamber with inner dimensions of 80 cm × 40 cm × 0.5 cm (Fig. 1). Glass beads with two different ranges in grain diameter were used as porous media. We applied a non-invasive optode technique to measure high-resolution vertical O_2-concentration profiles across the CF at several distances from the inlet of the flow-through chamber. In addition, the oxygen flux at the inlet and in the effluent of the flow-through chamber was monitored over time.

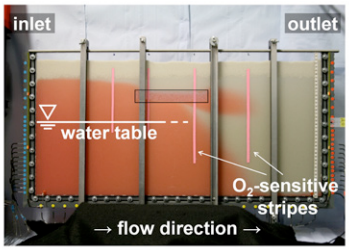

Figure 1. Experimental setup with coarse-material inclusion. The red dye (New Coccine) was used to visualize the flow field.

In homogeneous porous material, we quantified the effect of different water table dynamics, i.e., slow and fast water table fluctuations, on oxygen transfer. Enhanced O_2-supply was observed in case of slow fluctuations due to pronounced partitioning from entrapped air. In case of a fast draining water table the effect of specific yield has to be considered. The experiments performed in the heterogeneous system showed that oxygen transfer was significantly increased by the coarse-material inclusion due to flow focusing, the capillary barrier effect, and the presence of an air passage. These processes contributed to the overall enhancement of O_2-transfer through the CF to the underlying anoxic groundwater up to seven times compared to what was observed in the homogeneous experimental setup.

Influence of bacterial biomass on transport kinetics of phenanthrene

N. HACHICHO*, A. MILTNER, L.Y. WICK AND M. KÄSTNER

UFZ - Helmholtz Centre for Environmental Research Leipzig, Germany (*correspondence: nancy.hachicho@ufz.de)

Introduction

In soils, both pollutants and pollutant-degrading organisms are heterogeneously distributed. For an efficient site remediation by biodegradation, transport of either the pollutant or the microorganisms is necessary. Earlier studies show the effect of fungal hyphae on the transport of both chemicals and bacteria by fungal highways or pipelines [1]. In our study we investigated how the presence of bacterial biomass affects the diffusive transport of phenanthrene in aqueous solution in model systems (adapted from ref [2]) in the laboratory.

Phenanthrene Transport in Passive Dosing Systems

We studied the transport of phenanthrene from a silicone ring loaded with phenanthrene (source) to a larger clean silicone ring (sink). Both rings were placed in a vial containing 1 ml of medium with or without bacteria not able to degrade phenanthrene at different cell densities. After xy hours, source, sink and medium were analysed separately for phenanthrene.

Results and Discussion

The presence of bacterial biomass increased the medium's capacity for phenanthrene, but no difference in the phenanthrene contents in the source and the sink ring were found (Fig. 1). Further experiments with different soil bacteria with a range of surface properties and motilities will provide additional informationn to elucidate the role of bacterial biomass for the transport of chemicals in soil.

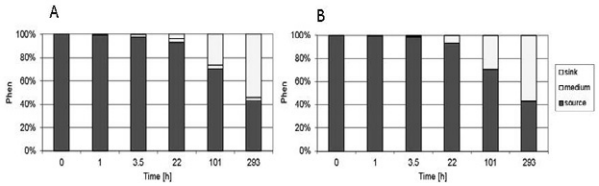

Figure 1: Phenanthrene distribution in passive dosing systems with biofilm of *Arthrobacter chlorophenolicus A6* on the surface (A) and sterile agar (B).

[1] Banitz *et al*(2012) *EnvironMicrobiolRep* 2012, 1-8. [2] Smith *et al* (2012) *Environ. Sci. Technol.* **46**, 4852–4860.

Campaign-style titanite U-Pb dating by laser-ablation ICP: Implications for crustal flow, phase transformations and titanite closure

B.R HACKER[1] A.R.C. KYLANDER-CLARK[1] T.B. ANDERSEN[2A] AND J.M. COTTLE[1]

[1]Earth Science, University of California, Santa Barbara CA 93106, USA (hacker@geol.ucsb.edu)

[2]Geosciences, Universitetet i Oslo, P.O. Box 1047 Blindern, 0316 Oslo, Norway

U-Pb dates of titanite from >150 samples of quartzofeldspathic gneiss and leucosomes were measured across the ultrahigh-pressure (UHP) Western Gneiss Region of Norway to understand deformation and metamorphism of continental crust during subduction and exhumation. Titanite is unstable at pressures > 1.5 GPa, and, indeed, most yielded post-UHP dates. A number of titanites sampled across large areas, however, have pre-UHP U-Pb dates, indicating that the titanites survived their excursion to and return from mantle depths metastably. This has three important implications. Titanite grains can remain closed to complete Pb loss during regional metamorphism at temperatures as high as 750°C and pressures as high as 3 GPa, implying that thermally mediated volume diffusion was not the principal factor controlling resetting of the U-Pb system. Phase transformations in and deformation of quartzofeldspathic rocks can be inhibited at the same conditions.

Interpretation of extreme diagenetic settings with a new thermodynamic activity model

LAURA HAFFERT[1], MATTHIAS HAECKEL[1], VOLKER LIEBETRAU[1] AND DIRK DE BEER[2]

[1]Helmholtz Centre for Ocean Research Kiel (GEOMAR), Germany (*correspondence: lhaffert@geomar.de, mhaeckel@geomar.de, vliebetrau@geomar.de)
[2]Max Planck Institute for Marine Microbiology, Bremen, Germany (dbeer@mpi-bremen.de)

A thermodynamic activity model (Pitzer approach) applicable to extreme environmental pTS-conditions (up to 1000 bar, 200 °C and 6 M NaCl) coupled to an extensive mineral database has been developed. The advantage of this code is the incorporation of a comprehensive pressure correction, as well as the flexibility on the choice of input datasets, allowing fine-tuning of the model according the relevant pTS range. This code is then integrated into our transport-reaction models, allowing for the interpretation of extreme diagenetic settings, where regular seawater models fail.

One such setting is the Mercator mud volcano in the Gulf of Cadiz, where the porewater profiles are characterised by a strong salinity gradient in the upper 1-2 mbsf created by the mixing of upward advecting hypersaline (halite and gypsum saturated) mud volcano fluids and seawater (S=35). In addition, various types of authigenic gypsum ($CaSO_4 \cdot 2H_2O$) and anhydrite ($CaSO_4$) crystals, typical for evaporitic environments, were found. We show, that here the precipation of authigenic $CaSO_4$ minerals is temperature driven and directly related to heat pulses that are typically occuring at mud volcanoes. The composition of the $CaSO_4$ mineral, in turn, is additionally controlled by the salinity gradient, raising the gypsum-anhydrite transition zone from >1 km to about 500 m sediment depth and during heat pulses (> 30 °C) even to within a few metres below the seafloor.

Another application is the geochemistry of the sediment-hosted natural CO_2 seeps in the southern Okinawa Trough. At the Swallow Chimney, located at 1380 mbsf, liquid CO_2 and CO_2 hydrates are encountered in the top decimetres below the seafloor. Here, the strong CO_2 and concomitant pH gradient induce silicate and complete carbonate dissolution downcore. However, some carbonate is reprecipitated towards the seafloor again, as suggested by the radiogenic and stable Sr isotopy. Our thermodynamic model is used to test this hypothesis and to quantify the diagenetic processes occurring in this extreme geochemical environment.

Carbon isotope gradients in the Eocene as a constraint on the biological pump, atmospheric CO_2 and the ocean's major ion composition

MATHIS P. HAIN[1], DANIEL M. SIGMAN[1], J. A. HIGGINS[1], AND GERALD H. HAUG[2]

[1]Princeton University, (mhain@princeton.edu)
[2]ETH Zürich

In the modern ocean surface the $\delta^{13}C$ of dissolved inorganic carbon (DIC) is high (^{13}C-enriched) relative to deep waters, due to isotope fractionation during biological carbon fixation and the subsequent export of organic matter from the surface to sequester ^{13}C-deplete carbon at depth, the soft-tissue component of the biological pump. In the Eocene, observations suggest that these isotope gradients where greater than today, leading to the inference that the biological pump was stronger. However, this argument ignores the much greater ocean carbon inventory under high atmospheric CO_2 levels during the Eocene, which would dilute the biologically driven $\delta^{13}C$ gradients. Box model simulations indicate a number of mechanisms to resolve this discrepancy, including changes in the ocean's major ion composition and meridional temperature gradient. When using observational constraints such as temperature reconstructions, the depth of seafloor carbonate preservation, fluid inclusion data and the absence of large-scale anoxia in the Eocene ocean, we find that the $\delta^{13}C$ gradients are inconsistent with atmospheric CO_2 levels greater than 1200 ppm. In these Eocene scenarios, the ocean's DIC is similar to today, but *p*H and buffer capacity are much lower, with implications for marine calcifying organisms.

Complete simulation of deglacial changes in atmospheric $^{14}C/C$: Implications for ocean circulation changes and CO_2 release

MATHIS P. HAIN[1], DANIEL M. SIGMAN[1] AND GERALD H. HAUG[2]

[1]Princeton University, (mhain@princeton.edu)
[2]ETH Zürich

We present a new deglacial budget (production and decay) of ^{14}C, the first to correctly predict the preindustrial global activity of ^{14}C. While ^{14}C production change accounts for most of the overall decline in atmospheric $^{14}C/C$ (i.e., $\Delta^{14}C_{atm}$) since the Last Glacial Maximum, it fails to explain the rapid observed $\Delta^{14}C_{atm}$ swings during deglaciation. We use a carbon cycle model to separate the contribution of ocean CO_2 release and circulation changes to the $\Delta^{14}C_{atm}$ history, which together yield an exceptional match to available terrestrial $\Delta^{14}C_{atm}$ data, both in terms of overall deglacial $\Delta^{14}C_{atm}$ decline and millennial scale variations. The previously hypothesized but not yet identified stagnant "mystery reservoir" in the ice age ocean is not required in our simulations.

Ocean chemistry before and after the rise of atmospheric O_2

I. HALEVY[1]

[1]Weizmann Institute of Science, Rehovot 76100, Israel,

The tight coupling among the biogeochemical cycle of O_2 and those of the major redox-sensitive elements, such as C, Fe and S [1-3], implies that the rise in atmospheric O_2 was likely preceded, accompanied and followed by radical rearrangements in the cycles of these elements. Indeed, the rise of O_2 appears to be recorded in a variety of marine geochemical and isotopic records, especially those of Fe and S. Among others, these include traditional and mass-independent S isotope ratios [4,5], Fe isotope ratios [6], detrital O_2-sensitive mineral grains [7], and banded iron formations [7]. Qualitative understanding of these records hinders insight into events that fundamentally reshaped Earth's surface environment. I have developed a chemically detailed, spatially resolved model of the coupled marine biogeochemical cycles of S and Fe [8], which I use here to provide quantitative constraints on ocean chemistry before and after the rise of O_2.

Prior to the rise of O_2, the main S reservoirs in the ocean are sulphate and thiosulphate, with concentrations up to ~60 and ~10 μM, respectively, consistent with recent constraints from mass-independent S isotopes in VMS deposits [9]. Elemental S particles (S_8), which settle rapidly, reach only sub-nanomolar concentrations, but contribute much of the S flux to the sediments. A balance between riverine and hydrothermal supply of Fe^{2+} and its oxidation in the photic zone governs water-column Fe^{2+} concentrations, which do not exceed 5 μM, unlike suggestions that mineral solubility allowed Fe^{2+} concentrations as high as ~100 μM [7]. After the rise of O_2, sulphate becomes essentially the only marine S reservoir, and its concentration exceeds 1 mM. Sulphide concentrations in hydrothermal fluids exceed those of Fe, resulting in a decline of the hydrothermal Fe influx. Deposition of Fe (as Fe^{3+}-hydroxides) becomes limited to near-shore environments.

Among other topics, I will discuss the implications of these results to the records S isotope ratios, to metabolic S and Fe utilization, and to the observed Precambrian sedimentary record.

Densities of dilute coenzyme M solutions to 0.80 MPa and 353.15 K

A. S. HALL[1] AND J. C. SEITZ[1] *

[1]California State Univ. East Bay, Hayward, CA 94542 USA
(*correspondence: jeff.seitz@csueastbay.edu)

Sodium 2-mercaptoethanesulfonate ($C_2H_5NaO_3S_2$), also known as coenzyme M is a thiol that is essential to the process of methanogenesis [1]. Coenzyme M is a cofactor involved in methyl transfer reactions within methanogenic archaea. Given that fossil evidence of methanogenic archaea may date back to 2.8 billion years [2], methanogenesis is likely an ancient metabolic process. Determining the thermodynamic properties of coenzyme M is essential for understanding the potential for its formation and reaction properties in high P-T environments that host extremophiles and may have hosted the emergence of life.

The volumetric properties of dilute aqueous solutions of coenzyme M (0.09966 m, 0.19950 m, 0.299921 m & 0.39815 m) were obtained using an Anton Paar DMA 5000 vibrating tube densimeter. Reproducibility of density measurements was $<\pm 0.00002$ g·cm^{-3}, exceeding propagated errors associated with uncertainty in the measurement of temperature, pressure, and fluid concentration.

Experimentally determined volumetric properties of coenzyme M have not been previously reported in the literature. Figure 1 shows partial molar volumes at infinite dilution (V^∞) derived from fluid density data; it is clear that V^∞ is not a sensitive function of pressure in the range examined.

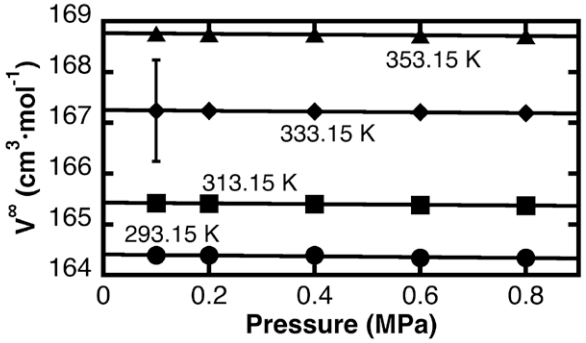

Figure 1. Experimentally determined partial molar volumes at infinite dilution of sodium 2-mercaptoethanesulfonate in aqueous solutions at 0.10-0.80 MPa and 293.15-353.15 K from this study. Lines represent simple linear regression fits to the data. The error bar represents the estimated uncertainty of ±1.0 cm^3·mol^{-1}.

Deep carbonate recycling and metasomatic enrichment of the sub-continental lithospheric mantle inferred from mantle xenoliths of the East African Rift system

S. A. HALLDÓRSSON[1]*, D. R. HILTON[1], P. SCARSI[2], T. ABEBE[2], J. HOPP[3] AND S. CHAKRABORTY[4]

[1]Scripps Institution of Oceanography, UCSD, La Jolla, USA
(*correspondense: shalldor@ucsd.edu)
[2]IGG-CNR, Pisa, Italy
[3]Mineralogisches Institut, Universität Heidelberg, Germany
[4]Department of Chemistry, UCSD, La Jolla, USA

The source region of the extensive magmatism driving the East Africa Rift System (EARS) is thought to involve one or more deep-seated mantle plumes with variable interactions with overlying crust and, in particular, sub-continental lithospheric mantle (SCLM). To assess the role of SCLM in modulating the volatile systematics of plume-related material, we report new results on the He-CO_2-N_2 isotope and relative abundance of mantle xenoliths from throughout the EARS (Red Sea, Ethiopia, Kenya and Tanzania).

Our analytical approach involves crushing mafic crystals to release CO_2 and N_2 trapped in fluid inclusions. This approach was used on a suite of gas-rich xenoliths (dominantly pyroxenites, n=25). The xenoliths display a large range in He-isotopes (5.9 to 13.9R_A) but have a limited range of $\delta^{13}C$ values (-3.3 to +0.8‰), with only two xenoliths showing values lower than -2‰. $\delta^{15}N$ values range from -4.11 to +5.89‰ and $CO_2/^3He$ and CO_2/N_2 ratios vary by orders of magnitude from 0.020 to 7.0 (x10^9) and 0.42 to ~3800, respectively.

The $\delta^{13}C$-$CO_2/^3He$ systematics of the xenoliths fall on a 2-component mixing line where the low $CO_2/^3He$ endmember is ~3x10^8, significantly lower than the DMM value (~2x10^9) This low ratio is consistent with low-end estimates of DMM and the mean $CO_2/^3He$ ratio of E-chondrite [1]. Thus, our new data are consistent with enrichment of the SCLM by CO_2-rich mantle fluids with $CO_2/^3He$ ratios >>3x10^8 and $\delta^{13}C$ ~0‰ - characteristics of recycled C from subducted carbonatitic material. Such CO_2 enrichments are also associated with positive $\delta^{15}N$ values reinforcing the link between the metasomatic fluid and subduction. Notably, xenoliths with high $^3He/^4He$ ratios (Afar) are also associated with $\delta^{15}N$ > -5‰, implying an important role for the deep-seated Afar mantle plume in supplying recycled volatiles to the SCLM. Oxygen isotope analysis (in prep) will further enable us to constrain the nature of the recycled component.

Volatile budgets and the late veneer

ALEX N. HALLIDAY[1]*

[1]Department of Earth Sciences, University of Oxford, Oxford, OX1 3AN, U.K. (correspondence: alexh@earth.ox.ac.uk)

The late veneer hypothesis was proposed to explain the budgets of refractory highly siderophile elements (HSEs) in the bulk silicate Earth (BSE) [1], which are too abundant to be in equilibrium with core-forming metallic liquids at low pressures. It was argued that they were added in chondritic proportions after the core formed. It has also been proposed that Earth's volatiles were added as part of this veneer after the Moon forming Giant Impact [e.g. 2]. However, a late veneer does not explain Earth's volatiles. The similarities in moderately siderophile elements [3] and identical isotopic compositions of Si [4] and W [5] in the BSE and Moon provide evidence that terrestrial core formation and accretion were limited following the Giant Impact [6]. For example, a veneer of ordinary chondrites [7] would need to be <0.3±0.3% to be consistent with W isotopes [6]. The H/C/N ratios of the BSE (including all surface budgets) are strongly non chondritic. The estimated BSE H/N is 45 whereas carbonacous chondrites have H/N <15 [8]. If Earth's N was contributed by a CI chondritic veneer, more than 70% of the H would need to be accreted from an additional source [8] requiring that major portions of Earth's volatiles predate any putative chondritic late veneer. Earth's Ne, Ar and Kr are also too abundant to be explained with a chondritic veneer. Cometary ices do have enriched Ar relative to major volatiles [9]. This would explain Earth's heavy noble gases but with amounts that are too small to also explain the H, C and N [8]. A more likely scenario is that after incorporation of early Solar components, Earth acquired most of its volatiles during main stage accretion. This included noble gases, in roughly chondritic proportions, with some fractionation from amorphous ices. A mechanism is required that will also fractionate the BSE's H, C and N from each other, as well as deplete them relative to noble gases. Possibilities for this are losses to space and partitioning into Earth's core before and / or during the Giant Impact [8,10]. However, a volatile rich late veneer does not readily explain the data.

The D/H ratio of the Deep Mantle

L. J. HALLIS*[1,2], G. R. HUSS[1,2], G. J. TAYLOR[1,2], K. NAGASHIMA[2] , S.A. HALLDÓRSSON AND D.R. HITLON

[1]University of Hawaii NASA Astrobiology Institute (*Correspondance: lydh@higp.hawaii.edu)

[2]Hawai'i Institute of Geophysics and Planetology, University of Hawaii, 1680 East-West Road, Room 503, Honolulu, HI 96822

The ratio of deuterium (^{2}H) to hydrogen (^{1}H) in the Earth's atmosphere has changed over geological time. The lighter hydrogen isotope (^{1}H) is preferentially lost to space via Jeans (thermal) escape, hence the atmosphere slowly becomes relatively enriched in deuterium and the ^{2}H/^{1}H ratio increases. To measure the initial ^{2}H/^{1}H ratio of the Earth we must sample a reservoir that has been totally isolated from surface processes.

Plate tectonics is known to drag surface water down into the upper mantle, but primitive areas of the lower mantle may be isolated from this circulation, hence uncontaminated by surface hydrogen [1,2]. Certain mantle plumes, such as those that formed the Hawaiian Islands, Iceland, and Baffin Island, appear to have tapped into primitive, un-degassed, deep mantle sources, as evidenced by helium isotope ratios in rock samples from these regions [2,3]. Therefore, ^{2}H/^{1}H analyses of hydrous melt inclusions from erupted lavas at these sites could give an accurate value for the Earth's primordial water. However, oxygen isotope data suggest that some contamination from crustal material does occur in areas where the crust is thick (e.g., Iceland and Baffin Island) [4]. Therefore, comparisons between oxygen and hydrogen isotope data should be made for samples from these areas.

We are currently measuring the ^{2}H/^{1}H and ^{18}O/^{16}O ratios in pristine olivine melt inclusions and glasses from numerous Icelandic and Baffin Island basaltic units [5,6]. A number of these units contain some of the highest ^{3}He/^{4}He ratios currently measured worldwide, indicating a primitive deep mantle origin [2,6]. Others have lower ^{3}He/^{4}He ratios. Helium isotope variations will enable us to determine whether samples with higher (more primitive) helium isotope ratios correspond to lower hydrogen isotope ratios.

Secular trends in the global ocean revealed through trace elements in sedimentary pyrite

J.A. HALPIN[1]*, R.R. LARGE[1], L.V. DANYUSHEVSKY[1], V.V. MASLENNIKOV[2], D. GREGORY[1], T.W. LYONS[3] AND E. LOUNEJEVA[1]

[1]ARC CODES, University of Tasmania, Private Bag 126, Hobart 7001, Australia (*correspondence: jahalpin@utas.edu.au, ross.large@utas.edu.au, l.dan@utas.edu.au, ddg@utas.edu.au, Elena.Lounejeva@utas.edu.au)
[2]Institute of Mineralogy, Urals Branch, Russia (maslennikov@mineralogy.ru)
[3]University of California, Riverside, CA, USA (timothy.lyons@ucr.edu)

Sedimentary pyrite incorporates trace elements (TE) during growth at levels far beyond the host bulk rock, making it a potentially powerful proxy for seawater chemistry in the marine rock record. We have developed a novel approach to simultaneously quantify a suite of TE via LA-ICPMS in sedimentary pyrite from marine black shales, as a proxy for chemical changes in palaeo-oceans. When our sedimentary pyrite data is compared with published whole-rock data, we see similar trends. We show that the temporal TE curves for 22 elements in sedimentary pyrite can be related to secular changes on Earth over 3.5 billion years.

The Mo trend increases through time attributed to the significantly lower levels of oxygen in the atmosphere and oceans in the early Earth system [1]. The effects of the Great Oxidation Events are shown by the jumps in Mo at ~2500 Ma and 650 Ma, similar to what is seen in the bulk shale data. The broad Ni and Co trends are the opposite to Mo, attributed to cooling upper mantle temperatures and decreased eruption of komatiitic lavas from ~2700 Ma [2]. Pulses of elevated Ni and Co correspond to episodes of Large Igneous Province eruptions, particularly obvious with the Siberian Traps at the Permian-Triassic boundary. Phanerozoic trends in all TE are far more cyclical. We identify Se as being particularly redox sensitive, which allows us to explore finer-scale fluctuations through the Phanerozoic [3]. As our database expands in both scope and temporal detail, this new approach in measuring TE in sedimentary pyrite has exciting potential for chemical palaeo-ocean research.

The oxidation state of uranium in basaltic magmas

H.R. HALSE[1,2,3]*, A.J. BERRY[1], P.F. SCHOFIELD[2], J.F.W. MOSSELMANS[3], K.O. KVASHNINA[4] AND G. CIBIN[3]

[1]Department of Earth Science and Engineering, Imperial College London, South Kensington, SW7 2AZ, UK (*correspondence: h.halse10@imperial.ac.uk)
[2]Department of Earth Sciences, Natural History Museum, London, SW7 5BD, UK
[3]Diamond Light Source Ltd, Didcot, OX11 0DE, UK
[4]European Synchrotron Radiation Facility, Grenoble, France

Recently erupted mid-ocean ridge basalt (MORB) often exhibits disequilibria between the series of isotopes associated with the radioactive decay of U to Pb. This suggests rates of melt trasport that are fast relative to the half-lives of the isotopes that are of anomalous abundance. Current U-series models are based on the assumption that U^{4+} is the only oxidation state of U important during the generation, transport, and differentiation of MORB magmas. However, if U^{5+} and/or U^{6+} were stable in the melt, then the chemical behaviour of U relative to Th^{4+} (and the other elements of the decay series) would vary significantly.

High resolution U M_4-edge X-ray absorption near edge structure (XANES) spectra were recorded for synthetic MORB and anorthite-diopside eutectic compositions glasses containing 0.5 wt % U_3O_8. Glasses were quenched from melts equilibrated at 1400 °C and a range of oxygen fugacities (fO_2) at one-atmosphere. The spectra were recorded in fluorescence mode at beamline ID26 of the European Synchrotron Radiation Facility, which allows U M_4-edge spectra to be acquired with an energy resolution that is not accessible at most synchrotron facilities. In addition, U L_3-edge XANES spectra were recorded for the same melt compositions *in situ* at magmatic temperatures at beamlines I18 and B18 of the Diamond Light Source.

The L_3- and M_4-edge spectra both vary systematically with fO_2. The M_4 spectra exhibit more complexity than the L_3 spectra and allow U^{5+} to be unambiguously identified as a major component in both glass compositions, and U redox ratios to be quantified. The proportions of U^{4+}, U^{5+}, and U^{6+} vary systematically in the glasses. U^{5+} is a significant oxidation state at the fO_2 conditions of MORB generation, with $U^{5+}/\sum U$ (where $\sum U = U^{4+} + U^{5+} + U^{6+}$) varying from ~0.25 at the QFM (quartz-fayalite-magnetite) fO_2 buffer to ~0.1 at IW (iron-wüstite) +2.

A multi-proxy record from a late Neoproterozoic volcano-sedimentary basin, eastern Arabian Shield

GALEN P. HALVERSON[1], GRANT M. COX[1], LUCIE HUBERT-THÉOU[1], MARK SCHMITZ[2], JAMES W. HAGADORN[3], PETER JOHNSON[4], PIERRE SANSJOFRE[1], AND MARCUS KUNZMANN[1]

[2]Dept. of Geosciences, Boise State University, Boise, ID 83725, U.S.A.

[3]Dept. of Earth Sciences, Denver Museum of Nature and Science, 2001 Colorado Blvd., Denver, CO 80205, U.S.A

[4]6016 SW Haines St., Portland, OR 97219, U.S.A.

Small, middle to late Ediacaran intermontane basins occur in the northern and eastern Arabian shield. The Jibalah basins are a subset of these basins that are minimally deformed and concentrated along the Najd strike-slip fault system, where they likely originated as pull-apart basins during the late stages of the East African orogeny. Whereas the Jibalah basins all appear to share similar sedimentary basin evolution and are broadly the same age, the nature of the basin fill is highly variable. The 10x50 km Jifn Basin, along the northwestern extent of the Halaban-Zarghat Fault Zone, has a carbonate-rich sedimentary succesion that was deposited between ~635 and 577 Ma. This succession includes a 340 m-thick shoaling upward section of mixed cherty limestone and dolostone, which overlies a basal, volcaniclastic conglomerate and in turn is overlain by a thick interval of medium- to coarse-grained arkosic sandstone. The carbonates are dominantly gravity flow deposits, transitioning upward into grainstones and heavily silicified microbial laminites—a facies that supplied many of the clasts to the deeper water gravity flow deposits. Felsic tuffs and tuffaceous siltstones, as much as 10 m-thick, occur throughout the succession. In several cases, these are directly overlain by a distinct sequence of organic-rich laminites, followed by rhythmites containing unusual, bubble-like (methane?) structures, and disrupted beds with evidence for fluid escape. We interpet the succession to record eutrophication of the water column following plinian volcanic eruptions. Here we report inorganic and organic C, O, S, and Sr isotopes, along with major and trace element abundances for the Jifn carbonates. We apply these proxies to evaluate the geochemical response in this small basin to massive input of volcanic material and to test its connection to the global ocean at a time of monumental environmental and biological change.

The ortho-para ratio of H_2O desorbed from ice: Implications for cometary coma

T. HAMA*, A. KOUCHI AND N. WATANABE

Inst. Low Temp. Sci., Hokkaido Univ., Japan (hama@lowtem.hokudai.ac.jp)

H_2O contains two protons with nuclear spin of I=1/2, leading to two nuclear-spin isomers: the ortho (I=1, triplet, parallel nuclear spin) and the para (I=0, singlet, antiparallel nuclear spin) with statistical weights of 3 :1. The lowest energy level of ortho-H_2O lies about 34 K above the lowest para-level in the gas phase. Nuclear-spin temperature (T_{spin}) is defined by a given ortho-para ratio (OPR), because the OPR depends on temperature in local thermodynamic equilibrium. T_{spin} of H_2O has been observed in comet coma, and it has been derived to be ~30 K. Although the T_{spin} values have been implicated as a temperature of cold grains at molecular condensation or formation in a molecular cloud, or in the solar nebula, the correlation between T_{spin} and temperatures of ice at condensation, formation, and desorption is yet to be investigated. The present study measured the T_{spin} of H_2O that was thermally desorbed from amorphous solid water (ASW) at the desorption temperature for cometary water ices, 150 K. The ASW samples were prepared at 8 K by several procedures in an ultra-high vacuum chamber: H_2O-vapor-deposited ASW and ASW produced by photolysis of CH_4/O_2 mixed solid. The sample solids were then heated to 150 K and the thermally desorbed H_2O molecules were analyzed rovibrationally. Desorbed H_2O molecules from all ice samples were found to show T_{spin} almost at the statistical high-temperature limit, indicating that T_{spin} of gaseous H_2O molecules thermally desorbed from ice does not reflect the surface temperature at which H_2O molecules condense or form under laboratory conditions.

IR spectra of thin film water sandwiched between two mineral plates

M. HAMAMOTO*, M. KATSURA AND S. NAKASHIMA

Department of Earth and Space Science, Osaka University, Toyonaka, 560-0043, Japan (*corresppondence: mhamamoto@ess.sci.osaka-u.ac.jp)

Physicochemical behaviours of water sandwiched between minerals are important to understand water-rock interactions including rock quality degradation by water. In order to examine these properties, pure water sandwiched between two mineral plates was measured by transmission infrared (IR) microspectroscopy.

Pure water is sandwiched between two mineral plates (Fig.1) and its thickness is monitored by the absorbance at 1643.5 cm^{-1}. The measurement area (100x100 μm^2) is selected to be occupied totally with water. This procedure is repeated to obtain IR transmission spectra for different pure water thicknesses.

The measured spectra include effects of reflection at air/plate/water interfaces. These effects were removed and the absorption index k was calculated.

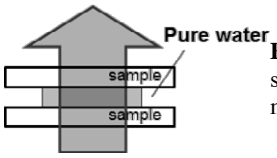

Figure 1 Pure water sandwiched between two mineral plates.

The extracted k spectra of thin film water sandwiched between two CaF_2 plates for different thicknesses from 20 nm to 1 μm were successfully obtained with high signal to noise ratio (Fig.2). These spectra match globally the k spetrum for different thicknesses within 5%.The k spectra of thin film water between different mineral plates such as Al_2O_3 and SiO_2 plates will be measured and compared.

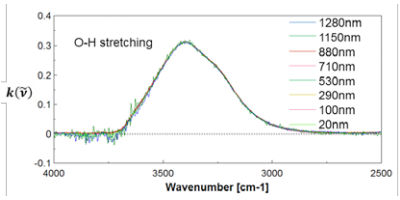

Figure 2 The absorption index k spectra of pure water with different thicknesses between two CaF_2 plates.

The sub-Arctic upper mantle, from Jan Mayen to Molloy Fracture Zone

CEDRIC HAMELIN[1] AND ROLF BIRGER PEDERSEN[1]

[1]Centre for Geobiology, University of Bergen, Postboks 7800, NO-5020 Bergen, Norway.

In recent years, sub-kilometer scale studies have revealed that regional mantle heterogeneity is generally better preserved in oceanic basalts where the melt supply is low. The Mohns and Knipovich ridges in the Norwegian Greenland Sea are among the slowest spreading mid-ocean ridges (15-17mm/yr) and present extremely low melting rates. This region is therefore a favorable location to study the different scales of geochemical mantle heterogeneity.

We present new Sr, Nd, Pb and Hf isotopic data from samples collected along Mohns and Knipovich ridges, during 4 differents cruises of the SUBMAR program (1999-2004). Our new dataset (≈ 90 samples) together with published data (60 samples), represent a dense sampling of the sub-Arctic upper mantle and allow us to look at regional variations as well as fine-scale, intra-segment, heterogeneity. A first order observation of geochemical variations along the ridge axis is a progressively decreasing influence of the Jan Mayen hotspot (71°N) toward the north (73°N). The rather large geochemical variations measured in samples from the northern part of Mohns ridge (73-75°N) and along Knipovich ridge (75-78°N), are unlikely related to hotspot-ridge interaction. The local upper mantle is influenced by the recent continental breakup and the presence of residual subcontinental lithosphere could therefore contribute to the observed geochemical variability.

Previous study of this region have documented an atypical radiogenic εHf values for a given εNd [1], which appears to be very comparable to the mantle signature discovered recently along the Mid-Atlantic Ridge near the Azores [2]. The origin of this mantle component is still a mater of debate. Our new dataset, together with published data from [1] is used to produce a detailed petrogenetic model for basalts erupted north of Jan Mayen and brings new constraints on the structure and nature of upper mantle components present in this area.

Laser $^{40}Ar/^{39}Ar$ dating of supervolcanoes and super gold deposits along the trace of the Miocene Yellowstone Hotspot

W. HAMES[1]*, M. BRUESEKE[2] AND J. SAUNDERS[1]

[1]Geology, Auburn Univ., Auburn, AL 36849, USA;
[2]Geology, Kansas State Univ., Manhattan, KS, 66506, USA.

Early volcanism of the Yellowstone hotspot began at ca. 16.5 Ma and produced abundant and extensive bimodal volcanics in northern Nevada and adjacent portions of Idaho and Utah along with some of earth's richest gold deposits. Within eruptive centers studied, volcanism tended to occur over a ~1.5 Ma interval. Tholeiitic flood basalts in this region, that are typical of the earliest Columbia River Large Igneous Province (LIP) lavas, are typically the earliest volcanics, though they were extruded in multiple events that overlap rhyolitic magmatism. Although coarse plagioclase phenocrysts are conspicuously abundant in these basalts, they tend to be low in potassium content and have high amounts of inherited, extraneous argon, such that the most robust age dating results are for laser incremental heating of the basalt's phenocryst-free, subophitic matrix. Single crystal laser fusion ages of sanidine from the rhyolites are very precise, with some samples that yield a distribution of ages with a single mode that is consistent with analytical uncertainty. However, sanidine from rhyolites in some eruptive centers yield more complex distributions of ages that are less than ~16.5 Ma, but that range beyond analytical uncertainty and comprise multiple age modes. Single crystal incremental heating analysis of sanidines from these more complex samples tend to result in release spectra with plateau and indicate the samples are not affected by extraneous, non-atmospheric argon. We interpret that the duration of magmatism and high geothermal gradients locally promoted isotopic closure at different times, in sanidine crystals of differing size and effective diffusion dimension. Adularia is associated with gold in many of the epithermal Au-Ag deposits and ores, and is commonly of sufficient grainsize to permit single crystal dating. $^{40}Ar/^{39}Ar$ fusion and plateau ages for adularia from many deposits in northern Nevada produce age distributions that are the same as the bimodal volcanics, however adularia from the Silver City district (southern Idaho) and associated Au-Ag deposits formed in one brief episode ~ 1 Ma after the earliest 16.5 Ma volcanics. In contrast with earlier models that invoke shallow crustal sources, the gold in these deposits is interpreted to have originated from a deep lithospheric or mantle source, and to have been transported by fluids to the epithermal systems as colloids.

Sensitivity boost for ICP-MS to enhance isotope ratio determinations

MEIKE HAMESTER[1]* AND RENÉ CHEMNITZER[1]

[1]Bruker Daltonik GmbH, Fahrenheitstr. 4, 28359 Bremen, Germany (*correspondence: meike.hamester@bruker.com)

ICP-MS is a powerful technique for the determination of trace elements in various matrices. Beyond that ICP-MS is able to determine isotope ratios with high accuracy and precision. In principle three intrumental ICP-MS solutions exist: Quadrupole based ICP-MS, single collector magnetic sector field ICP-MS and multicollector magnetic sector field ICP-MS. General assumption is that precision and accuracy for isotope ratio measurements increases with complexity of technology used. The work will describe the achievements in isotope ratio analysis by a new quadrupole based ICP-MS (Bruker aurora Elite). Key characteristic is a very high ion transmission achieved by an optimized interface, and a unique ion optical system with low chromatic and spherical aberrations, which focuses ions into one focal point. In result sensitivites of up to 4 Mio cps / ppb can be obtained, which exceeds sensitivities of magnetic sector field ICP-MS significantly. The high sensitivity attainable allows utilization of the fast scanspeed and short integration times (0.1 msec) without the limitation due to counting statistic.

The presentation will discuss all relevant instrumental characteristics, such as:

- Abundance sensitivity
- Scan speed
- Ion detection system
- Plasma robustness

which are important to obtain highest isotope ratio precision and accuracy.

Finally results accomplished for e.g. lead and uranium isotope ratios and lead / uranium ratios will be shown.

2-Methyl hopanoid production and anoxygenic photosynthesis: A model cyanobacteria isolated from a proterozoic ocean analog

T.L. HAMILTON[1], L.M. BIRD[1], K.H. FREEMAN[1] AND J.L. MACALADY[1]

[1]Department of Geosciences and Penn State Astrobiology Research Center (PSARC), University Park, PA 16802 USA (*correspondence tlh42@psu.edu)

Biomarkers recovered from ancient rocks provide invaluable tools to reconstruct early Earth microbial ecosystems as well as providing clues about planetary redox evolution. Bacteriohopanepolyols (BHPs) or hopanoids are membrane lipids produced by many bacteria and are among the most abundant and extractable organic compounds in ancient sedimentary rocks. Cyanobacteria are responsible for oxygenation of the atmosphere and examining their presence in the rock record with specific biomarkers such as 2-methyl BHPs can provide key clues regarding the rise of oxygen on early Earth. However, the lack of a model cyanobacterium capable of producing 2-MeBHPs as well as observations that other bacteria also produce these lipids has hindered our understanding of these biosignatures in ancient rocks. Here we demonstrate hopanoid production and anoxygenic photosynthesis in a cyanobacterium isolated from a Proterozoic ocean analog. We isolated a cyanobacterium that produces 2-MeBHPs from a red phototrophic mat in Little Salt Spring, a karst sinkhole in Florida with low levels of both dissolved oxygen and sulfide. The hopanol content of the phototrophic mat is high and rich in 2-methyl structures which are preserved in the organic-rich bottom sediments. Furthermore, we found the cyanobacterium is capable of primary productivity by anoxygenic photosynthesis. The isolation of a cyanobacteria from an environment with a Proterozoic-ocean chemical composition that produces 2-MeBHPs and is capable of anoyxgenic photosynthesis will greatly improve our understanding of the role of hopanoids in microbial physiology and ecology as well as the deposition of these biomarkers in the rock record.

The Cambrian explosion occurred between increases in atmospheric oxygen concentration in the later Neoproterozoic Eon [1, 2] and during the Paleozoic Era [3, 4]. To further constrain chemical conditions in the Early Cambrian ocean, a multi-proxy geochemical approach was applied to two new drill cores through a portion of the Early Cambrian succession of Yunnan, South China. Our results reveal a transition in local ocean chemistry that is captured in both cores. Sulfidic conditions, which were well developed in the lower Yu'anshan Formation (members 1-2), pass through a transitional interval into oxic conditions in the upper part of the Formation (member 4). In member 3, the interval bearing exceptionally-preserved fossils of the Chengjiang biota (~520 Ma), a prominent positive nitrogen isotope excursion occurs in both cores. This $\delta^{15}N$ excursion is noteworthy because it is indicative of extensive denitrification under oxygen-depleted conditions, and suggests that modern oxygen minimum-zone-like conditions were present. Results from Chengjiang suggest that the Cambrian radiation of the animals occurred in a relatively thin layer of shallow oxic waters that was sharply separated from toxic deep waters.

Plant establishment in sulfide ore-derived mine tailings stabilizes arsenic *in situ* despite promoting arsenopyrite oxidation

C. M. HAMMOND*, R. A. ROOT, R. M. MAIER AND J. CHOROVER

University of Arizona, Tucson, AZ 85721, USA
(*correspondance: schowalt@email.arizona.edu)

A compost-assisted phytostabilization strategy at the Iron King Mine tailings in Arizona, USA aims to establish a self-sustaining vegetative cover as a low cost option to reduce human exposure to metal(loid) contaminants. Plant growth on contaminated land reduces dispersion of particulate matter caused by erosion, but less is known regarding the effect of phytostabilization on subsurface metal(loid) speciation and lability. Biogeochemical mechanisms controlling arsenic speciation and lability were examined in a three year 1.5 ha field trial in which dairy compost and irrigation water were added to aid plant growth. Bench-scale chemical analyses were combined with synchrotron-based X-ray spectroscopic methods applied as a function of time, depth and specific treatment. Arsenic and iron K-edge X-ray absorption near-edge structure (XANES) of untreated samples show oxidation of pyritic [FeS_2, FeAsS] minerals to ferric (oxy)hydroxide [e.g. ferrihydtite] and (oxy)hyroxide sulfates [e.g. jarosite-type minerals; $XFe^{(III)}_3(OH)_6(SO_4)_2$, where X = K^+, H_3O^+, Pb^{2+}] in near-surface tailings, indicating an oxidation front penetrating the profile. Arsenic XANES indicate that both irrigation and compost are associated with enhancement of sulfide oxidative weathering (Figure). Importantly, an increase in As lability related to compost addition has not been observed. Sequential chemical extraction and Fe XAS results indicate that sulfide weathering may be associated with formation of an ammonium oxalate-resistant Fe mineral phase, affecting the mobility of Fe-sorbed As in the tailings.

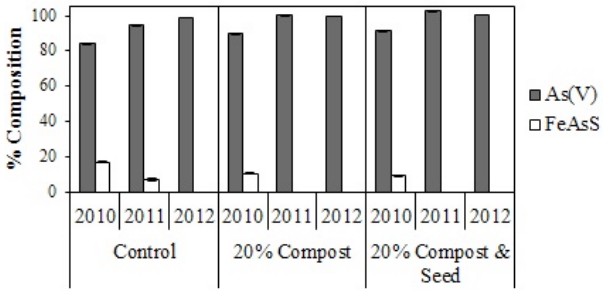

Figure 1. As Kα XANES linear combination fits of amended and control field samples, fit with arsenopyrite and 2-line ferrihydrite. The binary fits, not normalized to unity, account for 99-102% of the spectral features.

Major melting on EL enstatite chondrite parent body

T. HAMMOUDA[123]*, M. BOYET[123], B. MOINE[234], C. CARTIER[123] AND J.L. DEVIDAL[123]

Chondrites are amongst the most primitive objects of the solar system. Their constitutive chondrules represent either condensates, or interstellar dust that was once molten and quenched. Overall, chondrites are undifferentiated rocks that did not experience core separation associated with planetary formation. Some groups of chondrite are considered to represent building blocks at the origin of planets, including the Earth. Here we show that one group of enstatite chondrites (EL) bears evidence for large scale melting, yet showing little (if any) sign of differentiation. We have compared the two enstatite chondrite groups (EH and EL). Differences between EH and EL subtypes regarding both their bulk major element compositions as well as their mineralogy have long been recognized [1,2]. Here, we used in-situ, laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) analyses of minerals present in both enstatite chondrite subtypes (enstatite, and the two sulfides troilite (FeS) and oldhamite (CaS)). We show that each subgroup possesses a unique signature. EH chondrite trace element patterns are compatible with condensation signature, followed by equilibration during metamorphism from type 3 to type 5. They may thus be considered as primitive. On the contrary, EL chondrite patterns are suggestive of equilibrium during large scale melting on their parent body. They may therefore evidence melting processes that would yet essentially preserve the undifferentiated nature of their parent body, except in equilibrated types (EL5-6) wherein slight melt depletion is observed. Timescales for this melting should be long enough to allow for melt / crystal equilibration, but short enough to prevent metal / silicate separation. Alternatively, melting may have occurred in a low gravity field, either a small planetary body, or a molten disk following the collision of two large objects.

Noble gas isotope studies of Ningwu Ore District, Middle-Lower Yangtze River polymetallic ore belt, East China

DAN HAN[1], CHAO DUAN[1] AND YAN-HE LI[1]

[1]MRL Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, China, 100037

Different causes, such as the atmosphere, the Earth's crust, mantle and sources of abundance and of the noble gas isotopic composition is significantly different. Typical ratio of helium in the Earth's crust $^3He/^4He$ is 10^{-8}, $^3He/^4He$ value of 10^{-5} of mantle helium, difference of nearly 1000 times.

So helium argon and other noble gas isotope has become a research of crust-mantle interaction, the tracer mantle fluid mineralization and different ore-forming fluid mixed effective means and the most sensitive tracer.

In this study, the concentration and isotopic compositions of noble gases were measured in pyrite and magneti phenocrysts of 11 iron ore from Ningwu ore district Gaocun and dongshan, ^3He / ^4He ratio is 1 Ra ~ 0.04 Ra,□Ra :^3He / ^4He ratio of air 1.4□10^{-6} □, The He isotopic study shows, the environment of different $^3He/^4He$ ratio, showed there was no With the same degree of deep fluid. Typical characteristics can be seen as the mantle fluid.

Model-predicted and satellite-retrieved tropospheric NO_2 columns over East Asia

KYUNG M. HAN, CHUL H. SONG* AND SOJIN LEE

School of Environmental Science and Engineering, Gwangju Institute of Science and Technolgoy (GIST), Gwangju, 500-712, Korea
(kmhan@gist.ac.kr; *correspondence: chsong@gist.ac.kr)

In this study, we attempted to evaluate NO_x emission fluxes over East Asia for the year of 2006, using CMAQ-predicted and OMI-retrieved tropospheric NO_2 columns. The two retrieved OMI products were taken from the Level-2 DOMINO product version 2 (using KNMI algorithm) and from the Level-2 OMNO2 product version 2.1 (using NASA algorithm). The two OMI products were well correlated (R=0.98 over Central East China). Also, averaging kernels (AKs) taken from each OMI product were applied to the CMAQ-predicted NO_2 columns (Ω_{CMAQ}) for the comparison analysis. The applied AK_{KNMI} (i.e. AK retrieved from the KNMI algorithm) to the Ω_{CMAQ} showed seasonally good correlations with the $\Omega_{OMI,KNMI}$ (R=0.75, slope=0.92). Howere, the Ω_{CMAQ} with the AK_{NASA} showed larger values than the $\Omega_{OMI,NASA}$ from the OMI observations despite of good correlation coefficient (R=0.75) because the AK_{NASA} are vertically even larger by factors of approximate 2 – 10 than AK_{KNMI} over Central East China (CEC). The differences between the Ω_{CMAQ} and Ω_{OMI} using the NASA algorithm were much larger than those using the KNMI algorithm during the winter episodes, whereas the differences were smaller using the NASA algorithm than those using the KNMI algorithm. In addition, this study investigated the large discrepancies between CMAQ-predicted and OMI-retreived NO_2 columns during the winter episodes in terms of the sesonal variations of NO_x source and heterogenous NO_x sink. First, the seasonal variation of the NO_x emissions influenced greatly in the tropospheric NO_2 columns. For example, when non-seasonal factor were applied to the CMAQ model simulation, the $\Omega_{NO2,CMAQ}$ decresed by 38% over CEC regions during winter, compared to those from the our baseline simulation. For the latter, four parameterizations of gamma N_2O_5 were applied to the separete CMAQ model simulations during the cold seasons.

[4]University of North Carolina, Charlotte, NC 28223

Pb, Sr, and isotope data from a suite of basalts from ~35°, ~0-10 miles north of the Oceanographer Transform (OFZ) are interpreted as mixing between three chemically distnct mantle sources [1]. The transform offsets the ridge right-laterally by 130 km and lies within the geochemical gradient attributed to dispersion of the Azores plume and mixing with the depleted upper mantle MORB source [2]. The third mantle component's isotope and geochemical characteristics suggest that portions of the mantle in the region contain detached fragments of ancient sub-continental lithosphere. We have analyzed a subset of the the samples previously analyzed for Pb, Sr, and Nd [1] for Hf isotopes and high precision Pb isotopes.

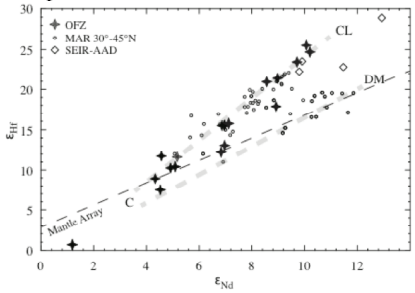

Figure 1: New Hf isotope data for the OFZ region. Also shown are published data [3-5] for the MAR and ultra-depleted MORB from the Southeast Indian Ridge-AAD Pacific-Indian mantle boundary.

Bifurcating trends bound the data and require at least 3 mantle components. An enriched C-like (low ε_{Nd} and ε_{Hf}), common to both trends, and two depleted components, one DM like (high ε_{Nd} and intermediate ε_{Hf}), the other (very high ε_{Hf}) similar to ultra-depleted MORB from the AAD, where the upper mantle is contaminated by continental material entrained during Gondwana rifting. The new OFZ Hf isotope data confirm the Pb and Nd isotope results [1] indicating pollution of the upper mantle MORB source by material derived from the continental lithosphere mantle, also advocated for the Azores plume [6]. This suggests that during plume-lithosphere interaction and rifting, accompanying the early opening of the Atlantic Ocean Basin, fragments of refractory continental lithosphere mantle were incorporated into the OFZ MORB source.

Novel approaches to reconstructing sulfur cycling in methane seeps

L.G. HANCOCK[1]*, T.W. LYONS[1], B.C. GILL[2], R.S. SHAPIRO[3] AND S.M. BATES[1]

[1]University of California Riverside, Riverside, CA, 92521 (*correspondence: lhanc001@ucr.edu)

[3]Chico State University, Chico, CA, 95929

Methane ranks among the key greenhouse gases throughout Earth history, particularly under the generally more reducing conditions of the Precambrian. The mechanisms of methane cycling have been studied extensively, but a complete understanding of its role in the chemical and organismal evolution of the ocean through time, including its closely coupled relationship to the sulfur cycle, are still largely unresolved. Modern and ancient seeps provide outstanding natural labs for studying coupled methane-sulfur cycles and their geochemical fingerprints. Many seep studies examine sulfide in pyrite, but pyrite formation in these settings is typically limited by the availability of reactive iron and thus only captures the earliest diagenetic processes. In such cases, a better way to track sulfur and its role in modulating methane production and consumption is by following the pathways of dissolved sulfate, specifically using carbonate-associated sulfate or CAS. This study focuses on modern and ancient seep sites marked by complex carbonate paragenesis and traces sulfur, carbon and oxygen isotopes to unravel ancient methane cycling, its relationship to sulfur metabolic pathways and the preservational history of proxies during early to late burial. Our initial results suggest that coupled isotopic and concentration measurements of CAS may closely track spatiotemporal variation in rates of microbial sulphate reduction as coupled to anaerobic methane oxidation. These rates in ancient settings seem highly variable spatially and temporally, as they are in modern seeps. CAS isotopic relationships also reveal the relative patterns of sulfate reduction and sulfide oxidation, thus providing an essential backdrop for interpreting thiotrophic and methanotrophic symbiosis among the seep-dwelling macrofauna.

Along-arc geochemical and isotopic variations in Javanese volcanic rocks: 'Crustal' versus 'source' contamination at the Sunda arc, Indonesia

HEATHER HANDLEY[1], JANNE BLICHERT-TOFT[2], SIMON TURNER[1], COLIN MACPHERSON[3], RALF GERTISSER[4]

[4]School of Physical and Geographical Sciences, Keele University, Keele, ST5 5BG, UK. (r.gertisser@keele.ac.uk)

Through detailed studies of individual magmatic systems it is possible to identify and establish the relative importance and contributions of the various potential source components and differentiation processes that modify magmatic composition, such as crustal contamination. Along-arc changes in lava geochemistry have long been recognised on Java in the Sunda arc, Indonesia, but debate still prevails over the cause of such variations and the relative importance of shallow (crustal) versus deep (subduction) contamination. We present new Pb isotope data for Javanese volcanoes, which, when combined with our recently published geochemical and radiogenic isotopic data of Javanese volcanic rocks and results from other detailed geochemical and isotopic studies, elucidate the potential changing nature of the arc crust and its control on lava chemistry. In $^{207}Pb/^{204}Pb$-$^{206}Pb/^{204}Pb$ space the Javanese volcanic data reveal two distinct trends which can be related to either a strong control by crustal assimilation processes or source contamination by local sedimentary material on the down-going plate. Sr isotope ratios of volcanic rocks generally increase from West to Central Java, showing a wide range within individual volcanic centres and broad correlation with inferred crustal thickness, implying a strong, shallow-level control on isotopic composition. However, East Javanese volcanic rocks show significantly lower Sr and Pb isotopic ratios and extremely restricted isotopic variation at individual volcanoes. Key trace element ratios combined with radiogenic isotopic data of Javanese volcanoes reveal three distinct trends, which roughly equate with the geographical boundaries West, Central and East Java. These results provide evidence for major transitions in the crustal architecture of Java.

Oxygen fugacity in the Kaapvaal cratonic lithosphere – Evidence from Fe XANES measurements of Fe^{3+} in garnet from the Kimberley pipe

BRENDAN J. HANGER[1]*, GREGORY M. YAXLEY[1], ANDREW J. BERRY[1], VADIM S. KAMENETSKY[2], DAVID PATERSON[3] AND DARYL L. HOWARD[3]

[1]Research School of Earth Sciences, The Australian National University, Canberra, ACT, 0200, Australia (*correspondence: brendan.hanger@anu.edu.au)
[2] ARC Centre of Excellence in Ore Deposits, University of Tasmania, Hobart TAS 7001, Australia
[3]Australian Synchrotron, Clayton VIC 3168, Australia

Oxygen fugacity is important in understanding the evolution of the cratonic lithosphere, but is more difficult to determine than other variables (e.g. temperature and pressure). It requires precise measurement of $Fe^{3+}/\sum Fe$ in garnet in peridotite xenoliths which until recently has been practically limited to the bulk technique Mössbauer spectroscopy. However, new highly spatially resolved, *in situ* techniques such as synchrotron-based Fe K-edge XANES [1] or the microprobe-based flank method [2] are enabling precise and rapid determination of garnet $Fe^{3+}/\sum Fe$. We have combined XANES measurements with experimental calibrations of oxybarometers applicable to peridotite [3] to determine the oxygen fugacities recorded in suites of garnet peridotite xenoliths from the Kimberley kimberlite, which sampled the Kaapvaal cratonic lithosphere.

The xenoliths examined are relatively fresh. Most contain lherzolitic garnet based upon the CaO-Cr_2O_3 systematics [4], although two contain harzburgitic garnet. Thermobarometry reveals a pressure range of 2.5-4.5 GPa and a temperature range of 880 – 1100 ºC. Fe XANES gave garnet $Fe^{3+}/\sum Fe$ values from 0.04 and 0.07. $\Delta \log fO_2^{[FMQ]}$ varies between -0.46 and -2.40, with most samples falling between -2.0 and -2.4 at pressures from 3.5 to 4.2 GPa. The xenoliths show a general trend of decreasing $\Delta \log fO_2^{[FMQ]}$ with depth, in broad agreement with previous studies [5,6].

Melt inclusions in mafic-ultramafic potassic volcanic rocks in British Columbia, Canada: A record of the transfer of PGE from mantle to crust in porphyry settings

JACOB J. HANLEY[1] AND ZOLTAN ZAJACZ[2]

[1]Dept. Geology, Saint Mary's University, Halifax, Canada (*correspondence: jacob.hanley@smu.ca)
[2]IGP, ETH Zürich, Zürich, Switzerland

Mafic-ultramafic subvolcanic intrusions composed of alkalic basalt are spatially/temporally associated with many alkalic Cu-Au deposits in the Canadian Cordillera that contain resources of platinum-group elements (PGE). In the Afton porphyry deposit, we have investigated melt inclusions preserved within leucite-clinopyroxene-olivine(>Fo_{90})-rich basalts (18-22 wt% MgO) in order to understand their relationship to porphyry evolution/metal tenor.

Olivine-melt and melt inclusion microthermometry for primary inclusions in growth zones in clinopyroxene primocrysts constrain the liquidus T of the basalt between 1370-1520ºC. However more evolved liquids, trapped as secondary inclusions in pyroxene, were likely trapped as low as ~900ºC and at low pressure. Shallow depths of emplacement for the basalt sills and dykes are confirmed by pepperite textures indicating interaction of the magma bodies with wet volcanic sediments, sandstones, and mudstones. The Cr content of early melt inclusions (Cr-in-melt oxybarometry[1]), determined by laser ablation ICP-MS, and chromian spinel-olivine oxybarometry indicate that the liquids were relatively oxidized (~FMQ+1.5).

Melt inclusion analysis is essential to characterize the trace element chemistry of the basalts because the intrusions are cumulates containing non-cotectic proportions of olivine and pyroxene, and the groundmass was extensively hydrothermally altered by the adjacent porphyry stock. Early melts are most similar to high Ca-Mg, high K_2O, silica-undersaturated arc ankaramites and their differentiates, formed by partial melting of amphibole or clinopyroxene-rich cumulates in sub-arc lithospheric mantle or lower crust.

heTearly melt inclusions are highly enriched in PGE, containing up to ~480 ppb Pd and a high Pd/Pt ratio (~10-20), identical to that of porphyry-stage ore in the deposit. The exact mechanism by which this high Pd/Pt was inherited by the porphyry magma (i.e., fractional crystallization, mixing with/contamination by crustal rocks/melts) is being evaluated.

Sr isotope anomalies in meteorites: Uniform distribution of *s*- and *r*-process Sr at the planetary scale

ULRIK HANS[1], THORSTEN KLEINE[2], CHRISTOPH BURKHARDT[1] AND BERNARD BOURDON[3]

[1]Institute of Geochemistry and Petrology, ETH Zurich, Switzerland (*correspondence ulrik.hans@erdw.ethz.ch)
[2]Institut für Planetologie, Westfälische Wilhelms-Universität Münster, Germany
[3]Ecole Normale Supérieure de Lyon, UCBL and CNRS, France

Planetary-scale nucleosynthetic anomalies have been identified for various refractory elements, indicating that the protoplanetary disk was not entirely mixed with respect to stellar sources or that thermal processing of solid material was uneven. In this study we re-address the presence of planetary-scale $^{84}Sr/^{86}Sr$ anomalies. Several bulk chondrites, eucrites, angrites as well as Ca-Al-rich inclusions (CAI) from the CV3 chondrite Allende were analyzed using the Thermo Triton TIMS at ETH Zürich in a dynamic acquisition mode. In contrast to static measurements (as used in previous studies [1]) no difference in $^{84}Sr/^{86}Sr$ ratios between the NBS987 standard and terrestrial rock standards was found. Furthermore, with the exception of CV and CM chondrites all bulk meteorites show within uncertainty a uniform and terrestrial $^{84}Sr/^{86}Sr$. The anomaly in the CM chondrite could be due to incomplete dissolution of presolar SiC grains, while the anomalies in Allende can be attributed to the high abundance of CAI which show $^{84}Sr/^{86}Sr$ anomalies of up to 1.3ε, most likely due to an excess in r-process Sr. Thus, our results do not confirm the planetary-scale Sr isotope heterogeneity reported in an earlier study. Instead they indicate that overall, the Sr isotope composition of the solar nebula prior to planetary accretion was rather homogeneous, which is essential to establish the Rb-Sr chronology of volatile element depletion in the early solar system.

Widespread production of extracellular superoxide by heterotrophic bacteria

C.M. HANSEL[1]*, J.M. DIAZ[2], B.M. VOELKER[3], P.F. ANDEER[1] AND T. ZHANG[1]

[1]Marine Chemistry and Geochemistry Department, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, U.S.A. (*correspondance: chansel@whoi.edu)
[2]Biology Department, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, U.S.A.
[3]Department of Chemistry and Geochemistry, Colorado School of Mines, Golden, CO 80401, U.S.A.

Superoxide, a reactive oxygen species (ROS), is a powerful and versatile reactant that is toxic to living organisms and can dramatically alter the geochemical landscape through a myriad of redox reactions. (A)biotic reactions that are directly or indirectly coupled to sunlight have been the only recognized sources of environmentally relevant ROS. Phytoplankton, for instance, have previously been shown to produce ROS, yet their abundance and distribution in nature is fundamentally constrained by sunlight. Thus, although ROS production has been frequently observed in the deep ocean and at night, superoxide and other ROS are regarded as pertinent only in sunlit systems, which represent merely ~5% of the habitable environment on Earth.

Here we show that common and abundant heterotrophic bacteria are a vast unrecognized source of ROS. We analyzed extracellular superoxide production by a broad range of ecologically and phylogenetically diverse heterotrophic bacteria using a high sensitivity flow-through chemiluminescence approach. Superoxide production was detected by 27 of 30 environmentally common isolates. Rates of superoxide production normalized to the proportion of metabolically active cells varied a few orders of magnitude, between 0.02 ± 0.02 and 19.4 ± 5.2 amol $cell^{-1}$ hr^{-1}. Although cell-normalized rates of superoxide production by heterotrophic bacteria are lower than those measured previously for marine phytoplankton, rates normalized to cell surface area are comparable to, and in several cases greater than, those of phytoplankton. Superoxide production by a model bacterium within the ubiquitous *Roseobacter* clade involves an extracellular NADH oxidoreductase, suggesting a surprising homology with eukaryotes.

Our discovery therefore introduces the likelihood of ROS cycling in ~95% of the global habitat that is untouched by light, a paradigm shift which will certainly transform our understanding of the geochemistry, ecology, and health of a wide range of modern and ancient environments.

Venus crustal plateaus as an analog for Archean cratons and SCLM

VICKI L. HANSEN *

Dept. of Geol. Sciences, University of Minnesota, Duluth MN 55812 USA; (*correspondence: vhansen@d.umn.edu)

A hypothesis is presented suggesting that Venus' ancient crustal plateaus and their mantle roots represent analogs for Archean cratons and their underlying subcontinental lithospheric mantle (SCLM). Crustal plateaus (~1500-2500 km diameter) are quasicircular features that rise 0.5-4.0 km above Venus' lowlands, supported by low density isostatic roots, and host a distinctive structural fabric called ribbon-tessera terrain (RTT). RTT also occurs as arcuate-shaped exposures in the lowlands, widely interpeted as 'collapsed' or rootless crustal plateaus. Crustal plateaus and RTT inliers represent Venus' oldest preserved features and surfaces. RTT fabrics and their host crustal plateaus are postulated to have formed as the solidified 'scum' of huge lava ponds, formed by large bolide (>25 km diameter) impacts with ancient thin lithosphere. Bolides pierced the lithosphere, leading to massive partial melting in the upper mantle. Melt rose to form huge surface ponds, burying bolide scars; high-Mg depleted mantle melt residuum formed a robust buoyant root, leading to plateau formation, and long-term stablity. The roots of lowland RTT were removed, likely due to mantle convection.

On Earth, Archean cratons comprise granite-greenstone terrains (GGTs) and associated high-Mg SCLM. Like crustal plateaus, GGTs are unique—lacking contemporary analogs—and they have been remarkably stable since formation; thus, they too record ancient geologic processes of their host.

Recent studies indicate that Late Heavy Bombardment (LHB) on Earth lasted through the Archean. Therefore, like Venus, early Earth's thin lithosphere would have been bombarded by numerous large bolides (>25 km), with a likely similar first-order response, resulting in massive partial melting of the mantle, escape of high-Mg melt to the surface (komatiites), and formation of a high-Mg residuum root, which protected the new-formed crustal features from younger planetary processes. GTTs that survived retain their roots; GTTs that lost their roots were likely accreted to stable GTTs or recycled by younger plate tectonic processes. The hypothesis suggests that Venus' crustal plateaus and Earth's GGTs both formed during LHB, when both of these young hot planets had relatively thin lithosphere, and record a unique era in the evolution of these sister planets. Large bolides punctured the thin lithospheres, which were strong enough to support the products of massive mantle partial melt; the high-Mg melt residuum roots protected these unique regions from younger planetary processes on both planets.

Numerical modeling of iron-corrosion and interaction with bentonite

C. HANSMEIER[1], G. BRACKE[2] AND B.REICHERT[3]

[1,2]Department of Final Disposal, GRS mbH, Schwertnergasse 1, 50667 Cologne, Germany, ([1]christina.hansmeier@grs.de, [2]guido.bracke@grs.de)
[3]Steinmann-Institute, Department Hydrogeology, Nussallee 8, 53115 Bonn, Germany, (b.reichert@uni-bonn.de)

In deep geological repositories, bentonite is preferred as a possible Engineered Barrier (EB) to isolate the High Level Waste (HLW) from the biosphere. Over time, the iron canister of the HLW corrodes under anaerobic conditions and interactions between the EB and the corrosion products of the iron canister modify the properties of the bentonite. Besides, formation water in the host rock (Opalinus clay) affects the bentonite, too.

The aim is to calculate changes in porewater chemistry, mineral dissolution and precipitation as well as its effects on permeability and porosity changes on process level to assess the long term behavior. Cation exchange and surface complexation are not considered in this model. The system is modeled as a 1D model for a timescale of 10.000 years. Due to low permeabilities of both bentonite and clay the mass transport entirely takes place by diffusion, leading to small changes of constituents only. Precipitation of corrosion products decreases the porosity of the system. For calculations the code TOUGHREACT [1] is used with PetraSim [2] as user interface. TOUGHREACT adds reactive geochemistry to the multi-phase flow code TOUGH2 [3].

We report the geochemical compositions of submarine basalts collected by a manned submersible from Rurutu, Tubuai, and Raivavae in the Austral Islands, French Polynesia, where subaerial basalts exhibit robust HIMU isotopic signatures. The $^{40}Ar/^{39}Ar$ ages of the submarine basalts overlap with those of the subaerial basalts with the exception of one sample from Tubuai. While the major element compositions are similar between the submarine and subaerial basalts for each island, the submarine basalts exhibit much larger variations in Pb, Sr, Nd, and Hf isotopic compositions than those previously reported in subaerial basalts. The submarine basalts with less-radiogenic Pb isotopes show systematically lower abundances in highly incompatible elements than the basalts with radiogenic Pb isotopes. The overall geochemical variations are best explained by a two-component mixing between the melt derived from the HIMU reservoir on one hand and the melt from the depleted asthenospheric mantle entrained by an upwelling plume on the other. The present and compiled data demonstrate that the HIMU reservoir has uniquely low $^{176}Hf/^{177}Hf$ for a given $^{143}Nd/^{144}Nd$, suggesting it being formed by subduction of an ancient slab. Moreover, the Nd/Hf ratios of the HIMU basalts, together with the curvilinear aspect of the $^{143}Nd/^{144}Nd$–$^{176}Hf/^{177}Hf$ mixing trend, suggest higher Nd/Hf for the HIMU reservoir than for the depleted mantle component. Such elevated Nd/Hf of the HIMU reservoir could reflect metasomatic enrichment processes of the mantle by a partial melt derived from subducted material during reservoir formation.

Impact of phenanthrene on the formation of microbial habitats in soil

J. HANZEL* AND K. U. TOTSCHE

Chair of Hydrogeology, Institute for Geosciences, Friedrich Schiller University Jena, Burgweg 11, 07749 Jena, Germany (*correspondence: joanna.hanzel@uni-jena.de)

Recent studies reveal that there is a strong interplay between the physical soil structure and the activity of soil microorganisms [1, 2, 3]. Yet, a quantitative understanding of this feedback loop and their consequences for the soil functions remain speculative. Two-layer soil columns packed with soil material and spiked with phenanthrene in its upper layer will be used after forced-gradient transport experiment has been performed. Thin sections prepared from soil aggregates taken from different depths of the column will be analyzed to examine the impact of phenanthrene on the formation of microbial growth habitats in soil. Epifluorescent microscopy will be applied to identify growth habits of DAPI-stained cells of soil microorganisms and to determine their abundance and spatial distribution in the soil column. The microbial habitats will be examined by scanning electron microscope (SEM) and the results will be compared with the data obtained from non-spiked controls, where soil interfaces will be characterize to elucidate how the activity of phenanthrene degrading soil microorganisms alters the physicochemical soil properties. Such knowledge will contribute to a mechanistic understanding of the interactions between soil structure, habitat and microbial activity and may ultimately help to better understand soil formation and the functions of a soil.

[3]Hokkaido University, Japan

The subarctic North Pacific including the Bering Sea is the area that efficient biological pump works [1]. According to the global compilation of sediment trap experiment [2], the subarctic North Pacific including the Bering Sea represents that biogenic opal/$CaCO_3$ ratios of settling particles is the highest in the world. The time-series observation of settling particles is valuable to understand the changes in the function of subarctic biological pump associated with climate changes. Thus, to understand characteristics of prymary fluxes of biogenic particles, plankton assemblages and to detect the environmental variation and changes in low trophic level ecosystem associated with current climate changes, settling particulate samples were collected for 19 years by sediment trap mooring system at St. SA (49°N, 174°W, water depth 5406m) in the central subarctic North Pacific and at St. AB (53°30'N, 177°W, water depth 3788m) in the central Bering Sea from 1990 to 2010 [3]. The diatom and radioralia having opal test were predominant components throughout the 19 years at both stations. The $CaCO_3$ was the secondly dominant component of settling particles [3]. The $CaCO_3$ was composed of calcareous nannoplanktons and micro zooplankton. *Coccolithus pelagicus* and *Eminiania huxleyi* were two major species. The relative abundance of *C. pelagicus* and *E. huxleyi* were average 55% and 42% to the total calcareous nannoplanktons [4]. Alkenone flux increased in August, September, October and November at both sites. In the presenation, more details about the alkenone flux will be shown. We will discuss the seasonal and annual changes in alkenone fluxes comparing with other components.

Basaltic magmas carry huge amounts of volatiles (CO_2, H_2O, SO_2) from their sources in the upper mantle up to the Earth surface. The dynamics and efficiency of basalt degassing are fundamental parameters for eruption dynamics, the environmental impact of volcanism, and the global cycle of volatile elements. Some models of basalt ascent and degassing are purely based on equilibrium solubility laws while others take into account disequilibrium processes such as bubble nucleation and growth (e.g. [1]). Attempts to integrate these disequilibrium processes are hampered, however, by the lack of experimental data on major variables, such as the basalt-CO_2 surface tension.

We investigated CO_2 degassing in an ascending basaltic melt by performing decompression experiments in a piston-cylinder apparatus. Series of experiments were run at a constant decompression rate and quenched at different pressures in order to characterize the kinetics of bubble nucleation and growth. The main parameters of interest are the bubble nucleation pressure P_N, the critical supersaturation pressure ΔP_N (= P_{SAT} - P_N, where P_{SAT} is the volatile saturation pressure), the bubble number density, the bubble size distribution and the residual CO_2 supersaturation in the melt.

A CMAS-Na basaltic glass cylinder was loaded along with silver oxalate powder (the source of CO_2) into a Pt container. The melt was first saturated with CO_2 at 2 GPa-1500°C and then decompressed at 1 MPa/s. Homogeneous bubble nucleation was observed in the experiment quenched at 1.2 GPa, but not in the ones quenched above 1.5 GPa. This yields a ΔP_N for CO_2 bubbles in basalt of 0.5 to 0.8 GPa, thus larger than the values reported in the literature (0.2 GPa [2] or 0.4-0.5 GPa [1]). Quantification of CO_2 in the decompressed quenched glasses is in progress to quantify the residual volatile supersaturation.

Bacteria produce a vast range of mineral deposits within the earth and are involved in the degradation of many materials. Experimental studies have demonstrated that extra-celluar DNA (eDNA) is a major component of the extra-cellular polymeric substance used to bind the bacteria to surfaces [1]. Understanding the mechanisms of eDNA attachment is necessary to understand biofilm development.

We have explored the mechanisms of attachment using molecular dynamics simulations that provide atomic-scale detail to analyse the interactions. We consider how eDNA binds at amorphous silica surfaces which provides an analogue to many geological and experimental systems. A range of different solvated cations is simulated to enable us to look at their effect on both the space-charge layer and on localised bonding. We discuss the implications of these results for bacterial attachment and the building of DNA based scaffolds on mineral surfaces comparing them with current experimental work where possible.

A record of paleoproterozoic surface ocean redox from iodine-to-calcium ratios

Despite geochemical inferences of surface ocean and atmsopheric oxygen accumulation prior to and at the Great Oxygenation Event (GOE) at 2.4 Gyr ago, a record of oxygen accumulation in the shallow ocean has yet to be demonstrated. Iodine-to-calcium ratios (I/Ca) in carbonates have recently been revealed as a paleoredox indicator, as iodate (IO_3^-) is restricted to oxic waters and is the exclusive iodine species associated with carbonate precipitation[1]. With a similar pE to that of O_2/H_2O, the presence/absence of IO_3^- is a more sensitive indicator of deoxygenation than other redox-dependent elements such as manganese and nitrogen, making I/Ca ideal for evaluating *in situ* redox in the early shallow ocean. Analysis of I/Ca in a series of Archean and Proterozoic dolomites show that the initial shift in I/Ca began at the GOE with a further increase following this at the Lomagundi carbon isotope excursion (LE). A tentative threshold for surface water oxygen accumulation of > 1 μM at the GOE is inferred from the shift in I/Ca from observations at modern oxygen minimum zones[2]. A second order control on I/Ca ratios is the total iodine reservoir size, which is largely controlled by the burial and remineralization of organic matter. The LE is widely accepted to have resulted from an intense relative increase in organic carbon burial rates. The increase in I/Ca at the LE, despite likely reduction in the total iodine reservoir size due to organic burial, suggests expanded oxygenation, potentially into deeper water settings. Increasing I/Ca from a stratigraphic section of the Mcheka Formation, representing the later stage of the LE, may reflect increasing total iodine reservoir size, as organic carbon remineralization begins to outpace burial as carbon isotopes begin to retreat from > 10 ‰ to near 6 ‰. More generally, these data highlight the potential strength of the I/Ca proxy even in Precambrian samples.

Dark organic matter in permanently shadowed craters on Mercury

E. R. HARJU[1], D. A. PAIGE[1]*, M. A. SIEGLER[2], M. L. DELITSKY[3], D. SCHRIVER[4]

[1]Department of Earth and Space Sciences, University of California, Los Angeles, CA 90095, USA (*correspondence: dap@mars.ucla.edu)
[2]Jet Propulsion Laboratory, Pasadena, CA 91109, USA
[3]California Specialty Engineering, Flintridge, CA 91012, USA
[4]Department of Physics and Astronomy, University of California, Los Angeles, CA 90095, USA.

Data from instruments aboard the MESSENGER spacecraft have confirmed that radar bright regions in permanently shadowed craters, with temperatures less than 100 K, in the north polar region of Mercury are water ice [1-3]. In areas with temperatures up to 350 K, the Mercury Laser Altimeter oberserved radar-dark regions which are most likely an amorphous carbon-rich organic layer with a distribution peaking around 160 K, covering and in some cases extending beyond near-surface water ice deposits [1,2].

Simple organic molecules and water are delivered to Mercury by cometary impacts. A portion of these molecules could migrate to the polar regions of Mercury and become cold-trapped in permanently shadowed craters [4,5]. The magnetic field lines of Mercury create a cusp where solar wind plasma is transferred to the planet's surface in the north polar region with a peak proton flux of 1.9 x 10^8 cm^2/s [6].

Ion radation processes organic molecules to species with greater molecular weights and greater C/H ratios as hydrogen ions escape. This process can continue until the organics become amorphous carbonaceous material or even graphite or other forms of elemental carbon which have low albedos similar to those of the dark material obseved in permanently shadowed craters. Based on estimated proton and electron fluxes to the north polar region of Mercury, 3.35 x 10^{27} molecules/cm^2 of polycyclic aromatic hydrocarbons can be created from processing methane over the lifetime of the solar system. Due to the ion radiation and source of organic molecules, it is likely that the radar-dark material is highly processed carbonaceous organic material.

Sr isotope stratigraphy of carbonate fraction in oil shales

Y. HARLAVAN* AND O. GOREN

Geological Survey of Israel, 30 Malkhe Israel St., Jerusalem. (*correspondence: y.harlavan@gsi.gov.il)

Oil shale is a term used for immature, organic-rich, fine-grained sedimentary rocks from which hydrocarbons can be produced. In Israel, these rocks are composed of four main components: carbonate, phosphate, organic matter, and detritus (mainly Al-Silicates). The studied oil shales sequence is dated by their stratigraphic position (Bio-Zone) to Campan-Maastricht.

The use of $^{87}Sr/^{86}Sr$ ratio from marine sediments is in one of two ways: to determine the Sr isotopic composition of the ocean water at deposition time, or to determine the age of the sediment based upon ocean water $^{87}Sr/^{86}Sr$ changes with time (Sr isotope stratigraphy).

In the present study we examined the potential of calcite in oil shales to reflect the $^{87}Sr/^{86}Sr$ of the ocean water at time of formation. The absence of dolomite in the studied oil shales sequence suggests that the associated calcite was not significantly altered and therefore should reflect the isotopic composition of Sr in the ocean water at time of formation . The carlcite and insoluble residue fractions in oil shales from different basins in Israel, were separated using sequential extraction and their Sr isotopic composition was determined. The numerical Sr ages of the calcit was calculated [1] and results show that the numerical stratigraphic age is in good agreement with the assigned bio-stratigraphic age. Moreover, the $^{87}Sr/^{86}Sr$ ratio of the insoluble residue should reflect the source of detritus transported to these basins and may shed light on their province. The $^{87}Sr/^{86}Sr$ ratio of the insoluble residue varies and has no correlation with the Sr isotopic ratio of the calcite. This strengthens the observation that the calcite fraction in oil shales can record the $^{87}Sr/^{86}Sr$ ratio of the ocean water. Furthermore, the observed strong correlations between (1) the $^{87}Sr/^{86}Sr$ ration and 1/Sr and (2) Sr, Ca and P concentrations in the insoluble residue, indicate a mixture of two PO_4-minerals which are likely to be of biogenic and magmatic origin.

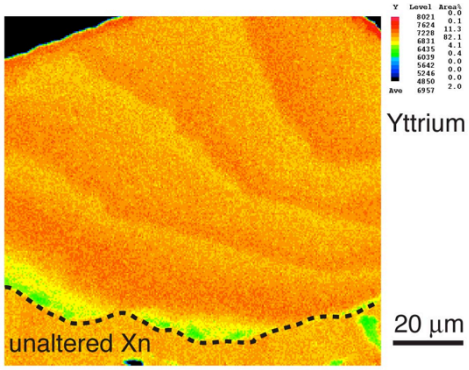
Experimental incorporation of U into xenotime at 900 °C, 500-1000 MPa utilizing alkali-bearing fluids

DANIEL E. HARLOV AND DIETER RHEDE

GeoForschungsZentrum, Telegrafenberg, D-14473 Potsdam, Germany (dharlov@gfz-potsdam.de)

In this study, specific areas of a natural Th-absent, low U, xenotime [$(Y+HREE)PO_4$] of uniform composition, are experimentally enriched in U + Si utilizing a NaF + H_2O fluid plus UO_2 and SiO_2 under both reducing (graphite-CO/CO_2 buffer) and oxidizing (Mt-Hm buffer) conditions. Charge and fluid were sealed in 2 cm long, 3 mm diameter Au and Pt capsules. In the reduced experiment the Au capsule was placed in the piston-cylinder apparatus (CaF_2 assembly; graphite oven; 1000 MPa; 900 °C; 8 days). In the oxidized experiment (500 MPa; 900 °C; 4 days) the Pt capsule was packed with Hm + H_2O into a 4 cm long, 5 mm diameter Pt capsule, which was placed in the gas apparatus. BSE imaging indicates that the altered areas occur as a series of curvilinear intergrowths with sharp compositional boundaries that extend from the edge of the xenotime grain into the interior. EPMA indicates that the altered areas from both experiments are enriched in U + Si via the coupled substitution $U^{4+} + Si^{4+} = (Y+HREE)^{3+} + P^{5+}$. WDS element distribution maps indicate that U + Si are concentrated close to the compositional interface between the altered and unaltered xenotime with corresponding depletion in Y+HREE. Across the altered region Y occurs as a series of concentric waves of relative enrichment and depletion with contrasting depletion and enrichment in HREE (see Y element map below).



Element movement is interpreted as a consequence of fluid-mediated coupled dissolution-reprecipitation in some sort of a chromatographic column effect across the altered area. Fluid-aided incorporation of U into xenotime has implications with respect to its utilization as a metamorphic geochronometer.

Phase identification of complex Cu-Fe sulfides using Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS)

YOGESH KALEGOWDA[1] AND SARAH L HARMER[1]

[1]School of Chemical and Physical Sciences, Flinders University, Bedford Park, Adelaide, South Australia 5042 (Sarah.Harmer@flinders.edu.au)

ToF-SIMS is a monolayer-sensitive surface analytical technique that has been extensively used in mineral processing to identify the elemental and molecular composition of a mineral surface. The combination of mass spectrometry and imaging makes ToF-SIMS a sensitive and capable technique for precisely identifying surface chemistry and its distribution across the surface. Traditionally, ToF-SIMS mass spectra have been used to provide the surface chemistry of an ore with little specificity to the local surface chemistry of a particular mineral phase. Some mineral specificity has been achieved by imaging particles using a major element of their composition. However, the identification of mineral phases that contain the same elements in a mixed multi-metal mineral system like chalcopyrite ($CuFeS_2$) and bornite (Cu_5FeS_4) presents a unique challenge for ToF-SIMS. The addition of precipitated, adsorbed, reacted and contaminant species in the outermost molecular layers produce complex mass spectra that are difficult to interpret using conventional methods.

For the effective analysis of such mineral systems, sufficient sensitivity and selectivity are required to detect significant components of the mass spectra. Furthermore the determination of surface chemistry, on a particle by particle basis, requires the selection of a particular mineral phase and statistical analysis of particles with an estimation of the variability of the value. The complex mass spectral data sets were analyzed using an adaption of principle component analysis – artificial neural networks (PCA-ANN). The analysis of ToF-SIMS data, has resulted in the successful classification of bornite, chalcopyrite, chalcocite and pyrite at different flotation stages. A method for phase identification of particles using ToF-SIMS has been used to track the surface chemistry of an individual particle throughout complex processing procedures[1].

Using isotopic and morphological evidence to determine biogenicity of gypsum precipitates in the Frasassi caves, Italy

KHADOUJA HAROUAKA[1]*, MATTHEW GONZALES[1], ANTON EISENHAUER[2] AND MATTHEW FANTLE[1]

[1]Penn State University, University Park 16802, USA *(correspondence: kuh121@psu.edu)

[2]IFM-GEOMAR, Kiel D-24148, Germany

The process of biomineralization can leave unique fingerprints in the chemical and physical properties of a mineral, specifically in its isotopic composition and morphology. In the Frasassi cave system (Italy), gypsum forms at the cave wall-atmosphere interface as a consequence of limestone corrosion by sulphuric acid, which is produced by H_2S oxidation mediated by microbes (i.e., *Acidithiobacillus thiooxidans*). We sampled gypsum, drip water, and $H_2S(g)$ from the Grotto Bella chamber near an active H_2S vent, and measured mineral aspect ratios, particle size, mineral and H_2S $\delta^{34}S_{CDT}$, mineral and limestone $\delta^{44}Ca_{SRM915a}$, and drip water elemental concentrations to find evidence of biomineralization. The gypsum occurs in three distinct morphologies: equant microcrystalline (<50 μm) crystals, wall crust, and needles up to 1 cm in length. The crust is characterized by small needles and aggregates of microcrystalline gypsum held together by biofilm. In Grotta Bella, smaller crystals are generally proximal to the H_2S source, whereas larger needles are found distally. The microcrystalline gypsum and needles are fractionated in $\delta^{34}S$ from the H_2S by -12 and -6‰ ($2\sigma \leq 1$‰) respectively. The $\delta^{44}Ca$ of the microcrystalline and needle deposits are offset from the limestone wall by -0.04 and -0.84‰ ($2\sigma \leq 0.23$‰) respectively. A biogenic origin of the microcrystalline gypsum may be deduced from the unusually low aspect ratios and highly negative $\delta^{34}S$ relative to the H_2S. The microcrystalline morphology may have arisen by crystal nucleation on individual cells embedded in the biofilm. The negative $\delta^{44}Ca$ of the needles may also suggest biogenicity, as the bacteria tend to colonize the larger gypsum needles more than the smaller morphologies.

Enhancing CO_2 sequestration in Mg-rich mine tailings

A. L. HARRISON[1]*, I. M. POWER[1], S.A. WILSON[2], G.M. DIPPLE[1] AND K. U. MAYER[1]

[1]The University of British Columbia, Vancouver, V6T 1Z4, Canada (*correspondence: aharriso@eos.ubc.ca; ipower@eos.ubc.ca, gdipple@eos.ubc.ca, umayer@eos.ubc.ca)

[2]Monash University, Clayton, VIC 3800, Australia (sasha.wilson@monash.edu)

Mineralization of atmospheric CO_2 within carbonate minerals occurs passively in Mg-rich mine tailings via weathering of Mg-bearing primary minerals [1]. Passive carbon mineralization has been documented at the Mount Keith Nickel mine (MKM) in Western Australia [1]. Field data and reactive transport modeling indicate that passive mineralization occurs primarily via carbonation of brucite [$Mg(OH)_2$], and is limited by the supply of CO_2. MKM produces ~0.1-0.3 Mt brucite/yr in tailings; complete carbonation of this brucite would sequester up to 60% of mine emissions [2]. Thus, modification of tailings management practices to enhance brucite carbonation rates could provide a significant offset of emissions.

Two strategies are proposed to enhance CO_2 sequestration. First, passive carbonation could be accelerated by maximizing the exposure of brucite to atmospheric CO_2. Mineral abundance profiles from tailings of different ages at MKM and reactive transport modeling with MIN3P [1,3] were used to calculate the rate of brucite carbonation with depth below the tailings surface. It is estimated that passive sequestration would be maximized if brucite remained at the surface for twice the current duration (i.e., burial rates decreased).

A second strategy is to actively supply CO_2-rich gas streams into tailings [2]. Column experiments containing brucite were conducted to assess carbonation efficiency with injection of CO_2-rich gas into partially saturated systems akin to mine tailings. The effect of brucite grain size, water content, and reaction path length were assessed. Experimental and modeling results indicated that brucite grain size should be minimized to prevent the development of a passivating surface layer. Moreover, tailings water content should be maintained above residual saturation to optimize carbonation. The experimental rates suggest that the CO_2 sequestration potential in tailings would become limited by the brucite content rather than the reaction rate if CO_2-rich gas were supplied. These results will guide implementation of accelerated CO_2 sequestration strategies at mine sites.

Magnetic nanostructures in meteorites: A window on the early solar system

R.J. HARRISON[1]*, J. BRYSON[1], N.S. CHURCH[1], T. KASAMA[2], J. HERRERO ALBILLOS [3]

[1]Department of Earth Sciences, Univ. Cambridge (*correspondence: rjh40@esc.cam.ac.uk)

[2]Center for Electron Nanoscopy, Technical University Denmark, Copenhagen (takeshi.kasama@cen.dtu.dk)

[3]ICMA, University of Zaragoza (Julia.Herrero@unizar.es)

Paleomagnetic signals recorded by meteorites are a potent source of information about processes occuring during the early solar system. This talk sets out the challenges that we face when attempting to extract meaningful magnetic information from such ancient and complex materials. To overcome these challenges we must search for the most ideal carriers of magnetic remanence (i.e. those displaying the highest magnetic stability and the highest resistance to thermochemical alteration and shock demagnetistion) – a search that leads us away from the conventional bulk paleomagnetic methods that have served us so well over the past 60 years, and towards the development of spatially resolved measurments that will take paleomagnetism to the micrometre scale and beyond.

Using a combination of state-of-the-art electron and X-ray imaging methods, we show that Fe-Ni metal carries a chemical transformation remanent magnetisation (CTRM) encoded within a spinodal decomposition nanostructure that formed continuously during slow cooling. This nanostructure is comprised of nanoscale islands of a magnetically hard phase (chemically ordered FeNi) coherently intergrown with a hitherto unobserved soft magnetic phase (chemically ordered Fe_3Ni), that developed progressively along pre-existing Ni concentration gradients. Dramatic variations in magnetic behaviour are observed across a lateral traverse of the spinodal region, which can be related to variations in the underying nanostructure that developed during progressive cooling. Asteroid cooling models predict that spinodal nanostructures within chondritic meteorites formed during a time when the proposed asteroid core dynamo was active. We argue that microstructures forming in Fe-Ni metal from chondritic meteorites have the potential to reveal a time-resolved record of asteroid dynamo activity during the first 100-200 Ma of the asteroid's history – a record that would be the nanometre scale equivalent of the kilometre scale magnetic anomalies recorded by oceanic crust on Earth.

Reconstructing Societal Dynamics of the Ancient Maya: Insights from Nd Isotopes

E. HARRISON-BUCK[1], J. G. BRYCE[2], J. BLICHERT-TOFT[3]

[1]UNH Dept. of Anthropology, Durham NH, USA, e.harrison-buck@unh.edu
[2]UNH Dept. of Earth Sciences, Durham, NH 03824, USA.
[3]Ecole Normale Supérieure de Lyon, Lyon, France.

Ethnoarchaeological studies of cultures, such as the Maya, suggest that technical choices, such as the selection of clay and temper for pottery production, are socially informed actions that are among the strongest indicators of a group's social identity. Yet, archaeologists typically carry out stylistic analyses of artifacts (e.g. examining the painted designs on pottery), and fail to analyze the technological aspects of the material culture. Geochemical studies offer a valuable method for examining the fabric of ceramic production that can reveal changes in local pottery manufacture and exchange and can also point to significant shifts in long-distance trading activity over time. Current methods for chemical sourcing use statistical analyses to group ceramics based on elemental compositions derived from Instrumental Neutron Activation Analysis and Inductively Coupled Plasma Mass Spectrometry. Both techniques yield data that can be analyzed statistically to determine differences within and between groups in order to generally distinguish the proportion of locally made pottery from those that appear to be imports. This approach is problematic in terms of its sample preparation and study and limiting in terms of its degree of accuracy. Strontium isotopes have been commonly used in many locations in Belize watersheds, but their interpretations for sourcing local clay deposits are complicated by overprinting by carbonate-based temper. Here, we present new Nd isotope data that appear to be especially useful for isolating imported pottery and determining shared provenance for specific types of local ceramics from ancient Maya sites in the eastern Belize Watershed. The Maya pottery shows a range of up to 6 ε_{Nd} units, enabling the detection of specific production locales and shifting trade orientation consistent with changes in socioeconomic organization, likely resulting from new social groups entering the eastern Belize Watershed during different periods of Maya history. The Nd isotopic data, integrated with the stylistic analyses of the artifacts, clearly reveal the complexity of ancient patterns of mobility and trade, particularly at the time of the collapse at the end of the Classic period, and afford new insights into the societal dynamics of the ancient Maya.

Can mineral inclusions in metamorphic rutile help to constrain P-T conditions of formation?

EMMA HART[1], CRAIG STOREY[1] AND EMILIE BRUAND[1]

[1]School of Earth and Environmental Sciences, University of Portsmouth, PO1 3QL, UK. (*correspondence: emma.hart@port.ac.uk)

Peak metamorphic temperatures of rutile can already be determined using the Zr-in-rutile geothermometer [1], however little work has been carried out to develop rutile as a geobarometer.

We therefore aim to investigate the use of rutile as a single grain geothermobarometer by analysing mineral inclusions found within rutile. This work will be used in conjunction with average P-T calculations using THERMOCALC 3.3, providing a novel way of constraining conditions of rutile formation.

Rutile grains from a number of localities been characterised using EPMA. Raman spectroscopy will be used to analyse quartz inclusions in UHP rocks, e.g. Dora Maira, to determine if coesite is present.

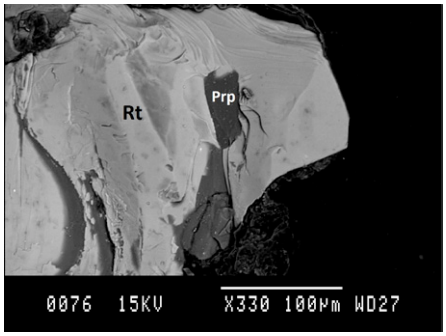

Figure 1: Back-scattered image of a rutile grain with a pyrope mineral inclusion from the Dora Maira Massif.

Preliminary EPMA data shows that inclusions in rutile comprise minerals useful for determining geothermobarometric conditions, e.g. glaucophane, omphacite and phengite. Pyrope and almandine garnet inclusions have also been discovered in UHP rocks from the Western Alps (fig. 1).

Source heterogeneities deduced from spatial and temporal geochemical patterns in continental basalts

W.K. HART[1]*AND M.E. BRUESEKE[2]

[1]Dept. of Geology and Env. Earth Sci., Miami Univ., Oxford, OH 45056, USA (*correspondence: hartwk@miamioh.edu)

[2]Dept. of Geology, Kansas State Univ., Manhattan, KS 66506, USA (brueseke@ksu.edu)

Deciphering the mantle source(s) of basaltic magmas erupted in continental settings is challenging due to the potential geochemical and isotopic overprints imparted by continental lithosphere. In addition, both lithospheric and sub-lithospheric mantle reservoirs are variously implicated in continental basalt generation. As a result, intracontinental locations with extensive exposures of time-transgressive basalt flows can be extremely important for unraveling the relative contributions of these reservoirs.

In this context, we describe the spatial, temporal, chemical, and isotopic characteristics of basaltic volcanism on the Owyhee Plateau, USA. The Owyhee Plateau (OP) lies at the intersection of the Snake River Plain-Yellowstone and Oregon High Lava Plains magmatic trends; a region affected by the initial upwelling of the Yellowstone hotspot ~17 million years ago. It is the only location in the Pacific Northwest directly affected by Yellowstone-hotspot related volcanism that also contains a continuous record of basaltic volcanism over the past ~17 Ma [1]. OP basalt compositions include primitive to fractionated tholeiitic and mildly alkaline varieties with incompatible trace element and Sr, Nd, and Pb isotope ratios that are decoupled from the bulk chemistries, and that are time dependent [1,2].

The OP basalt suite reveals how mantle sources of intracontinental mafic magmas can vary as a function of time and lithospheric structure in a geographically restricted location. In this region, the heterogeneous mantle sources result from location along a distinct continental lithosphere transition, a major episode of sublithospheric mantle upwelling, and prolonged regional subduction leading to geochemical modifications of the lithosphere-asthenosphere boundary region that influence the nature of subsequent magmatism. Recent geophysical and geodynamic modeling results support these geochemical-based interpretations [3].

Melt injections and metasomatism in the continental mantle lithosphere beneath southern Africa

BEN HARTE

Centre for Science at Extreme Conditions, School of Geosciences, University of Edinburgh, King's Buildings, Edinburgh EH9 3JW, Scotland, UK. (ben.harte@ed.ac.uk)

A wide spectrum of melt-related phenomena have been identified in mantle xenoliths and xenocrysts from southern African xenoliths. At one end of this spectrum are the megacrysts of the Cr-poor megacryst suite, which appear to be direct crystallisation products from a melt body. At the other end of the spectrum are peridotite xenoliths with no megascopic signs of melt injection, but showing trace element evidence of metasomatism by melt percolation. In between these extremes are xenoliths showing apparently intrusive sheets and injected veins, as seen in the MARID suite of the Kimberley area (South Africa) and the IRPS suite of Matsoku (Lesotho). Evidence of melt intrusion, disruption and metasomatism is also shown by the polymict peridotite suite.

Close major-minor element compositional links exist between megacryst suite minerals, some Fe-Ti-rich high-temperature deformed xenoliths, and the metasomatised peridotite host rocks to intrusive IRPS-rich sheets. The major-minor element compositions of minerals in the Matsoku IRPS suite show close similarities to the matrix minerals of polymict peridotites. Estimates of the trace element compositions of melts percolating through Jagersfontein peridotite xenoliths evolve from compositions close to those estimated for megacryst magmas to those estimated for kimberlites. It appears that many phenomena show evidence of a lineage going back to similar Cr-poor megacryst magmas interacting over thicknesses of ca 100km with a diverse mantle lithosphere.

Subducted carbon in stagnant slabs: Evidence from 'deep' diamonds

BEN HARTE

Centre for Science at Extreme Conditions, School of Geosciences, University of Edinburgh, King's Buildings, Edinburgh EH9 3JW, Scotland, UK.

Evidence has been accumulating of diamonds containing mineral inclusions of unusually deep origin (250 to 800 km). In the case of 'deep' diamonds with silicate inclusions indicating basic rock protoliths, the diamonds have $\delta^{13}C$ values extending as low as -24 ‰ and suggestive of organic carbon. Other evidence of an initial ocean floor protoliths is shown by Eu anomalies in some inclusions. 'Deep' diamonds with inclusions indicating ultrabasic protoliths, commonly appear to have formed at depths of 500 to 750 km and have 'normal' mantle $\delta^{13}C$ values of -4 to -6 ‰. However, these diamonds are also believed to be derived from subducted oceanic lithosphere in the form of hydrous meta-peridotites that have undergone dehydration reactions near the Upper/Lower Mantle boundary [1]. Time constraints from diamonds and inclusions erupted in the Juina area, Brazil, suggest the subducted lithosphere to be of early Mesozoic age, with diamond formation occurring as the oceanic lithosphere descended and formed a subducted stagnant slab near the Upper/Lower Mantle boundary (see figure). The diamonds were erupted back to the surface by kimberlites during the Cretaceous.

Colloidal metals in stalagmites: Potential for palaeohydrology

ADAM HARTLAND[1], IAN. J. FAIRCHILD[2], WOLFGANG MULLER[3] AND DAVID DOMINGUEZ-VILLAR[4]

[1] University of Waikato, Hamilton, New Zealand. a.hartland@waikato.ac.nz
[2] University of Birmingham, Birmingham, B15 2TT, UK.
[3] Royal Holloway University of London, Egham, Surrey, TW20 0EX, UK.
[4] Centro Nacional de Investigación sobre la Evolución Humana, Burgos, Espana.

There is increasing recognition of the role of organic colloids and dissolved natural organic matter (NOM) in trace metal trasport in karst systems. In particular, we now know that colloid-facilitated transport of trace metals responds in a coherent way to surface infiltration patterns [1] and that this may be encoded meaningfully in speleothems [2].

This study combines measurements of aqueous colloid-metal species from dripwaters, with trace metal and organic carbon data from a conjugate hyperalkaline speleothem. Thus, for the first time the capture of the inorganic and organic components of dripwaters by speleothems is studied in a quantitative way.

Our results indicate that the partitioning of NOM-transported metals into speleothems is proportional to the strength of the aqueous NOM-metal complex. In practice, this means that some metals (e.g. Cu, Zn) more closely reflect hydrological changes (readily dissociate to bind with calcite), while other elements (e.g. Co, Br) more closely encode information on NOM capture, i.e. they less readily dissociate from aqueous complexes.

We also provide evidence for kinetic effects on NOM incorporation in the speleothem and show that the ratio of certain trace metals (e.g. Cu/Ni) in stalagmites may also reflect compositional fluctuations in the NOM, consistent with high and low molecular weight trends also seen in dripwaters.

Arsenic in surface sediments of a harbor sludge dumping site and a natural deposition site in the Helgoland Mud Area, North Sea

JAN F. HARTMANN[1], SABINE KASTEN[2] , THOMAS KRENGEL[1] AND MARGOT ISENBECK-SCHRÖTER[1]*

[1] Inst. of Earth Sciences, Heidelberg Univ., Im Neuenheimer Feld 236, 69120 Heidelberg, Germany (*corr.: Margot.Isenbeck@geow.uni-heidelberg.de)

[2] Alfred Wegener Institute for Polar and Marine Research, Am Handelshafen 12, 27570 Bremerhaven, Germany

In order to analyse differences in concentration, speciation and total mobility of arsenic two different locations were studied near the Helgoland Mud Area, North Sea.

The first location is characterised by natural sedimentation, the second by deposited sediments dredged from the port of Hamburg. Porewater as well as sediment profiles were analysed with respect to arsenic compounds (As (III) and total As) and major redox species as total and reactive manganese and iron. The sediment samples were handled under inert atmosphere before and during extraction by water, phosphate, hydrochloric acid and aqua regia. Total element contents in porewater and leachable extracts of sediment fractions were analysed.

The results show a strong redox coupling of arsenic with manganese and iron. Oxidized arsenic seems to adsorb to manganese- and iron-oxyhydroxides in surface sediments. In contrast to the solid samples, the pore water data shows a release of As (III) into porewater when manganese- and iron-oxyhydroxides are reduced in the upper part of the cores. Also a remobilisation of As (V) occurs. Downward diffusing arsenic can be fixed by carbonate below the zone of manganese and iron reduction. In the anoxic parts of the sediments As (III) and As (V) are released and could be fixed at authigenic iron sulphide or arsenic sulphides formation. A sulfidic precipitation of arsenic in iron-dominated systems is limited by the occurrence of HS-.

Total solid-phase contents in leachable extracts of sediment fractions of the natural area show significant higher arsenic concentrations than the core of the anthropogenic dumping area. This is due to the higher fines content of the Helgoland mud area.

Higher total porewater contents of iron and arsenic in the core of the anthropogenic dumping area thus due to higher turnover rates of organic matter by iron reduction. Higher concentrations of arsenic may be due to a higher availability of iron in the dumped sediments.

Sub-arc $\delta^{11}B$: The introduction of boron isotope heterogeneity into the convecting mantle

JASON HARVEY [1]*, CARLOS J. GARRIDO[2], SAMUELE AGOSTINI [3], JOSÉ-ALBERTO PADRÓN-NAVARTA [4,5], VICENTE LÓPEZ SÁNCHEZ-VIZCAÍNO [2,4], IVAN P. SAVOV[1], CLAUDIO MARCHESI [2]

[5] Géosciences, Montpellier, CNRS (France)

The Cerro del Almirez Massif in Spain preserves field evidence for the prograde transition from antigorite-serpentinite (ant-serp) to chlorite-harzburgite (chl-harz) in a paleo-subducting slab. This study investigates B isotope fractionation in the sub-arc region, where fluid loss accompanies prograde metamorphism under well constrained pressure and temperature conditions (650 °C, 1.7 GPa [1]). Boron isotopes are strongly fractionated during the dehydration of ant-serp, with a sharp decrease of $\delta^{11}B$ across the ant-serp to chl-harz isograd. Ant-serp has a $\delta^{11}B$ of +22.6 ‰ (± 1.6), similar to the heaviest $\delta^{11}B$ in serpentinites recovered from the forearc region of the Mariana subduction zone [2, 3], whereas prograde lithologies preserve $\delta^{11}B$ of +3.3 ‰ (± 0.3) to $\delta^{11}B$ of -3.5 ‰ (± 0.3).

Although the rapid drop in $\delta^{11}B$ demonstrates that massive B isotope fractionation occurs at sub-arc depths, the absolute amount of boron lost during dehydration is negligible compared to B lost from the downgoing slab in the forearc at the onset of subduction (c. 85%)[4]. Lithologies on either side of the isograd contain 7-12 ppm B with only minimal loss of B accompanying dehydration. This means that any B that survives ant-serp dehydration has the potential to be transported past the sub-arc region and into the deep, convecting mantle. Prograde chlorite is not the major host of this boron - it is mostly contained in prograde olivine-hosted inclusions[5], unlikely to suffer any subsequent dehydration reactions. The delivery of B with $\delta^{11}B$ of +3.3 ‰ to $\delta^{11}B$ of -3.5 ‰ into the asthenosphere therefore provides a possible source for OIB (e.g.[6]) whose $\delta^{11}B$ is significantly lighter than primitive mantle.

Copper mineralization prevented by arc-root delamination during Alpine-Himalayan collision in Iran

MICHAEL HASCHKE[1], JAMSHID AHMADIAN[2], FATEMEH SARJOUGHIAN[3], BEHNAM SHAFIEI[4]

[1]UIT Dresden, Am Windkanal 21, 01109 Dresden, Germany
[2]Dept. of Geology, Payame Noor University, Tehran, Iran
[3] Dept. of Earth Sciences, Univ. of Kurdistan, Sanandaj, Iran
[4]Dept. of Geology, Golestan Univ., Gorgan, Iran

The formation of Cu-Au-Mo porphyry deposits in Iran is linked to continental collision, yet there are no clear temporal relations between geochemical signatures of Miocene (collisional) and Eocene (pre-collisional) intrusive arc rocks, and the presence/lack of ore mineralization. We compare geochemical scenarios from five different segments along the Urumieh-Dokhtar arc and propose a geodynamic model to explain this discrepancy. For instance, in the Natanz arc segment in central Iran, contrasting geochemical signatures of copper ore hosting Eocene and some barren undeformed Miocene diorites to granites temporally overlap with the Alpine-Himalayan collision. These changes provide key implications on the existence and lack of Cu mineralization during collisional magmatism. High Sr and low Y (and Yb) contents of Eocene arc rocks in the Natanz arc segment reflect thickened, Andean-type orogenic arccrust (~45 km), whereas barren Miocene Natanz arc rocks (21-19 Ma) indicate thin arc crust similar to collisional volcanism in Anatolia. Geochemical modeling indicates a change in the mineralogy of the melt residual, from precollisional Eocene basaltic garnet-bearing (5-30%) amphibolite to syn- or postcollisional Miocene metasomatized mantle peridotite, which can be explained by collision-induced delamination of the arc lithospheric root. Subsequent recharge of hot asthenosphere and melting of metasomatized mantle peridotite and lack of interaction with a garnet-bearing arc crustal keel explain the low Sr and high Y (and Yb) contents, the relatively enriched initial Sr isotope ratios of postcollisional Miocene Natanz rocks, and the lack of copper mineralization in postcollisional Miocene Natanz arc rocks. Arc-root delamination removes the copper- and sulfurenriched metasomatized lithospheric arc root and hydrous cumulate reservoir required to form copper ore deposits. Lack of the dense melt residues also provides an alternative explanation for the elevated, thin crustal Iranian back-arc plateau (38 km) as a result of uplift by isostatic rebound rather than uplift by anomalous shortening. Miocene arc-root delamination implies a minimum age of >21 Ma for the Alpine-Himalayan collision in central Iran.

Relationship between modern speleothem formation and surface weather in an Asian tropical cave

W. HASEGAWA[1]*, Y. WATANABE[1], H. MATSUOKA[1], S. OHSAWA[2], B. BRAHMANTYO[3], K. A. MARYUNANI[3] AND T. TAGAMI[1]

[1]Earth and Planetary Science, Kyoto univ., Kyoto, Japan (*correspondence: hasegawa-w@kueps.kyoto-u.ac.jp)
[2]Institute of Geothermal Science, Kyoto univ., Beppu, Japan
[3]Earth Sciences and Mineral Technology, Institut Teknologi Bandung, Bandung, Indonesia

For precise climate prediction, it is necessary to reconstruct high time and space resolution paleo-climate (especially past 2000 years) from paleo-climate proxies and assimilate the result to climate model. Tropical Asia, including Indonesia, is well affected by El Niño Southern Oscillation (ENSO). The ENSO does not only directly affect on precipitation in tropical Asia, but also indirectly on middle and high latitude climate through teleconnection [1]. In Indonesia, Watanabe *et al* [2] suggested inverse-correlation between $\delta^{18}O$ and $\delta^{13}C$ in speleothems and instrumental precipitation. However, relationship between modern speleothem formation and surface weather is not revealed clearly.

Thus cave monitoring program was initiated from 2011 in Petruk Cave (Central Java, Indonesia) in order to study the recording mechanism of precipitation variation into the $\delta^{18}O$ and $\delta^{13}C$ fluctuation in speleothems.

Air CO_2 concentration in Petruk Cave is fluctuated daily and seasonally until over 100 m deep site from the entrance.

It is revealed that cave air CO_2 concentration may be a significant factor that controls stable isotope value in speleothems, because temperature, humidity and drip rate in Petruk cave are nearly stable.

A scenario of precipitation recording is as follows: (1) surface rainfall cools outside air temperature; (2) cave airflow direction is inversed; (3) outside fresh air flows into the cave and air CO_2 concentration is dropped; (4) pCO2 difference between cave air and dripwater becomes higher and calcite precipitation is promoted; (5) $\delta^{18}O$ and $\delta^{13}C$ in speleothems are decreased.

Origin of laminations in BIF deciphered from N and Fe isotopes

K. HASHIZUME[1]*, D.L. PINTI[2], B. ORBERGER[3], C. CLOQUET[4], M. JAYANANDA[5] AND H. SOYAMA[1]

[1]Dept. of Earth & Space Sci., Osaka Univ., Toyonaka 560-0043, Japan (*kohash@ess.sci.osaka-u.ac.jp)
[2]GEOTOP, H2X 3Y7, Montréal, Qc, Canada

[4]CRPG-CNRS, BP 20, 54501 Nancy, France
[5]Dept. of Geology, Univ. of Delhi, Delhi 110 007, India

Elucidation of the formation process of banded iron formations (BIF) is the major purpose of this study. Not only the iron oxidation process itself, but the alternation between the quartz- and iron-rich layers may provide important clues on the emergence of the oxygen in the early atmosphere.

A >2.72 Ga old BIF from Dharwar Craton, southern India, was studied. Compositions of N, Fe and Ar isotopes, major and trace elements including REEs were analyzed among 10 qz- or Fe-oxide-rich bands from the sample. REE and trace element compositions of the samples indicate a minimal influence from the continental crust, allowing us to propose a relatively simplified view of the water column from which constituents of the BIF sample precipitated. Qz- and Fe-rich layers showed contrasting compositions of N, Fe and Ar isotopes and of REEs. A positive correlation between $\delta^{15}N$ and $\delta^{56}Fe$ values, which range from +2 to +12‰ and +0.9 to +2.2‰, respectively, is the major finding of this study. Qz-rich layers exhibit higher Eu anomalies correlated with $^{40}Ar/^{36}Ar$ ratios. This trend is explained by the contribution of a constant amount among all bands of a hydrothermal component, added to Y-rich REE and ^{36}Ar-rich Ar components, which possibly represent Archean oceanic and atmospheric air compositions, respectively, carried by Fe-bearing minerals. The lower $\delta^{56}Fe$ values observed among the Fe-rich bands could be explained either by anoxygenic photosynthetic oxidation or O_2-mediated abiotic oxidation from an oceanic ferrous iron with a mantle origin. We explain the higher $\delta^{56}Fe$ values among the qz-rich bands by dissimilatory iron reduction (DIR) by which lighter iron isotopes are consumed faster. The qz-rich bands are N-rich, in concentrations and C/N ratios, and ^{15}N-rich, in the isotope ratio. We propose that formation of the qz-rich bands may correspond to periods when the photosynthetic biological productivity at the surface of the ocean was active. The DIR could have been enhanced during this period by supply of abundant organic matter to the iron particles. The biological activity at the ocean surface could be the switch producing the laminations in BIFs.

Net community and gross primary production in the Southern California Bight based on carbon export, dissolved O_2/Ar and triple oxygen isotopes: Exploration of how the magnitude and timing of upwelling events may influence export efficiency

W.Z. HASKELL II [1], M.G. PROKOPENKO [1], D.E. HAMMOND [1], R.H.R. STANLEY [2], W.M. BERELSON[1]

[1]Dept. of Earth Sciences, University of Southern California, 3651 Trousdale Pkwy, Los Angeles, CA, 90089, USA whaskell@usc.edu
[2]Dept. of Marine Chemistry, Woods Hole Oceanographic Institution, 266 Woods Hole Rd., Woods Hole, MA, 02543, USA

Biologically driven deviation of dissolved O_2 from equilibrium concentrations, determined from O_2/Ar ratios, has long been used as a tracer of net community production (NCP) in the oceans, as O_2 is a counterpart of carbon in photosynthesis and respiration. Over the last decade, a technique using the triple oxygen isotope composition (TOI) of dissolved O_2 has been applied in many regions of the ocean to estimate gross biological oxygen production (GOP) in the surface mixed layer. The TOI approach rests on using the deviation from mass dependent fractionation of the three oxygen isotopes (^{16}O,^{17}O,^{18}O) in the mixed layer to distinguish between photosynthetic *in situ* produced O_2 and atmospheric O_2 supplied through gas exchange. This "dual-tracer" approach of simultaneous measurements of Net Community and Gross Production provides estimates of NCP/GOP ratios, which reflect efficiency of carbon export. However, applications of this *in-situ* technique have been limited in productive coastal upwelling zones because the mixed layer O_2 mass balance is altered by upward advection of water from the oxygen deficient zone, which has both O_2 concentration and TOI composition out of equilibrium with the atmosphere. The Upwelling Regime In-situ Ecosystem Efficiency (Up.R.I.S.E.E.) time-series study is an ongoing effort to expand the application of the O_2-based dual-tracer approach to the upwelling regimes. In this study, O_2/Ar and TOI measurements through the upper thermocline are combined with estimates of upwelling rates, constrained by a mass balance of ^{7}Be in the surface mixed layer and upwelling indices from wind stress curl. Accounting for the contribution of the deep water O_2 signal to the mixed layer O_2 and TOI inventory, we test whether the timing and/or magnitude of upwelling events affect an ecosystem's efficiency in exporting organic carbon from the surface ocean in this highly productive setting. Sediment trap deployments and budgets of DIC, DOC, and ^{234}Th are used to further constrain export estimates, and compared to NCP. Preliminary results from the first six months of a two-year study will be presented.

Metals zone distribution in old ore deposits Egypt: A pathfinder for site of chief metal accumulation

MAHMOUD M. HASSAAN [1]

[1]mah_hassaan@hotmail.com. Faculty of Sciences, AlAzhar University-Egypt.

Geochemical zoning, is a reliable exploration criterion for revealing site of accumulation of chief ore metal . Studies established the clark of concentration CC and zoning coefficient to investigate the old exploited deposits of gold, zinc-copper, molybdenum–silver hosted by the Pan-African ophiolitic, island arc and cordilleran-extension rocks of the Nubian shield. These studies considered the general zoning sequence. Be, Ni, Co, B, Sn, U, Mo, W, As, Bi, $Cu_{(1)}$, Zn, Pb, $Sn_{(2)}$, Au, Ag, B, $As_{(2)}$, Cu, Sb, Hg, Te, I. The zoning sequence of Sukkari mineralization upward is Au, Sn, Mo, Zn, As, Ni, Pb, Ba favoring gold accumulation site deeper than ~ 400 m .In Abu Marwat mine the zoning sequences favored increase of gold northward as follow :Upper zone northern part Ag, Zn , Mo, Pb, Ba, Au, sn, Cu, Au and lower zone northern part Sn, Ni. Pb, Ba, Au, Zn, Cu, Mo, Ag. The recommended site of gold accumulation is meta-volcanic rocks and quartz veins bordering Wadi Abu Marwat from north and their extension under the Wadi alluvial. The study of Gattar molybdenite-silver occurrence recorded gold. The vertical zoning sequence from altitude 10 m to 953 m . is Au, Cu Pb, (Co, Ni) , Ag, Zn, Sb, (Sn-W), Cr, Mo enhanced 2 mineralization phases and gold accumulation at deeper levels . In Um Zuriq mineralization at Wadi kid in Sinai , the data of a drill hole penetrated repeated sheared and altered chlorite schist and garnet biotitic andalusite schist forming two limbs of a recumbent fold placed basal mineralization zone at south western side above the top of the zone at north eastern part. The recorded sequence Cu(Zn, Pb), Au, Ag upward in the basal limb is normal and another inverted one for the upper limb. The mineralization is syngeneic to the schist. The arc-like island arc meta-volcanic rocks hosting seven As, Pb, Zn, Cu sulfides litho- structurally controlled forming a belt. In El Atshan mine variable high CC values of only Cu and Zn in all rock units favored that the volcanic magma was bearing Cu-Zn. The recorded high Pb and As contents in the talc carbonate and serpentinite enhanced its relation to dynamo-thermal activity during thrusting. The vertical zonal sequence is Fe, Cu , Zn (Pb-As) upward . These features were recorded at the Derhib mine. Similar deposit was recorded in Wadi Allaqi.

Late Neoproterozoic Nuqara Dokhan Volcanics, Central Eastern Desert, Egypt: Geochemistery and petrogenesis

The Neoproterozoic Nuqara Dokhan volcanics are one of the northernmost outcrops of the Arabian- Nubian Shield . The origin and tectonic setting of these rocks is highly debated .Debate concerns the tectonic setting they formed as a result of subduction (El Gabby et al, 1990) or crustal extension(Stern,1994).Nuqara dokhan volcanics comprises two main rock suites: (a) an intermediate volcanic suite, consisting of basaltic andesite, andesite and their associated pyroclastics rocks; and (b) a felsic volcanic suite composed of dacite, rhyolite and ignimbrites .The two suites display well-defined major and trace element trends and continuum in composition with wide ranges in SiO_2 (52-75.73%), CaO (9.19-0.22%), MgO(5.29-0.05%), Sr (1367-7.4ppm), Zr (688.5-172.7ppm), Cr (207-0.4 ppm), and Ni (86-0.2ppm).The Nuqara Dokhan volcanics are characterized by strong enrichment in LILE relative to HFSE and affiliated to the calc-alkaline subduction – related magmatism .Modeling results display that the evolution of these rocks was governed byfractional crystallization of plagioclase, amphiboles, pyroxene, magnetite and apatite in the intermediate varieties and plagioclase ,amphibole, magnetite ,apatite and zircon in the felsic varieties. The obtained mineral chemistry of these volcanics reveals: (a) Plagioclase range in composition from An_{59} to An_{55} in basaltic andesite and from An_{49} to An_{27} in andesite. (b) Alkali feldspars have sanidine composition. (c) Clinopyroxenes have augite composition .The low Al_2O_3 contents (2.055-5.588 wt %) indicate that clinopyroxene crystallized at low – pressure. (d) Amphiboles have ferro hornblende to ferro barrosite composition.

Specific ion effects on the wettability of sandstone particle

T. HASSENKAM, J. MATHIESSEN, M.P. ANDERSSON AND S.L.S. STIPP

Nano-Science Center, Dept. of Chemistry, University of Copenhagen, Denmark (tue@nano.ku.dk)

Specific ion effects control most reactions in nature. Adhesion, between organic molecules and mineral surfaces in aqueous solution, depends not only on the behaviour of the molecule and substrate but also on the specific set of dissolved ions. The complex behaviour between ions, water and organic molecules is reflected in various versions of what is known as the Hofmeister series where ion activity depends on size, charge and electron configuration. There is a wealth of experimental data on how organic molecules interact with sandstone, from oil industry work and from environmental studies of soil, sediments and aquifers but the picture of molecular scale interactions is not clear.

By using force spectroscopy and chemical mapping with AFM (atomic force microscopy) we can observe contact behaviour with a variety of molecules on real sand grains, while solution composition is changed. By using tips functionalised to behave as pure alkane (CH3), we have probed sand grains, and examined adhesion in NaCl solutions, with ionic strength close to that of seawater. Changing composition of the solution by adding small amounts (12 mM) of specific divalent ions (Ca2+, Mg2+), corresponding to about 2% relative to the number of Na+ ions, caused a dramatic adhesion increase between the alkane tips and the surface - by as much as 50%. Increased adhesion is a clear response to higher divalent ion density at the surface. However, in 0.5 M NaCl, the electrical double layer collapses to much less than the thickness of a single water molecule so the understanding of the data can only be founded in mechanisms involving ions and their behaviour specifically, at the molecular scale.

The biogeochemical ice core record: A new perspective on nitrate

MEREDITH G. HASTINGS[1], DOROTHY FIBIGER[2], NATHAN CHELMAN[1,3] AND JOSEPH R. MCCONNELL[3]

[1]Brown University, Department of Geological Sciences and Environmental Change Initiaitve, 324 Brook Street Box 1846, Providence, RI USA, meredith_hastings@brown.edu

[2]Brown University, Department of Chemistry, Providence, RI USA

[3]Desert Research Institute, Division of Hydrologic Science, Reno, NV USA

A major motivation in studying ice core nitrate is to reconstruct the atmospheric loading of its precursor, nitrogen oxides (NO_x). NO_x concentrations in the atmosphere play a significant role in determining tropospheric chemical composition and oxidizing capacity. Today, NO_x emissions are primarily the result of fossil fuel burning, with important contributions from biomass burning, lightning and biogenic processes in soils. The result of these emissions is deposition of nitric acid (i.e., nitrate), a component of acidic precipitation and a bioavailable nutrient. Recent studies utilizing the isotopic composition of nitrate in ice cores offer the possibility to trace the sources and chemical processes that contribute to nitrate deposition over time.

Studies of the isotopic composition of nitrate in surface snow and snowpits at Summit, Greenland reveal an atmospheric nitrate signal that is well preserved in recent snow. A seasonally resolved ice core record of the isotopic composition of nitrate, together with highly resolved (> 22 samples yr^{-1}) elemental and chemical tracers are used to investigate changes in NO_x sources and chemistry since 1760 C.E. A marked negative trend in $\delta^{15}N$ since industrialization (pre-industrial-era average of 12.0‰ vs. air N_2 to a modern-era average of 3.6‰) parallels a nearly three-fold increase in nitrate concentration, as well as pronounced increases in tracers such as excesss lead and non-sea-salt sulfur. This, along with independent estimates of oil burning and transport studies, indicate that North American oil combustion is the primary driver of the negative trend in $\delta^{15}N$ of nitrate. The pre-industrial record of nitrate and tracers such as amonium and black carbon ties the high, positive $\delta^{15}N$ values to biomass burning. Overall, this record provides constraints for $\delta^{15}N$-NO_x source signatures, which are poorly characterized. A quantitative tracer of the pre-industrial sources and chemistry of NO_x would allow for detailing connections between the atmosphere (lightning, chemistry, transport), the biosphere (biomass burning, soils), and climate.

Rare Earth Elements in the surface Ocean under the Saharan dust belt

ED C. HATHORNE[1], MARTIN FRANK[1], MICHIEL RUTGERS VAN DE LOEFF[2], TOBIAS ROESKE[2], AND JOERG RICKLI [3]

[1]GEOMAR, Helmholtz Centre for Ocean Research Kiel, Germany (ehathorne@geomar.de)
[2]Alfred Wegener Institute for Polar and Marine Research (AWI), Bremerhaven, Germany
[3]ETH Zürich, Switzerland

The supply of trace metals to the surface ocean via dust deposition is important for primary productivity and the global biogeochemical cycle of many elements. Here we utilise the systematic variation of the chemical properties of yttrium and the rare earth elements (YREE) to investigate trace metal release from dust in the equatorial Atlantic Ocean. We present YREE data for the dissolved (<0.45 μm) and suspended particulate matter (SPM) collected from the mixed layer during Polarstern cruise ANT-XXIII/1 in Oct-Nov 2005.

Saharan dust can be traced with the Al content of the SPM revealing a broad maximum extending from 15° to 3°N. The PAAS normalised YREE patterns of the dust dominated SPM are relatively flat with a broad peak centred around Eu and Gd. This dust dominated SPM is also characterised by lower Y/Ho and Er/Nd ratios than the particulate material from outside the high Al zone.

The dissolved YREE distributions show normal seawater patterns with the relative enrichment of heavy REE over light REE. The samples with dust dominated SPM are enriched in the light and middle REE by a factor of approximately 2 compared to the other samples and a Sargasso Sea surface water. The dissolved Y/Ho and Er/Nd ratios obtained from the dust dominated SPM zone are also low compared to the samples outside the zone but display a fractionation between the SPM and the dissolved phase. This comparison indicates a consistent incongruent dissolution of the dust associated YREE which are probably mainly hosted by oxide coatings on the particles.

Hydrogeochemical assesment of Pasinler (Erzurum- Turkey) geothermal fluids

E. HATIPOGLU[1]*, F. GULTEKIN[1] AND A. FIRAT ERSOY[1]

[1]Karadeniz Technical University, 61080 Trabzon, Turkey (*correspondence:hatipogluesra@gmail.com, fatma@ktu.edu.tr, arzufirat@gmail.com)

The Pasinler geothermal field is located to 37 km east of Erzurum Province. The basement of Pasinler Geothermal field consists of Upper Cretaceous ophiolitic melange, Eocene volcanic rocks, Oligocene volcanic rocks, Lower Miocene reef limestones, Upper Miocene pyroclastics, Plio-Quaternary (sandstone, marl, conglomerate) and Quaternary alluvium. The rhyolite is the reservoir for the geothermal fluid. The tuffs and marls are cap rocks of the system. The fault and related fractures around the Pasinler geothermal field provide pathways for the upward flow of geothermal fluid to the surface. The Alluvium around the Hasankale River is the most important unit as cold groundwater deposits in the study area. The thermal waters in the Pasinler geothermal fields have outlet temperatures 23 to 35°C in springs. But discharges in the wells vary between 38-52°C.

Geothermal well waters belong to the Na-Ca-Cl-HCO_3 type. The Pasinler geothermal water has discharge pH values of 6 to 7.5, electrical conductivity (EC) of 970 to 5800 μS/cm and TDS contents between 635 and 3700 mg/l. The Pasinler geothermal field is in class low enthalpy geothermal system, and its reservoir temperature was calculated as 46-169°C using silica geothermometer. The $\delta^{18}O$- $\delta^{2}H$ data clearly indicate a meteoric origin for the thermal waters.

According to analyses of heavy metal contents such as Cr, Pb, Zn, Ni, Al and Cu, the Pasinler geothermal water is suitable for the Turkish Thermal Standarts, on the other hand by the amount of Fe, Mn, As, B, Br is not suitable.

Laser ablation for spatially resolved radiocarbon measurements with gas source-accelerator mass spectrometry

B. HATTENDORF[1], C. MÜNSTERER[1,2], R. DIETIKER[1], J. KOCH[1], L. WACKER[2], M. CHRISTL[2], H.A. SYNAL[2] AND D. GÜNTHER[1]

[2] ETH Zurich, Laboratory of Ion Beam Physics, Schafmattstr. 20, 8093 Zurich, Switzerland

Accessing the spatial variability of ^{14}C in solids like for example speleothems, corals or wood, traditionally required laborious and time consuming sample preparation (milling, drilling, graphitization) to allow measurements by accelarator mass spectrometry (AMS). With the availability of gas ion source AMS [1] and new sample preparation techniques and the direct measurement of gaseous carbon species (i.e. CO_2) a wider range of applications has become accessible. Laser ablation can directly produce CO_2 from carbonates at a spatial resolution of several 10 μm and is considered to complement currently available measurement strategies when high resolution radiocarbon records are of interest. In this study, a prototype laser ablation sampling unit is developed, which can be directly connected to the ion source of a gas-source AMS instrument. It comprises an ArF excimer laser (193 nm) with beam delivery optics, a specific ablation cell and sample observation system. Initial tests showed that using rectangular ablation crater of 100 μm x 700 μm can generate a sufficient CO_2 flux to allow radiocarbon measurements with the gas ion source AMS. The ablation cell was designed in order to avoid carry over effects of particulate debris from adjacent ablation spots and to ensure minimum signal dispersion at the operating conditions of the gas source AMS (i.e. 200 μL/min He as carrier gas). It consists of a volume-optimized gas expansion head with targeting and observation window and a large volume sub-unit capable of hosting sample specimen with sizes of up to 100 mm x 20 mm. The system configuration and initial results from ^{14}C measurements will be discussed in this presentation.

Natural climate variation, such as that caused by volcanoes, is the basis for identifying anthropogenic climate change. However, knowledge of the history of volcanic activity is inadequate, particularly concerning the explosivity of specific events. Some material is deposited in ice cores, but the concentration of glacial sulfate does not distinguish between tropospheric and stratospheric eruptions. Stable sulfur isotope abundances contain additional information, and recent studies show a correlation between volcanic plumes that reach the stratosphere and mass-independent anomalies in sulfur isotopes in glacial sulfate. We describe a mechanism, photoexcitation of SO_2, that links the two, yielding a useful metric of the explosivity of historic volcanic events. A plume model was constructed including photochemistry, entrainment of background air, and sulfate deposition. Isotopologue-specifc photoexcitation rates were calculated based on the UV absorption cross-sections of $^{32}SO_2$, $^{33}SO_2$, $^{34}SO_2$, and $^{36}SO_2$ from 250 to 320 nm. The model shows that UV photoexcitation is enhanced with altitude, whereas mass-dependent oxidation, such as SO_2 + OH, is suppressed by *in situ* plume chemistry, allowing the production and preservation of a mass-independent sulfur isotope anomaly in the sulfate product. We are able to identify the process controlling mass-independent sulfur isotope anomalies in the modern atmosphere. This mechanism is the basis of identifying the magnitude of historic volcanic events.

Internal structure of a mid-crustal magmatic conduit: The Punta Falcone mafic pluton (Sardinia, Italy)

ANNE-CÉCILE HAUSER[1] AND FRANÇOIS BUSSY[2]

[1,2]Institute of Earth Sciences, University of Lausanne, Géopolis, CH-1015 Lausanne. ([1]anne-cecile.hauser@unil.ch, [2]francois.bussy@unil.ch)

The granite-hosted mid-crustal gabbroic pluton of Punta Falcone is built by many magmatic pulses with contrasting textures and composition. Gabbros can be divided into a supposedly older external zone (EZ) and a central zone (CZ) based on mineralogical, textural and geochemical arguments. CZ gabbros are more primitive in composition as indicated e.g. by higher mg-# in amphiboles. They contain relics of orthopyroxene, which are absent in the EZ gabbros. Whether the change in chemistry is due to more thorough interaction of the earlier pulses (EZ) with the host rocks during ascent/in the source region or whether it represents a change in the magma source should be resolved by radiogenic isotope compositions.

High An-contents of plagioclase as well as important amounts of amphibole in all gabbros express the high water content of the system. Phase diagrams based on water-saturated experiments allow linking the early stabilization of amphibole in the EZ gabbros (sub-euhedral grains) with cooling of the magma during ascent. The later appearance of amphibole in the CZ gabbros (poikilitic interstitial phase around euhedral plagioclase) on the other hand indicates higher temperatures for the same pressure and thus thermal maturation of the system over time. Furthermore the first pulses (EZ) crystallize as a whole with isotropic granular textures, whereas later pulses (CZ) show signs of crystal segregation and cumulate processes. They display remarkable rhythmic black and white layering at the cm-scale, which is roughly vertical and parallel to the limits of the cooling units. A second set of layers is crosscutting the main one at an angle of ca. 35°. Dark bands are defined by interstitial amphibole, which is absent in the white layers. The amount of lost liquid might reach several tens of wt%. The concentration of late crystallizing amphiboles in the dark layers indicates that liquid extraction is possibly linked to the development of the layering.

We interpret these magmatic structures as resulting from shearing of a crystallizing mush during its ascent or at its final emplacement level, with concomitant extraction of residual liquid, which escaped to higher crustal levels.

The effect of hydrothermal iron on marine dissolved organic carbon

J. A. HAWKES*[1], D. P. CONNELLY[1], A. DJURHUUS[2] AND E. P. ACHTERBERG[1]

[1]National Oceanography Centre Southampton, European Way, Southampton, UK

[2]University of Oxford, Department of Zoology, South Parks Road, Oxford, UK

High temperature hydrothermal vents produce particle rich plumes in particle deprived deep ocean regions. Dissolved organic carbon (DOC) may be adsorbed onto this iron rich particulate matter and as a result hydrothermal plumes may act as a sink for DOC [1]. It is estimated that the ocean's water is cycled through hydrothermal plumes on a 4000-8000 year timescale [2], making even very small DOC concentration changes in plume waters significant to the ocean budget of DOC. With an increasing variety of venting types being discovered [3,4], including environments which produce new DOC from magmatic CH_4 and CO_2 [5,6,7], a deeper understanding is required to assess the impact of hydrothermal vents on marine DOC.

We present new carbon and iron concentration data from plumes in three different hydrothermal settings: a back-arc vent site, a deep mid ocean ridge vent site and a ocean core complex hosted vent site. The plume characteristics (physical and chemical) are very different at these three sites, and samples were taken from vent fluids, diffuse areas of venting, the buoyant plumes and the dispersing (neutrally buoyant) plumes, allowing a comprehensive description of the interactions between dissolved and particulate iron and carbon in these three high-temperature vent environments. We will use the results to consider the overall impact that hydrothermal venting has on the concentration and nature of marine organic carbon globally.

[1]Durham University, Durham DH1 3LE, UK (correspondence: s.m.hawley@durham.ac.uk, kevin.burton@durham.ac.uk, h.m.williams2@durham.ac.uk

[2] University of Oxford, Oxford, OX1 2JD,UK (philipvs@earth.ox.ac.uk)

[3] University of Iceland, Reykjavik, 101 Reykjavik, Iceland (sigrg@raunvis.is)

Marine concentrations of bioavailable and reactive Iron can modulate the Carbon cycle and Earth's climate [1,2] Previous studies of glacial weathering [3,4] suggest that biogeochemical processes at rock-glacier interfaces promote the formation of highly bioavailable and reactive nano-particulate iron oxy-hydroxides. Consequently, because glacial weathering is a climatically dependent process the marine export of glacially derived oxy-hydroxide should strengthen the feedback loop between Fe and the climate.

Iron stable isotopes (δ^{57}Fe) have potential to trace weathering Fe exports as Fe oxy-hydroxide formation has been shown to fractionate Fe stable isotopes [5]. Preliminary data from Kangerlussuaq, Greenland indicates suspended particulate and dissolved material have heavy δ^{57}Fe values (~0.20 permil) compared to the surrounding bedrock and riverine bed loads (-0.10 to 0.00 permil). This study will incorporate further Fe isotope data from glacial and non-glacial catchments in Iceland and Greenland. Both Iceland and Greenland contain glacial and non-glacial systems that drain relatively uniform rock types allowing for the effects of the different weathering regimes to be compared. Comparisons between Greenland and Iceland then allow independent assessment of the role bedrock plays in controlling Fe exports from glacial and non-glacial weathering.

Exhalation and inhalation of Cera lattice Oxygen: A triple Oxygen isotope persective

JUSTIN HAYLES[1] AND HUIMING BAO[1]

[1]Department of Geology and Geophysics, Louisiana State University, Baton Rouge, LA 70803 (jhayle3@lsu.edu)

Ceria (CeO_2) is a fluorite type oxide that has been studied and used extensively as an oxygen storage media in three-way catalysts, as an oxygen partial pressure regulator, as a fuel additive for the reduction of soot, and for the production of syn-gas from water and CO_2. It is known that exposing ceria powders to low pO_2 and/or high temperature conditions will cause ceria to partially reduce. This partial reduction drives off oxygen from crystal lattice (exhalation) and leads to the formation of oxygen vacancies. When partially reduced ceria is exposed to high pO_2 environments, such as open air, the ceria powders will readily reoxidize even at room temperature. The reoxidation effectively fills the oxygen vacancies with new oxygen (inhalation). We expect that oxygen isotope fractionation is associated with both the exhalation and the inhalation processes. Understanding the isotope effect will help us explore the molecular mechanism for the dissociation, association, migration of oxygen on the surface and within the lattice of ceria.

To determine this isotope effect, we have devised an experimental procedure utilizing triple oxygen isotope labelled initial ceria powders. These powders are heated (700°C) for one hour and cooled under vacuum prior to exposure to air. By combining the results from six independent experimental sets using different initial oxygen isotope labels we have determined the kinetic isotope fractionation factors for both exhalation and inhalation using a graphical method. Our results indicate that there is a 1.6‰ ±0.6‰ increase in the δ^{18}O value of the remaining ceria upon heating in vacuum. When the vacuum is broken at room temperature, the heated ceria will inhale 3% to 12% oxygen from air, with a δ^{18}O of 1.6‰ (+4.6‰; −5.6‰). These fractionation factors are consistent with the magnitudes of kinetic fractionation associated with the dissociation and association of atomic oxygen at the surface of ceria. The issue associated with room-temperature oxygen inhalation renders ceria a poor choice of exchange medium for triple oxygen isotope analysis of CO_2 or other oxygen-bearing gases. We have discovered a similar result for yttria stabilized zirconia as well, suggesting that this behaviour may be intrinsic to the fluorite type oxides.

Contrasting tourmaline chemistry from late-Archaen orogenic gold deposits at Hutti and Hira-Buddini, eastern Dharwar craton, India: Implications for fluid source

PRANJIT HAZARIKA[1]*, BISWAJIT MISHRA[1] AND KAMAL LOCHAN PRUSETH[1]

[1]Department of Geology and Geophysics, Indian Institute of Technology, Kharagpur, India-721302 (correspondence:pranjit.hazarika@gg.iitkgp.ernet.in)

Textural and chemical features of tourmaline in the proximal alteration zones of the Hutti and Hira-Buddini deposits are: (i) warping of biotite-chlorite mylonitic foliation, (ii) inclusions in pyrite, and (iii) sharp decrease of Fe at rim. These imply (i) synchronous sulfidation of the wall rocks resulting in pyrite formation and (ii) early tourmalinization and its continuation until sulfidation of wall rocks and gold mineralization.

Tourmalines from Hutti are Mg-rich (X_{Mg}=0.63) while the unaltered rock is Fe-rich (X_{Mg}=0.30). Their high Al content (> 6 apfu) implies no substitution of Al by Fe^{+3} in the Z-site. The dominant substitutions observed are $MgFe^{+2}_{-1}$, and $\square AlNa_{-1}(Fe^{+2},Mg)_{-1}$. Participation of Fe^{+2} in most substitutions suggest a low Fe^{+3}/Fe^{+2} ratio, also supported by the compositions lying on the dravite-foitite trend. These observations suggest a reducing nature for the tourmaline precipitating fluid. The Mg-rich composition of tourmaline in Fe-rich amphibolite shows insignificant chemical control of the unaltered rock on the tourmaline chemistry and suggest their formation under high fluid by rock ratio [1]. Such Mg-rich, low saline (X-site vacancy upto 0.53) and reducing nature of the fluid is suggestive of a metamorphic source [1][2].

Tourmalines from Hira-Buddini belong to dravite-schorl series with relaively low Mg (X_{Mg}=0.53); low X-site vacancy (≤ 0.16) and show an oxy-dravite-povandrite (O-P) trend. Dominant substitutions observed are $Fe^{+3}Al_{-1}$, $Fe^{+2}Fe^{+3}(Al_{-1}Mg_{-1})$ and minor $NaMg(\square_{-1}Al_{-1})$. Al contents of < 6 apfu is possibly due to substitution of Al in the Z-site by Fe^{+3}, as evident from the substitution types and tourmaline compositions lying on the O-P trend. Tourmalines characterized by enrichment in Fe^{+3} and Na, depleted in X-site vacancy suggest oxidizing and relatively high saline fluid, which could be either from a meta-evaporitic [3] or a late stage granitic source [4].

Earth's Carbon through Deep Time

ROBERT M. HAZEN

Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch Rd NW, Washington DC 20015 USA. (rhazen@ciw.edu)

Earth's 4.567 billion year history is marked by a dramatic evolution in the chemical, physical, and biological roles of carbon [*1*,*2*]. Aspects of Earth's changing carbon cycle are revealed by a variety of investigations, including: (1) Abiotic organic systhesis, notably mineral catalyzed reactions of volcanic gases, yield essential biomolecules. Recent findings point to the critical role played by hydrogen fugacity in the synthesis and stability of these molecules [*3*]. (2) Small organic molecules display competitive and cooperative adsorption on mineral surfaces. We find that adsorption configurations are strongly affected by environmental conditions such as pH, ionic strength, and solute concentration [*4*]. (3) Experimental, theoretical, and field studies elucidate serpentinization reactions, as well as other deep interactions between C-bearing fluids and mafic and ultramafic rocks. Both volcanic and impact hydrothermal zones led to the first extensive carbonate mineral production [*5*]. (4) The subsurface biosphere modifies and cycles carbon. Deep microbial life often survives at metabolic rates and in concentrations far below those of near-surface communities [*6*]. And (5) carbon mineral evolution traces the changing diversity, distribution, and compositions (including trace and minor elements) in carbon minerals through deep time. Diamond was the first mineral in the cosmos, but many of the almost 400 known carbon minerals have appeared only recently in Earth history [*7*]. Collectively, these and other investigations of Earth's carbon through deep time underscore the co-evolution of the geosphere and biosphere.

Paleomineralogy of the Hadean Eon

ROBERT M. HAZEN

Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch Rd NW, Washington DC 20015 USA. (rhazen@ciw.edu)

The Hadean Eon, encompassing Earth's first 550 million years, was a time of significant planetary evolution. Nevertheless, prebiotic Earth's near-surface environment may have held no more than approximately 420 different rock-forming or accessory mineral species that were widely distributed and/or volumetrically significant [*1*]. This relative Hadean mineralogical parsimony is a consequence of the limited modes of mineral paragenesis prior to 4 Ga compared to the last 3.0 billion years. Dominant Hadean Eon mineralizing processes include the evolution of a diverse suite of intrusive and extrusive igneous lithologies; hydrothermal alteration over a wide temperature range, notably serpentinization; authigenesis in marine sediments; diagenesis and low-grade metamorphism in near-surface environments; and impact-related processes, including shock mineralization, creation of marginal hydrothermal zones, and excavation of deep metamorphosed terrains. On the other hand, the Hadean Eon may have been notably lacking in mineralization generated by plate tectonic processes, such as subduction zone volcanism and associated fluid-rock interactions, which result in massive sulfide deposition; convergent boundary orogenesis and consequent extensive granitoid-rooted continental landmasses; and the selection and concentration of incompatible elements in complex pegmatites, with hundreds of accompanying minerals. The dramatic mineralogical consequences of life are reflected in the absence of Hadean biomineralization; for example, the lack of extensive carbonate deposits and the associated restricted development of skarn and cave minerals prior to 4 Ga. Most importantly, it was not until after the establishment via photosynthesis of significant near-surface redox gradients that supergene alteration, redox-controlled ore deposition, and subaerial weathering in an oxidizing environment could diversify Earth's near-surface mineralogy. These post-Hadean processes may be responsible for more than 4000 of the more than 4800 approved mineral species. Any scenario for life's origins that invokes minerals as agents of molecular synthesis, selection, protection, or organization must take into account the limited mineralogical repertoire of the time.

[3] Department of Nuclear Engineering and Management, School of Engineering, The University of Tokyo, Japan (takumi@flanker.n.t.u-tokyo.ac.jp)

As a result of the nuclear accident in Fukushima, various radioactive elements such as cesium were dispersed in the atmosphere before being deposited on the soil within a distance of 80km around the nuclear power plant. Cesium with half-life of 30 years and properties similar to potassium accumulates in the clays, especially illite, of the upper soil horizons.

Among soil remediation methods, phytoextraction is the most appropriate one as it can be achieved *in situ* without any change of the biophysicochemical properties of the soil. Cesium uptake by plants depends on sorption/desorption reactions to/from the soil particles and on biogeochemical processes in the rhizosphere.

This work focuses on the bacterial mechanisms involved in Cs desorption from illite by estimating the amount of Cs released by desorption and/or as the result of illite alteration. Citric acid and oxalic acid that bacteria and plants are able to produce in soils were used in this work [1-2]. Illite alteration by these same bacteria also able to form biofilms at the surface of soil particles was studied [3-4]. Eventually experimental results were compared to those obtained by modeling.

Multiple exsolutions in a rare clinopyroxene megacryst from the Hannuoba basalt, North China: Implications for subducted slab-related crustal thickening and recycling

DETAO HE, YONGSHENG LIU*, XIRUN TONG, KEQING ZONG, ZHAOCHU HU, SHAN GAO

Faculty of Earth Sciences, China University of Geosciences, Wuhan, 430074, China (*correspondence: yshliu@hotmail.com)

A rare large clinopyroxene megacryst (type 1) collected from the Hannuoba basalt, North China was studied. It is distinguished from the prevalent clinopyroxene megacrysts (type 2) by garnet and orthopyroxene exsolutions and by chemical and Sr-Nd isotopic compositions. The type 1 clinopyroxene megacryst has higher Cr (2100 ppm) and Mg# (83) than the type 2 clinopyroxene megacrysts as well as more evolved Sr and Nd isotopic compositions. These characteristics suggest that the type 1 clinopyroxene megacryst could have been formed by a recycled crust-related melt-peridotite reaction. The type 2 clinopyroxene megacrysts exhibit good correlations between Mg# and major and trace element compositions. Their Sr-Nd isotopic compositions cluster in the least evolved field of the Hannuoba basalt. These observations imply that the type 2 clinopyroxene megacrysts were crystallized from the host lava at high pressure.

The type 1 clinopyroxene megacryst contains abundant coherent cryptocrystalline lamellaes and orthopyroxene exsolutions within it. The bulk composition of the cryptocrystalline lamellaes, composed of fine plagioclase and olivine, shows typical chemical features of garnet and Sr isotopic composition similar to the clinopyroxene host. These observations indicate that the cryptocrystalline lamellaes are decomposition products of garnet exsolutions in the clinopyroxene megacryst. This garnet exsolution could be caused by increasing pressure or decreasing temperature, as indicated by experimental results. Although the temperature decreases during basalt eruption, the much quicker decrease in pressure will suppress the garnet exsolution in clinopyroxene. Therefore, we suggest that the type 1 clinopyroxene megacryst could have experienced pre-Mesozoic crustal uplifting and thickening at the north margin of the North China Craton. Garnet decomposition could have taken place prior to orthopyroxene exsolution during the eruption of the host lava.

Noble gases in mantle xenoliths from the Tan-Lu fault zone, North China Craton

HUAIYU HE, FEI SU AND RIXIANG ZHU

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China

The Tan-Lu fault zone, which extends NNE-SSW for more than 3000km, is a major lithospheric discontinuity along the eastern Asia continent and is believed to have acted as a major channel for the ascending of asthenosphere and played an important role in the Mesozoic-Cenozoic thinning of the North China Craton (NCC) lithosphere. From North to South, there are many Cenozoic volcanic areas which are located in the Tan-Lu Fault Zone. Ultramafic xenoliths, mainly lherzolite and pyroxenite, are common in alkali basalts in these volcanic areas. Detailed petrological and geochemical studies suggest that these low Mg# peridotites (Fo 88-91) represent fragments of the newly accreted lithospheric mantle.

This study performed a comprehensive investigation of petrology, mineral chemistry and noble gases of mantle xenolith in Changle-Linqu (in the middle part of Tan-Lu Fault Zone) and Nvshan (in the south part of Tan-Lu Fault Zone) and try to trace the post destruction evolution of North China Craton (NCC) lithospheric mantle.

Olivines in wehrlites and lherzolites in Changle-Linqu and Nvshan yield $^{3}He/^{4}He$ ratio range from 6.9 to 7.6 Ra, a little bit lower than MORB value (8±1Ra), suggest that lithospheric mantle in the Tan-Lu fault zone would thus most likely have been metasomated by melts/fluids derived from an asthenospheric reservoir or lithospheric mantle is cooling from asthenospheric. However, wehrlites and lherzolites have significant lower $^{3}He/^{4}He$ ratios, lower helium abundance and lower $^{4}He/^{40}Ar^{*}$ in Cpx than in co-exist Ol. ^{4}He abundance and $^{3}He/^{4}He$ ratios of Opx are lower than co-exist Ol and higher than co-exist Cpx. Our thin section study indicates there is a direct link between sieve texture/melt-pocket and low helium abundance, low $^{3}He/^{4}He$ ratios and low $^{4}He/^{40}Ar^{*}$. This may suggest that the noble gas in Cpx were lost during partial melting and there is diffusive fractionation between ^{3}He, ^{4}He, and ^{40}Ar.

Novel bionanocomposites - Chitosan Goethite Bead - for arsenic remediation

J. HE[1,2], F. BARDELLI[1], A. GEHIN[1] AND L. CHARLET[1]*

[1]ISTerre, Université Joseph Fourier (Grenoble), P.O. Box 53, F 38041 Grenoble, France, (*correspondence:charlet38@gmail.com)

[2]School of Resource and Environmental Science, Wuhan University, Wuhan 430079, PRC

Since iron oxides/hydroxides have high sorption affinity toward both As(V) and As (III), many scientific and industrial researches focus on the application of iron oxides/hydroxides as adsorbents in water treatment. Nevertheless, most iron oxides/hydroxides are fine powders, difficult to separate from solution after the adsorption process. In this study we develop a novel method for the synthesis of chitosan-iron hydroxide composite leading to chitosan-goethite bead (CGB). Goethite nanoparticles and chitosan gel-beads were prepared simultaneously, obtaining 1mm-sized spherical bionanocomposites, consisting of homogenous distribution of the goethite nanoparticles in the chitosan phase with enhanced mechanical properties compared to pure polymer/pure mineral. The macroscopic structure of the composite determines that it can overcome the difficulty of separation procedure in water treatment, while its microscopic structure retains the superiority of nanomaterial with regard to high sorption efficiency. CGBs were characterized by Mössbauer spectroscopy to confirm the presence of goethite phase, and their morphology was investigated by FE-SEM. Batch sorption and kinetic experiments on CGB reactivity toward arsenate and arsenite were performed to quantify the sorption and diffusion-controlled kinetics of CGB with respect to As. In addition, the mechanism of arsenic uptake onto CGB was investigated by X-ray Absorption Spectroscopy (XAS), and the diffusion of As(V) and As(III) from aqueous into solid phase was monitored by micro X-ray fluorescence (μXRF) (Fig.1) and micro X-ray Absorption Near Edge Spectroscopy (μXANES).

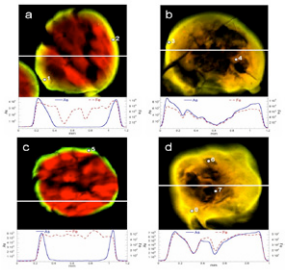

Figure 1. Color temperature distribution maps of As (green color) and Fe (red color) of As-loaded CGB samples, collected from kinetic experiments of As(V) sorption onto CGB a) at 1.5 h, b) at 120 h; As(III) sorption onto CGB c) at 1.5 h; d) at 120 h.

C4 plants expansion and the enhanced aridity from the late Miocene to Pliocene on the Chinese Loess Plateau

TONG HE, YANG CHEN, JUNFENG JI*

The MOE Key Laboratory of Surficial Geochemistry, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China (*Correspondence: jijunfeng@nju.edu.cn)

The Red Clay Formation, which underlies the well-known Quaternary loess sequence, extends the eolian deposits from 2.6Ma through the late Miocene making it a good archive to reconstruct Pliocene climate in North China. The carbon isotopic compositon of carbonate nodules in the Red Clay Formation has been suggested as potential proxy for paleoecology. The spatial and temporal pattern of carbon isotopes will provide new evidence for the drying history from late Miocene to Pliocene.

We studied four continuous sections (Duanjiapo, Lingtai, Bajiazui and Jiaxian) of the Red Clay Formations on Chinese Loess Plateau (CLP) by stable isotope mass spectrometer. The averages of carbon isotopes were at -9.3‰, -8.0‰, -5.3‰ and -4.9‰, respectively. The carbon isotopes of carbonate nodules show a northward positive gradient on CLP, suggesting an increasing trend of C4 plants abundance, which may relate with increasing aridity.

Two C4 plants expansion events were revealed from our Red Clay carbon isotope records. C4 plants greatly expanded in two intervals at ~6.4Ma and ~3.6Ma on CLP. The enhanced aridity may account for the two events.

A thermodynamic entrapment model for the quantitative description of selenite coprecipitation with calcite

F. HEBERLING[1]*, V.L. VINOGRAD[2,3], R. POLLY[1]

[1] Karlsruhe Institute of Technology, Institute for Nuclear Waste Disposal, Karlsruhe, Germany, Frank.Heberling@kit.edu

[2] Forschungszentrum Jülich, Institute of Energy and Climate Research-6, Jülich, Germnany

[3] Goethe Universität Frankfurt, Institute of Geosciences, Frankfurt, Germany

The trace element Selenium is of environmental relevance as a nutriant as well as a toxic element for animal and human life. The long lived fission product ^{79}Se is of special concern in the context of nuclear waste management.

A possible retention mechanism for selenite in natural environments is the structural incorporation of the trigonal pyramidal oxyanion $Se(IV)O_3^{2-}$ into the calcite structure.

EXAFS and polarization dependent EXAFS measurements confirm, in agreement with previous results [1], the structural incorporation of selenite in calcite and the substition of carbonate for selenite, leading to the formation of a $Ca(SeO_3)_X(CO_3)_{(1-X)}$ solid solution.

Selenite incorporation, quantified in coprecipitation experiments at surface controlled steady state conditions and low supersaturation, is much higher (partition coefficient, $D_{exp} = 0.015 \pm 0.012$) than expected according to DFT calculations and thermodynamic considerations ($D_{theo} = 2 \cdot 10^{-10}$).

To bridge the gap between experiment and theory we present a thermodynamic entrapment model based on the assumption, that experimental observations reflect preferential incorporation of selenite into the calcite surface and subsequent entrapment upon crystal growth, while bulk DFT calculation reflect the high strain induced upon incorporation of selenite into the bulk calcite structure.

DFT calculations confirm that surface incorporation is energetically more favourable than bulk incorporation. Batch type adsorption experiments at calcite equilibrium confirm the analogy between surface adsorption (ion-exchange [2]) and coprecipitation.

The observation of growth inhibition in aragonite to calcite recrystallization experiments in the presence of selenite in solution is interpreted as experimental evidence for the energetical difference between bulk and surface incorporation of selenite in calcite.

Tawlah Specialized Alkaline Granite Prospect, Midyan Region, Arabian Shield, Kingdom of Saudi Arabia: Petrology. Structural Implications and REEs-RM Characterization

MOHAMED TH.S. HEIKAL[1] AND MAHER A. AMMAWY[2]

[1]Geology Department, Faculty of Science, Tanta University, Tanta 31527, Egypt (Mohamed.heikal2010@yahoo.com)

[2]Geology Department, Faculty of Science, Benha University, Egypt

The Tawlah albite granites-quartz synites is one of promising sites of REE- Ta-Nb- bearing alkaline granites in the Midyan Suite, NW Arabian Shield. The granite-syenite association is a highly lecucratic, albite-rich rocks with accessory columbite-tantalite, thorite, monazite, allanite, xenotime, zircon and cassiterite. Ages of 577± 4 Ma (Hedge, 1985) were obtained from isotopic ratios of Sr and Nd by $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ method. The precision is sufficient to indicate that the albite granite is post-orogenic with respect to Najd orogeny. The Tawlah granite is divided into abite-granite (in major) and quartz-syenite (in part). The albite granite is more highly mineralized, has higher modal albite contents and higher Nb/Ta ratios, both in whole surface rocks and in drill hole samples.

On the structural point of view, the relationship between fault system and/or shear zones reported and mineral potential provides excellent and interesting evidences of its occurrence. Bearing in mind the Najd fault zone provides interesting evidences concerning the relationship between such faults and REEs-Nb-Ta-Th mineralization. Therefore, the distribution of mineralizations are closely related to the main trends; WNW-ESE, NW-SE and ENE. On the other hand, reactivation of NW Najd fault system has been affected by Teriary rift tectonics, leading to the development of mineralization in Tawlah alkaline granites.

On the basis of petrographic, mineralogical signature and geochemical interpretations, it is suggested that the albite granite-quartz syenite of Jabal Tawlah has a magmatic origin indicating post-orogenic overprinting of A-type granites. By analogy with other Nb-Ta-REEs –bearing granites, the sodic bulk composition of Tawlah granite can be explained by fluorine enrichment in the magma, but much of the magmatic fluorine was lost upon crystallization because the low CaO, P_2O_5 and Al_2O_3 contents of melt precluded fixation of F in crystalline phases.

In fact, the Tawlah alkaline granite prospect is considered to be a promising metallogenic site for REEs and Nb-Ta-Th, where its geologic environment, structural framework and tectonic setting are reasonable for achievement.

Why so much gold in the Archean? Some thoughts linking the Witwatersrand gold endowment to hydrothermal processes

CHRISTOPH A. HEINRICH

ETH Zurich, Department of Earth Sciences, 8092 Zürich, Switzerland; heinrich@erdw.ethz.ch

Archaean cratons constitute a tiny fraction of today's continental surface, but are disproportionately endowed by gold mineralization, amounting to more than half of the known economic resources. Through Earth's history, gold ore accumulation in veins and shear zones by metamorphic and/or deep-seated magmatic fluids broadly correlates with the rate of continental crust formation, both showing a prominent peak in the Archean at 3.2 – 2.5 Ga. The Witwatersrand basin in the Kaapvaal Craton also formed in this period, hosting some 40% of economic gold ore in fluviatile conglomerate layers that also contain pyrite pebbles, uraninite grains and reduced carbon. The enrichment of these minerals within conglomerate layers occurred near the paleosurface, but the mechanism of gold deposition (clastic or early hydrothermal), the transport medium (fluvial or shallow marine water; mechanical or chemical) and the source of the gold remain debated.

Mass-balance estimations indicate that craton-scale erosion of normal crustal rocks could deliver enough gold to produce the Witwatersrand ores. However, if transport and enrichment occurred mechanically in placer deposits, this requires that particles of native gold were available in the eroding crust. The process that may have precipitated these primary gold particles may well be a critical step in the exceptional endowment of Archean crust with economic gold deposits. In today's surface environment, most of the hydrothermal flux of gold through the upper crust becomes dispersed, ending up in slightly gold-enriched black shales that are liable to recycling, but only locally contribute to later ore formation. By contrast, the acid surface environment in Archean times may have acted as a near-perfect "screen" for the precipitation of all the gold transported upward from the lower crust or the mantle by crust-forming processes. Vein deposits in greenstone belts probably trapped only a small fraction of this hydrothermal gold flux, while a far greater fraction of native gold may have been precipitated near the land surface, also above widespread granitoids. Gold particles would have been ready for further concentration by mechanical transport into conglomerate reefs, but some direct precipitation of dissolved gold by reduction on local organic material in permeable aquifers may have upgraded the ore.

Changing mantle wedge geometry and magma generation processes in the Central Andes

ROSANNE HEISTEK[1]* AND GERHARD WÖRNER[1]

[1]GZG, Georg-August Universität, 37077 Göttingen, Germany (*correspondence: rheiste@gwdg.de)

Miocene andesitic volcanoes in the Central Andes typically overly plateau-forming ignimbrites. These "early" andesites form low angle volcanic shield volcanoes succeeded by more evolved steep-sided strato-cones. These cover smaller areas and are characterized by amphibole phenocrysts. Such a transition could be either due to a change in the melting regime in the mantle wedge from decompression (hot and dry?) to flux melting (wet and lower T?) or to different magma production and effusion rates.

We studied samples that represent different ages, petrography, composition, and volcanic style in order to test differences in processes of magma generation. Based on a survey of >4000 chemical analyses (http://andes.gzg.geo.uni-goettingen.de/) and the distribution of SiO_2 we selected three representative sample types 1) the most mafic samples (50-55 % SiO_2), 2) the intermediate andesites representing 63 % of the data (55 -60 % SiO_2) and 3) felsic samples (60-65 % SiO_2) which were identified before as important endmember magma type in the Central Andes. Using a range of geothermometers and hygrometers, we show that the most significant parameters regulating viscosity at the time of eruption remained surprisingly constant throughout Andean history (e.g. 940°C to 1020°C for 2 pyroxene thermometry). Therefore, the rate of effusion, and by implication, magma production and upper crustal stress regime rather than eruption temperature are the primary factors that influenced flow length and flow field type.

Another important parameter maybe preferential erosion of Miocene stratocones relative to distal lava fields. An increase in slab dip after a time of flat-slab subduction may increase melt production in the mantle wedge and result a change in stress regime in the upper Andean plate. Ensuing high effusion rates during the Miocene produced lava shields with stacks of long lava flows at the base of (now eroded) steeper stratovolcanoes. Erosion of the central stratocone left isolated lava fields. By contrast, lower melt production and effusion rates during the Pliocene the Quaternary reflect more diverse ascent paths and crustal magma systems with more diverse cooling, crystallization, assimilation, and mixing histories. At the same time, the depth of magma evolution changed as represented by increasing garnet signatures from Miocene to Pleistocene lavas.

Soil heterogeneity and surfactant desorption influence PAH distribution at a tar-contaminated site

KATJA HEISTER[1]* AND ANA T. LIMA[2]

[1] Lehrstuhl für Bodenkunde, Technische Universität München, 85350 Freising-Weihenstephan, Germany (*correspondence: heister@wzw.tum.de)

[2] Department of Earth and Environmental Sciences, University of Waterloo, Waterloo, N2L 3G1, Canada

A remediation field experiment utilising electroosmosis and a non-ionic surfactant was conducted successfully at the site of a former asphalt production plant with a long-term tar-oil contamination [1]. After 159 days, the question arose whether the scattered distribution of the polycyclic aromatic hydrocarbons (PAHs) was due to soil's heterogeneity itself or to electroosmosis efficacy [1]. In this study, we assess the heterogeneity of the soil itself by analysing various soils samples with respect to amount and type of organic matter (OM) and PAH content. No relationship between either amount of OM, amount of aromatic carbon and PAH concentrations was observed. A relationship between PAHs and tar oil (represented by aromatic carbon) was *a priori* expected. Hence, soil's heterogeneity dominated this site rather than a considerable redistribution of PAHs during the electroosmotic treatment. Batch desorption experiments were then carried out with and without 1% Tween 80 on a representative sample of intermediate OM and PAH content and a sand sample with pure tar oil. The surfactant significantly enhanced PAH desorption and inhibited microbial degradation by forming micelles that entrap PAH molecules, making them unavailable to microorganisms. The PAH aqueous phase concentrations in the batch experiments were comparable to those obtained in the field experiment. Therefore, we conclude that the surfactant seems to be inevitable for the success of the remediation. As a consequence, in order to describe the transport of desorbed PAHs, micelles should be considered instead of single PAH molecules.

Noise is now signal: Capturing the relevant from the distraction

MATTHEW T. HEIZLER[1]

[1]New Mexico Bureau of Geology, 801 Leroy Place, Socorro, NM, 87801, (matt@nmt.edu)

It is truly an exciting time for noble gas applications, and in the particular, geochronology precision is undergoing a revolutionary increase that allows incredible insight into complex geological processes. However this improvement is not immediately allowing for new discovery in geo and thermochronology. Removing the impediment towards new discovery lies in determining the causes for age scatter that is now recorded in most geological samples. Ultra-high precision age measurements (0.1-0.2 per mil) on individual volcanic crystals typically show ~0.2% standard deviation thereby reducing the MSWD to ridiculously high values. This leads to the question "What part of the scattered distribution records the geological event of interest?" Cases can be made for the young part, the middle part and the old part. Accurate young ages can be argued for by interpreting older results to be contaminated with excess and/or inherited argon. Excluding the young part in favor of the old part implies argon loss is the cause of inaccurately young grains. Perhaps our planet operates at a high standard deviation and natural variation caused by a host of mechanisms can be averaged such that the mean value of a scattered distribution remains the preferred choice for an event such as eruption. Determining the geological uncertainty for the time of eruption of a scattered distribution has no obvious value or statistical approach. Classical crosscutting relationships or stratigraphic order will always be the ground truth measure of accuracy and proper interpretation despite the level of precision reached in 2020. In addition to volcanology studies vastly improved spatial resolution at high precision will be the norm thereby increasing the utility of *in situ* analyses. Unfortunately, in many cases argon concentration profiles occur at a spatial resolution that will continue to confound our best current instrumentation. Despite the fact that new ultra sensitive, ultra clean multicollector mass spectrometers have jumped our science surprisingly forward, another leap will be required to achieve what every thermochronologist desires – an accurate concentration profile at a geologically relevant length scale. Lastly, the seemingly straightforward task to get geochronology labs intercalibrated remains a perplexing obstacle that inhibits productivity and causes unnecessary confusion. Because calibration and operation of the new and highly stable multicollector instruments will soon become routine, we as a community can have every expectation that this nagging issue will soon be a topic of the past.

$^{234}U/^{238}U$ in speleothems revisited: Are there generally applicable relationships of this proxy to past environmental change?

JOHN HELLSTROM

School of Earth Sciences, The University of Melbourne, Australia

The initial activity ratio of ^{234}U to ^{238}U, $(^{234}U/^{238}U)_i$, is the ratio of ^{234}U to ^{238}U atoms at time of formation of a sample, relative to that at secular equilibrium. It is found using their measured present ratio and the known age of a sample, and is a by-product of all U-Th disequilibrium dating as well as some U-Pb dating of Quaternary samples. As such there is now an enormous body of these data in the published literature. A number of publications have addressed paleoenvironmental significance of $(^{234}U/^{238}U)_i$ over the last few decades but no clear consensus has emerged, other than that this initial disequilibrium is caused by some combination of alpha recoil and selective dissolution of ^{234}U as seepage water makes its way to the cave, and that hydrological factors probably have the greatest influence. General observations are that $(^{234}U/^{238}U)_i$ tends to gradually fall with time at a given location, often to values well below one in relatively old, stable settings, and that significant paleoenvironmental changes invariably lead to some form of change superimposed upon this. The nature of these latter changes remains poorly understood. They vary hugely in magnitude with $(^{234}U/^{238}U)_i$ values as high as 10 and as low as 0.5 having been observed, and are sometimes highly responsive to reconstructed external environmental change and sometimes lagged by thousands of years. Here I will report progress in understanding of the hydrological significance of $(^{234}U/^{238}U)_i$ in speleothems, and of its significance for paleoenvironmental reconstruction and also for dating using the U-U and U-Pb techniques

Hidden hotspot track beneath Eastern United States

DON HELMBERGER, RISHENG CHU, WEI LENG AND MICHAEL GURNIS

Seismological Laboratory, California Institute of Technology, Pasadena, CA 91125 USA

More than two thirds of surface hotspots associated with volcanism can be explained by the interaction between a moving plate and deep-seated mantle plumes[1]. Most of these hotspot tracks are observed on oceanic or thin continental lithosphere. Although there are not many traditional hotspot tracks on old continents, there are diamondiferous kimberlites indicative of deep mantle origins[2]. This poses the question that there could be many more hotspot tracks beneath old continental regions than suggested by the record of surface volcanism. Here we show that seismic waveforms recorded by USArray from a recent Virginia earthquake reveal an unexpected linear, lower lithosphere seismic anomaly extending from Missouri to Virginia without a clear relationship to surface geology. This east-west corridor has *P* velocity reduced by 2.1% along with high attenuation and crosscuts prominent regional features suggesting a link to plate motions. We suggest that a thermal plume-like upwelling interacting with the base of the continental lithosphere can produce the requisite seismic signal. A Late Cretaceous kimberlite in Kentucky, dated 75 Ma, pins a hotspot track that bends northward beneath Virginia. Seismic data indicates that the lower lithospheric anomaly along this northeastern segment is even stronger than the east-west segment, supporting such a hypothesis.

Pre-nucleation clustering of noble metals in high-temperature magmatic liquids

H. M. HELMY[1]*, C. BALLHAUS[2], R. O. C. FONSECA[2], R. WIRTH[3], T. NAGEL[2], M. TREDOUX[4]

[1]Minia University, Minia, Egypt (correspondence. hmhelmy@yahoo.com

[2]Steinmann Institute, University of Bonn, Bonn, Germany (ballhaus@uni-bonn.de)

[3]GFZ Potsdam, Germany (wirth@gfz-potsdam.de)

[4]University of the Free Sate, Bloemfontein, South Africa (mtredoux@ufs.ac.za)

The conventional view is that magmatic trace minerals nucleate and grow by assembling cationic and anionic species from the melt. Experiments reported here suggest that this view may be simplistic. We have investigated on the nanometer-scale the distribution of Pt in Fe-Cu-S sulfide matrix. When ligands like arsenic are added to the sulfide, Pt and As self-organize to Pt-As molecules, non-crystalline $(Pt-As)_n$ clusters, $PtAs_2$ nanoparticles, and at very high temperature to nanometer-sized droplets of Pt-rich Fe-As melt. With the addition of As, the partitioning of Pt among sulfide phases is shifted relative to simple (As-free) systems by at least an order of magnitude. Similar to minerals crystallizing from aqueous solutions, magmatic trace minerals may grow by oriented attachment of nanoparticles and nanophases when they crystallize from magmatic solutions. This explains how noble trace elements could form discrete mineral phases in subsolidus range although their concentrations in magmatic melts do not exceed tens of ppb to few ppm. Pre-nucleation clustering should be considered when highly siderophile elements (HSE) partition coefficients determined by simple system experimentation are used to model HSE fractionations among chemically more diverse reservoirs of the Earth

Reaction rims of dolomite ($CaMg[CO_3]_2$) were produced by solid-state reactions of oriented calcite ($CaCO_3$) and magnesite ($MgCO_3$) single crystals using a gas-deformation apparatus at 400 MPa confining pressure, 750 °C, and run durations ranging from 4 to 76 h. In addition, we applied a differential stress up to 40 MPa perpendicular to the contact interface.

The resulting dolomite reaction rims consist of two different textural domains. Granular dolomite grains (2.2–5 μm grain size) grew next to calcite, while elongated palisade-shaped grains (2.2-5.2 μm diameter) grew perpendicular to the magnesite interface. The thickness of the granular dolomite layer is 2.9-11.2 μm, smaller than the palisade-like layer (5.2 to 13.2 μm). Platinum markers show that the initial interface is located between granular and palisade-forming dolomite, indicating that rim growth occurred by counter diffusion of MgO and CaO.

As expected, rim thickness increased with increasing run duration. The effect of the applied load is not systematic and causes a maximum variation in rim thickness of less than 11% at fixed time.

Diffusion of MgO across the dolomite reaction rim into calcite produced newly formed magnesio-calcite grains with an average diameter of 20.7 to 34.8 μm. Grain size of magnesio-calcite grains increased with increasing distance to the dolomite boundary. The magnesio-calcite layer increased from 29.1 to 63.3 μm with time, but was also not affected by the differential stress conditions.

The experiments indicate that differential stresses up to 40 MPa do not significantly change the kinetics of reaction rim growth in the carbonate system. Possibly this is because volume diffusion is the dominant transport mechanism, which presumably is less strongly affected by deformation than grain boundary diffusion.

Picking apart paleoredox proxies: What regulates them?

GEORGE R. HELZ*[1]

[1]Department of Chemistry, University of Maryland, College Park, MD 20742 USA (*correspondence: helz@umd.edu)

Certain trace elements that are oxyanions (broadly defined) with long seawater mean residence times (e.g. HVO_4^{2-}, CrO_4^{2-} AsO_4^{3-}, MoO_4^{2-}, $Sb(OH)_6^-$, WO_4^{2-}, ReO_4^{2-}, and $UO_2(CO_3)_2^{2-}$) are modestly to strongly enriched relative to Earth's crust in sediments below O_2-depleted waters. Their enrichment in sedimentary rocks is cited to support qualitative conclusions about redox conditions in ancient sedimentary basins. More nuanced, possibly quantitative conclusions require better knowledge of events that regulate conversion of these particle-inert oxyanions to particle-reactive species. Each of these elements exists in multiple oxidation states in nature, inviting the assumption that pE regulates conversions. But pE is indefinable in natural waters, so this is at best a superficial explanation. In some cases, abiotic or biotically mediated electron transfer, leading to insoluble products, is indeed a regulating mechanism (U the most studied example). In other cases (e.g. Re), evidence for an electron transfer mechanism is lacking. In sulfidic solutions, most of these oxyanions undergo O ↔ S exchange. If the particle reactivity of the thioanions exceeds that of the oxyanions, then O ↔ S exchange could be a deposition-regulating mechanism. Often exchanges are labile, probably abiotically and thermodynamically controlled, and thus invariant over geologic time. Important gaps remain in knowledge of what regulates deposition of these elements--for example, polysulfides' role. Recent evidence demonstrates polysulfides' importance, at least for Mo and As. Another gap concerns organic matter's role. Correlations between the above elements and TOC are well known in sediments beneath O_2-depleted waters. Correlations might be incidental or might point to specific biotic or abiotic organic reactions that participate in trace element deposition mechanisms. Good evidence exists for organic hosting of V and Re in TOC-rich sediments, but this may arise after deposition, during early diagenesis.

Rare Earth Element distributions as tracers of micronutrient input and Nd cycling in the South Atlantic

DEBORAH J. HEMBURY*, XINYUAN ZHENG, PHILIP HOLDSHIP, PETER SCOTT, MATTHEW POINTING, AND GIDEON M. HENDERSON

Department of Earth Sciences, University of Oxford, South Parks Road, OX1 3AN, UK (*correspondence: debbie.hembury@earth.ox.ac.uk)

Concentrations of the REEs in seawater reflect their inputs and their cycling in the water column. Because the behaviour of the REE have some similarities to that of micronutrient elements (such as Fe, Zn, Cu, Cd) but are not directly biologically utilised, their distribution has potential to constrain the cycling of micronutrients. The cycling of Nd is also of particular interest because Nd isotopes are widely used as tracers of past ocean circulation. In this study, we have measured REE concentrations on filtered samples collected during the UK-GEOTRACES GA10 cruises (D357, JC068) across the South Atlantic at 40ºS. CTD profiles and a full range of other chemical parameters provide a comprehensive context for these new REE measurements. REE samples were obtained for the full- water column and concentrations determined by isotope-dilution MC-ICP-MS on 250 ml samples. This samples all the major deep-water masses of the Atlantic, and a clear water-mass dependence is observed in the concentrations of heavy REEs. The light REEs show significantly less water-mass dependence, however, suggesting the importance of downward particulate transport for their cycling, with implications for the interpretation of Nd isotopes. Ce concentrations demonstrate the lack of significant input in intermediate waters, reflecting O_2 levels that are insufficiently depleted to drive Mn cycling in the sediment, but are notably high in surface waters due to additional inputs and active release from particles.

The K/Ar system for tracing fine-grained terrigenous sediments: A survey of Atlantic clay fractions

SIDNEY R. HEMMING[1,2]*, PIERRE E. BISCAYE[2], RAHUL SAHAJPAL[3], JENNIFER M. COLE[2,4] AND WALLACE S. BROECKER[1,2]

[1]Department of Earth & Environmental Sciences, Columbia Univ. sidney@ldeo.columbia.edu (* presenting author)
[2]Lamont-Doherty Earth Observatory of Columbia University
[3]School of Earth and Environmental Scinces, Queens College.
[4]Western Kentucky Univ., Dept. of Geography & Geology

The provenance of terrigenous sediments provides important constraints on the processes that bring them to their depositional sites in the ocean. Terrigenous sediments are formed by weathering and are delivered to the ocean by wind, water, and ice, and are redistributed within the ocean by currents. The mineralogical content and geochemical composition of sediments reflect the source rock types, weathering style and intensity, as well as sedimentary sorting evidence for sedimentary transport and delivery mechanisms. Radiogenic isotopes provide a measure of the temporal geologic history of sediments that is different depending on the geochemical characteristics of the parent and daughter isotopes. The K/Ar system in fine-grained terrigenous sediments reflects the latest stages of the geologic history of the sediments' sources. Thus the K/Ar "age" of fine-grained sediments provides a useful measure of sediment provenance, previously demonstrated by several studies (e.g., Hurley *et al*, 1961, GSAB, 1963a, GCA, 1963b, GCA; Jantshik and Huon, 1992, Eclogae Geol. Helv.; Huon and Ruch, 1992, Mar. Geol.; Pettke *et al*, 2000, EPSL; Hemming *et al*, 2002, Chem. Geol.; vanLaningham *et al*, 2006, JGR, 2008, QSR, 2009, EPSL; vanLaningham and Mark, 2011, GCA).

An initial survey of the <2 μm fractions of samples from the Biscaye (1965, GSAB) clay mineral study, demostrates that in contrast to the strong latitudinally-controlled distribution of kaolinite/chlorite in Atlantic sediments, K/Ar model ages trend from oldest in the NW Atlantic to youngest in the SW Atlantic. Intermediate ages are found in the tropical belt as well as off the coast of Europe. Though the data are still sparse, the general trends are well matched to the known distribution of geologic ages of continental sources around the Atlantic basin, with extreme old ages in Canada and Greenland and extreme young ages in active tectonic settings like the southern tip of South America and the Scotia Arc.

This study will produce a map of sediment distribution that serves as a benchmark to explore ocean circulation of sediment transport questions over a variety of timescales.

The Central Indian Upper Mantle 50 MY ago: Continental crust versus oceanic crust recycling contributions within the Central Indian Basin MORB

C.HEMOND[1], H. DELAVAULT[1], M. JANIN[1], P. DAS[2,] AND S. IYER[2]

[1]UMR Domaines Océaniques, Univ. Brest – CNRS, Plouzané, France. (chhemond@univ-brest.fr)
[2]National Institute of Oceanography, Dona Paula, Goa, India

The central Indian Ocean Basin (CIOB) results from the activity of both the Central and Southeast Indian Ridges and carries also the tracks of the Rodrigues triple junction and the Reunion Hotspot 53 Ma ago.

We discuss the composition of the Indian upper mantle 50 Ma ago i.e. its level of isotope heterogeneities within a model in which the breakup of the Gondwana has introduced continental derived material in it. The potential input of Reunion hotspot derived material is also investigated.

All samples dredged in an area comprised between 72-80°E and 9-15°S. They are on axis MORBor off axis MORB seamounts and are tholeiitic in composition and slightly depleted in incompatible trace elements.

Isotopes (Sr,Nd, Hf and Pb) lead to class samples in four groups: 1) very depleted in Sr-Nd and Hf isotopes including amongst the least radiogenic Pb isotope sof the Indian MORBs regarded as the depleted Indian MORB mantle 50Ma ago. 2 and 3) Similar low ^{206}Pb for higher ^{208}Pb and intend to have even lower ^{206}Pb than the previous group but very radiogenic Sr and unradiogenic Nd or DUPAL signature. The last group has more radiogenic Pb isotopes, and slightly lower Nd for identical Sr isotopes of the DMM group. This is clearly regarded as representative of recycled oceanic crust material such as seen in Ocean Island Basalts (C, Fozo, HIMU).

Mixing models suggest three components and two stages of mixing to account for the results. The local DMM is first contaminated by African Lower Continental Crust (LCC) material such as granulites during continental breakup.

In conclusion, the very depleted local DM and the extreme DUPAL compositions support the concept of LCC contamination of the upper mantle during the Gondwana breakup as 50Ma ago, the mixing and assimilation of the LCC being less advanced than in today Indian upper mantle. This leads to more extreme resulting isotope composition than today

Evolution of photosynthesis

JAMES HEMP[1], LAURA A. PACE [2], JENA E. JOHNSON[1] AND WOODWARD W. FISCHER[1]

[1] California Institute of Technology (jim.hemp@gmail.com)
[2] University of Utah

The evolution of chlorophyll-based phototrophy was one of the most important bioenergetic innovations in the history of life on Earth, but key first-order questions about its evolution remain. Here we present genomic and biochemical data that place new constraints on the acquisition of phototropy in different clades. There are currently six known phlya of bacteria that have chlorophototrophic members; Cyanobacteria, Proteobacteria, Chloroflexi, Chlorobi, Firmicutes, and Acidobacteria. Cyanobacteria perform oxygenic photosynthesis using H_2O as an electron donor, generating O_2 as a product. All of the other clades perform anoxygenic photosynthesis using a variety of reduced compounds as electron donors. Despite these differences, all known chlorophototrophs share only three common molecular elements; (bacterio-)chlorophyll, reaction centers, and quinol:electron acceptor oxiodoreductases (complex III).

Chlorins can be classified into two types; chlorophylls and bacteriochlorophylls, with the latter only found in anoxygenic phototrophs. Recent analyses of chlorin biosynthesis pathways provide support for the evolution of chlorophyll preceding that of bactriochloropyll[1].

Reaction centers are proteins that convert light energy into high energy electrons. Two evolutionarily related types of reaction centers exist, RCI and RCII. Anoxygenic phototrophys contain either RCI (Firmicutes, Chlorobi, and Acidobacteria) or RCII (Chloroflexi and Proteobacteria). In oxygenic photosynthesis RCI and RCII are coupled together in series, which allows electrons to be transferred from H_2O to ferredoxin. Evolutionary analysis of reaction centers show that their distribution reflects lateral gene transfer[2].

Complex III proteins convert high energy electrons into a protonmotive force. There are two evolutionarily unrelated complex III's—the b_6f/bc_1 superfamily and alternative complex III (ACIII). These enzymes are part of a high potential redox module that is shared with aerobic respiration and denitrification. The distribution and evolutionary relationships of complex III and the high potential module support the inferences from chlorin biosynthesis and reaction centers and demonstrates the remarkable conclusion that most currently known anoxygenic phototrophs acquired photosynthesis after the evolution of aerobic respiration, and therefore after the evolution of oxygenic photosynthesis.

The zinc isotopic composition of siliceous marine sponges: Investigating nature's sediment traps

KATHARINE R. HENDRY[12] AND MORTEN B. ANDERSEN[23]

[1]School of Earth and Ocean Sciences, Cardiff University, Main Building, Park Place, Cardiff, CF10 3AT, UK
[2]Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queens Road, Bristol, BS8 1RJ, UK
[3]ETH Zürich, Inst. f. Geochimie und Petrologie, Clausiusstrasse 25, 8092 Zürich, Switzerland

The Zinc (Zn) content and isotopic composition of marine biogenic opal has the potential to yield information about the nutrient availability, utilisation and organic matter export from surface to deep waters. Here, we report the first measurements of Zn isotope composition of deep-sea benthic sponge skeletal elements (spicules) from the Southern Ocean. Our results highlight different Zn uptake and fractionation behaviour between the two major siliceous sponge clades (hexactinellids and demosponges), which is most likely linked to sponge filter-feeding strategy and internal physiology. Hexactinellid spicule Zn isotopic compositions are not fractionated with respect to seawater, and so hold potential as proxies for past ocean Zn cycling. In contrast, demosponge spicules exhibit a wide range of Zn isotopic compositions that are related to the opal Zn concentration, most likely reflecting fractionation processes during feeding. As such, demosponge Zn isotope records may be able to shed light on past changes in photic zone organic matter formation in the ocean.

Effect of increased glacier melt on diagenetic Fe cycling in marine sediments at King George Island (Antarctica)

S. HENKEL[1]*, S. KASTEN[2], H. SALA[3], A.S. BUSSO[3] AND M. STAUBWASSER[1]

[1] Institute of Geology and Mineralogy, Uni. of Cologne, GER *correspondence: susann.henkel@uni-koeln.de
[2] Alfred Wegener Institute, Bremerhaven, GER
[3] Dirección Nacional del Antártico - Instituto Antártido Argentino, Buenos Aires, ARG

The glacier melt of the Western Antarctic Peninsula and its surrounding islands influences biogeochemical processes in the water column and the marine sediment by changing the flux of mineral particles and nutrients (e.g. Fe) into the ocean. Sediment and pore water samples were collected at King George Island (South Shetland Islands) to unravel how the vicinity of ice-covered and -uncovered terrestrial environment affects redox zonation and diagenetic processes in the coastal sediments. The post-depositional dissolution of Fe-minerals and the stable Fe isotope signatures of pore water and specific Fe minerals were of special interest since changing Fe supplies - as reactive particles via melting icebergs or meltwater streams or dissolved via diffusion from the sediment into the bottom water - might not only impact local biogeochemical cycles but most likely also impact productivity in the Southern Ocean.

Sediment cores of up to 45 cm length were retrieved in Potter Cove, Marian Cove, and Maxwell Bay. In vicinity to the glaciers the sediments showed an extended redox zonation. The post-oxic zone with Fe^{2+} concentrations of up to 300 μM ranged from 1 to 25 cm depth. Most probably, microbial activity in sediments close to the glaciers is sluggish due to low input of organic matter (OM). More condensed redox zones prevailed in troughs where OM from terrestrial or marine sources accumulates and in vicinity to research stations. The upward directed diffusive Fe^{2+} fluxes as inferred from pore water profiles range between 0 and ~1050 μM m^{-2} d^{-1}. However, the correlation to the intensity of diagenesis is not straightforward. Fe isotopes of specific minerals were used to assess the intensity of Fe cycling. With ongoing Fe-oxide dissolution, the residual Fe pool becomes enriched in ^{56}Fe, whereas dissolved Fe and secondary Fe-oxides become enriched in ^{54}Fe. Thus, easily reducible Fe oxides show lowest δ^{56}Fe values at the top of the sediment column. We suggest that the retreat of the glaciers indirectly results in higher OM fluxes to shelf areas fueling diagenetic processes/nutrient recycling.

P-T evolution of Neoproterozoic and Ordovician metamorphic rocks in the Iberian Massif, Central Portugal

S.B.A HENRIQUES[1]*, M.L. RIBEIRO[1], A.M.R. NEIVA[2], G.R. DUNNING[3] AND L. TAJCMANOVA[4]

[1]LNEG, Dpt. of Geology, Ap.7586, Amadora, Portugal; (*correspondence: susana.henriques@lneg.pt); (mluisa.ribeiro@lneg.pt)
[2]Earth Sciences Dpt. and Geosciences Centre, University of Coimbra, Portugal (neiva@dct.uc.pt)
[3]Earth Sciences Dpt., Memorial University, St. John's NL A1B 3X5 Canada (gdunning@mun.ca)
[4]Department of Earth Sciences, ETHZ, Clausiusstrasse 25, CH-8092, Zurich, Switzerland; (lucie.tajcmanova@erdw.ethz.ch)

The study area is located at the boundary of the Ossa Morena-Central Iberian zones in the Iberian Massif. An island arc and a continental margin setting were active during the Ediacaran period. Both events are represented in the Sardoal Complex (SC) by amphibolites and felsic orthogneisses, respectively. An Ordovician rift magmatic event is recorded, in the Mouriscas Complex (MC), by a protomylonite trondhjemite and a garnet amphibolite with a MORB signature. We present the first *P-T* diagrams based on the thermodynamic modelling, which were computed using the Perple_X. The ID-TIMS U-Pb metamorphic zircon age from the SC amphibolite is 539 ± 3 Ma. The estimated *P-T* conditions were based on the compositional isopleths for key mineral phases in the stability field (Cpx-Am-Pl-Ilm-Ttn) at 7–8 kb and 640-660º C. The ID-TIMS U-Pb metamorphic monazite age from the felsic orthogneiss is 539 ± 2 Ma. The *P-T* path indicates an evolution from 4.5 kb and 590º C in the Bt-Pl-Ms-Grt-Sil-Qtz-Rt-Ilm field towards lower pressure and temperature field Bt-Pl-Ms-Grt-Qtz-Ilm at 4-4.5 kb and 570-580º C. The ID-TIMS U-Pb igneous zircon age from MC protomylonite trondhjemite is 483 ± 1.5 Ma. The estimated *P-T* conditions were based on the compositional isopleths for key mineral phases in the stability field (Bt-St-Pl-Ms-Grt-Sil-Qtz) at 4.5-6.2 kb and 590-650º C. The ID-TIMS U-Pb igneous zircon age from the MC garnet amphibolite is 477 ± 2 Ma. The estimated *P-T* conditions were based on plagioclase and biotite isopleths in the stability field (Bt-Chl-Ep-Am-Pl-Ilm-Mag-Grt-Qtz) at 6.5 kb and 550º C. Two major geodynamic events at the amphibolite facies conditions were identified in this study. The first one, the continental arc accretion of the Ossa Morena Zone to the Iberian Autochthon passive margin (Northern margin of Gondwana) occurs at ca. 540 Ma. The second one, younger than ca. 477 Ma is probably connected to the opening of the Rheic ocean.

Parallel budgets of excess thorium and protactinium in grain-size separates of marine sediments from the North Atlantic over the past 20,000 years

LEONARD E. HENRY[1]*AND JERRY F. MCMANUS[1]

Lamont-Doherty Earth Observatory Of Columbia University, Geochemistry Division, Palisades, Ny, 10964 Usa, [2]Lhenry@ldeo.columbia.edu (*Presenting Author) JMcManus@ldeo.columbia.edu

Abrupt shifts in the Atlantic's circulation regime have been inferred from carbon isotopes within benthic foraminfera, geostrophic gradient shifts captured in oxygen istopes from benthic foraminifera, changes in the burial ratio of $^{231}Pa/^{230}Th$ in bulk sediment, and variations in sortable silts. Drift deposits, those regions of the ocean where the energy of currents slaken and sediment is deposited in excess of the local vertical particle flux, are often selected for $^{231}Pa/^{230}Th$ and other paleoceanographic reconstructions because the sedimentation rates far in excess of he mean ocean, thus allowing for greater resolution of transient climate events than in other seafloor sediment cores. Most of the fine sediment (<20micron) that constitutes a large fraction of mass within these deposits is laterally transported. Previous work suggested the fine fraction of the sediment carries a disproportionately high concentration of excess ^{230}Th, or $^{230}Th_{xs}$, produced by the decay of ^{234}U in sea water and scavenged by settling particles, and extra-terrestrial helium, $^{3}He_{ET}$, two nuclides whose mass flux aids in the reconstruction of past climate events. While the results are consistent with past findings for $^{230}Th_{xs}$, we find a contrasting distribution of $^{231}Pa_{xs}$ that serves as a cautionary tale towards assuming that a similar size-dependence applies to all particle-reactive elements.

This study presents side-by-side size-fraction budgets of $^{230}Th_{xs}$ and $^{231}Pa_{xs}$ over the last deglacial from core CDH19 taken from a North Atlantic drift deposit, on the Bermuda Rise. Our results suggest that $^{231}Pa_{xs}$ is more evenly distributed among size-fractions than is $^{230}Th_{xs}$, possibly indicating that $^{231}Pa_{xs}$ is less susceptible to the biasing effects of particle focusing and more sensitive to the drivers of vertical particle flux. Further, ^{230}Th normalized fluxes of the size-fraction separates imply that the maximum changes in the $^{231}Pa_{xs}/^{230}Th_{xs}$ ratio that occurs across Heinrich Event 1 are evenly distributed across all size fractions.

Element outgassing in BABB: An example from the Havre Trough

[5]National Oceanography Centre, Southampton, Empress Dock, European Way, Southampton SO14, 3ZH, UK

Trace element data have been acquired for glass rinds and corresponding whole-rock samples of back-arc basin basalts from the Havre Trough in the SW Pacific. For most elements the match in compositions between glass and whole-rock pairs is essentially identical to within analytical uncertainties. In other cases, small variations exist that can be explained by the lack of olivine (for example) phenocrysts in digests of the handpicked glass.

In contrast, volatile elements show more marked differences that we attribute to outgassing of the magmas during vesiculation and eruption. Although most researchers would agree that Cd is highly volatile, our observation is that Cd is only slightly enriched in the glass (glass averaging Cd contents only ~7% higher than rock). In contrast, the largest discrepancies between the whole rock and glass compositions are in W (enrichment factor of ~30) and Mo (enrichment factor of ~5), and these elements also show an excellent correlation with each other. Given that these two elements are broadly believed to be less volatile compared with Cd, the most reasonable conclusion might be that the glass rinds lost much of this highly volatile element prior to quenching. Similar comparisons have been made with other elements in order to assess their relative volatilities in this back-arc basin setting.

Exhumation rates from orogenic areas

FREDERIC HERMAN[1], JEAN-DANIEL CHAMPAGNAC[2], MARTEEN LUPKER[2] AND SEAN D. WILLETT[2]

[1]Institute of Earth Sciences, University of Lausanne, (Frederic.Herman@unil.ch)
[2]Department of Earth Sciences, ETH

A critical issue in the global mass balance of sediment is assessment of the importance of the rates and links between physical erosion and chemical weathering in tectonically active, high relief regions. There are two issues in these regions. First is determining the physical erosion rates in these areas which is problematic given the high variance in measured erosion rates, low concentrations and high errors in cosmogenic ages and young thermochronometric ages. The second problem is in generalizing erosion laws calibrated to low relief areas to these high relief areas. For example, erosion laws based on linear or non-linear diffusion of hillslopes saturate at high erosion rates and high slope and have no predictive capability. We address each of these problems through a detailed analysis of a new global compilation of more than 17,000 low-temperature thermochronometric ages. Here we focus on erosion rates and topographic characteristics of the highest relief regions of the active orogenic regions of the world. We compare erosion rates to common geomorphic metrics including mean slope and relief on different scale. We find no statistically significant relationship between relief or slope and erosion rate. Our result is consistent with theory that predicts that hillslopes reach a maximum value at which there is no relationship between slope and erosion rate. Our results demonstrate the difficulty in generalizing or predicting erosion rates in high-relief areas that lack direct measurement and contrasting these values to low-uplift regions where physical processes and governing equations differ.

Experimental constraints on carbon recycling in subducted sediments and altered oceanic crust

JÖRG HERMANN[1] AND LAURE MARTIN[1,2]

[1]Reasearch School of Earth Sciences, The Australian National University, ACT Australia. Joerg.Hermann@anu.edu.au
[2] Centre for Microscopy, Characterisation and Analysis, UWA, 35 Stirling Highway, Crawley WA6009 Asutralia.

Altered oceanic crust and sediments are the main host rocks within the subducted lithosphere to transport carbon from the Earth's surface to the mantle. Whether carbon is effectively recycled toward the atmosphere through arc magmatism located above subduction zones, or buried into the deep mantle, remains controversial.

We have conducted experiments in a carbonate-bearing metapelite and in altered oceanic crust at 2.5-4.5 GPa and 700-1000°C, i.e. under conditions relevant for subducted slabs at sub arc depth. The experiments contained 2-7 wt% H_2O, simulating interaction of the rocks with an externally derived aqueous fluid. The wet solidus in both rock types is very similar and occurs at ~700°C at 2.5 GPa and at 800-850°C at 4.5 GPa. At subsolidus conditions residual carbonates are common and they coexist with hydrous phases such as phengit, epidote and lawsonite. We have developed a new method to determine the proportion of CO_2 in the fluid, where the experimental capsules are pierced under vacuum and the gas is directly analysed with a gas chromatograph. We show that the molar proportion of CO_2 in the aqueous fluid in altered oceanic crust decreases with increasing pressure from 0.06 to 0.03 and thus 70-90% of the original carbonate are retained in the rocks. Above the solidus at pressures ≤3.5 GPa hydrous silicate melts coexists with carbonates and less then 25% of the original carbonate is dissolved in the melt. The carbonate solubility in hydrous silicate melts increases with increasing pressure. Additionally, at 4-4.5 GPa, T≥850°C globules of Fe-Ca-rich carbonate-quench occur in the hydrous silicate melt in altered oceanic crust and in sedimets, indicating that immiscible silicate and carbonate melts coexists. These carbonate melts contain SiO_2, Al_2O_3 and P_2O_5 and TiO_2 at a wt.% level and high amounts of U and Th. There are only accessory amounts of residual carbonate at these conditions and 90-100% of the original carbonate is removed from the protholith.

Our results suggest that fluid fluxed partial melting of altered basalts and sediments provides an efficient mechanism by which significant amounts of subducted carbon can be brought back to the atmosphere via arc magmatism on relatively short time scales of less than 10 Ma.

Mineral-fluid interactions and time-integrated fluxes in tin-bearing greisens, Krušné hory (Erzgebirge) Mts., Central Europe

MATYLDA HEŘMANSKÁ[1] AND DAVID DOLEJŠ[1]

[1]Institute of Petrology and Structural geology, Charles University, 128 43 Praha 2, Czech Republic

Hydrothermal fluids are major mass transport agents in the lithosphere and reactive fluid flow underlies alteration and ore-forming mechanisms in diverse settings. In contrast to our advanced knowledge of alteration mineralogy and geochemistry, little is known about the volume of fluids responsible for specific mineralization or about the nature of replacement, i.e. dissolution-precipitation reactions on the microscale. We use alteration zoning of cassiterite-bearing greisens from the Krušné hory (Erzgebirge) Mts. in Central Europe as model example to interpret the fluid-mineral reaction mechanisms and calculate the time-integrated fluid fluxes. The greisen veins and swarms are hosted by highly evolved Li-F-P-rich biotite and zinnwaldite granites with topaz and tourmaline. Magmatic plagioclase ($An_{<10}$) and K-feldspar ($Or_{>84}Ab_{<16}$) exchanged Na and K prior to greisenization. Dark micas are represented by lithian annite continuosly evolving to zinnwaldite, whereas white mica corresponds to lithian Fe-bearing muscovite. Greisenization occurs in several stages: (i) breakdown of feldspars to quartz and sericite or muscovite. Silicification and muscovite formation are spatially decoupled and represent dissolution-precipitation process, which requires local transport of Al, (ii) replacement of dark mica by celadonitic muscovite under volume-conserved conditions. This reaction requires significant Al addition and Mg, Fe release, (iii) breakdown of muscovite to topaz and quartz. This is a dissolution-precipitation reaction under Al-conserved conditions but declining fugacity of HF, and (iv) hydraulic fracturing and open-space filling by quartz greisens and monomineralic veins. Thermodynamic simulation of fluid-mineral interaction during disequilibrium infiltration in a pressure-temperature gradient reveals that the formation of mica-quartz and topaz-quartz greisens requires time-integrated fluid fluxes 10^2 to 10^3 m^3 fluid per m^2 rock, and the corresponding fluid flow rate of 10^{-10} to 10^{-8} m s^{-1}. The formation of a single greisen vein with a typical volume of 10^3–$5{\cdot}10^4$ m^3 would thus require 10^5–$3{\cdot}10^7$ m^3 aqueous fluid that must have exsolved from an intrusion measuring 80-700 m in each dimension. This approach illustrates use of reaction stoichiometries and non-equilibrium transport theory in estimating fluid fluxes in hydrothermal ore-forming processes.

Calcification rate and carbon-isotope fractionation in coccolithophore calcite through laboratory culture experiments

M. HERMOSO[1,*], F. MINOLETTI[2], Y. CANDELIER[2], H. MCCLELLAND[1], G. ALOISI[3] AND R.E.M. RICKABY[1]

The physiology of marine calcifiers such as haptophytes substantially affects the fractionation of carbon isotopes into biominerals. The resultant offset from equilibrium fractionation is often referred to as the "vital effect". The geological record of climate and the composition of seawater reconstructed from sedimentary biominerals is therefore not completely faithful. The aim of this work is to examine and quantify this biologically-induced distortion of the carbon isotopic signature in coccoliths in order to develop a mechanistic understanding of the vital effect in the coccolithophores, determine species-specific fractionation factors to derive the actual composition of seawater, and eventually be able to reconstruct climates more reliably using species separation techniques for fossil coccoliths.

Calcifying strains of haptophytes were subjected to a series of perturbation experiments in the laboratory in order to determine the effect of changes in the physico-chemical composition of the ambient environment (temperature, DIC level, pH, calcium concentration and phosphate concentration) on that of the biominerals and the organic matter. For all these experiments and for all the species, the partitioning of carbon into photosynthetic versus calcification pathways seems to be the primary driver of differences in the carbon isotopic composition of coccoliths. A second-order but still important parameter to consider for interpreting carbon isotopes is the active mechanisms used by the cells to concentrate carbon (CO_2) within the chloroplast and the coccolith vesicle. Empirically revealed through *p*H and TDIC perturbation experiments, variations in CCM efficiency can lead to 4‰ offsets between species. Finally, frequent malformations of coccoliths are observed for specimens grown under carbon limited conditions, or when cells reach their physiological maximum division rate.

Hydrogeochemical and isotopic signatures of Carboneras-Palomares Fault Area aquifers (SE Spain)

P. HERNANDEZ-PUENTES[1], R. JIMENEZ-ESPINOSA[1]* AND J. JIMENEZ-MILLAN[1]

[1]Department of Geology and CEACTierra, Associated Unit IACT (CSIC-UGR), Faculty of Experimental Science, University of Jaén, Campus Las Lagunillas s/n, 23071 Jaén, Spain (ppuentes@ujaen.es; *correspondence: respino@ujaen.es; jmillan@ujaen.es)

Groundwater from Palomares-Carboneras Active Fault Area has been studied using geochemical (major ions) and isotopic (data $\delta^{18}O$ and $\delta^{2}H$). The study area is located in the eastern of Betic Cordillera (SE Spain). Hydrological changes that follow major earthquakes has been investigated and found to be dependent on the style of faulting [1]. We try to establish a circulation model of groundwater and to identify the sources of fluids from aquifers and the influence of water flow on the nucleation of new earthquakes.

Chemical composition of the waters reflects different types and degrees of water–rock interaction and several geochemical families have been found:

(i) Na-Ca-Mg-SO4-Cl and Na-Mg-Cl-SO4 waters: extreme EC (4000-14000 µS/cm): related to Pliocene marine marls in Vera Depression and Pulpí Corridor. ii) Na-Ca-Mg-SO4-Cl and Na-Mg-HCO3-Cl-SO4 waters: high EC (2000-3500 µS/cm): related to dissolution of evaporites and carbonates along deep faults. (iii) Ca-Mg-Na-HCO3-SO4 waters: low EC (300-1000 µS/cm): in relation to dissolution of carbonates from Sierra Cabrera, Sierra de Filabres and Sierra de Almenara.

The δ18O / δ 2H diagram indicates that the distribution of the samples define a local meteoric line less steep than the World Online rainwater. The samples are better suited to the meteoric water line of the Mediterranean, indicating that precipitation of Mediterranean origin must contribute significantly to the recharge area. However, a mixed origin, Mediterranean and Atlantic rainfalls, could be taken into account. Samples from Sierra Cabrera and Fuente Alamo springs are more isotopically depleted. While Cuatro Caños and La Zanjilla springs appear more isotopically enriched. The prevalence of more negative values of ^{18}O is associated with a greater height in recharge, regarding the two groundwater samples from the northern area.

[4] School of Geography, Univ. Plymouth, Plymouth, UK.

Photosynthetic carbon isotope fractionation (ε_p) is mainly controlled by CO_2 concentrations, but also other factors such as nutrient availability, carbon uptake or cell size; thus, it can provide insights into the marine carbon cycle. Most relevant for paleoclimate and despite its high dependence on algal growth rates, alkenone ε_p has been invoked as a robust proxy for reconstructing ancient pCO_2 [1]. pCO_2 reconstructions rely on measured ε_p and a b coefficient (which integrates physiological factors affecting isotope fractionation) which is generally assumed to be constant (or corrected for cell size) over time at a given location. Previously, the wide variations in b coefficient of suspended particulate matter alkenone ε_p in the modern ocean was shown to correlate with seawater phosphate concentrations but in fact hypothesized to arise due to trace metal regulation of growth rate [2].

We further explore the effect of trace metal and light intensities on ε_p of different phytoplankton biomarkers (including alkenones) for a smaller dataset in the modern ocean. ε_p is positively correlated with light intensities that vary with collection depth, a trend which cannot be explained by lower growth rates at lower light but is consistent with prediction of light limitation of carbon concentrating mechanisms. ε_p is inversely correlated with trace metals (Co and Co+Zn), a correlation that is stronger than that bore with CO_2 concentrations. Although further research is needed, our observations suggest that trace metals and light intensity affect the b coefficient, and that variations in the b coefficient at a given site must be accounted for in calibrations to reconstruct ancient pCO_2 accurately.

The fate of iodine-129 released from the Fukushima-Daiichi nuclear accident

MATT N. HEROD[1]*, MARTIN SUCHY[2], IAN D. CLARK[1], W.E. KIESER[3] AND GWYN GRAHAM[2]

[11]University of Ottawa, Department of Earth Sciences, Ottawa, ON, Canada, (mhero065@uottawa.ca)
[2]Environment Canada, Vancouver, BC, Canada
[3]University of Ottawa, Department of Physics, Ottawa, ON, Canada

The Fukushima-Daiichi nuclear accident (FDNA) released large amounts of fission product radionuclides into the environment in the spring and summer of 2011. Along with short lived fission products, iodine-129 (15.7 million year half-life) was also released. ^{129}I is recognized as a useful tracer due to its mobile geochemical behaviour. To test if ^{129}I released by the FDNA was reaching Canada, rain samples were collected in Vancouver from March 2011 to March 2012. Archived precipitation samples from Environment Canada's station on Saturna Island and from the National Atmospheric Deposition Program in northern Washington State were also measured to establish a pre-accident ^{129}I background. Groundwater from the Abbotsford-Sumas Aquifer was sampled to determine the fate of ^{129}I. The mean pre-accident background for ^{129}I in rain is 38.15 x 10^6 atoms/L (n=4). Immediately following the FDNA, ^{129}I values increased sharply to 227.2 x 10^6 atoms/L and quickly returned to near-background levels. However, pulses of elevated ^{129}I continued for several months. The ^{129}I in shallow (^{3}H/^{3}He age <1.4 yrs) [1] groundwater were unchanged through November 2012 with an average of 11.39 x 10^6 atoms/L (n=21). The 6-fold increase in ^{129}I concentrations from both Vancouver and Saturna Island are coincident, and occur directly after the initial release from the FDNA. This indicates atmospheric transport and deposition of ^{129}I and agrees well with the timing of elevated ^{131}I and ^{137}Cs measurements in the United States [2]. The lack of groundwater response suggests that ^{129}I is possibly attenuated in soil, which is consistent with its geochemical behaviour.

X-ray magnetic circular dichroism (XMCD) is the preferential absorption of X-rays by a magnetic sample for left and right circular polarized light. XMCD is produced at the resonance absorption energies of the different atoms, and therefore provides element-specific magnetic information. Since its discovery in 1987 by Schütz, XMCD has been pivotal in the understanding of magnetic materials and it is nowadays routinely used in both basic and applied research in magnetism. X-rays with variable polarization at a wide range of energies are readily produced in nearly 50 synchrotron radiation facilities around the word, offering varied sample environments (temperatures, pressure, magnetic fields, etc.) and XMCD-related techniques.

One of the most exciting of those techniques is X-ray Photo-Emission Electron Microscopy (XPEEM). Using XMCD as a contrasts mechanism, in combination with a spatial resolution down to 30 nm, element-specific spatially resolved magnetization maps can be obtained. Moreover, recent developments in dedicated instruments, allow performing experiments at low temperatures (40 to 600 K), under applied magnetic fields (up to about 100 mT) and with electrical contacts, as well as time resolved experiments (in the nanosecond range) to study magnetization dynamics.

In this talk I will present the capabilities of those two techniques in the study of the fundamental properties of natural magnetic rocks and how a deep understanding of their nanostructure can shed light onto their macroscopic magnetic properties.

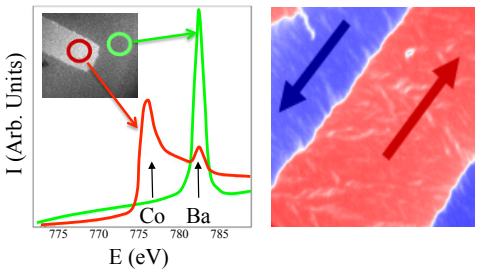

Figure 1. Capabilities of XPEEM: Chemical map and related spectra where the distribution of Co and Ba on a sample is observed (left). Magnetization map on a Fe film, with two magnetic domains (right).

Submicrometer exsolution lamellae in volcanic pyroxenes as indicators of magma residence times

J HERRIN[1,2]*, F COSTA[2], Y.Y TAY[1], H LIU[3] AND S PRAMANA[1]

[1]Facility for Analysis, Characterization, Testing, and Simulation, Nanyang Technological University, Singapore. (correspondence: jsherrin@ntu.edu.sg)
[2]Earth Observatory of Singapore, Nanyang Technological University, Singapore.
[3]School of Materials Science & Engineering, Nanyang Technological University, Singapore.

Pyroxene geothermometry is a well-established tool for the determination of thermal conditions of magmatic systems. Such applications are based largely on the presence of solvus relations within the pyroxene group that govern shifts in equilibrium composition as a function of temperature. These same solvus constraints can result in the subsolidus formation of exsolution lamellae in pyroxene. Many natural examples exist in plutonic pyroxenes. Since coarsening of these lamellae is largely a diffusion-moderated process [1], examination of their size and spacing can potentially be exploited to obtain timescales or cooling histories of magmatic systems, provided that empirical calibrations of controlling parameters (e.g. activation energies) are available. Volcanic systems present a unique challenge for this application because the pyroxene lamellae that they contain are typically nm-scale, owing to rapid cooling, and are also highly localized. Here we report the results of a chemical and crystallographic study of three suites of rhyodacitic samples. To locate, image, and analyze multiple exsolution lamellae of tens to hundreds of nm in size within clinopyroxene phenocrysts, we used a combined approach consisting of initial characterization by SEM/EPMA/EBSD, targeted FIB sampling, and detailed imaging and analysis by TEM/ATEM/SAED/EELS. Coupling these results with laboratory-calibrated models of lamellae formation and various end-member thermal cooling models of magma reservoirs [2] allows us to propose that these rhyodacites, erupted decades apart, originated from a common long-lived (several thousands of years) and relatively large (tens of km^3) magma reservoir. The study of exsolution lamellae in volcanic pyroxenes should prove useful to constrain the thermal histories and sizes of magma bodies below active volcanoes, but analytical obstacles abound. One significant challenge is to obtain quantitative TEM-based chemical analysis (EDS and EELS) with sufficient precision for geothermometry.

Molybdenum and uranium isotope dynamics in a Paleozoic epicontinental black shale

ACHIM D. HERRMANN[1], THOMAS ALGEO[2], STEPHEN ROMANIELLO[3], GWYNETH W. GORDON[3] AND ARIEL D. ANBAR[34]

[1]Coastal Studies Institute and Department of Geology and Geophysics, Louisiana State University, Louisiana, USA

[4]Department of Chemistry & Biochemistry, Arizona State University, Arizona, USA

Reconstructing the history of global ocean anoxia during the Neoproterozoic and the Paleozoic is challenging since plate tectonic activity has destroyed the majority of the deep ocean floor from those time periods. In recent years, Mo and U isotopes have been used as a proxy to track global O_2 levels. However, these studies generally have to rely on the sedimentary record of shallow epicontinental seas. Here we present Mo and U isotope variations of a Paleozoic black shale (Hushpuckney Shale) from three different cores from across the same depositional basin to test whether global marine redox conditions can be determined reliably from a single section within an epicontinental settings.

We find that, based on Mo and U enrichment factors (EF) and nitrogen isotopes, three different intervals within the black shale can be distinguished. These intervals are characterized by strong spatial and temporal geochemical gradients that indicate that the basin experienced non uniform environmental conditions along the black shale horizon. These gradients are reflected in systematic offsets of U isotopes across the basin by up to 0.5‰. Furthermore, during the transition to the most reducing conditions (based on several geochemical proxies), the U isotopes attain their heaviest values while Mo isotopes attain their lightest values. This indicates that local redox conditions can lead to anomolous isotopic signatures as current understanding of these isotope systems suggests that both Mo and U should track each other during that transition. These results suggest that chemical gradients across an epicontintenal basin can lead to local redox conditions that have a strong effect on the Mo and isotopic signatures. This spatial heterogeneity potentially challenges our ability to accurately reconstruct the accumulation of O_2 on Earth from only one section from such settings.

Natural organic matter and our current capacity to depict molecular dissimilarity in complex mixtures

N. HERTKORN*, M. HARIR, PH. SAND CHMITT-KOPPLIN

Helmholtz Zentrum München, German Research Center for Environmental Health, Research Unit Analytical Biogeochemistry, Ingolstaedter Landstrasse 1, D-85764 Neuherberg, Germany. (*correspondence: hertkorn@helmholtz-muenchen.de)

Natural organic matter (NOM) is the most abundant fraction of organic carbon on earth. NOM occurs in all terrestrial ecosystems such as soils, sediments, freshwater and marine environments, in the atmosphere and, throughout the universe, in the form of prebiotic organic matter synthesized by interstellar chemistry. NOM is an exceedingly complex mixture of organic compounds that collectively exhibits a nearly continuous distribution of properties (size-reactivity continuum).

NOM incorporates the hugely disparate characteristics of abiotic and biotic complexity. While biotic complexity derives from a plethora of evolutionary tested molecules with a rich three-dimensional structure designed to execute specific functions, abiotic molecular complexity is rather governed by "mathematical synthesis" which maximizes compositional diversity under given conditions of reaction partners, radiation and temperature. Molecular level NOM composition and structure at first depend on system characteristics and exhibit far more variance than anticipated from often rather uniform bulk parameters. Nevertheless, all NOM on earth is connected in a boundless carbon cycle.

Successful non-target molecular-level analyses of NOM attempts to characterize the entire molecular complement present in NOM by means of information-rich detection methods, like NMR spectroscopy (provides unsurpassed insight into short-range molecular order) and FTICR mass spectrometry (provides depiction of the compositional space with unsurpassed resolution).

This presentation provides an overview how modern organic structural spectroscopy can reveal key characteristics in composition and structure of various NOM. Examples will include secondary organic aerosols (SOA) as well as marine organic matter and NOM in organic chondrites.

Variations of $\Delta^{17}O$ in terrestrial rocks

D. HERWARTZ[1]*, A. PACK[1] AND D.P. KRYLOV[2]

[1]Universität Göttingen, Geowissenschaftliches Zentrum, Abteilung Isotopengeologie, Goldschmidtstraße 1, 37073 Göttingen. (*correspondence: dherwar@gwdg.de)

[2]Institute of Precambrian Geology and Geochronology, Russian Academy of Science, Makarova 2, 199034, St Petersburg, Russian Federation, (dkrylov@dk1899.spb.edu)

Large mass independent effects in $\Delta^{17}O$ are well known for extraterrestrial and stratospheric substances. Small variations in $\Delta^{17}O$ are expected in terrestrial rocks and minerals due to variations in the triple isotope fractionation exponent [3]. In this contribution we demonstrate that high-precision measurements of $\Delta^{17}O$ allow identification and quantification of the interaction between rocks and ancient meteoric water.

We have developed a technique to measure $\Delta^{17}O$ in silicates with a precision of 5 ppm (1σ SD), which is an order of magnitude better than had been achieved previously. To characterize the $\Delta^{17}O$ composition of the Earth we have measured minerals from mantle xenoliths and a variety of crustal rocks and minerals. Our sample set included peculiar gneiss samples from Karelia, Russia with $\delta^{18}O = -25‰$ [2].

Silicate samples do not plot on a single terrestrial fractionation line (TFL), as frequently assumed. This is explained by differences in triple isotope fractionation exponent in high- and low-T fractionation processes as well as by interaction between reservoirs with different $\Delta^{17}O$.

Rock assemblages that have interacted with water fall on well-defined arrays in the $\Delta^{17}O$ vs. $\delta'^{18}O$ space. These arrays can be utilized to reconstruct the original oxygen isotope composition of both, the samples and the hydrous fluid.

We apply our finding to reconstruct the composition of water from low-$\delta^{18}O$ rocks from Karelia (Russia) that likely interacted with glacial melt waters during a snowball Earth event.

Petrological evidence for deep lower mantle melting

CLAUDE HERZBERG

Department of Earth and Planetary Sciences, Rutgers University, Piscataway, NJ, U.S.A. (herzberg@rci.rutgers.edu)

Olivine phenocrysts in picrites from Baffin Island and West Greenland (BIWG) have elevated Ni contents consistent with derivation from a Ni-rich peridotite source [1]. Interaction of a silicate melt with the core may have provided the excess Ni [1]. Partial melting is consistent with experimental results on the solidus of peridotite near the core-mantle boundary [2]. Ni/Co in BIWG lavas and olivine phenocryst are also higher than those in MORB, consistent with experiments on liquid silicate/metal systems that show the effect of pressure is to make Ni more lithophile than Co [3]. But experiments at pressures near the core-mantle boundary are needed to confirm or falsify this conjecture. Also, the provenance of metal melt that supplies Ni may not be restricted to the core. Late accretion of dense metal-bearing chondritic bodies at subsonic velocites may have settled as piles on the core-mantle boundary [4].

Olivine phenocrysts in Hawaiian shield lavas have even higher Ni contents than those from BIWG [5]. Ni contents can be elevated by reaction of peridotite with either basaltic crust or partial melts of basaltic crust to make a second stage pyroxenite source. Petrological modeling indicates that the Hawaiian peridotite end-member is likely to be Ni-rich, not MORB-like, similar to BIWG. This petrological evidence supports the presence of partial melt at the base of the Hawaiian mantle plume.

Ultra low velocity zones (ULVZs) may originate by partial melting [6] and appear to be irregularly distributed at the boundaries of large low shear velocity provinces (LLSVPs) [7] which are also the proposed sites of mantle plume generation for both LIPS and ocean islands [8]. ULVZs have been located below BIWG and Hawaii [7,9], consistent with petrological inferences of partial melt.

Calcium isotope fractionation in vertebrates

A. HEUSER[1]*, A. EISENHAUER[2], K. SCHOLZ-AHRENS[3] AND J. SCHREZENMEIR

[1]Steinmann-Institut, Universität Bonn, Bonn, Germany (*correspondence: aheuser@uni-bonn.de)

[2]GEOMAR, Helmholtz-Zentrum für Ozeanforschung Kiel, Germany

[3]Max Rubner-Institut, Bundesforschungsinstitut für Ernährung und Lebensmittel, Kiel, Germany

Earlier investigations showed that there is considerable biological fractionation of Ca isotopes in vertebrates. Consequently it was suggested that Ca isotope fractionation may be applied as a diagnostic tool for the detection of Ca metablic malfunctions like osteomalacia or osteoporosis. In order to further investigate Ca isotope fractionation in vertebrates, we analyzed the Ca isotopic composition ($\delta^{44/40}$Ca) of diet, feces, blood, bones and urine of Göttingen miniature pigs from an animal trial. Samples of three different groups were investigated: 1. Control group (Con), 2. Glucocorticosteroid induced osteoporosis group (GIO) and 3. Calcium and vitamin D deficiency induced osteomalacia group (-CaD).

While $\delta^{44/40}Ca_{diet}$ values are in average 0.42±0.07 ‰ the observed Ca isotope variations in feces, bones, blood and urine is significantly higher. $\delta^{44/40}$Ca values vary in total by 3.28 ‰ ranging from –0.54 ‰ (feces) up to 2.74 ‰ (urine). It is not possible to distinguish the three groups solely based on $\delta^{44/40}Ca_{urine}$, $\delta^{44/40}Ca_{bone}$ or $\delta^{44/40}Ca_{blood}$ values only. In contrast, group –CaD is clearly marked by their low $\delta^{44/40}Ca_{feces}$ values. Average $\delta^{44/40}Ca_{feces}$ of group –CaD is–0.27 ‰ while it is 0.39 ‰ and 0.28 ‰ for groups Con and GIO, respectively.

The $\delta^{44/40}Ca_{feces}$ represents the unabsorbed fraction of dietary Ca and thus can be used to identify Ca fractionation during intestinal absorption. The $\delta^{44/40}Ca_{feces}$ values of –CaD are lighter than corresponding $\delta^{44/40}Ca_{diet}$ by ~0.6 ‰ which indicates that Ca isotopes are fractionated during intestinal absorption. In contrast, group Con and GIO $\delta^{44/40}Ca_{feces}$ values do not indicate Ca fractionation during intestinal absorption. Observed $\delta^{44/40}Ca_{feces}$ values of group–CaD may be caused by either the addition of isotopically light Ca from intestinal fluids or fixation of light Ca isotopes in unmetabolizable compounds like Ca oxalates or Ca phytates.

[2]Institut de Chimie Séparative de Marcoule, ICSM UMR 5257 – CEA / CNRS / UM2 / ENSCM, Site de Marcoule, BP 17171, F-30207 Bagnols sur Cèze Cedex, France

[3]RWTH Aachen University, Institute of Crystallography, D-52066 Aachen, Germany

Lanthanide monazite-type ($Ln$$PO_4$) ceramics are promising candidate materials for the immobilisation of minor actinides resulting from reprocessing of spent fuel. Particularly with regard to the long-term safety in a deep geological repository, monazite-type ceramics present a good alternative to the widely used borosilicate glasses for the specific conditioning of actinides. In terms of their crystal structure (SG $P\ 2_1/n$) they offer outstanding properties concerning radiation resistance and chemical stability. Their normalised dissolution rates are several orders of magnitude lower than these of glasses [1-4]. This behaviour can also be confirmed by their natural analogues (no metamictisation occurs).

Therefore we investigated different monazite-type phases as potential waste forms for minor actinides. We prepared and characterised $SmPO_4$-$TbPO_4$ and $SmPO_4$-$CaTh(PO_4)_2$ solid solutions, using wet-chemical synthesis routes like precipitation at room temperature and solid state reactions (1600 °C), respectively. The presented data obtained by Raman and IR spectroscopic investigations will be discussed in conjunction with X-ray powder diffraction data as well as thermal analyses within a comparison to the available literature. An increasing distortion of the PO_4 tetrahedra should be demonstrated with increasing Th-substitution of the *Ln*-position. Additionally, the monazite-cheralite solid solution data will be compared to that of a Thorium containing natural monazite sample. Completely new data could be generated for the solid solutions. Results of temperature dependent Raman spectroscopic investigations on the partly metastable (Sm,Tb)PO_4 solid solutions will be presented, where depending on the composition one-two exothermic phase transitions are expected.

Searching for evidence for Mo isotope fractionation in the mantle

KATE HIBBERT[1]*, MATTHIAS WILLBOLD[1,2], MORTEN ANDERSEN[1,3] AND TIM ELLIOTT[1]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Bristol, UK (*correspondence: kate.hibbert@bristol.ac.uk)

[2]Department of Earth Science and Engineering, Imperial College London, London, UK

[3]Institute of Geochemistry and Petrology, ETH Zurich, Switzerland

Molybdenum is a highly siderohpile element which was strongly depleted in the mantle by the process of core formation. Its mantle inventory is therefore strongly influenced by the addition of material during the late veneer when highly siderophile elements were enriched in the mantle after core formation.

Recent experimental data suggest that molybdenum isotopes are fractionated during metal-silicate equilibration, with lighter isotopes preferentially entering the silicate phase [1]. Therefore the mantle should be isotopically lighter than the chondritic material which is presumed to have accreted to form the Earth as heavy isotopes were concentrated into the core. However, the addition of the late veneer may have somewhat obscured the isotopic signature of core formation.

We describe two approaches taken to investigate the isotopic composition of the mantle relative to chondrites in an attempt to verify these experimental findings. Firstly, we measure a range of ~3.8Ga samples from Greenland which have been shown to retain an isotopic signature of the mantle prior to the addition of the late veneer [2].

Secondly, we measure the Mo isotopic composition of mid-ocean ridge basalts (MORBs) which we compare to chondrite samples in an effort to detect residual fractionation of molybdenum isotopes associated with core formation post late veneer.

MORB samples are known to carry some signature of recycling; however we suggest that they are sufficiently representative of the mantle for our purposes. Whilst scatter in both the MORB and chondrite datasets currently prevents the identification of a resolvable difference, we find a tantalising offset of 0.1 permil between the most primitive MORB sample and the least altered chondrite.

Isotopic evidence for an activity of the early Sun studied from the isotopic measurements of Kapoeta

HIROSHI HIDAKA[1] AND SHIGEKAZU YONEDA[2]

[1]Department of Earth and Planetary Systems Science, Hiroshima University, Higashi-Hiroshima 739-8526, Japan (hidaka@hiroshima-u.ac.jp)
[2]Department of Science and Engineering, National Museum of Nature and Science, Tsukuba 305-0005, Japan

The Kapoeta meteorite (howardite) is a regolith breccia meteorite, and is known to be a highly gas-rich meteorite that experienced early irradiation by cosmic rays, however, its irradiation history is complicated and still disputed with respect to evidence of early solar irradiation. Our previous study on neutron capture history of Kapoeta suggests the existence of preirradiation materials migrating into the meteorite parent body [1]. The existence of space-weathered rims in several regolith grains in the Kapoeta meteorite is resulted from the irradiation of cosmic-ray on the regolith parent body [2]. In this study, Sr, Ba, Ce, Nd, Sm and Gd isotopic compositions of the sequential acid- leachates from the Kapoeta meteorite were determined to find systematic and correlated variations of their p-process isotopic abundances and to understand the neutron capture record due to cosmic-ray irradiation.

Significantly large isotopic excesses of ^{84}Sr, ^{130}Ba, ^{132}Ba, ^{136}Ce, ^{138}Ce and ^{144}Sm were observed particularly in the first leaching fraction (L1). Interestingly, a large isotopic shift of ^{150}Sm/^{149}Sm and ^{158}Gd/^{157}Gd due to neutron capture reactions was also found in the first fraction, corresponding to the neutron fluence of 2.6×10^{16} n cm^{-2}, which is more than 10 times higher than those in the other fractions. The large difference of neutron capture records of L1 from the other three suggests the existence of preirradiation materials migrating into the Kapoeta parent body.

Systematic isotopic data in this study reveal the enrichment of several p-process isotopes of the fraction L1 leached probably from a very surficial part of regolith grains of Kapoeta, suggesting the production of p-process isotopes resulted from the interaction of SCR during the regolith process of the Kapoeta parent body. The result provides isotopic evidence for an activity of the early Sun.

Fulvic and Humic Acid interaction with Phosphate at synthetic and natural oxide surfaces

TJISSE HIEMSTRA[1], SHAMIM MIA, PIERRE-BENOÎT DUHAUT, AND BASTIAAN MOLLEMAN

[1]Dept. Soil Quality, PO box 47, 6700 AA, Wageningen University, Netherlands tjisse.hiemstra@wur.nl

Fulvic acid (FA) and humic acid (HA) have a large variability in binding to metal (hydr)oxides and interact differently with oxyanions, as studied experimentally for goethite, phosphate, and a series of soil HAs that cover the large natural variation in molecular charge and size. A surface complexation approach has been developed that aims to describe the pH-dependent competitive behaviour of natural organic matter (NOM) in soil as well as model (hydr)oxide systems, using variable inner and outersphere complexation as well as protonation of RCOO ligands.

Modelling shows that the competition of phosphate with various HAs is linearly related to the HA charge. Expressed per unit charge, HA competes as well as FA (or even better), which is unexpected since the various humics highly differ in molecular size (~1-10 nm) suggesting variation in mean distance of approach [1]. Modelling suggests that at low loading, both FA and HAs are predominantly adsorbed in the Stern layer domain which points to a strong change of the molecular conformation of the humic acids. Our calculations suggest that the metal (hydr) oxide surfaces are efficiently covered by an ultra-thin layer of NOM. Therefore, realistic surface complexation modeling of natural systems should account for this pervasive NOM surface coverage.

From the perspective of global carbon sequestration, adsorption of NOM is also important since minerals may protect adsorbed carbon against oxidation. In soils, the reactive metal (hydr)oxide fraction consists of nanoparticles, typically representing ~3-30 m^2 g^{-1} soil [2]. When covered by an ultra-thin layer of NOM, it may represent at least 0.2-2% NOM. Surface-associated NOM may be even three times higher. In our competition study, we have also included pyrogenic HA since it will be released to the environment in case of large-scale application of biochar, potentially creating Darks Earths or Terra Preta soils. Terra Preta soils are fertile, rich in carbon as well as phosphate. Our charge distribution model for NOM predicts a more than 10-fold increase in dissolved phosphate for soils rich in black carbon. This is due to the relatively high molecular charge of pyrogenic HA.

Multi-stage Cl-rich fluid activity and behavior of REE-bearing minerals in a Neoproterozoic granulite terrane

FUMIKO HIGASHINO[1]*, TETSUO KAWAKAMI[1], M. SATISH-KUMAR[2], MASAHIRO ISHIKAWA[3], NORIYOSHI TSUCHIYA[4] AND GEOFF GRANTHAM[5]

[1]Department of Geology and Mineralogy, Kyoto University, Japan (correspondance: fumitan@kueps.kyoto-u.ac.jp)
[2]Niigata University, Japan
[3]Yokohama National University, Japan
[4]Tohoku University, Japan
[5]Council for Geoscience, South Africa

Cl-rich fluid is a powerful solvent, and can coexist with CO_2-rich fluid under granulite facies conditions [1]. Despite such important roles, the scale and timing of its activity during high-grade metamorphism are still not clear. Field distribution of Cl-rich biotite, amphibole and apatite, which are evidence for the presence of Cl-rich fluid, is investigated in detail in the Sør Rondane Mountains (SRM), East Antarctica where granulites are widely exposed.

Cl-rich biotite preserved as inclusions in garnet shows linear distribution in the SRM. Among them, a pelitic gneiss from the east SRM (Balchenfjella) shows Cl-rich fluid infiltrated around near-peak metamorphism at ca. 800 ºC, 0.8 GPa [2]. In this sample, monazite is present in the garnet core, whereas zircon and xenotime are included in the garnet rim. This suggests that the Cl-rich fluid infiltration that took place at the garnet core/rim boundary lead to the change of REE-bearing mineral species. This implies that Cl-rich fluid carried LREE and Th away and brought HREE, Zr and Y in. U-Pb dating of zircon included in the garnet rim gave 603±14 Ma [2], representing the timing of Cl-rich fluid infiltration. Biotite in the matrix is Cl-poor, suggesting that the retrograde metamorphism occurred in a Cl-poor environment. The rim of zircon in the matrix might represent a timing of this fluid activity (564±17 Ma), which is consistent with the zircon ages obtained from metacarbonates (ca. 545 Ma) that represent the timing of fluid activity [3, 4].

In addition, the mafic gneisses from the central SRM (Brattnipane) host cm-thick veinlets composed of garnet and Cl-rich amphibole that discordantly cut the penetrative gneissosity. In our presentation we discuss the processes associated with multi-stage Cl-rich fluid infiltration in the SRM during the peak- to retrograde stages.

Magnesium isotope evidence for a link between low-temperature clays, seawater Mg/Ca, and climate

HIGGINS, J.A.[1]* AND D.P. SCHRAG[2]

[1]Dept.of Geosciences, Princeton University, (jahiggin@princeton.edu)
[2]Dept. of Earth and Planetary Science, Harvard University, (schrag@eps.harvard.edu)

Cooling of Earth's climate over the Cenozoic has been accompanied by large changes in the magnesium and calcium content of seawater. The processes that control these changes affect the magnesium isotopic composition of seawater, rendering it a useful tool for elucidating the processes that control seawater chemistry. We use measurements of magnesium isotopes in both pore fluids and carbonate sediments together with a numerical model of sediment diagenesis and show that the magnesium content of seawater has increased by 10-15 mmol over the last 15-25 Myr with little change in its isotopic composition. These observations are best explained by a reduction in removal of Mg from seawater in marine clays formed at low temperatures. A temperature-dependent Mg sink in marine clay directly links the major element chemistry of seawater to global climate, providing an additional explanation for the co-variation of seawater Mg/Ca and climate on ~100 million year timescales over the Phanerozoic.

Holocene records of chlorin N isotopes

MEYTAL B. HIGGINS[1], REBECCA S. ROBINSON[2] AND ANN PEARSON[3]

[1]Department of Geosciences, Princeton University; mbhiggin@princeton.edu
[2]Graduate School of Oceanography, University of Rhode Island; rebeccar@gso.uri.edu
[3]Department of Earth and Planetary Sciences, Harvard University; apearson@eps.harvard.edu

Nitrogen isotope ratios measured in sedimentary chlorophyll degradation products provide a diagenetically unaltered signal of the marine nitrogen cycle during deposition. Additionally, due to taxonomic differences in fractionation associated with chlorophyll biosynthesis, these records can be used to reconstruct the cyanobacterial contribution to buried organic matter. If diazotrophic cyanobacterial contribution to biomass increases during enhanced N_2 fixation, then chlorin N isotope records may provide an additional constraint on the importance of this source of N to surface waters in the geologic past. We reconstructed low resolution records of chlorin $\delta^{15}N$ values from the last glacial maximum to recent sediments in four oceanographically distinct settings. Samples were taken from ODP sites 1234 (Chile Margin), 1237 (Nazca Ridge, Peru), 1063 (Bermuda Rise), and core 17964 from the South China Sea. These four globally-distributed sites represent different nutrient regimes characterized by a wide range of modern P* values and potential rates of N_2 fixation. Chlorin $\delta^{15}N$ data were compared to new or previously published bulk N data to examine for diagenetic enrichment of bulk N (causing ^{15}N offsets to increase) or cyaobacterial contribution to export (causing ^{15}N offsets to decrease). Preliminary data show an average $\delta^{15}N$ offset of ~5-5.5‰ between bulk and chlorin N at all sites, suggesting predominantly algal export production irrespective of N_2 fixation regime and bulk values of $\delta^{15}N$.

Efficient preservation of terrestrial organic carbon offshore Taiwan: Implications for the global carbon cycle

R. G. HILTON[1,*] AND S. J. KAO[2,3]

[1]Durham University, United Kingdom, (*correspondence: r.g.hilton@durham.ac.uk)
[2]Academia Sinica, Taiwan, (sjkao@gate.sinica.edu.tw)
[3]Xiamen University, China.

Photosynthesis on land produces terrestrial biomass and sequesters atmospheric CO_2 within living matter. Geological sequestration of CO_2 can occur if this terrestrial organic carbon (OC) is eroded and transported to marine sediments where accummulation rates are high[1], influencing Earth's radiation energy balance. Mountain rivers draining islands of Oceania have amongst the highest erosion rates of terrestrial OC and sediment[2,3] and it is of critical importance to understand its fate upon entering the ocean. Here we use radiocarbon ($\Delta^{14}C_{org}$, ‰), stable isotopes ($\delta^{13}C_{org}$, ‰) and OC content (C_{org}, %) to track terrestrial OC from Taiwan from river sediments to ocean sediment traps and box-cores collected from around the island. We account for fossil OC from sedimentary rock, while assessing the range of delivery mechanisms to the ocean by mountain rivers.

During floods at high suspended sediment concentrations, we observe efficient transfer of terrestrial OC (both fossil and non-fossil) to the deep ocean, and evidence for its longer-term presveration in marine sediments. Large amounts of terrestrial sediment are also delivered to the surface ocean by rivers, dispersing OC over a larger area[3]. Marine sediments sourced by this mechanism have a positive relationship between $\Delta^{14}C_{org}$ and $\delta^{13}C_{org}$, and a negative relationship between $1/C_{org}$ and $\Delta^{14}C_{org}$. Employing end member mixing analysis and by modelling OC loss scenarios, we show that these are the product of mixing between marine OC and terrestrial OC (itself a fossil and non-fossil mixture) and that 80-100% of terrestrial OC is preserved in marine sediments, suggesting much higher burial efficiencies than previously hypothesed[2]. Our findings allow for a conservative estimate of recent CO_2 sequestration by terrestrial OC burial across Oceania, which comprises a significant proportion of global OC burial. We thus postulate that tropical mountain islands provide a strong coupling between tectonic uplift and the carbon cycle, one that is moderated by the climatic variability that controls terrestrial OC delivery to the ocean.

Experimental determination of the Si isotope fractionation factor between metal and silicate liquids

REMCO C. HIN[1], CAROLINE FITOUSSI[1,2], MAX W. SCHMIDT[1] AND BERNARD BOURDON[1,2]

[1]Institute of Geochemistry and Petrology, ETH Zurich, Switzerland (*correspondence: remco.hin@erdw.ethz.ch)
[2]Ecole Normale Supérieure de Lyon and CNRS, France

The conditions of core formation on Earth are still debated and stable isotope fractionation is explored as a new tool to further constrain metal-silicate segregation conditions. It has been shown that chondrites and (ultra)mafic terrestrial silicates have different Si isotope compositions[1-3], although there is no consensus yet[4]. Recent experimental work has found -1.77±0.32‰ fractionation between liquid metal and olivine at 1800°C[5], which implies that Si isotope fractionation may occur during core formation in planetesimals and on Earth.

To better constrain the conditions of core formation, Si isotope fractionation between metal and silicate must be well calibrated. We therefore performed liquid metal, liquid silicate equilibration experiments at 1450°C and 1750°C at 1 GPa in a centrifuging piston cylinder at ETH Zurich. The physically segregated liquids were mechanically separated prior to dissolution by alkali fusion. After ion exchange chromatography, isotopic analyses were carried out on a Nu Instruments 1700 MC-ICPMS at ETH Zurich.

The silicate liquids had consistently heavier Si isotopes than the equilibrated metal liquids. The average fractionation factor between metal and silicate liquids ($\Delta^{30}Si_{Metal\text{-}Silicate}$) was -1.48±0.08‰ at 1450°C and -1.11±0.14‰ at 1750°C. Given a $1/T^2$ functional form, the temperature dependence of Si isotope fractionation between metal and silicate liquids can be described as $\Delta^{30}Si_{Metal\text{-}Silicate}$ (‰) = $-4.47(\pm0.31)\times10^6/T^2$.

Our equilibrium data yield a smaller fractionation than previously deduced[5]. Calculations at 2500-3500 K for metal-silicate equilibration during core segregation on Earth imply a bulk Earth δ^{30}Si of -0.38 to -0.33 (±0.02‰ propagated error), respectively, for a bulk silicate Earth δ^{30}Si of -0.29±0.01‰ and 6 wt% Si in the Earth's core. Although the calculated values fall in the range of observed chondrite Si isotope compositions, they do not match all observations for the Si isotope composition of chondrites.

Combining radiogenic and stable Ca isotopes to explore sub-glacial weathering reactions

R. HINDSHAW[1]*, B. BOURDON[2], J. RICKLI[3] AND J.WADHAM[4]

[1]Øystein Møylas veg 16, Trondheim, Norway (correspondence : ruth.hindshaw@googlemail.com)
[2]Laboratoire de Géologie de Lyon, ENS Lyon, France
[3]Institute of Geochemistry and Petrology, ETH, Switzerland
[4]Bristol Glaciology Centre, University of Bristol, UK

The interpretation of weathering processes based on the stable isotopes of calcium (Ca) is complicated by the difficulty of distinguishing between source and process fractionation effects. The combination of radiogenic Ca isotopes (ε^{40}Ca) with stable Ca isotopes ($\delta^{44/42}$Ca) would provide the ability to separate source and process fractionation effects. The aim of this study was to combine both the stable and radiogenic Ca isotope systems to investigate the sources of Ca and Ca isotope fractionation processes in glaciated environments, providing great potential to increase understanding of the behaviour of Ca during weathering.

This study is based on a one month sampling campaign to Leverett Glacier, West Greenland in July 2009. The bedrock (granite/gneiss) is of Archean age (ca 1850 Ma), theoretically old enough to have acquired radiogenic ^{40}Ca anomalies. Water samples were collected twice daily for a period of 28 days together with spot samples of water end-members (ice, supra-glacial water) and four representative rock samples from which the main Ca bearing minerals were separated.

The bulk rock samples exhibit a range in both stable ($\delta^{44/42}$Ca = +0.20 to +0.50‰) and radiogenic (ε^{40}Ca = -1.0 to +6.9) Ca isotopic compositions. Two of the analysed mineral separates had significant radiogenic Ca anomalies: sanidine (ε^{40}Ca = +15.3) and biotite (ε^{40}Ca = +7.7). Radiogenic anomalies up to ε^{40}Ca = +5.3 were detected in river water samples, coincident with an outburst event. The change in ε^{40}Ca measured in the river water samples during the outburst event indicates a change in the relative contribution from different mineral sources to the dissolved load of Ca. In contrast, the stable Ca isotopic composition of river water showed no discernable temporal variation and had an average $\delta^{44/42}$Ca of +0.60‰, which was significantly higher than the source rocks. The combination of ε^{40}Ca and $\delta^{44/42}$Ca data clearly indicates that $\delta^{44/42}$Ca values cannot be reconciled with mixing processes and have been fractionated.

Effect of phosphate and sulfate on Fe(II)-catalyzed trace metal incorporation into and release from Fe(III) oxides

MARGARET ANNE G. HINKLE[1]* JEFFREY G. CATALANO[1]

[1]Earth & Planetary Sci., Washington Univ., St. Louis, MO 63130 USA (*correspondence: mhinkle@eps.wustl.edu)

Trace element concentrations in natural systems are often controlled by adsorption-desorption reactions on iron oxide surfaces [1]. Biogeochemical iron cycling leads to the coexistence of aqueous Fe(II) with solid Fe(III) oxides, which undergo Fe(II)-Fe(III) interfacial electron transfer and atom exchange (ET-AE) reactions [2]. These reactions result in Fe(III) oxide recrystallization, causing the incorporation of structurally compatible adsorbates, e.g. Ni(II), into solid Fe(III) oxides as well as the release of preincorporated ions into solution [3-5]. Recent research has shown that oxoanions common to natural systems, such as phosphate, do not affect the rate or extent of Fe(II)-Fe(III) atom exchange reactions [6]. However, these species may still potentially alter trace metal incorporation and release by complexing with metals at the iron oxide surface or by changing growth and dissolution mechanisms via processes such as step pinning.

We have investigated the interaction of phosphate and sulfate with Fe(II) on goethite and hematite surfaces and the resulting impact on Ni incorporation and release. Macroscopic adsorption and ATR-FTIR studies demonstrate that oxoanions enhance Fe(II) adsorption through a direct interaction on the mineral surface. XAFS spectroscopy indicates that both phosphate and sulfate decrease Fe(II)-catalyzed Ni(II) incorporation into goethite and hematite; the effect of phosphate was more substantial. Ni(II) release from these minerals during Fe(II)-catalyzed recrystallization was also suppressed by phosphate and sulfate, with the former again producing the larger inhibititory effect. This research suggests that phosphate and sulfate affect trace element partitioning between aqueous solutions and Fe(III) oxides during Fe(II)-Fe(III) ET-AE reactions, potentially impacting contaminant fate and micronutrient bioavailability in soil and aquatic environments.

The future of lipids as tools to study microbes and biogeochemical processes in the deep biosphere

KAI-UWE HINRICHS[1]*, JULIUS S. LIPP[1], TRAVIS B. MEADOR[1], GUNTER WEGENER[1,2], SITAN XIE[1]

[1]MARUM-Center for Marine Environmental Sciences, University of Bremen, 28359 Bremen, Germany (*Presenting author, khinrichs@uni-bremen.de)

[2]Max Planck Institute for Marine Microbiology, 28359 Bremen, Germany

Recent work has demonstrated that the predominant microbial intact polar lipids (IPLs) in marine sediments, i.e., glycerol-based ether lipids with a glycosidic polar headgroup, are impacted by a considerable fossil fraction derived from past microbial generations [1]. Although IPL concentration profiles provide useful quantitative constraints on slowly growing archaeal communities [1], their use as direct markers of live biomass in deeply buried sediments is compromised. Hence lipid-based investigative strategies will have to be modified in order to sustain a central role of microbial lipids in future studies of subseafloor life.

Future avenues will need to focus on IPLs that have little or no fossil bias, such as phospholipids [cf. 1] or new target compounds that are diagnostic for actively growing cells as identified by culture studies. Detection of these often far less abundant compounds will require implementation of more sensitive approaches [2]. Some novel groups of orphan lipids are concentrated in the subseafloor [3]; the elucidation of their biological sources and function will likely provide important clues on the deep biosphere. Novel, minimally invasive stable isotope probing assays that target microbial lipids will have a key role in quantifying microbial growth and substrate specificity [4]. This paper will review the state-of-the-art and provide new examples that illustrate future directions of lipid-based research of subseafloor life.

Complex *in situ* cosmogenic ^{10}Be-^{14}C data suggest Mid-Holocene climate change on the Bolivian Altiplano

K. HIPPE[1]*, F. KOBER[2], S. IVY-OCHS[1], M. LUPKER[3], L. WACKER[1], M. CHRISTL[1] AND R. WIELER[3]

[1]Laboratory of Ion Beam Physics, ETH Zürich, 8093 Zürich, Switzerland (*correspondence: hippe@phys.ethz.ch)
[2]Institute of Geology, ETH Zürich, 8092 Zürich, Switzerland 3 Isotope Geology and Mineral Resources, ETH Zürich, 8092 Zürich, Switzerland
[3] Institute of Geochemistry and Petrology, ETH Zürich, 8092 Zürich, Switzerland

In a recent study on basin-averaged denudation rates on the Bolivian eastern Altiplano, long-lived ^{10}Be and ^{26}Al have been used to provide long-term estimates on sediment production while the short-lived *in situ* ^{14}C allowed to identify interruptions of sediment exposure by episodes of sediment storage [1]. Based on comparatively low *in situ* ^{14}C concentrations sediment storage over at least the past 11- 20 ka has been suggested.

Following this approach, we have chosen to focus on one single catchment on the eastern Altiplano (~350 km^2) to trace the spatial pattern of sediment deposition and quantify individual storage durations. Sediment samples were taken along the main channel and from tributaries as well as from three hilltop sites. Results from the analysis of ^{10}Be and *in situ* ^{14}C are in agreement with previous data [1] showing a high ^{10}Be content and significantly too low *in situ* ^{14}C concentrations for all but one sample, including two of the three hilltop samples. Excluding sediment storage/burial on the hilltop for obvious reasons and excluding soil mixing or slab breakoff from field observations, we propose a change in denudation rate to account for the discrepancy of ^{10}Be and *in situ* ^{14}C on the hilltop. Using a simple model of a rapid, one-step denudation increase, the two samples suggest a minimum 30-40 times increase in denudation rate about 4-6 ka ago.

Assuming that the analyzed fluvial sediments have already an inherited complex ^{10}Be-^{14}C signal from the sediment-producing hilltop areas, the total duration of sediment storage reduces to ~1-5 ka, thus much shorter than previously assumed. Our data further show that sediment storage occurring on the floodplain does not contribute to the complex cosmogenic nuclide signal. In contrast to the channels in the upstream area, that incise a few metres in depth, the material deposited on the floodplain is apparently only rarely reworked.

Mantle structure below the petit-spot

N. HIRANO[1]*, J. YAMAMOTO[2] AND S. OKUMURA[3]

[1]Center NE-Asian Studies, Tohoku Univ., Japan (*correspondence: nhirano@m.tohoku.ac.jp)
[2]Hokkaido Univ. Museum, Hokkaido Univ., Japan
[3]Dept. Earth Sci., Tohoku Univ., Japan

The petit-spot volcanoes, erupted due to lithospheric bending related to the plate subduction, were found on the subducting plate off Japan and Chile trenches [1, 2]. An old and flexed lithosphere might cause brittle fractures at the upper lithosphere. Incipient melts in the asthenosphere can be squeezed upward by tectonic forces associated with plate flexure [1]. The presence of the tiny submarine volcanoes, petit-spot, is an important indicator of the stress field of the plate [3], in addition to providing information on the geochemical composition of the mantle below the petit-spot [4, 5, 6, 7].

The lavas and entrained xenolithes were newly dated and analyzed in this study. Accordingly, monogenetic petit-spot volcanoes located on the NW Pacific Plate yield ages of 1.8, 3.8, 4.2, 6.0, 6.2, 8.5, and 9.2 Ma by Ar-Ar datings, suggesting the episodic eruption of magma over a large eruption area (over 800 km of plate motion) of the concave part of the plate, but with low volumes of magma production [8]. Most of lavas have the differentiated composition of approximately 50 wt% SiO2 and 60 of Mg number with extremely high contents of carbon dioxide. The petrography and geobarometer of peridotitic xenolithes show that they rapidly ascended through the upper lithosphere. These data implies the magma differentiated at the depth deeper than middle of lithosphere where the carbon dioxide does not exsolve in magmas.

Continuous developments in inorganic mass spectrometry techniques, including a combination of an ICP ion source and a magnetic sector-based mass spectrometer equipped with a multiple-collector array (MC-ICPMS), have revolutionized the precision of the isotopic ratio measurements. Although the magnitude of many analytical problems is clearly exacerbated, the analytical community is actively solving problems, such as spectral interference, mass discrimination drift, high-yield chemical separation and purification processes, or reduction of the contamination of analytes, and the applications of the heavy element-stable isotope geochemistry are beginning to appear over the horizon [1, 2]. The variations in isotopic ratios of the heavy elements, such as Fe, Zn, Cu, Sr, Ce-Nd, W, or U can provide new insights into past and present geochemical and biochemical processes [2]. Among the heavy elements, mass-dependent isotopic fractionation of the bioessential metals (e.g., Ca, Fe, Zn or Cu) was extensively applied to investigate the nutritional status of elements or to evaluate the elemental metabolism for plant and animals [e.g., 1,3,4]. This is well demonstrated by the diagnosis for specific diseases through the changes in isotope ratios of the elements [5,6]. To take a full advantage of the heavy element-isotope systematics, we are currently trying to obtain *in situ* isotope ratio data of the elements using MC-ICPMS technique coupled with a femtosecond-laser ablation sample introduction technique (fLA-MC-ICPMS). Analytical advantages achieved by the fLA-MC-ICPMS technique or by the LAL-MC-ICPMS technique [7] will be presented in this presentation.

Crystal structure in Earth's inner core

KEI HIROSE[1]*, SHIGEHIKO TATENO[2] AND HARUKA OZAWA[1,3]

[1]Earth-Life Science Institute, Tokyo Institute of Technology, Tokyo, Japan (*Correspondence: kei@elsi.jp)
[2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan
[3] Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology, Yokosuka, Japan

Composition and state of the core remain uncertain to a large extent [1], in part because static experiments performed on candidate compositions at such extreme conditions have been difficult until recently. Nevertheless, ultrahigh-pressure experimental techniques using laser-heated diamond-anvil cell (DAC) combined with synchrotron x-rays have greatly advanced in recent years. Now static experiments are being performed at the core ultrahigh pressure and temperature conditions, even beyond those at the center of the Earth [2]. Recent experimental and theoretical studies indicated that hexagonal-close-packed (hcp) structure is a stable form of iron in the Earth's inner core. Earlier calculations suggested that body-centered-cubic (bcc) Fe is stable above ~5500 K at 330 GPa [4]. However, the temperature at the inner core boundary may be as low as 5200 K, inferred from recent estimates of core-mantle boundary temperature of ~3800 K. The nature of stable crystalline phases and physical properties are strongly affected by impurity elements in the core. We have performed x-ray diffraction measurements so far up to 412 GPa and 5900 K and examined stable crystal structures of iron-compounds including Fe-10wt%Ni, FeO, Fe-9wt%Si, and Fe-S alloys under the core conditions. Considering a small density deficit, our data so far suggest that hcp is a plausible crystal structure in the inner core.

Deep Time: How did the early Earth become our modern world?

MARC M. HIRSCHMANN

U. Minnesota, Minneapolis, MN USA (mmh@umn.edu)

One of the salient challenges in Deep Time studies is understanding how the Earth made the transition from early violent events –accretion, core formation, and impacts– to the rather normal equable conditions recorded in the Hadean Jack Hills zircons, with oceans, granitic crust derived in large part from partial melting of mature sediments, and perhaps even dynamical behavior similar to plate tectonics[1]. An unresolved question is how the Earth's deep volatile cycles evolved through this time. One interpretation is that the combination of core formation, magma ocean degassing, and atmospheric loss produced an early mantle largely devoid of volatiles, which were then added chiefly in a late veneer. But if the late veneer was mixed in to the mantle only gradually over time scales of > 1 Ga[2], then the Hadean near surface environment would have been dominated by super-oceans, flooding protocontinents and massive supracrustal storage of C, presumably as carbonate. Similarly, the consequences of a nearly volatile-free mantle on mantle dynamics and tectonics are poorly understood. However, there is reason to believe that a significant portion of Earth's present-day volatiles were delivered to the mantle prior to the late veneer. At a minimum, the distinct noble gas compositions of the mantle and atmosphere require retention of some early (including nebular) volatiles in the mantle. But more importantly, H/C[3] and N/C[4] ratios of the bulk silicate Earth demonstrate that Earth's major volatile inventories remember the processing associated with magma ocean and core formation stages, suggesting that significant fraction of Earth's early volatiles avoided catastrophic escape or core sequestration. The mechanisms of this retention are poorly understood, but may have been critical to the early approach to dynamical and climatic stability.

Chemical diffusion in the deep Earth: Is it all about grain boundaries?

MATTHEW HISCOCK[1] AND GEOFFREY D. BROMILEY[1]

[1]School of GeoSciences (Grant Institute) and Centre for Science at Extreme Conditions, University of Edinburgh, Edinburgh EH9 3JW, UK

Diffusion of chemical species in Earth's interior plays a controlling role in many of the large-scale processes which first formed and continue to reform the Earth through time. Traditionally, diffusivity of species has been considered to occur under subsolidus conditions mainly via lattice diffusion; i.e. the movement of species through bulk crystal structures. Recently however, researchers have started to attempt to constrain the importance of grain boundary diffusion (GBD) in the deep Earth: i.e. the mobility of species along grain boundaries. Grain boundaries provide alternative, fast pathways for mobile species which may be chemically and structurally very distinct from the bulk crystalline structure of polymineralic materials. It has recently been suggested that GBD provides a mechanism for transporting highly incompatible elements from the core into regions of lower mantle melting, and is an important component of H mobility in the upper mantle. Here we present results from an experimental study aimed at constraining the importance of GDB in 3 geochemically important but contrasting systems: H mobility in olivine, Li diffusion in olivine and Ti diffusion in quartz.

Experimental data demonstrate similar diffusivities for GBD and lattice diffusion of H under mantle conditions. When scaled to mantle grain sizes, results suggest that GBD of H is of minor importance, except at marked discontinuities in the mantle where there are abrupt changes in H solubility. In contrast, data suggest that GBD of Li is between 2 and 4 orders of magnitude faster than lattice diffusion. Differences in the behaviour of H and Li can be understood in terms of incorporation mechanisms and the contrasting nature of crystalline material vs relatively amorphous grain boundaries. Critically, these differences result in contrasting temperature dependences for GB vs lattice diffusion which imply that GBD always dominates at low temperatures. Similarly, we find that GBD of Ti in polycrystalline quartz is orders of magnitude faster than lattice diffusion, as result which has immediate implications for the applicibility of the Ti in quartz geothermometer. Based on these results, we present a predicitive model for determining the relative importance of GBD in the deep Earth.

Release of antimony from contaminated soil induced by redox changes

KERSTIN HOCKMANN[1]*, SUSAN TANDY[1], MARKUS LENZ[2] AND RAINER SCHULIN[1]

[1]Institute of Terrestrial Ecosystems, ETH Zurich, Switzerland, (*correspondence: kerstin.hockmann@env.ethz.ch)
[2]University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Institute for Ecopreneurship, Muttenz, Switzerland

Due to its rapid growth in industial use, soil contamination by antimony (Sb) has become a matter of increasing environmental concern. A key factor of Sb mobility in soils is its redox state, which is closely related to soil aeration and thus to the soil water regime. Under aerobic conditions, thermodynamics predicts Sb to be stable as the pentavalent $Sb(OH)_6^-$, while under reducing conditions, the more toxic trivalent $Sb(OH)_3$ predominates [1]. Both species strongly differ in their affinity to iron (Fe) and manganese (Mn) (hydr)oxides, which, in turn, may be reductively dissolved under reducing conditions.

Here, we investigated how the interplay of reduction, sorption and dissolution processes affects Sb mobility in saturated soil subject to alternating redox conditions induced by autochthonous bacterial communities. Columns with Sb-contaminated shooting range soil (pH 7.8) were eluted with 15 mM sodium lactate solution for ~60 pore volumes (PV), interrupted by a 24 days stop-flow phase after 30 PV. With the transition to reducing conditions, Sb(V) and Mn concentrations showed a concomitant increase, providing evidence that sorbed Sb(V) was released by reductive dissolution of Mn minerals. As reducing conditions continued, Sb was immobilized again by reduction of Sb(V) to Sb(III), since the latter binds stronger to Fe (hydr)oxides at circumneutral pH. However, as these Fe phases started to dissolve with the onset of Fe-reducing conditions, the previously bound Sb(III) was released back into the solution. Characteriztion of the solid phased by laser ablation inductively coupled plasma-mass spectrometry (LA ICP-MS) underpinned the important role of Mn and Fe (hydr)oxides as Sb sorbents.

Our study shows for the first time that Sb can be mobilized under reducing conditions in soil also in form of Sb(V) with the dissolution of Mn and thus provides further reason for concern that release of Sb from insufficiently drained contaminated soil may pose a significant risk to the environment.

The role of earthworm-produced $CaCO_3$ in the terrestrial calcium and carbon cycles

MARK E. HODSON[1]*, EMMA A. A. VERSTEEGH[2] AND STUART BLACK[3]

[1]Environment Department, University of York, Heslington, York YO10 5DD, UK, (mark.hodson@york.ac.uk *presenting author)
[2]Department of Geography and Environmental Science, University of Reading, Reading RG6 6DW, UK, (e.a.versteegh@reading.ac.uk)
[3]Department of Archaeology, University of Reading, Reading RG6 6AB, UK, (s.black@reading.ac.uk)

Earthworm-produced calcium carbonate granules form a considerable proportion of soil carbonate and can be preserved for up to ~2 Ma. They may play an important role in the immobilisation of metals [1,2] and can be used to reconstruct temperatures of the past [3]. The physiological function of these carbonates and their role in the terrestrial calcium and carbon cycles remain poorly understood.

Experiments were performed with *Lumbricus terrestris*, one of the two main earthworm producers of $CaCO_3$ granules in many temperate soils. Earthworms were kept at different temperatures (3–20 °C) and, in a separate experiment, at different atmospheric CO_2 levels (440–3800 ppm). Granule production rate was correlated with temperature ($R^2 = 0.55$, $p < 0.0005$) increasing from 0.8 to 2.7 $mgCaCO_3$ $earthworm^{-1}$ day^{-1} between 3 and 20 °C. In contrast, granule production rate only showed a non-significant increasing trend under elevated $[CO_2]$.

In the variable temperature experiment the stable carbon isotopic composition ($\delta^{13}C$ values) was measured for soils, food (manure), air, earthworm tissues, and $CaCO_3$ granules. $\delta^{13}C$ values show that the majority of C in the granules comes from the food offered to the earthworms. As such, $\delta^{13}C$ values of granules originating from archaeological finds could be a useful proxy for vegetation type or agricultural practice (manuring) employed by past societies. In addition it suggests that earthworms are converting carbon from a more labile organic-hosted form to a less labile mineral-hosted form.

Geochronology of the Lithospheric Mantle underneath the Gibeon Kimberlite Field, Namibia

C.E. HOEFER[1,2]*, G.P. BREY[1], T. LUCHS[1], A. GERDES[1], H.E. HOEFER[1]

[1]Institut für Geowissenschaften, Goethe-Universität, Altenhöferallee 1, D-60438 Frankfurt, Germany;
[2]Institut für Geochemie und Petrologie, ETH-Zürich, Clausiusstrasse 25, CH-8092 Zürich, Switzerland (*carolin.hoefer@erdw.ethz.ch)

Recent comparative work has shown that differences and similarities exist between the mantle underneath the Archean Kaapvaal craton and the attached Proterozoic terranes [1]. Differences are: higher average forsterite in olivines from the Kaapvaal craton, lower Al_2O_3 and CaO in their bulk rocks, Re depletion ages mostly older than 2.5 Ga and a thicker lithosphere. Similarities are: similar geothermal gradients, an overabundance of orthopyroxene in part of the mantle samples and the existence of garnets with sigmoidal REE patterns. Re depletion ages are all younger than 2.2 Ga [2].

The 70 Ma old Gibeon Kimberlite Province is located in Namibia within the mixed age Rehoboth Terrane (0.9-1.2 and 1.8-2.1 Ga). Three major localities with mantle xenoliths are known: Hanaus, Gibeon Townsland and Louwrensia. Luchs *et al* [3] distinguished for Hanaus and Gibeon Townsland two types of garnet peridotites by their REE patterns: i) peridotites with flat middle to heavy REE in their garnets and ii) a minor proportion with sinusoidal REE patterns as they are known from the Kaapvaal craton. Bulk rock isotope trace element and isotope compositions were calculated from the analysis of garnets and clinopyroxenes and their modal abundances. A Lu-Hf isochron for the peridotites with the sinusoidal REE patterns gave 1852 Ma as the age of enrichment of a previously strongly depleted mantle (εHf = 29). The garnet peridotites with the flat middle to heavy REE patterns yielded a Lu-Hf age of 810 Ma with εHf = 3.3. These ages overlap with crustal ages of the mixed age Rehoboth Terrane. We have extended our studies to samples from the Louwrensia kimberlite pipe and find a similar division as in Hanaus and Gibeon Townsland for the garnet peridotites. First results from isotope studies yield a Lu-Hf age of 1100 Ma which is within the age range of the adjoining Namaqua-Natal belt. Different mantle portions with ages reflecting different events seem to be hoisted to the Earth's surface by the Gibeon kimberlites. The grt-cpx Lu-Hf two-point isochron ages give an alignment of increasing age with decreasing temperatures between 1000 to 1200 °C. We interpret these ages as cooling ages. Since kimberlite eruption ages are obtained for some samples at 1200 °C we conclude that the closure temperature for the Lu-Hf system must lie around that temperature for peridotite systems.

Fe^{3+} determination in garnet: A crystal chemical test with the EPMA flank method

H.E. HOEFER[1]*, C.E. HOEFER[1], V. MATJUSCHKIN[1], G.M. YAXLEY[2] AND G.P. BREY[1]

[1]Institut für Geowissenschaften, Goethe-Universität, Altenhöferallee 1, 60438 Frankfurt am Main, Germany (*hoefer@em.uni-frankfurt.de,)
[2]Australian National University, Canberra, Australia

We established the „flank method" for *in situ* determination of garnet iron oxidation state with the electron microprobe at micron-scale spatial resolution [1]. Besides the high spatial resolution, the great advantage of this method is the ability to analyse simultaneously the major element chemistry on the same spot.

The flank method has been calibrated with a large number of synthetic and natural garnets. We apply it here for the first time, to garnets with grain sizes of 10-15 μm. They were synthesized at various oxygen fugacities at high pressures. We determined $Fe^{3+}/\Sigma Fe$ together with the major element composition.

The test for the reliability of the $Fe^{3+}/\Sigma Fe$ determined with the flank method uses a crystal chemical approach i.e. is based on constraints from the structural formula. In garnet with general formula $A^{2+}{}_3B^{3+}{}_2Si_3O_{12}$, the number of trivalent cations on the octahedral B site is 2. A linear correlation of Fe^{3+} per formula unit and the sum of further trivalent cations plus Ti^{4+} must therefore exist. This is the case for the synthetic high-pressure garnets of this study (Fig. 1). The excellent correlation is independent proof of the high quality of garnet Fe^{3+} data determined using the flank method.

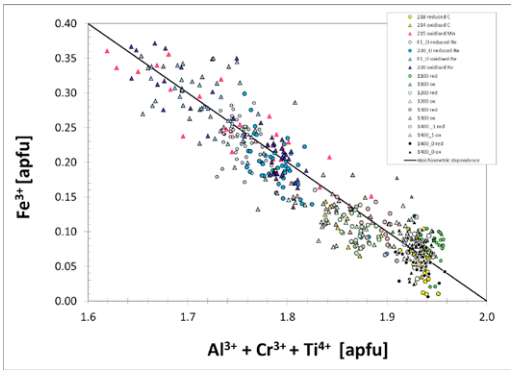

Figure 1: Fe^{3+} determined by the flank method versus the total of the remaining cations on the octahedral site.

Zircon U-Pb, Lu-Hf and REE Composition of Sorocaba and São Francisco Granites, São Paulo State, SE Brazil

TABATA HOEGER LUQUE[1]* AND SILVIO R.F. VLACH[1]

[1]IGc-USP,04280-000 , Brazil.*correspondence: [tabatahl,srfvlach]@usp.br

The granitic massifs of Sorocaba (SG, 180 km^2) and São Francisco (SFG, 150 km^2) are located southeast of São Paulo State, southeastern Brazil. They crop out near the Paraná Basin and intrude low-grade meta-vulcano-sedimentary rocks. SHRIMP U-Pb ages, Lu-Hf (LA-MC-ICP-MS) isotopic data and REE (LA-ICP-MS) abundances in zircon were considered together with WR geochemistry (XRF and ICP-MS) to understand petrogenetic processes.

The U-Pb ages for SG granodiorites are 617±4, 610±7 Ma, syeno- and monzogranites are 585±4 and 603±4 Ma. For the SFG ages are 592±3 Ma for the syeno-monzogranites and 599±4 Ma for the minor quartz-monzodiorites.

Lu-Hf isotope system from all the analyzed zircon crystals display strongly negative εHf_0 values, compatible with crustal signatures. The granodiorites εHf_0 values vary between -12.2 and -21.5. These values are slightly less evolved than those observed in the other samples; in the syeno- and monzogranites from SG, εHf_0 are between -12.8 and -33.1. Zircon crystals from quartz-monzodiorites of SFG displays εHf_0 between -30.5 and -33.5 varying in a more limited range, and the syeno-monzogranites εHf_0 varies between -32.5 and -54.4.

REE patterns are characterized by negative Eu anomalies, variable positive Ce anomalies and variable enrichment of HREE regarding to MREE. The REE concentrations were used to calculate partition coefficient data and then compared with the model from Blundy & Wood [1] considering: r_o= Zr site in zircon, 0.84 Å [2]; Young's modulus for Zr was deducted from equation 15 [3]; $D_o = D_{Zr}$ and T= Zr saturation temperature in WR. The best-fit curves were those of the SFG quartz-monzodiorites. Calculated partition coefficients of HREE show good correlation. Meanwhile, the LREE are slightly discrepant for the more felsic-studied rocks. Those discrepancies, joined with the other *in situ* analyses are a robust dataset that allow to analyse petrogenetic processes.

Preparation of micrometer sized soil particles for NanoSIMS analysis

C. HOESCHEN[1]*, T. HOESCHEN[2], C.W. MUELLER[1], T. RENNERT[1], J. LUGMEIER[1] AND I. KÖGEL-KNABNER[1,3]

[1] Lehrstuhl für Bodenkunde, Technische Universität München, 85350 Freising-Weihenstephan, Germany (*correspondence: hoeschen@wzw.tum.de)

[2] Max-Planck-Institut für Plasmaphysik, EURATOM Association, 85748 Garching, Germany

[3] Institute for Advanced Study, Technische Universität München, Lichtenbergstraße 2a, 85748 Garching, Germany

The study of biogeochemical interfaces in soils requires an adequate technique capable of revealing processes occurring at a sub-micron spatial scale.

NanoSIMS analysis provides information about elemental/isotopic distributions at such a scale. Soil architecture is revealed by imaging the spatial distribution of organic matter (e.g.: $^{12}C^-$, $^{12}C^{14}N^-$ are detected) and mineral constituents (e.g. $^{28}Si^-$, $^{27}Al^{16}O^-$, $^{56}Fe^{16}O^-$).

Samples relevant in soil science obtained by density and/or particle size fractionation are usually single particles or microaggregates with sizes in the micrometer range. Organic matter potentially distributed as a thin coating (few nm) on mineral particles could be lost during the presputtering/implantation process before NanoSIMS measurement. The challenge is to prepare such primary particles as flat, well-polished samples and to investigate them in cross-section. Embedding in a carbon containing resin results in ambiguities in distinguishing between the resin and the organic matter.

We present a method for preparing polished cross sections of micrometer-sized primary soil particles. The particles were coated with a marker layer, embedded in epoxy resin and polished. In the cross section organic coatings and assemblages on the primary soil particles can be distinguished.

This method can essentially improve the quality of NanoSIMS measurements on grainy mineral samples to better characterize soil biogeochemical interfaces.

Archean mantle heterogeneities revealed by Hf-Nd isotope systematics of the 3.33 Ga Commondale komatiites

J. ELIS HOFFMANN[1,2] AND ALLAN H. WILSON[3]

[1]Universität zu Köln, Germany; hoffmaj1@uni-koeln.de
[2]Steinmann-Institut, Universität Bonn, Germany
[3]University of Witwatersrand, Johannesburg, South Africa

The modern Earth's mantle is strongly heterogeneous, bearing ancient depleted portions that escaped homogenization. For the Archean depleted mantle, the degree of heterogenity is comparably unconstrained. Powerful tools to investigate the degree of depletion of the mantle at a given time are the radiogenic ^{176}Lu-^{176}Hf and ^{147}Sm-^{143}Nd decay systems that can be applied on mafic and ultramafic rocks that directly tapped depleted mantle sources.

Here we report the first ultra-depleted mantle reservoirs for the Palaeoarchean tapped by the extraordinary well preserved 3.33 Ga Commandale komatiites [1] from the eastern Kaapvaal Craton, South Africa. The best preserved samples yield identical Lu-Hf and Sm-Nd isochron ages of 3334 ±27 Ma (MSWD: 0.21) and 3334 ±13 Ma (MSWD: 0.76), respectively, also in agreement with the Re-Os regression age of 3393 ±440 Ma [2]. Initial εHf(t) and εNd(t) values are +6.5 to +9.2 and +1.6 to +2.4, revealing a decoupling of both isotope systems during previous melt extraction in the stability field of garnet. Moreover, a contamination with older crust during ascent can be excluded. In contrast, γOs(t) values are about chondritic, hence showing also decoupling from εNd(t) and εHf(t). This can be explained by the partition behaviour of Re-Os during mantle melting under oxidized conditions, leading to no fractionation of Re from Os in the source [3]. Primitive mantle normalized trace element patterns of the Commondale lavas show strong depletion of Nb-Ta, positive Zr-Hf, Ti and Y anomalies as well as comparably enriched LREE and Th for some samples. As alteration can be excluded here, the re-enrichment process might have been related to re-enrichment processes in an arc setting. This is supported by experimental data for the Commondale suite arguing for a hydrous mantle source [4]. Overall, the Commondale komatiites are the first reported strongly radiogenic Hf isotope compositions reported from the Palaeoarchean revealing initial εHf(t) well above the average depleted mantle at 3.3 Ga.

Chemical reactions at the air-water interface in the troposphere

MICHAEL R HOFFMANN*, HIMANSHU MISHRA AND A. J. COLUSSI

Linde+Robinson Laboratory and Center for Global Environmental Science, California Institute of Technology, Pasadena, California 91125 USA
(*correspondence: mrh@caltech.edu)

An in depth investigations of chemical and physical phenomena at air-water interface are critical for understanding heterogeneous processes on cloud droplets, dew, fog, and haze aerosol. With this mind, the report that gas-phase isoprene (2-methyl buta-1,3-diene, ISO) is protonated as $ISOH^+$ and oligomerized into a dimer, $(ISO)_2H^+$, and a trimer, $(ISO)_3H^+$, during collisions with pH < 4 aqueous microdroplets during gas-droplet collisions over 50 μs. Based on these observations, determined the probability of protonation per collision as $\gamma \sim 10^{-5}$ corresponding to a process hindered by a 7 kcal mol^{-1} kinetic barrier. During the $\lambda > 305$ nm photolysis of H_2O_2 in aqueous dilute ISO solutions yields $C_{10}H_{15}OH$ species as primary products, whose formation both requires and is inhibited by O_2. A minimum of seven $C_{10}H_{15}OH$ isomers are resolved by reverse-phase high-performance liquid chromatography and detected as MH^+ (m/z = 153) and MH^+-18 (m/z = 135) signals by electrospray ionization mass spectrometry.

Canonical trace element ratios and partitioning during global differentiation

A.W. HOFMANN[12]*

[1]LDEO, Columbia University, Palisades, NY 10964, USA
[2]Max Planck Institute for Chemistry, 55020 Mainz, Germany
(*correspondence: albrecht.hofmann@mpic.de)

For the past 16 years, the concept of "canonical" trace element ratios - concentration ratios that do not systematically change during global magmatic differentiation processes - has been variously questioned, declared invalid (e.g. [1]), or reaffirmed by many geochemical studies on oceanic basalts. Partitioning of such element pairs is sufficiently similar so that their ratios in melts reflect those of the source. Like isotope ratios, they are useful as tracers of mantle source composition, but they can be more diagnostic of global differentiation processes than the parent-daughter pairs of long-lived radioactive decay systems. Thus, Pb is partitioned similarly to the moderately incompatible LREE during intra-oceanic mantle melting, but it is highly incompatible (similar to U) during arc magmatism leading ultimately to formation of continental crust. Thus, although Pb isotopes do not distinguish well between continental and mantle sources, Pb/Ce ratios are sensitive discriminators. However, the basis for using Pb/Ce as a diagnostic ratio has been criticized, in part because Pb has similar ionic properties as Sr, which is strongly affected by gabbroic plagioclase fractionation, so that primary Pb/Ce ratios should be sufficiently modified to invalidate Pb/Ce as a tracer of mantle composition.

I use recent, comprehensive, high-quality data on the composition of global ocean floor basalts [2, 3, 4] to reassess canonical ratios involving Pb, Nb, Ta, K, U and other trace elements relevant to global differentiation processes. Plagioclase fractionation affects Pb/Ce ratios remarkably little, presumably due to the presence of sulfide during gabbroic fractionation. Overall, the bulk partition coefficient D(Pb) is between the values for Ce and Pr . D(K) is between Ta and La, and D(Nb) between Th and U. The bulk terrestrial K/U ratio is not well defined by MORB data, because K/U varies with absolute trace element enrichment [2].

CD-MUSIC to interprete drifting primary charge of ferrihydrite

A. HOFMANN[1], T. HIEMSTRA[2] AND J. LÜTZENKIRCHEN[3]

[1]Géosystèmes UMR 8217, Université Lille 1, 59655 Villeneuve d'Ascq, France

[3]INE, Karlsruher Institut für Technologie, 76344 Eggenstein-Leopoldshafen, Germany

In recent years, « environmental minerals », especially nanoparticles, have come into the focus of research because their short order structure confers them high chemical reactivity. Many of these minerals are formed in heterogeneous soil/water systems under ambient conditions. They reflect transitional, metastable phases that ultimately convert to thermodynamically stable phases, although this process can take very long periods of time. We will focus on surface complexation modeling and show how CD-MUSIC can contribute to understanding dynamic phase transformations.

When 2-line ferrihydrite is synthesized under « environmental conditions », i.e. relatively low ionic strength, no desalination and no drying steps, a material is formed which is marked by drifting of the primary charge over time and blurring of the point of zero salt effect.

Modeling these data with CD-MUSIC suggests that the affinity of electrolyte ions changes during aging of the primary material and that aggregational growth plays a role. We show that the particles' surfaces reflect the subtle changes occurring in the bulk material. Surface complexation modeling helps to decipher them, while classical spectroscopic and X-ray means hardly can.

Interaction of Eu(III) with calcite surfaces in presence of $NaNO_3$

S. HOFMANN[1]* AND T. STUMPF[2]

[1]Karlsruhe Inst. of Techn., Inst. for Nuclear Waste Disposal (KIT-INE), Eggenstein-Leopoldshafen, Germany (*correspondence: sascha.hofmann@kit.edu)
[2]KIT-INE, Eggenstein-Leopoldshafen, Germany

Calcite is one of the most abundant minerals in the earth's crust, playing an important role as a geochemical barrier in nuclear waste deposits. It is known to adsorb and even incoporate many metal ions including lanthanides and actinides [1, 2]. In this study, we present the influence of $NaNO_3$ on the calcite surface and the uptake of Eu(III), investigated by site-selective time resolved laser fluorescence spectroscopy (TRLFS) and atomic force microscopy (AFM).

Discussion of results

TRLFS measurements with Eu(III) as a molecular probe showed that the lanthanide ion is not incorporated into the calcite crystal itself. Excitation and emission spectra (Fig. 1) differ considerably from the well-known Eu^{3+}/calcite solid solution [3]. The fluorescence lifetime of this Eu^{3+}/NO_3^- /calcite species was determined to be 630 ± 50 μs, indicating the presence of only one water molecule in the first coordination shell of Eu.

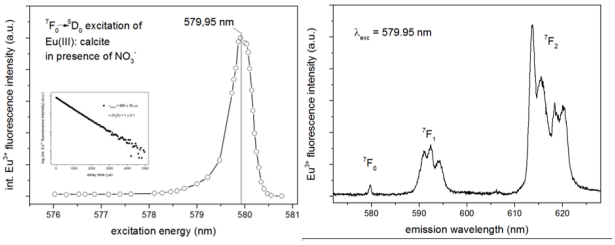

Figure 1: TRLFS excitation and emission spectra.

For further characterization of the influence of $NaNO_3$, calcite single crystals were equilibrated in aqueous $NaNO_3$ solutions (10^{-7} to 10^{-2} M) and measured *in situ* with AFM. Images of these samples reveal critical changes of the surface morphology (roughening of the facets and rounding of step edges). An amorphous, soft layer forms rapidly on top of the calcite lattice. Europium seems to be incorporated into this layer, which is about 0.8 ± 0.1 nm thick.

Using compound-specific isotope analysis to assess biodegradation of nitroaromatic explosives in the subsurface

RETO S. WIJKER[1,2], JAKOV BOLOTIN[1,2], SHIRLEY F. NISHINO[3], JIM C. SPAIN[3], AND THOMAS B. HOFSTETTER[1,2] *

[1]Eawag, Environmental Chemistry, CH-8600 Dübendorf, Switzerland, *thomas.hofstetter@eawag.ch
[2]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zürich, CH-8092 Zürich, Switzerland
[3]School of Civil & Environmental Engineering, Georgia Institute of Technology, Atlanta, GA 30332, USA

Assessing the fate of nitroaromatic explosives in soils and sediments is challenging because these contaminants are present in different phases, that is bound to the organic and mineral matrix or as solid-phase residues, and transformation takes place via several competing pathways over time-scales of decades. To infer the type and extent of biotransformation of nitroaromatic compounds (NACs) from the combined evaluation of their C, N, and H isotope signatures, we have developed procedures for compound-specific analysis of 2,4,6-trinitrotoluene (TNT), dinitrotoluene isomers (2,4-DNT and 2,6-DNT), and mono-nitrotoluenes in subsurface material from a contaminated site.

Because of repeated spill events during decades of site operation as well as the perturbed subsurface at the study site, neither concentration nor $\delta^{13}C$, $\delta^{2}H$, or $\delta^{15}N$ profiles provided evidence for transformation. Correlation of N vs. C and H vs. C isotope fractionation, in contrast, enabled to the identification of three biodegradation routes.

Indicative trends of $\Delta\delta^{15}N$ vs. $\Delta\delta^{13}C$ and $\Delta\delta^{2}H$ vs. $\Delta\delta^{13}C$ were obtained from laboratory model systems with pure cultures for reaction pathways initiated via (i) dioxygenation, (ii) reduction, and (iii) CH_3-group oxidation. The comparison of $\Delta\delta^{15}N$ vs. $\Delta\delta^{13}C$ from field and laboratory data enabled a distinction of reductive and oxidative transformation of TNT, 2,4-DNT, and 2,6-DNT while $\Delta\delta^{2}H$ vs. $\Delta\delta^{13}C$ was used to quantify the relative shares of dioxygenation and CH_3-group oxidation. Based on the apparent kinetic isotope effects of the three biodegradation routes, our data imply that 86-89% of 2,4-DNT transformation in the field was due to dioxygenation while TNT was mostly reduced to aminonitrotoluenes and 2,6-DNT reacted via a combination of reduction and CH_3-group oxidation. Isotopic and historic site information suggest biodegradation of 2,4-DNT with half-lives of up to 9 to 17 years compared to 18 to 34 years for co-metabolic transformation of TNT and 2,6-DNT.

Multi-proxy study of shallow- and deep-water Doushantuo carbonates, Yangtze Platform, South China

S.V. HOHL[1], H. BECKER[1], S. HERZLIEB[1], Q. GUO[2] AND A. GAMPER[3]

[1]Freie Univ. Berlin, Germany, shohl@zedat.fu-berlin.de
[2]Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing 100101, China
[3]Museum für Naturkunde, Berlin, Germany

The wide distribution of shallow and deep-water sedimentary facies has established the Yangtze Platform in South China as a key site for the study of ocean oxidation and Ediacaran animal evolution following the Marinoan glaciation. We have studied mineralogy, textures, major and trace elements and Sr-C-O isotopic compositions of carbonates of the Doushantuo formation from shallow- (Xiaofenghe, Hubei Province) and deep-water (Yanwutan, Hunan Province) sections in order to distinguish diagenetic overprint from primary signatures and to constrain compositional variations of Ediacaran seawater in space and time. Carbonate rocks from the lower part of Yanwutan section show elevated $^{87}Sr/^{86}Sr$ (0.7099 to 0.7220) and high Mn/Sr. Negative correlation of $^{87}Sr/^{86}Sr$ with $\delta^{18}O_{carb}$ in the upper part of the section indicates meteoric fluid-rock interaction. At Xiaofenghe, $^{87}Sr/^{86}Sr$ in cap carbonates (D1) is near 0.713, dropping to seawater-like ratios upsection (0.7079 in D3). REE+Y patterns of deep water slope facies carbonates at Yanwutan reveal preservation of seawater signatures, cap carbonates show no Ce anomalies, but high Eu/Eu* (1.9) and enrichment in MREE, which, given the high $^{87}Sr/^{86}Sr$, may reflect strong hydrothermal overprint. In contrast, the upper part of the section displays HREE enrichment, negative Ce, and variable positive Eu anomalies, indicating oxidizing conditions of deep water during this time interval. REE+Y patterns of carbonates at Xiaofenghe section are flat to variable HREE enriched, with Y/Ho_{PAAS} (>2.1), indicating the presence of a seawater signature. While the cap carbonates have no Ce anomalies, D2 and D3 carbonates show strongly negative Ce anomalies, indicating precipitation from an oxidized water column. A main conclusion from the data is that deep water of the Yangtze basin was oxidized as early as the middle Doushantuo, with likely anoxic conditions before that time. Fluid-mobile elements in deepwater sections are more overprinted than in shallow water sections, presumably by hot reducing fluids of variable origin. Although fluid-mobile elements (Ba, Sr, Ca, Mg) commonly show evidence for modification by post-depositional fluid flow, REE+Y in these rocks often preserve seawater signals.

Decay constants for dating

NORMAN E. HOLDEN[1]

[1]National Nuclear Data Center, Brookhaven National Laboratory, Upton, New York 11973-5000, USA

Two generations ago, the International Union of Geological Sciences (IUGS), through a sub-committee, recommended values for reporting isotopic data. A quarter century ago, the International Union of Pure and Applied Chemistry (IUPAC) recommended values for half-lives (decay constants) for a series of long-lived nuclides, many of which could be used for dating materials. The IUGS and the IUPAC recommendations differed in many cases. More than a decade ago, geochronologists began writing articles suggesting that updates should be made to the original IUGS recommendations because of the existence of more recent data on the original isotopic information that had been presented and because of the absence of any uncertainties that were associated with that data.

A few years ago, an inter-Union Task Group of members of IUGS and IUPAC was formed to make 'Recommendations for Isotopic Data in the Geosciences' and was approved by their Executive Boards. The rationale was similar, there were new data now available and the associated uncertainties need to be added to all recommended values.

The procedure for any recommendation of isotopic data would involve a re-evaluation of the measurement uncertainty budgets for each experiment, especially for the 'type-B' or non-statistical uncertainties, before combining the overall uncertainties and determining a recommended value. A number of isotopes will be discussed.

Deep fracture fluids isolated in the crust since the Precambrian

G.HOLLAND[1,2], B. SHERWOOD LOLLAR[3], L. LI[3], G. LACRAMPE-COULOUME[3], G.F. SLATER[4] AND C.J. BALLENTINE[1]*

Water bearing macrosystems that have been isolated from the surface and preserved on geological timescales (>10Ma) are seemingly rare. Nevertheless, the unique insight they provide into the evolution of chemolithotrophic life makes these systems important areas of study. The Witwatersrand Basin in the South African Precambrian Crystalline Shield provides the case type [1,2]. Here, we have determined the noble gas concentration and isotopic composition of 6 gas samples, co-produced with water, from deep exploratory boreholes in a producing mine in the Timmins region of the Canadian Precambrian Crystalline Shield.

We show that ^{124,126,128}Xe excesses in the Timmins mine fluids can be linked to Xe isotope changes in the ancient atmosphere [3] and can be used to calculate a minimum mean residence time for this fluid of ~1.5Ga. We also resolve in all samples a clear ^{129}Xe signal in excess of atmospheric values. Mass fractionation and U fission can be excluded as sources of ^{129}Xe, and a mantle source is unlikely. We postulate ^{129}Xe is sourced in carbon rich metamorphic material of sedimentary origin and extracted by fluid migration processes at ~2.64Ga. Neon isotopic compositions are similar to the Witwatersrand study and are used to validate the closed system assumption for the radiogenic noble gases [1]. Closed system radiogenic noble gas residence times are 1142±64,5 1655±789, 1498±784, 1610±825Ma for ^{4}He, ^{21}Ne, ^{40}Ar, ^{136}Xe respectively. Combined together, these complementary strands of evidence lend further support to the hypothesis that ancient pockets of water can survive the crustal fracturing process and remain in the crust for billions of years [4].

Influence of different organic carbon substrates on denitrification rates in riparian sediment

MELISA HOLLINGHAM[1]*, RAOUL-MARIE COUTURE[1,2], FEREIDOUN REZANEZHAD[1] AND PHILIPPE VAN CAPPELLEN [1]

[1]University of Waterloo, Waterloo, Ontario, Canada, (*correspondence: m.hollingham@gmail.com)
[2]Norwegian Institute for Water Research, Oslo, Norway

Nitrate (NO_3^-) is an ubiquitous groundwater contaminant in agricultural and wastewater discharge areas [1]. The prediction of microbially mediated NO_3^- removal in subsurface environments requires an understanding of the rates at which electron donors are utilized by denitrifying microbes [2]. This study focuses specifically on the following organic carbon compounds as electron donors: glucose, acetate, adenine, cysteine and fulvic acid. Six triplicate series of flow through reactors (FTRs) containing 35cm^3 of natural, organic-poor, riparian sediment were supplied for 10 weeks with solutions containing nitrate and the individual carbon compounds, along with a no-carbon added control. The organic carbon compounds were selected to yield a range of Gibbs Free Energy (ΔG) values when their oxidation is coupled to denitrification. The initial flow rate of the FTRs was 1 ml h^{-1}. Once steady NO_3^- concentrations were reached in the outflow, the flow rate was increased to 2 ml h^{-1} and, subsequently, 4 ml h^{-1}. Maximum potential denitrification rates (R_{max}) measured for the different carbon substrates spanned an order of magnitude, ranging from 0 to 91nmol cm^{-3} h^{-1}. Fulvic acid did not induce denitrification, while acetate yielded the highest rate. The outflow solutions for FTRs supplied with adenine and cysteine contained ammonia and sulfate, respectively. These results are consistent with the structure of the organic components of adenine, containing an amine, and cysteine, containing a thiol group. R_{max} values for the studied carbon substrates are relatively low compared to those in the literature for similar experiments, which have values ranging from 98 to 933 nmol cm^{-3} h^{-1} [3]. Most likely, the low rates reflect a low abundance of denitrifying organisms in the riparian sediment used.

Tectonic evolution of the Cerro Casale Cu-porphyry system, Chile: Implications for mineralisation

PETE HOLLINGS[1]*, HUAYONG CHEN[2,3] AND DAVID R. COOKE[2]

[1]Dept. of Geology, Lakehead University, Thunder Bay, Ontario, Canada, P7B5E1. (*correspondence: peter.hollings@lakeheadu.ca)
[2]CODES, ARC Centre for Excellence in Ore Deposits, Private Bag 126, Hobart, Tasmania 7001, Australia
[3]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Tianhe, PO Box 1131, Guangzhou, China

The Cerro Casale porphyry Cu-Au deposit is located at the southern end of the Maricunga belt, near the northern boundary of the modern nonvolcanic, flat-slab region of the Chilean Andes (28-33°S). Oligocene andesitic volcanic rocks in the Casale district have been intruded by the Cerro Casale, Roman, Eva, Estrella and Anfiteatro dioritic to granodioritic plutons, of which the Casale diorite is the main host to mineralisation (1300 Mt @ 0.7 g/t Au and 0.35% Cu).

U-Pb dating of zircon from the mineralized granodiorite yielded an age of 13.9 ± 1.1 Ma, consistent with previous Ar-Ar ages of 13.89 - 13.91 Ma from hydrothermal biotite and alunite [1]. Weakly mineralised to barren intrusions in the district range in age from 28 to 14 Ma, with a major porphyry-high sulfidation system forming at the Caspiche prospect ~10 km to the north in the late Oligocene, implying repeated mineralising episodes in the region.

The volcanic and intrusive rocks from the Casale district are predominantly medium-K andesites and diorites. The intrusive rocks show a trend to increasing Gd/Yb_n ratios in younger samples comparable to trends in Miocene rocks related to porphyry mineralisation in Central Chile interpreted to be the result of subduction of the Juan Fernandez ridge and associated slab flattening [2]. ε_{Nd} values for the intrusive rocks are uniformly negative (-0.6 to -2.8), consistent with contamination by older crustal sources, and show a weak trend to less negative values with time. $^{87}Sr/^{86}Sr_i$ values range from 0.70490 to 0.70547 and increase in younger intrusions. The less negative ε_{Nd} in the younger intrusions in conjunction with a slight increase in Ni contents suggests a more primitive source for the mineralising magmas.

Khatyrka occurs as clastic grains within clay-rich layers along the banks of a small stream in the Koryak Mountains of far eastern Russia. The recovered grains share in common the presence of metallic Cu-Al-Fe alloys that include the quasicrystalline phase icosahedrite ($Al_{63}Cu_{24}Fe_{13}$), along with khatyrkite ($CuAl_2$) and cupalite (CuAl). Some of the ~ mm-sized meteorite grains clearly are CV3 (oxidized) chondrite fragments having Type IA porphyritic olivine chondrules enclosed in matrices that have the characteristic platy olivine texture, matrix olivine composition, and mineralogy of oxidized-subgroup CV3 chondrites. Other grains are fine-grained spinel-rich calcium-aluminum-rich inclusions (CAIs) with spinel oxygen isotopic compositions ($\Delta^{17}O$ ~ -19 – -23 ‰) typical of such objects in CV3 chondrites. One grain is an achondritic intergrowth of Cu-Al-Fe metal alloys with forsteritic olivine ± diopsidic pyroxene. The latter, along with silicates from the chondritic grains, have ^{16}O-enriched ($\Delta^{17}O$ ~ -4 – -8 ‰) oxygen isotopic compositions that plot on the CCAM mixing line in the region occupied by bulk CV3 chondrites [1, 2]. Finally, some grains consist almost entirely of Cu-Al-Fe alloys The Cu-Al-Fe metal alloys and the alloy-bearing achondrite clast are either a unique accretionary component of what otherwise is a fairly normal CV3 (oxidized) chondrite, or else formed in place via an as-yet undetermined process. Either way, the reducing conditions required to form such metallic aluminum-bearing alloys are approximately those of a hot gas of solar composition. Understanding what specific process(es) formed these alloys of two such cosmochemically-dissimilar elements as aluminum and copper remains the focus of our on-going research program.

Fe(II) in early abiotic processes

NILS G. HOLM

Department of Geological Sciences, Stockholm University, SE-106 91 Stockholm, Sweden; (nils.holm@geo.su.se)

Recently, it was suggested that Fe(II) preceded Mg(II) as an efficient co-factor in prebiotic catalysts on the early Earth [1]. Mg(II) has a special role in the folding and catalysis of biomolecules such as RNA because of its small size and ability to coordinate six oxygen atoms, including oxygens in oxyanions, in its first coordination shell [2]. In principle, Fe(II) can replace Mg(II) in this function and be even more efficient [1], but on Earth today Fe(II) is quickly oxidized to Fe(III) in the presence of molecular oxygen. However, before the Great Oxidation Event about 2.5 Ga Fe(II) would have been abundant in aqueous systems. Iron metabolism in modern organisms is controlled by small RNAs molecules (sRNA) [3]. Because of the ability of Fe(II) to coordinate oxyanions, Fe(II) minerals can catalyze the formation of pyrophosphate from activated phosphate compounds, such as acetyl phosphate, and inorganic phosphate [4]. It has also been found, that even though modern deep-sea water is oxidized, Fe(II) originating in hydrothermal fluids are stabilized because of its affinity to lipids, polysaccharides and proteins [5]. Abiotic formation of acetyl phosphate has been reported. It is, therefore, likely that Fe(II) would have been a powerful component in the formation of pre-RNA types of information molecules in early life systems.

Compositional constraints on the mantle below part of the Andes SVZ

P.M. HOLM[1]*, N. SØAGER[1] AND C.T. DYHR[1]

[1]Institute of Geosciences and Natural Resource Management, Univ. Copenhagen, Ø. Voldgade 10, DK-1350 Copenhagen, Denmark
(*correspondence: paulmh@geo.ku.dk)

This contribution discusses along and across arc differences in Pleictocene-Recent volcanic rocks of the SVZ based on new major and trace element and Sr, Nd and Pb isotope data from the T- and N-SVZ. We limit our discussion to little evolved compositions with high Mg#. Dispite their primitive character most of these arc magmas display a strong negative correlation between silica and Ba/Th. Relative HFS-depletion is not caused by residual rutile is demonstrated by La-Nb systematics. Therefore, the relative enrichment in LILEs and LREEs is a reflection of source compostion and show that that continental material with e.g. low Ba/Th rather than fluid was added to a source. The pre-enrichment mantle was more depleted in the C-NVZ than in the more northern T- and N-SVZ. Furthermore, all mantle below the arc is distinctly more depleted than the back-arc mantle, and compositional variation is thus indicated both N-S and E-W. Isotopically the depleted end-member is comparable to South Atlantic MORB mantle. Two distinctly different isotopically enriched endmembers show a similar elemental crustal signature. A Pb, Sr and Nd isotopic array of the northern backarc to T-SVZ arc magmas allow the arc-backarc mantle to be identified as distinct from the upwelling enriched Río Colorado component (Søager *et al*, in prep.). There is a general decrease in water soluble components away from the trench. This may indicate that the fluid enriched source is generated over a more shallow part of the subducting slab than the crust enriched source. We model the crustal component that is added to the source as melts of subduction eroded continental crust that reacted with the overlying mantle.

Tracing the rise of atmospheric oxygen using Cr isotopes in carbonates as a paleoredox proxy

C. HOLMDEN[1] AND A.D. BEKKER[2]

[1]Saskatchewan Isotope Laboratory, Department of Geological Sciences, University of Saskatchewan, SK, S7N 5E2 CANADA (*correspondence: chris.holmden@usask.ca)
[2]Department of Geological Sciences, University of Manitoba, MB, SK R3T 2N2 CANADA (bekker@cc.umanitoba.ca)

The Great Oxidation Event (GOE) is now well-constrained in age to ca. 2.4–2.3 Ga, but questions remain whether the pathway to oxidized surface environments was gradual, oscillatory with transient oxidation events, or stepwise. Various proxies, including fractionation of Cr isotopes in iron formations (Frei *et al*, 2009), have been used to infer, at least locally, the development of oxidizing conditions as early as 2.7 Ga. Alternatively, Konhauser *et al* (2011) argued that Cr concentrations were low in iron formations until 2.5-2.3 Ga when acidic groundwaters formed in response to the GOE and delivered reduced Cr to shallow-water environments.

Here, we tested whether δ^{53}Cr values in shallow-water carbonates spanning the GOE might also record steps in the rise of atmospheric oxygen. Cr isotopes are fractionated by redox reactions such as those occuring during Mn-mediated Cr oxidation on the continents or Cr reduction in anoxic marine environments. In the absence of molecular oxygen, the range of Cr isotope fractionation in exogenic materials would likely be confined to the range of igneous rocks (δ^{53}Cr = –0.1 ± 0.1‰). Carbonates from 15 formations were chosen with depositonal ages ranging between 2.5 Ga and 1.9 Ga. Carbonate is more abundant than iron formation in the rock record, but there are pitfalls with carbonate-hosted seawater records that must be borne in mind. These include dolomitization, local cycling effects, depositional fractionation, and detrital sediment contamination.

δ^{53}Cr data collected, thus far, show no fractionation in samples older than 2.4 Ga, a very mild amount of fractionation at ca. 2.3 Ga of ~0.1‰, and permil level fractionation at 2.15 Ga in the peak inerval of the Lomagundi carbon isotope excursion. Interestingly, the fractionations are both positive and negative relative to δ^{53}Cr in igneous rocks. Although fractionated Cr may be hosted in both carbonate and lithogenic components, Cr/Al ratios support the predominantly authigenic origin of the Cr in the carbonate fraction. These data are consistent with acidic weathering at the beginning of the GOE and Mn-mediated Cr oxidation during the Lomagundi carbon isotope excursion.

The Hf-W chronology of FUN CAIs

J. C. HOLST[1], M.B. OLSEN[1], C. PATON[1], K. NAGASHIMA[2], M. SCHILLER[1], D. WIELANDT[1], K.K. LARSEN[1], J. N. CONNELLY[1], J. K. JØRGENSEN[1], A.N. KROT[1,2], Å. NORDLUND[1] AND M. BIZZARRO[1]

[1]Centre for Star and Planet Formation, University of Copenhagen, Copenhagen, Denmark.
[2]Institute of Geophysics and Planetology, University of Hawaii at Manoa, HI 96822, USA

Refractory inclusions (CAIs) represent the oldest solar system solids and provide information regarding the formation of the Sun and its protoplanetary disk. CAIs contain evidence of now extinct short-lived radioisotopes synthesized in one or multiple stars and added to the protosolar molecular cloud before or during its collapse. Understanding the origin of short-lived radioisotopes is necessary to assess their validity as chronometers and constrain the birthplace of the Sun. Whereas most CAIs formed with the canonical abundance of ^{26}Al corresponding to ^{26}Al/^{27}Al of ~5×10^{-5}, rare CAIs with fractionation and unidentified nuclear isotope effects (FUN CAIs) [1] record nucleosynthetic isotopic heterogeneity and ^{26}Al/^{27}Al of $<5\times10^{-6}$, possibly reflecting their formation before canonical CAIs [2]. Thus, FUN CAIs may provide a time-window into the earliest solar system, but their chronology is unknown.

Using the ^{182}Hf-^{182}W chronometer, we show that a newly discovered FUN CAI, dubbed STP-1, formed coevally with canonical CAIs [3], but with ^{26}Al/^{27}Al of ~3×10^{-6}. Moreover, the mineralogy and the group II rare earth element (REE) pattern coupled with a ^{16}O-rich composition, suggest that the precursor material of STP-1 formed by condensation from a gas of solar composition depleted in the most refractory REEs, similar to fine-grained CAIs. The level of ^{26}Al/^{27}Al in STP-1 is higher than the galactic background and suggests that our Sun formed as part of a cloud that was chemically enriched by earlier generations of massive stars. The observed decoupling between ^{182}Hf and ^{26}Al requires distinct stellar origins: steady-state galactic stellar nucleosynthesis for ^{182}Hf and late-stage contamination of the protosolar molecular cloud by a massive star(s) for ^{26}Al. Admixing of fresh stellar-derived ^{26}Al to the protoplanetary disk occurred during the epoch of CAI-formation and, therefore, the ^{26}Al-^{26}Mg systematics of CAIs cannot be used to define their formation interval. In contrast, our results support ^{182}Hf homogeneity and the chronological significance of the ^{182}Hf-^{182}W clock.

Microbially-induced carbonate precipitation, Moodies Group (3.2 Ga, BGB, South Africa)

M. HOMANN[1]*, C. HEUBECK[1], A. AIRO[1], M. TICE[2] AND S. NABHAN[1]

[1]Freie Universität Berlin, Institute of Geological Sciences, Malteserstr. 74-100, 12249 Berlin, Germany (*correspondence: martin.homann@fu-berlin.de)

[2]Texas A&M University, College Station, Texas 77843, USA (mtice@geos.tamu.edu)

The Archean Moodies Group, Barberton Greenstone Belt (BGB), ~3.2 Ga, represents Earth's oldest known tidally influenced siliciclastic sequence and includes well-preserved microbial mats which can be traced laterally for >15 km.

We investigated the microstructure of crinkly intertidal-facies mat morphotypes and tufted supratidal-facies mats, both preserved as abundant kerogenous laminae ~1mm thick overlying individual depositional events in medium- to coarse-grained sandstones. Mats are widely underlain by up to 40 cm long and few mm-thick monomineralic layers; microbial tufts (1-2 cm in height) show increased calcification within their interior. XRF elemental scanning of fresh slabbed and polished handsamples indicates (1) that the monomineralic layers underlying the microbial mats consist of pure carbonate (calcite, dolomite), now largely replaced by microcrystalline quartz, and that (2) Fe is enriched in the kerogenous mat remnants. SEM observations of freshly exposed kerogenous surfaces show interwoven, bundled and twisted filaments 1-3 μm in diameter, confirming mat biogenicity.

The close association of carbonate layers and microbial mats suggests that mat metabolic activity promoted their formation. An autotrophic metabolism, such as CO_2 fixation, would have increased the alkalinity of the pore fluid beneath the mat and induced carbonate precipitation. Alternatively or additionally, carbonate could have formed as a byproduct of a Fe-reducing metabolic pathway. Middle Archean photic-zone filamentous microbial mats may have, at least in its upper layers, employed a photosynthetic strategy.

Trace metal inputs from river-fed and river-starved margin sediments of the South Atlantic Ocean

Trace metal exchange between sediments and seawater may play an important role in providing micronutrients to the ocean. Continental margin fluxes of metals such as Fe remain poorly constrained but may be important in the global carbon cycle [1]. A selection of micronutrient trace metals have been measured in porewaters and sediments from the slopes on both sides of the South Atlantic Ocean to determine such margin fluxes to a region of high primary productivity in the surface ocean. Intact surface sediments were collected by coring activities on two UK GEOTRACES expeditions (D357 and JC068; GA10) from 12 sites between the River Plate-fed Uruguyan margin and the comparatively river-starved Cape margin of South Africa.

Macronutrient and micronutrient concentrations are principally coupled to organic carbon oxidation at all sites. Fe and Mn inputs to the South Atlantic are calculated from the relationship between porewater metal and high-resolution oxygen data. Dissolved fluxes of Fe and Mn on the Uruguyan and South African margins have notable differences in their magnitude and down-slope distribution. We show the variability of metal supply reflects (a) enhanced organic carbon respiration on the river-fed Uruguyan margin, and (b) the depleted metal substrate reservoir on the comparatively river-starved Cape margin of South Africa. This study provides new constraints on dissolved micronutrient inputs to South Atlantic deep waters which subsequently upwell in the Fe-starved Southern Ocean. It also provides information about the general role of sediments in micronutrient fluxes to seawater.

Diffusive fractionation of lithium isotopes in polycrystalline olivine

V HOMOLOVA* AND E B WATSON

Department of Earth and Environmental Sciences, Rensselaer Polytechnic Institute, Troy, NY 12180, USA (*correspondence: homolv@rpi.edu)

Diffusive fractionation of Li isotopes has recently been reported in silicate melts, aqueous fluids and single crystals [1, 2, 3]. Here, we present an experimental study which investigates diffusive fractionation of Li isotopes in polycrystalline olivine. The experimental procedure consists of annealing oxide powders in an iron capsule at 1.4 GPa and 1250˚C for 48 hours. The annealing step produces a synthetic rock comprising olivine (Fo90) plus 15 wt% pyroxene (En92), with grains 50 - 75um in diameter. The capsule is then sectioned, polished and juxtaposed to a spodumene powder, which acts as the Li source. The diffusion couples were held at 1.4 GPa and 700 - 1000˚C for 12 - 120 hours. Li abundances and isotopic (7Li/6Li) profiles were analyzed using LA-ICP-MS.

Maximum lithium abundances measured near the Li source in the olivine and pyroxene reach ~550 and ~700 ppm, respectively. Li abundances decrease as a function of distance from the source to the background Li concentration of ~3 ppm. Preliminary data suggest an effective diffusivity of Li in polycrystalline olivine plus pyroxene of ~5E-13m^2/s at the highest temperature investigated. In both olivine and pyroxene, 7Li/6Li ratios decrease linearly or in a concave down fashion for the entirety of the diffusion profile before abruptly jumping back up to the initial isotopic ratio of the synthetic rock. This decrease in 7Li/6Li along the diffusion profile is similar to previous studies investigating diffusive fractionation of Li isotopes and suggests a higher diffusivity of 6Li relative to 7Li. The shape of the isotopic profile may be replicated well with a model previously developed by [3] for Li diffusion with reaction in single crystal olivine, in which Li simultaneously diffuses via two different mechanisms. Application of the data to diffusive transport of Li in the upper mantle will be discussed. Experiments at higher temperature and utilizing alternate Li sources are underway.

Abrupt variations of Indian and East Asian summer monsoons during the last deglacial stadial and interstadial

B. HONG[1]*, Y.T. HONG[1], M. UCHIDA[2], Y. SHIBATA[2] AND Y.X. ZHU[1]

[1] Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: hongbing@vip.skleg.cn)

[2] National Institute for Environmental Studies, Onogawa 16-2, Tsukuba, Ibaraki 305-0053, Japan

The recent study comparing marine and terrestrial palaeoclimate records from South Asia suggests that during the deglaciation the ISM fluctuated widely, with weaker monsoons during colder episodes, such as the Younger Dryas (YD), and stronger monsoons during warmer episodes, such as the Bølling-Allerød (BA) [1]. However, this study does not cover the palaeoclimate records from some East Asian regions influenced by the Indian Summer Monsoon (ISM), such as the Tibetan Plateau and its adjacent regions, and it does not include the activity of the East Asian Summer Monsoon (EASM). Another study on global climate evolution during the last deglaciation briefly discusses the behaviours of the ISM and EASM during the transient period and mainly focuses on the results of a few stalagmite ^{18}O records from the southern Chinese mainland [2]. To complement these studies, we present a continuous peat cellulose $\delta^{13}C$ record of ISM covering the past 15000 years. By comparing this record with a variety of other monsoon proxy records, especially with the EASM proxy records published in recent years, we attempt to clarify the abrupt variation, phase relationship, and possible forcing mechanisms of two Asian monsoons during the last deglaciation.

Distribution, Fluxes in the water column and early diagenesis in the bottom sediments of ^{210}Po and ^{210}Pb in the sea

G.H. HONG[1]*, H.M.LEE[1], M. BASKARAN[2], S.H.KIM[1], Y.I.KIM[1] AND C.J. KIM[1]

[1]Korea Institute of Ocean Science and Technology,, Ansan 426-744, R. Korea (correspondence: ghhong@kiost.ac)
[2]Wayne State University, Detroit, MI 48202, U.S.A.(baskaran@wayne.edu)

The ^{210}Po activity, granddaughter of ^{210}Pb activity, has been widely studied to elucidate various oceanic processes, such as quantifying the scavenging and removal of particle-reactive species including organic matter. The deficit and excess of ^{210}Po with respect to its grandparent ^{210}Pb in dissolved and particulate phases in the surface ocean is well documented through the ocean. However, in deep waters below 1000 m, secular equilibrium between ^{210}Po and ^{210}Pb was observed in some areas, but a large deficiency of ^{210}Po with respect to ^{210}Pb in dissolved phase was also observed in several places in the world ocean. Recent efforts were made extensively by GEOTRACES [1, 2] to resolve the unresolved issues in determination of ^{210}Po and ^{210}Pb remaining from the earlier GEOSECS studies in late 1970s. He we report new measurements of dissolved, particulate, and sediment porewater ^{210}Po and ^{210}Pb in a deep marginal sea in the Northwest Pacific (East Sea/Japan Sea) using the state of the art measurement methods considering all relevant correction factors in the calculation of the final *in situ* their activities provided by GEOTRACES ^{210}Po/^{210}Pb group. The earlier discrepancy may be resolved as we can generalize the vertical distribution of dissolved ^{210}Po with respect to dissolved ^{210}Pb in the sea as the surface deficit, subsurface excess and secular equilibrium below the 500 m or 1000 m depth based on our measurements with great variation of total activities due to their variation in the sources as well as the amount of suspended particulate matter in the water column. An order of magnitude greater concentration of dissolved ^{210}Po and ^{210}Pb concentration activities were present in the interstitial waters of the bottom sediment with ^{210}Po deficit or excess with respect to ^{210}Pb in the East Sea. Detailed quantitative analysis on the distribution, chemistry, flux, and early diagenesis be presented at the meeting.

Redox behavior of uranium incorporated into hematite

DERRELL HOOD[1], YI WEN[1], LINDSAY SHULLER-NICKLES*[1]

[1]Clemson University, 342 Computer Court, Anderson, SC, USA 29625 (*correspondence: lshulle@clemson.edu)

The development of long-term geological waste repositories is an important response to ever increasing amounts of spent nuclear fuel. One of the principle considerations at any potential storage site is the possibility for radionuclides to leach from waste forms and undergo sub-surface transport. The solubility of radionuclides in the repository environment, their redox behavior, and possible incorporation into proximal mineral phases are inter-related mechanisms that synergistically affect the subsequent hydrological transport of the nuclides.

It has been shown that U(VI) can be incorporated into bulk hematite with a similar coordination environment as Fe(III) [1,2]. In this study, we analyze the incorporation of U(VI) into hematite as a possible mechanism of limiting the aqueous uranyl concentration in contaminated areas. Atomistic simulations were conducted to evaluate the incorporation mechanism (*i.e.*, substitution reaction energies and substitution geometries). The redox behavior of uranyl incorporated into bulk hematite was investigated using cyclic voltametry with a powder microelectrode. In addition, the redox behavior of uranyl incorporated into hematite is compared with that of uranyl at the hematite surface to evaluate the role of hematite as a uranyl host and as a substrate for uranyl sorption, reduction and precipitation.

The sample was preconditioned for thirty minutes at –0.25V and scanned between ±0.7 V at a rate of 50 mV/s. Under these conditions, uranyl was observed to undergo an irreversible oxidation from U(IV) to U(VI) on the first positive voltage scan. Subsequent cycles indicate reduction and re-oxidation between U(VI) and U(V). Similar experiments examined uranyl in solution with hematite and measured comparable uranyl redox behavior. Due to the strong relation between uranium solubility and oxidation state, these initial results are significant with regards to potential aqueous uranyl immobilization.

Os isotope constraints on crustal contamination in Auckland Volcanic Field basalts, New Zealand

J.L. HOPKINS[1]*, A. POIRIER[2], M-A. MILLET[3], C. TIMM[4], G. LEONARD[4] AND C.J.N. WILSON[1]

[1]SGEES, Victoria University of Wellington, PO Box 600, Wellington, New Zealand. (*jenni.hopkins@vuw.ac.nz)
[2]GEOTOP, Université du Québec à Montréal, Montréal, Canada
[3]Origins Laboratory, Department of the Geophysical Sciences, University of Chicago,USA
[4]GNS Science, Lower Hutt, New Zealand

Basalts from the monogenetic Auckland Volcanic Field (AVF) have been inferred to derive from the partial melting and mixing of varying proportions of three distinct components from within two mantle sources: (a) ambient asthenospheric mantle consisting of mid ocean ridge-like peridotite containing HIMU-type eclogitic domains (recycled oceanic crust); and (b) a subduction metasomatised lithosphere[1]. However the contribution of lithospheric (mantle and crust) contamination has not been assessed in detail. We present Re-Os isotope systematics of basalts representative of the range in the AVF geochemistry and use the differences of Os isotope systematics between crust and mantle derived lithologies to assess the extent of lithospheric contamination in these data.

Our results show there is a large range in Os concentrations (6-579ppt) and $^{187}Os/^{188}Os$ isotope ratios (0.123-0.547). $^{187}Os/^{188}Os$ vs. $1/^{188}Os$ diagram shows a broad positive trend (decreasing Os concentration and increasing Os isotope ratio). Samples showing only little contamination also display $^{187}Os/^{188}Os$ values (0.128-0.138) similar to or slightly higher than average mantle values (0.121-0.128), consistent with their derivation from partial melting of a peridotitic source containing HIMU-type eclogitic/pyroxenitic domains. The more radiogenic Os isotopic compositions (>0.15) and low Os content, entirely decoupled from tracers of the mantle sources under the AVF are suggestive of contamination of asthenospheric mantle-derived magmas by assimilation of continental crust during ascent.

Ancient thermal events on 4 Vesta recorded in zircon U-Th-Pb-Ti depth profiles from a brecciated eucrite

M. D. HOPKINS[1]*, S. J. MOJZSIS[1,2,4], W.F. BOTTKE[3,4] AND O. ABRAMOV[5]

[1] University of Colorado, Geol. Sciences, Boulder, CO USA (*correspondence: michelle.hopkins@colorado.edu)
[2] Laboratoire de Géologie de Lyon, ENS & UCBL1, France
[3] Southwest Research Institute, Boulder, CO, USA
[4] Center for Lunar Origin and Evolution, NLSI
[5] United States Geological Survey, Flagstaff, AZ, USA

Zircons in asteroidal meterorites are rare, but a modest number have been previously documented, including those in the howardite-eucrite-diogenite (HED) achondrite group. The HEDs probably originate from 4 Vesta. Sub-micrometer distributions of trace elements (Ti, U, Th) and $^{235,238}U$-$^{207,206}Pb$ ages were investigated in four zircons (>7-40 μm ∅) separated from bulk samples of Millbillillie, a brecciated eucrite. Ultra-high resolution (sub-μm) ion microprobe depth profiles reveal different age domains correlative to mineral chemistry in cores and mantles within individual zircons. These compositional differences (e.g. $[Th/U]_{zrc}$ and Pb* isotope discordance) can be related to ancient thermal events to the crust of the parent body asteroid. Our results confirm that the crust of 4 Vesta solidified within a few million years after the formation of CAIs (4561±13 Ma), in good agreement with previous work. Subsequent zircon age re-setting occurred less than 40 Myr later (ca. 4530 Ma), which has also been seen in some $^{40\text{-}39}Ar$ age plateaux [1]. Analytical modeling shows that for a single impactor to be responsible for this effect, it had to have been ≥10 km in diameter and at high enough velocity (>5 km s^{-1}) to account for the thermal field required to re-crystallize zircon. Model output also shows that the thermal regime from impact could have penetrated at least 10 km into Vesta's crust. Later events at ca. 4200 Ma have been recorded in an HED apatite $^{235,238}U$-$^{207,206}Pb$ age [2] and $^{40\text{-}39}Ar$ age spectra [3]. These younger ages, as well as those coinciding with the Late Heavy Bombardment (LHB; ca. 3900 Ma) are not present in Millbillillie zircon. This is attributable to differences in mineral closure temperatures (T_c zircon >> apatite) and changes to the velocity distributions of impactors in the asteroid belt during and after the LHB.

Early diagenetic alteration of zeolites in subseafloor sediment of the South Pacific Gyre

BRYCE HOPPIE* AND ALYSSA WITT

Department of Chemistry and Geology, Minnesota State University, Mankato, Minnesota 56001 USA (*correspondence: bryce.hoppie@mnsu.edu)

Zeolite minerals are distributed throughout much of the subseafloor sediment of the South Pacific Gyre (SPG). Previous studies of deep-sea zeolites suggest that they form through the early diagenetic alteration of volcanic debris within the first meter of the subseafloor and subsequently undergo dissolution at burial depths exceeding 50 m. In SPG subseafloor sediment, porosities frequently exceed 80% and pore water residence times are greater than 10^5 years. Consequently, substantial opportunities exist for zeolites beneath the SPG to undergo post-depositional mineral-to-pore water interactions.

For this study, over 1,200 randomly selected zeolite crystals were isolated from clay-rich samples of SPG subseafloor sediment obtained during IODP Expedition 329. Crystals were analyzed using optical microscopy, SEM-EDS, and X-ray diffraction techniques. Strata were found to include the zeolite minerals phillipsite, $(Na, K)_2 (Mg, Ca) Al_6Si_{10}O_{32} \bullet 12H_20$, and harmotome, $(Na, K)_2 (Ba, Mg, Ca) Al_5Si_{11}O_{32} \bullet 12 H_2O$. The zeolites generally exhibit up to 100x increases in prismatic length within the first 4 to 15 m below the seafloor. Larger mean diameters of the phillipsite crystals correspond to elevated $[K^+]$ and $[Si^{4+}]$ whereas increased $[Ba^{2+}]$ corresponds to smaller harmotome crystals. Individual crystal volumes exhibit no consistent trend versus burial depth and do not correlate to euhedralism, a proxy for crystal dissolution; sub- and anhehdral crystals are found at all depths and are particularly prevalent in the upper 10 to 25 m of the western study sites. All crystals maintain overall charge balance; however, none of the alkali or alkaline earth elements within the zeolites vary consistently with the other cations of similar electron valence or with $[Al^{4+}]$ or $[Si^{4+}]$.

These results show that SPG subseafloor zeolite minerals are not uniform or predictably variable with respect to their textural attributes or composition. Furthermore, they do not readily corroborate previous explanations of deep-sea zeolite diagenesis. Although the observed mineral characteristics could derive from local, shallow subsurface environmental disparities, they are also suggestive of cation-change and non-uniform interactions among zeolites and pore water within the SPG subseafloor environment.

A comparison of geothermometers for shallow silicic magmas

J.M. HORA[1]*, G. WÖRNER[1], A. KRONZ[1], AND A. K. SCHMITT[2]

[1]GZG-Abt. Geochemie, Georg-August Universität, 37077 Göttingen, Germany (* correspondence: jhora@gwdg.de)
[2]Department of Earth and Space Sciences, University of California, Los Angeles, CA 90095, USA

Several geothermometers can be applied to silicic systems. Aside from 'traditional' two phase thermometers, recent calibrations involving partitioning of Si, Ti, and Zr among quartz, titanite, and zircon offer the promise of being able to extract T-t paths from zoned crystals. Recognition of P, a_{TiO2} a_{SiO2} dependence have resulted in some controversy and revisions to these thermometers over the past few years. Difficulty in testing calibrations of these thermometers lies in having to assume values of input variables such as P and activities of components when comparing to only one or two other thermometers. Another complication is that the chemical species involved in various thermometers diffuse at different rates, and may result in comparing temperatures locked in at different times during a cooling history.

By choosing a natural system where there are more applicable thermometry equations than free variables (e.g. P, component activities), we can evaluate consistency of results among thermometers in the contexts of (a) differing diffusivities, (b) testing various calibrations of the same thermometer, and (c) a magmatic thermal history. We compared Fe-Ti oxide, amhibole, amphibole-plagioclase, two-feldspar, Zr-in-titanite, Ti-in-zircon, and Ti-in-quartz thermometers in rhyodacite dome lavas at Parinacota volcano, Chile. This also includes thermometry of U-Th-dated zircon with crystallization ages ranging from >350 ka to near-eruption (~47 ka), and oxide inclusions in titanite. This comparison indicates: (a) good agreement (T = 740-760°C) among phases where diffusion is slow when P = 3.5kbar, a_{TiO2} = 0.85, a_{SiO2} = 1, interpreted as conditions of crystallization, (b) progressively lower temperatures with increase in diffusivity (quartz ≈ 720°C, oxides ≈ 710°C), likely reflecting latest storage and syn-eruption temperatures, respectively; and (c) both the pressure-dependences of the Ti-in-zircon thermometer suggested by [1] and [2] agree with other thermometers, whereas the calibration of Ti-in-quartz by [3] produces the most consistent results at the low pressures and temperatures experienced by these magmas.

Improved Pd-Ag isotopic systematics by MC-ICP-MS

M.F. HORAN*[1], R.W. CARLSON[1] AND M.SCHÖNBÄCHLER[1,2]

[1] Carnegie Institution of Washington, Washington DC 20015 (*correspondence: mhoran@ciw.edu)
[2]ETH Zürich, 8092 Zürich, Switzerland

The short-lived ^{107}Pd-^{107}Ag radiogenic decay system has been used to date volatile depletion, crystallization and shock in meteorites. Palladium is siderophile with a condensation temperature (T_c) similar to Fe-metal alloy, while Ag is chalcophile with T_c several hundred degrees lower. The contrasting characteristics allow Pd-Ag data to provide chronologic information on early solar system processes complementary to that provided by other long- and short-lived systems.

Early Pd-Ag measurements by thermal ionization mass spectrometry (TIMS) yielded the first internal isochron for high Pd/Ag Group IVA iron meteorites [1]. Because Ag has only two isotopes, however, the inability to correct for instrumental mass bias limited precisions in ^{107}Ag/^{109}Ag by TIMS to 10-20 ε units (parts in 10,000). Over the past decade, our group refined a technique for MC-ICP-MS measurements of Ag isotopic composition by Faraday cup using added Pd to correct for mass bias [2,3]. External precision for tens of ng of Ag initially was ±1.3 ε, which allowed resolution of the ^{107}Pd decay contribution to the Ag isotopic compositions in low Pd/Ag iron meteorites and pallasites. Subsequent use of wet plasma, instead of desolvation, produced more constant mass bias of Ag relative to Pd, yielding precisions of ±0.5 ε, and showed Pd/Ag correlated with Ag isotope compositions in carbonaceous chondrites, but also many epsilon units of natural Ag mass fractionation effects in ordinary chondrites. [3,4]

To measure low Ag abundances (100s of pg) in volatile depleted irons, we used simultaneous collection of Ag isotopes by ion multipliers on the Nu Plasma MC-ICPMS. Mass bias was corrected by comparison with Ag standards without added Pd. Although precision was only ±10 ε, a precise solar system initial ^{107}Pd/^{108}Pd of 2.8(±0.3) x 10^{-5} was obtained from the Group IVA iron Muonionalusta by assuming that the Pd-Ag system closed at its ^{207}Pb-^{206}Pb date (4565.3±0.1Ma). Pd-Ag systematics indicated the interval between volatile depletion and crystallization in the IVA parent body was short, <0.5Ma, suggesting that volatile depletion occurred during planetesimal breakup[5].

Reduction process of Cr(VI) by Fe(II) and humic acid using high-time resolution XAFS analysis

MAYUMI HORI*, KATSUMI SHOZUGAWA, AND MOTOYUKI MATSUO

Graduate School of Arts and Sciences, The University of Tokyo, Tokyo 153-8902, Japan
(*correspondence: 5953061388@mail.ecc.u-tokyo.ac.jp)

The reduction of Cr(VI) to Cr(III) starts immediately when Cr(VI) is released in the soil. However, Cr(VI) species have high mobility in subsurface soil, so the behavior of Cr (VI) released in the soil is not well understood. In this study, we clarified the detailed initial reduction process at high time resolution.

Three kinds of samples were prepared, 1) Fe(II) pellet, 2) humic acid (HA) pellet, 3) Fe(II)-HA pellet which contributed to Cr(VI) reduction in soil, and then they were spiked with Cr(VI) solution. In order to estimate the initial reduction process of Cr(VI) in samples, we continuously observed the valence of Cr and the concentration of Cr(VI) in samples after spiking Cr(VI) solution by measuring consecutively by Quick X-ray absorption fine structure (QXAFS) for several hours.

The decrease of concentration of Cr(VI) was observed for all samples just after Cr(VI) was spiked to samples. However, the reduction of Cr(VI) with Fe(II)-HA experiment showed reduction process unlike both Fe(II) and HA experiment, because of HA could also reduce Fe(III) to Fe(II). 97 % of total Cr(VI) was reduced to Cr(III) in 140 min. There were three phases of reduction processes. Firstly, there was an immediate sharp decrease of concentrations of Cr(VI), which means rapid reduction reaction. And then, the concentration of Cr(VI) gradually decreased. Thereafter, the concentration of Cr(VI) decreased sharply again, the reduction reaction was rapid. In the first phase, Cr(VI) was rapidly reduced by both Fe(II) and HA. In the second phase, Cr(VI) was mainly reduced by Fe(II). In the third phase, Cr(VI) was reduced by Fe(II), which was reduced by HA. The reduction reaction became rapid again due to increase of Fe(II). We clarified that the initial reduction process consisted of three phases, and Fe(II) and HA do different contribution to reduction of Cr(VI) in each phase.

Geochronological evidence of rapid progression of regional metamorphism in Hida Metamorphic Complex, southwest Japan

K. HORIE[1]*, M. TAKEHARA[2], Y. TSUTSUMI[3] AND M. CHO[4]

[1]National Institute of Polar Research, Japan (*correspondence: horie.kenji@nipr.ac.jp)
[2]Department of Earth and Planetary Sciences, Kyushu University, Japan (3sc12025r@s.kyushu-u.ac.jp)
[3]National Museum of Nature and Science, Tokyo, Japan (ytsutsu@kahaku.go.jp)
[4]Seoul National University, Seoul, Korea (moonsup@snu.ac.kr)

Geochronological constraints from metamorphic rocks provide important information for understanding crustal evolution as well as metamorphic processes. The Hida Belt, situated at the northern part of southwestern Japan, consists of low P/T metamorphic rocks (Hida Metamorphic Complex) and Permo-Triassic granitoids, and is an important geological unit for discussion about crustal evolution at continental margin. In this study, zircon U–Pb geochronology was applied to the Hida gneisses and the Unazuki metamorphic rocks situated at the northeastern part of the Hida Belt to discuss the timing and the duration of regional metamorphism.

Zircon grains collected from the Hida gneisses have a dark CL response mantle and a bright CL response rim around igneous zoning core. The youngest age population of the igneous zoning core is 253 ± 5 Ma. The mantle and the rim yielded same age of 247 ± 4 Ma, suggesting a rapid progression from igneous activity to regional metamorphism. REE patterns of the rim suggest overgrowth of zircon under hydrothermal fluids.

Protoliths of the Unazuki metamorphic rocks are sedimentary and felsic volcanic rocks of late Carboniferous to early Permian age, based on the fossil evidence. U–Pb data of quartzo-feldspathic schist derived from felsic volcanics yield an eruption age of 258 ± 2 Ma, indicating that regional metamorphism occurred after 258 Ma. On the other hand, U–Pb age of a granite intruding the schist is 253 ± 1 Ma. The granite contains some xenoliths of the Unazuki schist, in which staurolite is replaced by andalusite and cordierite due to thermal flux from granitic magma. Therefore, the regional kyanite-sillimanite type metamorphism occurred between 258 and 253 Ma, suggesting a rapid metamorphic progression. Further work is needed to confirm this rapidity of crustal-thickening process.

Helium isotope map of Japan

KEIKA HORIGUCHI[1], NORITOSHI MORIKAWA[1], MICHIKO OHWADA[1], ATSUKO NAKAMA[1] AND KOHEI KAZAHAYA[1]

[1]Crustal fluid Research Group, The Institute of Geology and Geoinformation, Geological Survey of Japan, AIST, Tsukuba, Ibaraki 305-8567, Japan. (keika-horiguchi @ aist.go.jp)

A helium isotope ratio(^{3}He/^{4}He ratio) could be a good tracer for estimating the extent of upwelling deep fluids. This is because the helium has two origins, ^{3}He in terresial sample is considered to be a primordial isotope derived from the mantle, while ^{4}He is mainly from the crust. The spatial distribution of helium isotope ratios is characterized by high values of 4 to 8Ra (where Ra is the atmospheric ^{3}He/^{4}He ratio of 1.40×10^{-6}) along the volcanic front and in the back-arc region at northeastern Japan. In contrast forearc region shows low values less than 1Ra. This trend has simply been interpreted that helium in the back-arc region originates from the mantle and that in the fore-arc region is from the crust [e.g. 1, 2]. On the other hand, ^{3}He/^{4}He ratio of the southwestern Japan shows no clear and complex distribution. The complexity cause a lot of discussion for many years [e.g. 1, 3, 4, 5, 6]. However, no end to this discussion is currently in sight.

In recent 20 years, an increasing number of hot spring wells have been constructed in Japan. We collected gas and water samples from hot springs, deep wells, and mineral springs whole of Japan, and carried out the analysis of helium isotope ratio. At the same time, the helium data of previous studies are compiled.

The total number of data points is over 2000 including 1091samples obtained in our study and 1121 samples from previous studies. We show helium isotope map of Japan.

Carbon isotope biosignatures: A surface-deep Earth abiotic connection

JUSKE HORITA

Department of Geosciences, Texas Tech University, Texas 79409-1053 (juske.horita@ttu.edu)

Our quest for identifying the beginning of life in terrestrial (and possibly extraterrestrial) environments has been hampered by the lack of unequivocal biosignatures in the absence of many other lines of evidence. The claim for finding early life in the ≥3.85 Ga Istaq Gneiss Complex at Akilia Island [1] reignited the half-century old debate on the use of low $\delta^{13}C$ values (<-20‰) of ancient carbonaceous materials as an isotope biosignature. It is now well demonstrated that a number of possible abiotic pathways exist near Earth-surface that lead to the synthesis of various organic and reduced carbon compounds depleted in ^{13}C due to large kinetic isotope effects [2]. Mantle carbons (graphite, diamond, dissolved carbons, carbide) with low $\delta^{13}C$ values (<-20‰) have previously been considered recycled sedimentary organic carbons or surface contamination. Other possible origins of these low $\delta^{13}C$ values have been suggested, including (a) possible mantle heterogeneity since the accretion from the solar nebula and the core–mantle segregation and (b) unidentified mechanisms and processes for large carbon isotopic fractionation at high temperatures and pressures.

Our recent theoretical calculations, along with some experimental studies [3], show that Si/Fe-carbide is very depleted in ^{13}C relative to other mantle compounds (diamond and calcite) even under deep-Earth conditions (>1000°C). Our modelling shows that redox-controlled C-cycle in the mantle between diamond and Fe-carbide can produce low $\delta^{13}C$ values (<-20‰) in addition to a primary mantle value (-5±2‰), a pattern similar to that observed from a global $\delta^{13}C$ distribution of diamond. These mantle-derived diamond and carbide with low $\delta^{13}C$ values can be brought up to near surface by mantle upwelling over geologic time. Thus, now a viable mechanism exists that can produce low $\delta^{13}C$ values of diamond and other carbonaceous materials that could have originated from the deep-Earth. Abiogenic processes that can produce carbonaceous materials with low $\delta^{13}C$ values, both near-surface and in deep-Earth, further challenge our notion of carbon isotope biosignatures for early life.

Suboxic sediments as an oceanic sink of isotopically-light cadmium

T.J. HORNER[1,2,*], W.B. HOMOKY[3], S.V. GEORGIEV[4], H.J. STEIN[4,5], J.L. HANNAH[4,5], R.A. MILLS[3], M. REHKÄMPER[6] AND G.M. HENDERSON[2]

[6]Dept. Earth Sci. Eng., Imperial College London, UK

Riverine and dust fluxes are thought to be the only two quantitatively significant sources of dissolved cadmium to the ocean. These inputs are balanced, within uncertainty, by burial of Cd into suboxic continental margin sediments [1]. Recent studies have characterized the Cd isotopic composition of the source terms [2, 3], indicating that the overall Cd isotopic composition of the inputs is isotopically lighter than average deep-ocean seawater by $\delta^{114/110}Cd \approx -0.2$ ‰ [4]. The offset between seawater and the inputs implies that either the system is not in steady state, or that suboxic sediments should also be characterized by a Cd isotopic composition that is close to the input value, and therefore also fractionated toward a lighter composition than seawater.

Here, we present Cd isotopic and multi-element geochemical data for suboxic sediments that were sampled from the Cape Margin, South Africa, during the UK GEOTRACES 40 °S cruise in 2011 (D357; GA10E). Our Cd isotopic data suggest that suboxic sediments are indeed fractionated from seawater by $\delta^{114/110}Cd \approx -0.2$ ‰, and represent a significant sink of isotopically light Cd in the modern oceans. Our isotopic mass balance – the first of its kind for Cd – demonstrates that the isotopic composition of suboxic sediments balances the inputs, and therefore the isotopic budget of Cd in the oceans.

We explore possible mechanisms for the immobilization of isotopically light Cd in suboxic sediments using multi-element geochemical data from both the solid phase and sediment porewaters. The temporal sensitivity of the Cd isotopic composition of deep-ocean seawater is also investigated using a simple numerical model, as well as implications for the use of Cd isotopes in paleoceanography.

[6]Dept. of Earth Sciences, Memorial University, St. John's NL A1B 3X5 Canada (pjsylvester@gmail.com)

The inter-laboratory comparison (ILC) of laser ablation (LA-)ICP-MS U-Th-Pb data is currently compromised by the use of multiple and disparate 1) mass spectrometer and laser ablation platforms, 2) data processing packages and independent spreadsheets, and 3) geological factors, which in combination, result in differing results for the same materials and potentially misleading and inaccurate interpretations. Since 2006, an international network of LA-ICP-MS U-Th-Pb specialists has been addressing these issues, and measures and documentation are now in place to inform new and existing practitioners of better practice in acquiring, handling, reducing and interpreting LA-ICP-MS U-Th-Pb data. These measures include: completion and documentation of a detrital zircon-focussed ILC, a defined uncertainty propagation protocol, defined tables for publishing data and acquisition information, peer-reviewed publications [1], provision of reference material sets for long-term validation of lab performance, the running of workshops and shortcourses, recommendations with respect to the interpretation of detrital zircon data and a maintained website with resources and information (www.plasmage.org). These measures will: a) improve the standard and accuracy of published LA-ICP-MS U-Th-Pb data, b) allow better comparability of published data, c) ensure appropriate age uncertainty quantification and, ultimately, d) improve the rigour of geological interpretation. New insights into achievable ILC performance and future Network activities will be highlighted.

A global molecular ecological survey of subseafloor microbial communities

TATSUHIKO HOSHINO[1], MASAZUMI TSUTSUMI[1], YUKI MORONO[1] AND FUMIO INAGAKI[1]

[1]Geomicrobiology Group, Kochi institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Monobe B200, Nankoku, Kochi 783-8502, Japan

Recent advances of the culture-independent molecular ecological survey such as deep sequencing enable us to provide precise and detailed views of naturally occuring microbial communties [1]. For the deep subseafloor microbial communities, an improved hot-alkaline DNA extraction method have singificantly improved the cell-lysis efficiency, providing less-biased DNA pools for the subsequent moleculer ecological analyses [2]. Regarding the molecular quantification, the conventionary used real-time PCR assay is highly sensitive to the PCR inhibitors such as humic acids and polysaccharides in organic-rich ocean margin sediments. However, a new technique using digital PCR and microfluidic devices is free of such an inhibitory effect, providing absolute quantification of the target genes [3]. Using these newly standardized molecular ecological techniques, a new global-scale molecular survery of subseafloor microbial communities has been planed.

In this project, we have currently extracted DNA from over 200 deep-frozen samples from 15 drilling sites using a new hot-alkaline method: e.g., off Peru and eastern equatorial Pacific (ODP Leg 201), Juan de Fuca ridge flank (IODP Exp. 301), South Pacific Gyre (IODP Exp. 329), Nankai Trough (IODP Exp. 315 and 316), off Shimokita of Japan (CK0606, IODP Exp. 337), Gulf of Mexico (IODP 308), Porcupine carbonate mound (IODP Exp. 307). These envionmental DNA pools provide an unprecedented opportunity to study biogeographical distribution and diversity of bacterial and archaeal 16S rRNA and some other ecologically significant functional genes with a systematic analytical scheme.

In situ lithium isotope measurements for spodumene using LA-MC-ICP-MS

KEJUN HOU

Key laboratory of Metallogeny and Mineral Assessment, Ministry of Land and Resources, Institute of Mineral Resources(kejunhou@126.com)

As a useful geochemical tracer, the lithium isotope system has been used to study some important geological or geochemical problems. Lithium isotope can be readily fractionated during geological processes in nature because of the large mass difference (16.7%) between its stable isotopes, 6Li and 7Li, whose abundances are 7.52% and 92.48%, respectively. Therefore, the application of the lithium isotopic system has important significance in the fields of cosmochemistry, continental crust weathering processes, oceanic crust thermal activity and alteration, continental plate subduction and crust-mantle material recycling, surface water geochemistry, halogenic water origin and evolution, and so on. Therefore, this technique will surely become a useful geochemical tool in the Earth sciences.(Tian *et al*, 2012)

In this study, we have developed a direct *in situ* lithium isotope analytical method for spodumene using LA-MC-ICP-MS. Our LA-MC-ICP-MS homogeneity testing results show that the four in-house spodumene standards have constant $^{7}Li/^{6}Li$ compositons. The precision of measured $\delta^{7}Li$ in these homogeneous spodumene is better than 1.5‰. And all of these *in situ* analytical results are in good agreement with those results measured by solution MC-ICP-MS method within error.

Stable isotopic record of a Himalayan ice core during the last millennium

S. HOU*

School of Geographic and Oceanographic Sciences, Nanjing University, Nanjing 210093, China. (*correspondence: shugui@nju.edu.cn)

A 108.8 m ice core to bedrock recovered from the East Rongbuk (ER) Glacier (28.03 N, 86.96 E, 6518 m a.s.l.) on the northeast ridge of Mt. Qomolangma (Everest) provides a high-resolution stable isotopic record of the last millennium (3044 samples). Interpretation of the Himalayan ice core δD and δ^{18}O records is multivocal. For instance, Thompson *et al* [1] suggested that the long-term δ^{18}O variability recorded in the Himalayan Dasuopu ice core was attributed to changes in local temperature, while Cai *et al* [2] suggested that precipitation, rather than temperature, was a major factor controlling δ^{18}O in precipitation on orbital time scales in the south-central Tibetan Plateau. However, the linear combination of δD and δ^{18}O (i.e., deuterium excess or $d=\delta D-8\delta^{18}O$) is a good proxy for changes in atmospheric circulation in the Himalayas [3]. A feature for the *d* time series of the ER ice core is the significantly positive phase during the period of middle 15th century and the significantly negative phase during the period of middle1] Thompson *et al* (2010). Science 289, 1916-1919. [2] Cai *et al* (2010). Geology, 38(3), 243–246. [3] Pang *et al* (2012). Climatic Research, 53(1), 1–12. 18th century, with a reversal around middle 17th century (Figure 1). This might indicate a changeover of the atmospheric circulation regime during the 17th century. We suggest that, on the centennial time scale, the Indian Summer Monsoon weakened since the early 15th century, reaching its minimum around the middle 17th century. The time interval of the 15-17th centuries is the transition from the Medieval Climatic Optimum to the Little Ice Age, and the modification of the atmospheric processes in the Asian monsoon regime may be the reflection of global change in the climatic processes during this time interval.

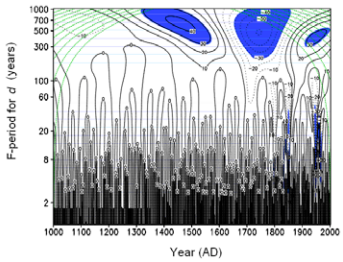

Figure 1. Result of wavelet analysis of *d* (solid lines stand for positive values, dotted lines for negative values, and dashed lines for the boundary effect. The shadow denotes the area passing the significant test with confidence of 95.

The Cihai diabase in the Beishan region, NW China: Isotope geochronology, geochemistry and implications for Cornwall-style iron mineralization

TONG HOU[1] AND ZHAO-CHONG ZHANG[1]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, 100083, China (houtong08@gmail.com)

Diabase dykes in Cihai, Beishan region, NW China are spatially and temporally associated with 'Cornwall-type' iron deposits. U-Pb dating of zircons from a diabase dyke using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) yields an age of 128.5±0.3 Ma. Most of the diabases show low Mg-numbers, suggesting evolved magmas. The diabase dykes show typical ophitic or sub-ophitic textures, and are dominantly composed of phenocrysts of plagioclase and clinopyroxene, with minor and varying amounts of biotite and hornblende, and minor disseminated magnetite. The diabase dykes are characterized by minor variation in SiO_2 (44.67-49.76 wt.%) and MnO (0.14-0.26 wt.%), but show a marked range of Al_2O_3 (10.66-14.21 wt.%), total Fe_2O_3 (9.52-13.88 wt.%), TiO_2 (0.66-2.82 wt.%) and relatively high MgO (4.87-9.29 wt.%) with an Mg# value [atomic $Mg/(Mg+Fe^{2+})$] of up to 66. The Cihai diabases possibly experienced fractional crystallization of olivine + clinopyroxene and minor crustal contamination during the differentiation process. Prominent negative Nb, Ta and Ti anomalies suggest derivation from subduction-modified mantle. Furthermore, the rocks have relatively unradiogenic Sr- and Nd-isotopic ratios. These characteristics probably reflect partial melting of a subduction component in the source mantle lithosphere through heat input from an upwelling asthenospheric mantle. Such processes probably occurred within an extensional setting during the Early Cretaceous in the Beishan area. The iron-rich fluids were derived from deep sources, and the iron ores were concentrated through a convection cell driven by temperature gradients established by the intrusion of the diabase sills. The combined processes of subduction-related enrichment in the source, shallow depth of emplacement, and the involvement of large-scale circulation of basinal brines from an evaporitic source are inferred to have contributed to the formation of the 'Cornwall-type' mineralization in Cihai.

Challenges in constraining and understanding Strombolian volcanism

BF HOUGHTON[1], J TADDEUCCI[2] AND M EDMONDS[3],

[1]School of Ocean and Earth Science and Technology, University of Hawaii at Manoa, Hawaii, USA.
[2]Dept. of Seismology and Tectonophysics, Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy
[3]Earth Sciences Department, University of Cambridge, Downing Street, Cambridge CB2 3EQ, UK

Activity at Stromboli is exceptionally well characterised on most time scales but it remains a challenge to identify what portion of that activity should be defined as “Strombolian’ in the strict sense of naming the eruption style, in a fashion that is useful elsewhere. Here we look at delineating the limits of ‘Strombolian style’, particularly in the context of demarcation from Hawaiian fountaining eruptions.

That demarcation has generally been articulated in terms of transient versus sustained activity linked to mechanical decoupling versus partial coupling of exsolved volatiles. However, while sustained fountains are steady, they are seldom steady, and violent Strombolian events can last for minutes.

Plotting basaltic activity in viscosity-mass eruption rate space reveals some of the issues. Individual Strombolian explosions occupy the short duration, low eruption rate corner of such a plot, very clearly distinguished from high Hawaiian fountains that have durations that are 3 to 5 orders of magnitude longer and mass discharge rates that are 10 to 100 times larger. However the spectrum of activity called names such as ‘low fountains’, ‘gas pistoning’ and ‘violent Strombolian’ defines a grey scale between these extremes. Finally on what time scale can we define a Strombolian (or Hawaiian) ‘eruption”, i.e., what is the most characteristic time scale - a transient explosion of seconds duration or centuries of continual but varied activity?

Lithospheric mantle downwelling beneath the Southeast Carpathians

GREGORY A. HOUSEMAN, PIROSKA LORINCZI, YONG REN AND GRAHAM W. STUART

School of Earth and Environment, University of Leeds, Leeds, LS2 9JT (correspondance to: greg@earth.leeds.ac.uk)

The South Carpathian Project, a major seismological experiment carried out during 2009-2011 by the University of Leeds, the National Institute of Earth Physics in Bucharest, the Eötvös Loránd Geophysical Institute in Budapest, and the Seismological Survey of Serbia in Belgrade, has resulted in the most detailed tomographic images yet obtained of the upper mantle structure beneath the Pannonian – Carpathian region [1]. These images shed new light on the unique geological structure which is responsible for the damaging earthquakes that occur in the upper mantle beneath the Vrancea Zone of the South-east Carpathians. A sub-vertical high-velocity body extending down to the top of the Mantle Transition Zone is interpreted as downwelling mantle lithosphere. The main mass of fast (presumably dense) material is located directly beneath the seismic activity. The earthquakes are caused by vertical stretching at strain-rates which imply that the mantle at 200 km is moving downward at about 20 mm/yr relative to the surface.

Three-dimensional numerical experiments assuming viscous flow support the interpretation that the drip-like structure that we image may be a natural consequence of a Rayleigh-Taylor instability developing from an unstable stratification of mantle lithosphere above asthenosphere, and triggered by recent convergence of Adria and Europe. The depth distribution of seismic-moment release rate is most easily explained if this high velocity structure is produced by a Rayleigh-Taylor instability. The present high rate of tectonic activity in this region is probably short-lived on a geological scale (< 1 Myr) but is likely to increase in energy before it is abates. The circumstances of this tectonic activity support the idea that Rayleigh-Taylor instability of the mantle lithosphere requires relatively dense mantle lithosphere activated by local plate convergence.

Newly measured enthalpies of K-Na mixing for low albite - microcline crystalline solutions

GUY L. HOVIS[1]

[1]Department of Geology & Environmental Geosciences, Lafayette College, Easton, PA 18042 USA

Earlier studies [1,2] on the thermodynamic mixing properties of the low albite - microcline system reported enthalpies of K-Na mixing that were nearly symmetric with regard to composition, despite a solvus [3] and Gibbs free energies of mixing [4,5] that require compositionally asymmetric relationships. To refine earlier results, new data have been collected at a particularly large number (21) of compositions across this series. Duplicate solution calorimetric experiments on each of these samples at 50 °C in 20.1 wt% HF have produced highly precise calorimetric data having an average standard deviation per sample of just 0.06% of the heats of solution. The new study, which reveals a maximum 8.7 kJ/mol enthalpy of mixing (H_{ex}) at N_{Or} = 0.39, demonstrates that detail in data at the sodic end of the series is crucial to definition of asymmetry in H_{ex}. The greater mixing magnitudes for this series relative to those for analbite - sanidine solutions (newly investigated via a 20-sample series) correlate well with the comparatively higher critical temperature of the low albite - microcline solvus [3] relative to that for analbite - sanidine [e.g., 6]. Entropies of K-Na mixing have been calculated by combining the new enthalpy data with Gibbs free energies of mixing derived from phase equilibrium studies [4,5]; these may be compared with entropy data based on the recent heat capacity measurements of Benisek and others [7].

[5]Geophysical Laboratory, Carnegie Institute of Washington, 5251 Broad Branch Road NW, Washington DC, 20015, USA.

Mixed-habit diamonds form when growth occurs by two different simultaneous growth mechanisms [1, 2]. The two crystal habits are smooth, flat {111} crystal faces (octahedral growth) and curved, hummocky, non-faceted surfaces with a mean orientation of {100}, but this can be inclined by up to 30º (cuboid growth). This type of growth can produce a range of centre-cross or star-shaped patterns within the diamond [3], which are the result of light-scattering defects that occur only in the cuboid sectors. When these defects are graphitized and thus opaque, the cuboid growth sectors appear much darker than the gem-quality octahedral sectors.

Analysis of this type of diamond has shown that carbon isotopes show no partitioning between growth sectors [4]. However, nitrogen contents are much higher in the octahedral sectors (enriched by up to 160% compared with that of cuboid sectors), while nickel and cobalt are partitioned into the cuboid sectors if available in the diamond-forming fluid [5]. Few nitrogen isotope data exist for these types of diamonds. One study showed no N-isotope fractionation between growth sectors [6] but the sample used in that study is not thought to be a true mixed-habit diamond.

This study compares nitrogen-isotope data obtained via SIMS and by step-wise oxidation mass spectrometry from both octahedral and cuboid growth sectors, with the goal of investigating both isotopic fractionation and the source of nitrogen in these unusually N-rich diamonds.

Sorption behavior of lithium

MANDY HOYER AND NICOLAI ALEXEJI KUMMER

TU Bergakademie Freiberg, Department of Hydrogeology, D-09599 Freiberg, Mandy.Hoyer@student.tu-freiberg.de

Salar the Uyuni is one of the greatest sources for Li being presently assessed. It is not yet understood why one observes great Li enrichment in the delta areas of past and presently inflowing rivers. One theory is temporary sorption and subsequent desorption by clay minerals that are enriched in these inflow areas.

Li sorption on clay minerals, namely kaolinite and bentonite, and on clinoptilolite, a zeolite, was studied in batch experiments with subsequent ICP-MS analysis. Solid/solution ratio was 1:4; shaking time was 24 hours; pH was varied between 2 and 10, with focus on pH 6 and 8 as pH in the Salar is circum-neutral. Li concentration in the solutions was varied between 1.5 and 750 mM; sodium concentration between 0.01 and 5 M.

It was found that Li was sorbed by all minerals; highest sorption being achieved at lowest sodium and highest Li concentration for clinoptilolite (3890 ppm) and bentonite (3820 ppm); at 3 M Na and highest Li concentration for kaolinite (1250 ppm). Absolute Li sorption at pH 6 and 8 was similar and increased with increasing Li concentration in the initial solution at constant Na concentration. Relative Li sorption decreased due to limited exchange sites on the mineral's surface. At constant Li concentration, increasing Na caused Li sorption decreased by competition.

pH changes altered minerals' surface charge by (de)protonation, caused structural changes, or decomposition. For bentonite and clinoptilolite, pH-dependent sorption results scattered. The reason for that is not known. For kaolinite sorption was maximal at pH 2-4 which could be explained by surface complexation or incorporation in the crystal structure. Above pH 5, kaolinite probably transformed to gibbsite with effects on surface charge and on Li sorption.

This study showed that clay minerals and zeolites are effective Li sorbents and may contribute to elevated Li concentration at the freshwater inflows of Salar de Uyuni.

Thermodynamics of the C-H-O fluids: High pressure experiments on dissociation of carbonates and hydrides

R. HRUBIAK[1]*, V. DROZD[1] AND S.K. SAXENA[1],

[1] Department of Mechanical and Materials Engineering, Florida International University, Miami, FL 33199, USA (*correspondence: rhrub001@fiu.edu)

Understanding the chemistry of carbon in deep Earth's interior requires thermodynamic data on the multicomponent C-H-O fluid. Experimental data on such fluids at high temperature and high pressure mantle conditions is quite rare. In this study we use new experimental methods and computations to produce pressure-volume-temperature (P-V-T) equation of state (EoS) data on CO_2 and H_2 fluids to pressures of 100 GPa and very high temperatures.

The thermodynamic properties and P-V-T EoS for CO_2 and H_2 fluids are assessed by combining experimental data on equillibrium conditions for several carbonate and hydride dissociation reactions involving these fluids with P-V-T EoS' of solid phases involved in the given reactions. Experimental P-V-T data on several carbonates and hydrides used in this study was extensively collected from literature and missing P-V-T data was measured using resistively heated and laser heated diamond anvil cell and *in situ* x-ray diffraction. The P-V-T EoS' for the CO_2 and H_2 are thus self consistent with experimental phase equilibrium data and standard thermochemical data. The EoS' are also shown to be consistent with results obtained independently using molecular dynamics calculations [1].

The newly created thermodynamic database was used to calculate high pressure and temperature phase equilibrium in several binary, ternary and multicomponent systems.

The authors wish to acknowledge the supoort and collaboration of the Deep Carbon Observatory

[6]Plymouth Marine Laboratory, UK

Diapycnal mixing from below is a critical route by which nutrients and other chemical species are introduced to the sunlit surface ocean. Instantaneous mixing rates can be assessed by shipboard measurements of velocity microstructure in the water column. Radium-228, a daughter of ^{232}Th, has a half life of 5.75 years, and is mixed into the ocean interior from ocean shelves and downwards from the surface by diapycnal mixing. It therefore provides a means to assess the long-term average mixing rates in the oceans. In this study, we compare instantaneous mixing rates from velocity microstructure with long-term rates from ^{228}Ra for waters of the Cape Basin. We use these measured mixing rates to assess the supply of nutrients to the surface ocean in this region, and the temoral variability of this supply.

Twenty five seawater samples were collected from the Cape Basin during the 2010 UK GEOTRACES cruise (GA10E) and analysed for high-precision ^{228}Ra and ^{226}Ra concentrations by MC-ICP-MS. We estimated vertical and horizontal ocean mixing rates from this data using 1D mixing models to derive rates of 0.9 – 2.1 cm^2s^{-1} and 3.8 × 10^7 cm^2s^{-1} respectively. The rates of diapycnal mixing indicate sufficient nutrient supply to drive the productivity in downward organic carbon fluxes of 3.1 – 3.3 mmol C $m^{-2}d^{-1}$ in this region – in close agreement with estimates from other proxies. The long-term averages are compared with instantaneous mixing rate and nutrient supply derived from microstructure measurements from the same cruise to assess the merits of the two approaches and variation in the mixing environment.

DFT+*U* investigations of spin crossovers in lower-mantle minerals

HAN HSU

Department of Physics, National Central University, Jhongli City, Taoyuan 32001, Taiwan (hanhsu@ncu.edu.tw)

The total electron spin of a transition-metal ion in a crystalline solid can vary with many factors, including temperature, pressure, and strain. This phenomenon, known as spin crossover, is of great technological potential, as it allows artificial control of magnetic properties of materials. Not as widely known, spin crossover may also play a significant role in geophysics. As pressure and temperature increase with depth in the Earth, iron incorporated in minerals can undergo a spin crossover. A well studied example is ferropericlase, the second most abundant mineral in the Earth's lower mantle. In this mineral, a high-spin (HS) to low-spin (LS) crossover occurs in the pressure range of 40-55 GPa, accompanied by elastic, thermodynamic, optical, and conducting anomalies.

In contrast to ferropericlase, spin crossovers in magnesium silicate ($MgSiO_3$) perovskite and post-perovskite, the major mineral phases in the lower mantle, have been controversial for years, due to the complicated nature of these minerals and the difficulty in probing iron spin state directly. Using density functional theory + Hubbard *U* (DFT+*U*) calculations, we investigated spin crossovers in $MgSiO_3$ perovskite and post-perovskite, and our results clarify the iron spin controversy in both mineral phases. We also show that Mössbauer spectroscopy, combined with first-principles calculations, can be a reliable tool to unambiguously identify iron spin state at high pressure [1-4].

Meso- to Neo-proterozoic magmatic events and their geological significance: evidences from detrital zircon U-Pb ages of the Jurassic and Cambrian sedimentary rocks in Xishan area, Beijing city, China

BO HU [1], MINGGUO ZHAI[2], PENG PENG [2] AND FU LIU [2]

[1]Key Laboratory of Western Mineral Resources and Geological Engineering, Ministry of Education, College of Earth Science and Resources, Chang'an University, Xi'an 710054, China (hubowork@126.com)

[2]Institute of Geology and Geophysics, Chinese Academy of Sciences, P. O. Box 9825, Beijing 100029, China

Whether any magmatic records corresponding to the assembly and breaking up of the supercontinent Rodinia are preserved in the North China Craton (NCC) is a key issue to understand the Proterozoic tectonic evolution of the NCC and its correlation to the supercontinent Rodinia. LA-ICP-MS U-Pb dating results of detrital zircons from Jurassic and Cambrian sedimentary rocks in the Xishan area, Beijing city, central part of the NCC show that there are not only ~507 Ma cambrian age peaks, but also ~2.5 Ga, ~2.1 Ga, 1.8-1.66 Ga, ~1.56 Ga, ~1.38 Ga, ~1.14 Ga, ~912 Ma, ~814 Ma, ~740 Ma and ~630 Ma precambrian age records in Cambrian fine sandstone. Also, there are not only ~484 Ma, ~267 Ma, ~241 Ma and ~188 Ma phanerozoic age peaks, but also ~2.77 Ga, ~2.5 Ga, ~2.0 Ga, ~1.78 Ga, ~1.6 Ga, ~1.2 Ga and 848Ma precambrian age records in Jurassic silty mudstone and fine sandstone. Most of Neoarchean and Paleoproterozoic age peaks correspond to significant tectono-magmatic-thermal events previously recognized in the NCC. 1.78-1.38 Ga age peaks correspond to late Paleoproterozoic to Mesoproterozoic multi phase rifting events in the NCC. Zircon ages of 1.3-1.0 Ga and 1.0-0.6 Ga indicate that during the deposition of these sediments there have been significant contributions from 1.3-1.0 Ga and 1.0-0.6 Ga magmatic rocks in the NCC. The magmatic rocks during these periods, which were common in the South China Craton (SCC) and were explained to relate to the assembly and breaking up of the supercontinent Rodinia, were seldom reported in the NCC so far. The finding of 1.3-1.0 Ga and 1.0-0.6 Ga detrital zircons in the NCC may provide clues to understand the possible relationship of the NCC, the SCC and the supercontinent Rodinia.

Altitudinal $\delta^{18}O$ gradients from Chinese stalagmites provide records of Holocene humidity variation

CHAOYONG HU[1] GIDEON M. HENDERSON[2] JIN LIAO[1] JIAOYANG RUAN[1] CHENGZHAN LI[1] SHUCHENG XIE[1] AND KATHLEEN JOHNSON[3]

[1]State key laboratory of biology and environmental geology, China University of Geosciences, Wuhan, 430074 (chyhu@cug.edu.cn)

[2]Department of Earth Sciences, University of Oxford, South Parks Road, Oxford OX23AN, UK. (gideonh@earth.ox.ac.uk)

[3]Department of Earth System Science, University of California, Irvine, CA 92697.

Humidity is one of the fundamental variables controlling the energy balance of the climate, and plays a critical role in Earth's ecosystems. Its reconstruction would aid considerably in assessing the mechanisms driving past changes observed in paleoclimate records. Paleohumidity has been reconstructed qualitatively from the pollen and tree ring data, but not yet from speleothem records, due to the uncertain interpretation of speleothem geochemical proxies. Here we propose a novel proxy for paleo-humidity based on the altitudinal $\delta^{18}O$ gradient derived from two speleothems with different altitude of rainfall recharge in closely spaced caves. We then use this proxy to reconstruct a Holocene humidity record in the middle reaches of the Yangtze river. Two factors affect the altitudinal $\delta^{18}O$ gradient of precipitation, the lapse rate of temperature and relative humidity. In the case of speleothems, the cave temperature effect (negative effect) offsets the temperature induced isotopic fractionation in precipitation (positive effect), and relative humidity is likely to be the major controller of $\delta^{18}O$ gradients between speleothems with recharge from different heights. $\delta^{18}O$ in recently formed carbonate from two caves in Qingjiang valley, Hubei, China, supports this interpretation, with larger $\delta^{18}O$ gradients in periods of lower relative humidity. Based on this observation, we reconstruct Holocene relative humidity from the high resolution speleothem $\delta^{18}O$ records from Heshang and Sanbao caves. The reconstructed record indicates a slight increase in RH during the Holocene, with lowest values at 8.2 kyr BP. Independent hydrological records of Mg/Ca and $\delta^{13}C$ from the Heshang speleothem vary in a similar pattern to the altitudinal $\delta^{18}O$ gradients, which supports the reconstruction of humidity for the Holocene of this region.

Hydrochemistry and isotope evidence of groundwater evolution and recharge in Poyang Lake, South China

HU CHUNHUA [1,2], ZHOU PENG[1,2] , HUANG DAN[1,2], LI LIYANG[1,2] AND ZHOU WENBIN [1,2]*

[1]School of Environmental and Chemical Engineering, Nanchang University, Nanchang, 330031, China (*correspondence: ouyangyinghui@126.com)

[2]Key Laboratory of Lake Poyang Environment and Resource Utilization, Ministry of Education, Nanchang University, Nanchang, 330029, China

In recent decades, a systematic research of groundwater system is imperative for the increasingly prominent contradiction between supply and demand of water. In this work, environmental factors, main zwitterions, hydrogen and oxygen isotopes composition in groundwater were researched in dry season and wet season. Groundwater evolution and recharge were studied with the purposes of anzlyzing hydrochemical characteristics and evolution laws [1], as well as helping rebuild the geochemical evolution [2]. In addition, the recharge rates of different landscape units were estimated by hydrogen oxygen isotopes during investigation period.

The results show that: Na^+ and Ca^{2+} are the main cations of groundwater in research area, and HCO_3^- is the main anion, seasonal change has influence on spatiotemporal variation of area hydrochemistry, and its type is mainly present in HCO_3^-—(Na^++K^+); the composition of δD and $\delta^{18}O$ has different characteristics for seasonal change, it mainly controlled by precipitation. Groundwater anions type transforms from HCO_3^-—SO_4^{2-} to HCO_3^-—Cl^- when the season changes from dry season to rainy season, and cation type drifting and evoluting from (Na^++K^+)—Ca^{2+} to (Na^++K^+). The results of hydrogen and oxygen isotopic mixing ratios shows that there is significant difference on water recharging of groundwater system in different geomorphic units, and it reflects that the origin and evolution of groundwater response to geomorphology sensitively.

The characterastics of polycyclic aromatic hydrocarbons (PAHs) in the drainage basin of the Liao River, Northeast China

JIAN HU [1]*, YAN-LIN ZHANG [1,2] BAO-JIAN LIU [2,3] , SI-LIANG LI [1] AND JIN GUAN [123]

[1]Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, PR China (*correspondence: hujian@vip.skleg.cn)
[2]Graduate University of Chinese Academy of Sciences, Beijing 100049, China
[3]Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China

Sixteen polycyclic aromatic hydrocarbons (PAHs) in surface water and suspended particulate matter (SPM) in the drainage basin of Liao River were determined by GC/MS. The concentration and distribution characteristics, pollution levels, and sources of PAHs were discussed. The total PAHs concentration ranged from 0.41 to 76.45μg·g^{-1} (dry weight) in SPM, and 32.57 to 108.47ng·L^{-1} in surface water, respectively. The PAHs concentration in west Liao River is higher than that in east Liao River and Liao River main stream. The compositions of PAHs are predominant by low ring PAHs (two and three-ring PAHs), and the percentage of low ring PAHs in dissolved phase is higher than that in SPM. The percentage of two-ring PAHs in dissolved phase is highest with an average of 68.19%, while the percentage of three-ring PAHs in SPM is highest with an average of 66.28%, respectively. Compared with other rivers in China and the world, the PAHs concentrations in Liao River drainage basin are at a lower level, but some branches are PAHs-contaminated to some extent.

Diagnostic ratios of Ipy/(Ipy+Bpe) and Fla/Fla+Pyr) were used to identify the PAHs sources, and the result suggested the main sources of PAHs would be petroleum and fossil fuel combustion-based, which are resulted from complex energy structure of Liaoning province.

Mineral compositions of Lower Silurian Longmaxi Formation, Sichuan Basin, China

PEI-QING HU, JUAN SHEN AND WAN-XIANG RAO

Key Laboratory of Mineral Resources in Western China(Gansu Province) &School of Earth Sciences, Lanzhou University, Lanzhou 730000, China (hupq@lzu.edu.cn)

The Sichuan Basin is a prolific hydrocarbon region and is currently China's largest gas-producing region. In order to study the mineral properties, composition and the relationship with the organic matter characteristics in Lower Silurian Longmaxi Formation shale, 30 shales from Longmaxi Formation fresh outcrop cross sections located in Changning County in Sichuan basin were analyzed.

The analysis result shows that mineral compositions are brittle(fragment) minerals: quartz, feldspars, mica, pyrite; siliciclastic and calcite minerals: Chalcedony, calcite and dolomite; and clay minerals: Illite, chlorite and montmorillonite. These samples display significant variations in the proportions of detritus derived extrabasinal and intrabasinal sources. Quartz in particular occurs in both clay-size and silt-size fractions of both intrabasinal and extrabasinal origin and it is important that lots of dark luminescing microcrystalline (clay-size) quartz closely intergrown with clay minerals in the samples. The organic matter occurrence modes have important relationship with the mineral character. The finer fracture in the fragment minerals have huge influence to the produce and travel of the shale gas.

This study was supported by The National Basic Research Program of China (2012CB214701) and NSF of China (40873005).

Kinetic experiments of actinolite in $CaCl_2$ –HCl-H_2O up to 400°C

SHUMIN HU*, RONGHUA ZHANG AND XUETONG ZHANG

Laboratory of Geochemical Kinetics, MLR Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources, Chinese Academy of Geological Sciences, Baiwanzhuang Road 26, Beijing 100037, P.R.China (*correspondence: zrhhsm@cags.ac.cn)

Actinolite dissolution rates in HCl-H_2O and $CaCl_2$-HCl-H_2O were measured at temperature ranging from 25 to 400°C and at 23 MPa. The dissolution experiments were performed in a flow-through reactor. The results provide new insight into the rate limiting reactions governing actinolite dissolution behavior at far from equilibrium, particularly at temperatures above 300°C. As actinolite dissolves in aqueous solutions, the relative release rates for breaking various metal–oxygen bonds in actinolite are different. Results show that Ca, Mg, Fe and Al dissolve faster than Si at temperatures of 25-300°C, but slower at 300°C. Ca and Mg release faster than Si at temperatures of 350°C-374°C. All of release rates vary with temperatures and pH. The release rate of Si increases with temperature from 20 to 300°C, and then decreases with continued increasing temperature from 300 to 400°C. The maximum release rate of Si is reached at 300°C. Experiments show that dissolution stoichiometry of actinolite is affected by temperature and pH. Results of actinolite dissolved in $CaCl_2$-HCl-H_2O indicate that the release ratios of m_{Ca}/m_{Si} and m_{Mg}/m_{Si} in the effluent at 200°C are close to stoichiometric number of these element moles in one mole of actinolite and actinolite dissolution in HCl-H_2O at 100°C is close to the stoichiometric.

The reacted surfaces of actinolite are observed using EPMA, HRTEM, SEM and XPS. The surface after reacted at temperature <300ºC is quite different from that after reacted at≥300ºC. At temperature ≥300ºC, metal-hydrogen exchange reaction is weak and the release rates of Si increases. HRTEM and SEM studies indicate that a Fe (Al)-rich, Si-deficient layer is formed at surface. Experiments prove that each metal–oxygen bond within the silicate structure breaks at a distinct rate, which is affected by temperature. XPS and SEM-TEM study indicates that the surface layer after reacted at 300-400°C is not only amorphic, but also hydrated silicate, composed of Si-O-Si, Mi-OH^-, and Mi-O bonds. This project is supported by the project of k[2013]01-062-014, SinoProbe-07-02-03, SinoProbe-03-01-2A and 2010G28.

Hydrocarbon geology characteristics and exploring prospect of ultradeep layers onshore China

HU SUYUN[1], ZOU CAINENG[2], HOU LIANHUA[3] AND ZHU RUKAI [4]

[1] Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, China, husy@petrochina.com.cn
[2] Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, China, zcn@petrochina.com.cn
[3] Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, China, houlh@petrochina.com.cn
[4] Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, China, zrk@petrochina.com.cn

As the geology knowledge becoming deeper and the exploring technology developing, the hydrocarbon exploring prospect in deep-ultradeep layers is being recognized by the world. Chinese petroliferous basins suffered divergency in Eopaleozoic, transition between marine and continent in Neopaleozoic, and strong compression in Meso-cenozoic. The basins are mainly superimposition basins, which have upper and lower tectonic layers. Previous exploration mainly focus on upper layer, in recent years, CNPC has achieved a series of discoveries in deep-ultradeep layers of petroliferous basins onshore China through strengthening hydrocarbon geology research and discovery in deep layers, which shows great prospect of hydrocarbon exploring in deep layers. Basing on newest exploring results and research, it can be proposed that: ⊖ There are two kind of sources, normal source rock and inner source resident liquid hydrocarbon cracking, which can provide hydrocarbon, causing the deep layer resource potential may be out of our expectation. ⊜ Deep-ultradeep layers onshore China are affected by several geological factors. In the deep layers of superimposed basins, there are carbonate, volcanic and clastic reservoirs. ⊛ Large area of accumulation can happen in carbonate rocks, clastic rocks and volcanic rocks in deep-ultradeep layers. The reserve abundance is not so high but the scale can be very large. ④The exploring degree in deep layer onshore China is low and the remaining resource is high, it can be predicted that the deep layers onshore will become an important replace area for the oil and gas industry of our country.

Dolomitization process and its effect on the behavior of trace elements in carbonate rocks

WENXUAN HU [1,2], LICHAO WANG [1] AND XIAOLIN WANG[1,2]

[1]School of Earth Sciences and Engineering, Nanjing University, Nanjing, 210093, P.R. China
[2]Institute of Energy Sciences, Nanjing University, Nanjing, 210093, P.R. China

The origin of dolomite has been considered to be a long-standing enigma in sedimentary geology. It has been accepted that dolomitization of limestone by solutions with high Mg^{2+}/Ca^{2+} ratio is one of the most important mechanisms to produce dolomite. Therefore, understanding the geochemical behaviors of major and trace elements during dolomitization is vital towards deciphering the mysterious "dolomite problem".

An example section is selected in this study of Geshan profile of the middle Triassic age in the Lower Yangtze area, China. This outcrop develops various carbonate rocks ranging from limestone, through dolomitic limestone and calcareous dolomite, to dolomite. The carbonate series represent a gradual increase in dolomitization degree.

The geochemical signatures of these carbonate rocks are well preserved as supported by two folds of evidence: (a) most of the dolomites are micritic or fine-grained with planar-s in fabric, and (b) the Mn/Sr ratios of these samples are generally less than 1. The average Sr concentrations of limestone, dolomitic limestone, calcareous dolomite and dolomite are 1357.7 ppm, 271.2 ppm, 121.8 ppm and 99.9 ppm, respectively; whereas the average Mn concentrations are 15.37 ppm, 17.46 ppm, 27.85 ppm and 44.09 ppm, respectively. Therefore, the Sr concentration of carbonate rocks decreases with increasing dolomitization processes. However, the Mn concentration shows an opposite variation trend.

Previous studies suggest that, in the dolomite lattice, Sr mainly substitutes Ca sites. However, our observations show that the Sr concentration exhibits a non-linear decrease along with the decrease of CaO content during dolomitization. This reflects that, apart from the substitution of Ca, Sr exists in dolomite in other forms, such as in the crystal defects, or in fluid inclusions. In addition, compared with the published Sr concentration in microbial dolomite precipitated in culture experiments, our results ruled out the possibility of bacterial origin for the dolomite in this report.

Carbon and Oxygen Isotopic Compositions: How to Respond the Lacustrine Environmental Factors in Northwestern and Northeastern China

HU XIAOLAN ZHAO QI

College of Resource and Environmental Sciences, Lanzhou University, Lanzhou, 730000, China
*correspondence: huxl2011@lzu.edu.cn

The sediments, that 28 closed-lake sediments from Hoh Xil, 24 from Northeastern China, 99 surface sediments from Lake Bosten, 31 from Ulungur and 26 from Heihai were collected to determine the $\delta^{13}C$ and $\delta^{18}O$ values and discussed the impacting factors to the $\delta^{13}C$-$\delta^{18}O$. The closure and residence time of lakes can influence the correlation between $\delta^{13}C$ and $\delta^{18}O$. Mg/Ca in the bulk sediment indicates the characteristic of residence time, Sr/Ca and Fe/Mn infer the salinity of lakes. Carbonate forming and types can influence the $\delta^{13}C$-$\delta^{18}O$ correlation. When carbonate content is less than 30%, there is no relationship both $\delta^{13}C$ and $\delta^{18}O$, and no relationship between $\delta^{13}C$ and $\delta^{18}O$. But more than 30%, carbonate content highly co-varies to $\delta^{13}C$ and $\delta^{18}O$, and has high correlation between $\delta^{13}C$ and $\delta^{18}O$ also. Vegetation condition and primary productivity of lakes can influence the characteristic of $\delta^{13}C$ and $\delta^{18}O$, and their co-varying. Organic matter content (TOC) in the sediments is higher with more terrestrial and submerged plants filling. When organic matter comes from endogenous floating organisms and algae (C/N<6), $\delta^{13}C$ value is heavy. $\delta^{13}C$ is in -4~0‰. $\delta^{13}C$ is in the range of -4~8‰ as organic matter comes from diatom (C/N=6~8). $\delta^{13}C$ is in the range of -8~-4‰ as organic matter from aquatic and terrestrial plants (C/N>8).

Rapid bulk rock decomposition by ammonium fluoride (NH_4F) in open-vessels by an elevated digestion temperature

ZHAOCHU HU [1]*, WEN ZHANG [1], QION NI [1], YONGSHENG LIU [1], RICHARD M. GASCHNIG [2], LIAN ZHOU [1] AND LAISHI ZHAO [1]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

[2]Department of Geology, University of Maryland, College Park, Maryland 20742, USA

Complete dissolution is essential to achieve accurate analytical results for geological samples. Hydrofluoric acid is the most effective mineral acid for breaking up strong Si-O bonds to form SiF_6^{-2} ions in acidic solution. In this study, decomposition technique using the neutral solid compound NH_4F in open vessel (Savillex Teflon vial) has been investigated for multi-element analysis of different types of rock reference materials. The higher boiling point (260 °C) of NH_4F allows for an elevated digestion temperature in open vessels, which enables the decomposition of refractory phases. It took 1-1.5 h for Zr to be completely recovered in GSP-2 at 250 °C, which is ~12 times faster than using conventional closed-vessel acid digestion at 190 °C (high-pressure PTFE digestion bomb). Unlike in NH_4F-assisted high pressure acid digestion, our results clearly indicate that adding HNO_3 severely inhibited the digestion capabilities of NH_4F for refractory minerals such as zircon in open vessel. The most outstanding advantage of the new method is that the digestion can be performed in a conventional Savillex Teflon vial instead of using a high pressure PTEF digestion bomb. Moreover, the NH_4F–open-vessel acid digestion is not hampered by the formation of insoluble fluorides, which represent another important advantage of this new sample decomposition method. Similar to HF and HNO_3, ultra-pure NH_4F can be produced using a conventional PFA sub-boiling purification system, and it does not induce new interference species in ICP-MS analysis. It is also worth emphasized and this reagent is removed by taking the sample to dryness, which is important to keep the total dissolved solid of the final solution presented to the instrument low. The developed NH_4F–open-vessel acid digestion has been successfully applied to the digestion of a series of international geological reference materials. This simple, effective, and comparatively safe dissolution method shows a great potential for the digestion of geological samples.

Fluid inclusion study of Maoping W deposit, southern Jiangxi province

R.M. HUA AND D.Q. HU

State Key Laboratory of Mineral Deposit Research, Nanjing University, Nanjing 210093, China

The Maoping tungsten deposit is a large W-Sn-polymetallic deposit discovered recently in southern Jiangxi province. It comprises two types of ore-bodies, i.e. quartz-vein type and greisenized-granite type. The present paper studies the fluid inclusions in quartz and topaz occurring in wolframite-quartz-veins, which mainly includes microthermometry and Laser Raman analysis. Besides, the homogenization temperatures of fluid inclusions in wolframite were also determined under an infra-red microscope. Result shows that fluid inclusions in both quartz and topaz are mainly of liquid-rich two-phase aqueous solution (H_2O-NaCl), in addition of small amount CO_2-bearing three-phase aqueous solution in quartz. The homogenization temperatures from quartz show wider variation range and can be divided into two main periods, indicating two stages of ore precipitation. The CO_2-bearing three-phase inclusions have similar homogenization temperatures to the higher temperature period of above inclusions, but lower salinities and different homogenizing ways. Fluid inclusions in wolframite have highest homogenization temperatures and salinities, whereas those in topaz also show high homogenization temperatures and salinities, and narrow variation range. The characteristics of homogenization temperatures and salinities from fluid inclusions in quartz reveal the multiple-stage of ore-forming process and the complexity of fluid evolution. It is concluded from this fluid inclusion that the early-stage boiling and late-stage mixing is probably the major mechanism of formation of wolframite-quartz-vein type ore in the Maoping deposit.

As the second most abundant element in rocky planets, Si exhibits limited isotopic variations among different chondrite groups [1]. The δ^{30}Si of Bulk Silicate Earth (BSE), estimated based on basalts and peridotites, is higher than chondritic value. The heavier Si of BSE is proposed to be balanced by lighter Si in the Earth's core. In detail, a range of $\delta^{30}Si_{BSE}$-$\delta^{30}Si_{Chondrite}$, from 0.04 to 0.20‰, has been reported [e.g., 1-3]. Kempl *et al* [4] reported Si isotopic fractionation coefficient between metal and silicate under high P-T conditions, and they concluded that "the core contains between 11 and 29 wt% Si" depending on the value of $\delta^{30}Si_{BSE}$-$\delta^{30}Si_{Chondrite}$. Such high Si content in the core conflicts with seismic observations.

We calculated equilibrium fractionation factors of Si isotopes at high P-T conditions using density functional theory for mantle silicate minerals. Our calculations reveal significant Si isotope fractionation among mantle minerals with different Si coordination numbers (CN), especially between Mg-perovskite (CN=6) and olivine polymorphs (CN=4). Using our *ab initio* calculation and the magma ocean crystallization model of [5], the lower mantle, dominated by perovskite, is estimated to have lower δ^{30}Si (by ~0.1‰) than the upper mantle, dominated by olivine polymorphs. If such primordial Si isotope heterogeneity between the upper and lower mantle is not completely destroyed through the Earth's history, δ^{30}Si of BSE could be lighter than that inferred based on peridotites and basalts which are derived from the shallow upper mantle. Consequently, it does not require an unrealistically high Si content in the core.

The mercury in the low latitude Holocene peat profile associated with monsoon variation

JING HUANG, LIMIN ZHOU AND XIANGMIN ZHENG[1]

[1]Key Laboratory of Geographic Information Science, Ministry of Education, East China Normal University, Shanghai, China, 200241, correspondence author:Limin Zhou, (lmzhou@geo.ecnu.edu.cn)

Mercury is key trace metal in earth surface system. The gasous elemental Hg takes over 90% and has a long resident time in atmosphere. Mercury in ice core has been researched for a long time. The total element Hg changes from interglacier and glacier period, although there exits the argument on the driving process. The thermal lability of mercury in peat bog could be considered as an important paleoclimate proxy. The 1.3m peat core at the Caohai Lake was collect. By the AMS dating age the core covered 3.8 ka up to 9.4 ka. The total mercury concentration with the different temperature heating pretreatment associated with the organic carbon analysis including the stable carbon isotope analysis. The results show the mercury concentration is consistent with the organic carbon variation. The clear fluctuation at 8.2 ka and 4.3 ka could be detected. The mercury concentration variation is consistent with the solar radiation change from Dongge Cave which is closed to this peat core site. Compared to the mercury in the ice core, by this result, the mercury in peat at low latitude takes the different variation pattern from the high latitude region, which implies that the deposition pattern with the climate change varies with the latitude.

Unmasking enigmatic xenolithic eclogites: Progressive metasomatism on a key Roberts Victor sample

*JIN-XIANG HUANG[1,2], W. L. GRIFFIN[1], Y. GREAU[1], N. J. PEARSON[1] AND S. Y. O'REILLY[1]

[1]CCFS/GEMOC, Macquarie University, Sydney, Australia (*correspondence: jinxiang.huang@mq.edu.au)
[2]Institute of Geology and Geophysices, China Academey of Sciences, Beijing, China

Extensive studies of xenolithic eclogites have generated two contradictory hypotheses about their origin. One regards the eclogites as deep-seated magmatic rocks, while the other regards them as basaltic components of subducted oceanic slabs. To test the hypotheses, it is essential to find out if the samples being studied actually carry primary information.

Previous work on Roberts Victor eclogites (South Africa) divided the samples into Types I and II. Type I eclogites show sequential degrees of metasomatism by melts/fluids in the carbonatitic-kimberlitic spectrum; Type II eclogites may be the protoliths of Type I.

Progressive metasomatism inferred from studies of the whole eclogite suite, has now been revealed within one sample RV07-17. Four zones (progressively 1, 2, 3, and 4) are distinguished using the compositions of garnets. From Zone 1 to Zone 4, the microstructure becomes less equilibrated; secondary minerals and fluid inclusions become abundant; pyrope content of the garnets increases gradually; cpx shows progressive enrichment in MgO. The cross-cutting pattern strongly suggests that Zone 1 represents an early stage of the metasomatism, and Zone 4 the latest stage.

The garnets of Zone 1 have flat REE patterns from Lu to Sm, but a strong depletion in the LREE. Toward Zone 4, the relative abundance of the MREE of the garnets drops significantly, giving smoother patterns. A large cpx grain in Zone 1 shows a strong depletion in the LREE, but the LREE/MREE of the cpx increases from Zone 1 to Zone 4. From Zone 1 to 4, $^{87}Sr/^{86}Sr$ of cpx increases along with Sr content; $\delta^{18}O$ of the garnet decreases from ~8.5 to ~6.0 ‰ as the MgO content increases.

These observations indicate that the eclogite was metasomatized by Mg-rich melts/fluids, changing through time from carbonatitic to more kimberlite-like. The metasomatism has swept away all original information on compositions, making it nearly impossible to define a protolith. To know the origin of the xenolithic eclogites, and to use them as evidence for different dynamic scenarios, the least metasomatised samples must be studied more than has been done previously.

Carbon isotopic evidence for methane release during the end-Permian mass extinction

JUNHUA HUANG[1], LIDAN LEI[1], GENMING LUO[1,2] AND QUNFENG ZHOU[3]

[1]State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China
[2]State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan 430074, China
[3]Institute of Geophysics & Geomatics, China University of Geosciences, Wuhan 430074, China

The largest mass extinction in the Phanerozoic that occurred mainly at the end-Permian about 252 Ma ago, eliminated ~90% of marine invertebrate species and ~70% of terrestrial vertebrate species [3]. The succedent recovery of the whole marine ecosystem lasted for more than 5 Ma [2] This mass extinction was known to be accompanied by large perturbations in the global carbon cycle. However, the cause-and-effect relationship between the mass extinction and the global carbon cycle perturbation remains unclear [1].

Here we analyzed paired carbonate and organic carbon isotopic composition at the biostratigraphically-constrained Ganxi section which was located in northern deep water basin that attached to the Yangtze carbonate platform during the P-Tr transition. The $\delta^{13}C_{carb}$ underwent two episodes of negative shifts. The first one, from ~1.5‰ to 0‰, occurred before the main mass extinction horizon. The corresponding $\delta^{13}C_{org}$ also show a negative shift from ~-25‰ to ~-28‰. The second shift, from ~1‰ to -1‰, occurred at the lower Triassic, which might correspond to the second episode identified at the Meishan section (Xie *et al*, 2007). However, the corresponding $\delta^{13}C_{org}$ shows a distinct positive shift from ~-28‰ to ~-25‰. During the extinction interval, the $\delta^{13}C_{carb}$ increased to ~1‰, and the $\delta^{13}C_{org}$ kept relatively constant.

In addition to the two episodes of general negative shifts, it is interesting to note that there are two intervals characterized by sharp negative shifts in $\delta^{13}C_{carb}$. One of them was found to occur around the P-Tr boundary, in which the $\delta^{13}C_{carb}$ declined from +1‰ to -1.3‰ within 3-cm thick strata. On the basis of recent high-resolution dating (Shen *et al*, 2011), this shift produces a variation rate as high as 80‰/Ma for the $\delta^{13}C_{carb}$, suggesting the occurrence of huge methane release.

Our data in Ganxi section indicate that the significant negative shifts in $\delta^{13}C_{carb}$ and $\delta^{13}C_{org}$ were not caused by the mass extinction. Episodic release of methane, combining with other events, might have occurred during the mass extinction interval, which could make a contribution to the extinction and environmental perturbation.

Replacement of authigenic and detrital pyrrhotites by marcasite and pyrite in cold-seep sediments offshore SW Taiwan

KO-CHUN HUANG[1] AND WEI-TEH JIANG[1]

[1]Department of Earth Sciences, National Cheng Kung University, Tainan, Taiwan., R.O.C. l48001016@mail.ncku.edu.tw; atwtj@mail.ncku.edu.tw

Complex formation sequences of pyrrhotite, marcasite, and pyrite in two 5-m piston cores of muddy sediments offshore southwestern Taiwan were investigated by FESEM-EDS-EBSD techniques. The cored sites were characterized by a shallow sulfate methane interface at ~2 meters below seafloor and located in a ridge area (Fengliao Ridge) with cold-seep activities.

Two intriguing types of iron-sulfide microtextures were identified for the sediments. Firstly, sub-millimeter stacks of detrital pyrrhotite crystals were largely replaced by pyrite and minor marcasite. Later formed platy crystals (lathy section) of pyrrhotite developed from the edges of such stacks and were locally replaced by marcasite and pyrite as well. The second type involved the occurrence of millimeter-sized iron-sulfide nodules. The nodules had a core made of aggregates of lathy grains consisting of a mixture of pyrite and minor marcasite, and were fringed with pyrrhotite crystals and carbonate. Regardless of the microtextural differences, the marcasite EBSD data collected within single lathy grains invariably exhibited six intensity clusters aligned parallel to the long axes of the lathy grains in the {010} pole figure and two intensity clusters oriented perpendicular to the same axes in the {100} pole figure, and displayed an orientation relationship of $\{100\}_{Mrc} \parallel \{0001\}_{Po}$, $\{010\}_{Mrc} \parallel \{1000\}_{Po}$, and $\{001\}_{Mrc} \parallel \{1\,\bar{2}\,10\}_{Po}$ whenever the pyrrhotite relicts were present. No specific orientation relationships between pyrite and pyrrhotite or marcasite were detected. All of the pyrrhotites had a Fe/S atomic ratio of ~0.87.

The formation of marcasite occurred through epitaxial replacement of detrital or diagenetic pyrrhotite and was related to the oxidation of pyrrhotite that led to chemical changes in microenvironments. Relatively reducing pore fluids with low flux of hydrogen sulfide were favorable for the authigenesis of pyrrhotite. The multiple stages of phase replacement and precipitation were suggestive of temporal variations of redox conditions and hydrogen-sulfide activities associated with fluctuations of the sulfate-methane interface in the region.

Comparative characterization of charcoals prepared from pyrolysis and hydrothermal carbonization and their water extractable organic carbon

R.X. HUANG[1]*, W.C. HOCKADAY[1], B.L.T. LAU[1], X.W. LU[2] AND D. JACK[3]

[1] Department of Geology, Baylor University, Waco, Texas, USA (*correspondence:rixiang_huang@baylor.edu)
[2]Department of Civil and Environmental Engineering, University of South Carolina, Columbia, USA
[3]Department of Mechanical Engineering, Baylor University, Waco, Texas, USA

Understanding the properties and the environmental behavior of charcoals produced from biomass is important within the context of carbon sequestration and sustainable agriculture. The present study compares the physicochemical properties of different types of chars and dissolved organic carbon (DOC) derived from them, as a means of making qualitative inferences about their stability and organo-mineral interactions in soils.

Chars were synthesized by slow pyrolysis at 250 °C and 500 °C and hydrothermal carbonization (HTC) at 250 °C using wheat straw as feedstock. The charcoals were characterized by solid-state ^{13}C nuclear magnetic resonance spectroscopy (NMR) and thermogravimetric analysis (TGA). A higher proportion of aromatic carbons (78%) were formed in char pyrolyzed at high temperature than low temperature pyrolysis (47%) and HTC charcoals (51%). Statistical correlations between ^{13}C NMR peak areas and mass loss data from TGA demonstrated that the aromatic carbons were mostly oxidized at temperature above 350 °C, while the alkyl carbons being oxidized at temperature below 350 °C. This suggests that the formation of aromatic structures was responsible for the thermal stability of charcoal. The leaching of labile organic carbon from chars was simulated using aqueous Soxhlet extraction. Leaching released a relatively small proportion of the charcoal carbon as DOC (<3%). The HTC charcoal leached more DOC than pyrolysis charcoal, and low-temperature pyrolysis charcoal leached more DOC than high-temperature pyrolysis charcoal. Spectroscopic characterization (proton and ^{13}C liquid NMR and UV-vis) of the DOC impied that they are mostly low molecular weight neutral molecules (e.g., sugars and alcohols). Batch adsorption experiments showed no significant adsorption of the DOC onto kaolinite and goethite over a wide range of pH in the presence of 10 mM $NaNO_3$, which suggests that adsorption potential of the DOC onto common soil minerals is low.

Effects of glycine on oligomerization of methionine under high temperature and high pressure

R. HUANG[1]*, Y. FURUKAWA[1] , AND T. KAKEGAWA[1]

[1]Guraduate school of Science, Tohoku Univ., Japan
(*correspondence: b2sm6036@s.tohoku.ac.jp)

Abiotic polymerization of amino acids seems to be an important process for the formation of the first life. Previous studies have implied the importance of pressurized conditions for the production of longer peptides, simulating the conditions of marine sediments [1, 2, 3]. These previous studies also suggest the skepticism about the formation of peptides composed of plural amino acids, showing a variety in reactivity of amino acids. In this study, we investigated the oligomerization of methionine and glycine under the conditions of high temperature and high pressure (at 175°C, 150 MPa, and 0-96 hours).

Methionine and glycine were used for representatives of each low and high reactive amino acid, respectively. Starting materials were solid methionine or solid methionine mixed with solid glycine, water, aqueous ammonia, or ammonium hydrogen carbonate. The additives other than glycine (water, aqueous ammonia, and ammonium hydrogen carbonate) are simulated decomposition products of glycine. Each starting material was sealed into a gold capsule. Then, high temperature and pressure conditions were applied using a test-tube-type autoclave system. After these experiments, experimental products were analyzed with a high performance liquid chromatograph connected to a mass spectrometer.

The rates of methionine decomposition and methionine-peptide formation were increased with additives. These rates were especially increased in samples containing aqueous ammonia and ammonium hydrogen carbonate, suggesting that ammonia promote both the production rates of peptides and the decomposition reactions of methionine. The difference in reaction rates might have been caused by the difference in pH as suggested in a previous study [4]. Our results suggest that amino acids of lower reactivity may have been activated by amino acids of higher reactivity, and then promoting peptide formation composed of plural amino acids. Such new finding may have happened commonly in prebiotic environments.

A newly identified microorganism affecting the N cycle: Ammonium oxidation in iron reducing soils

SHAN HUANG[1] AND PETER R. JAFFE[1]*

[1]Department of Civil and Environmental Engineering, Princeton University, Princeton, NJ, jaffe@princeton.edu
(* presentimng author)

A novel anaerobic ammonium (NH_4^+) oxidation process coupled with iron reduction was first noted in a forested riparian wetland in New Jersey [(1, 2)]. In this reaction, NH_4^+ is oxidized using ferric iron as the electron acceptor. Either this same pathway, or a very similar one, was also reported in a biological reactor [(3)], and a tropical rainforest soil [(4)] and coined Feammox [(3)].

Here we focus on characterizing the microbiology responsible of the Feammox process described for our previous study site [(1,2)], through an anaerobic incubation experiment and using 16S rDNA PCR-DGGE and qPCR analysis. Production of both nitrite (NO_2^-) and ferrous iron were measured repeatedly during incubations when soil slurries were supplied with iron oxide (ferrihydrite or goethite) and ammonium chloride. Significant changes in the microbial community were observed during the incubation, and one of the dominant microbial species (an uncultured *Acidimicrobiaceae* bacterium A6), belonging to the *Acidimicrobiaceae* family, similar to *Ferrimicrobium acidiphilum* (with 92% identity), is believed to be responsible for this Feammox pathway. This novel bacterium is considered to be autotrophic since its activity increased substantially when inorganic carbon was supplied. Through qPCR analysis using specific designed primers, *Acidimicrobiaceae* bacterium A6 was also found at a storm-water detention pond, which has similar high NH_4^+ and iron oxide content, indicated that the Feammox pathway might be widespread in soil environments.

The Feammox process provided denitrifiers and anammox bacteria with the necessary NO_2^- under this anaerobic incubation, and achieved total nitrogen loss via denitrification and anammox pathways. Therefore, Feammox may be an important process in the nitrogen cycle in soil environments under oxygen limited conditions, and reveals a new linkage between these two significant biogeochemical cycles (iron and nitrogen cycle).

Sm/Nd ratio of the Earth

SHICHUN HUANG[1], STEIN B JACOBSEN[1] AND SUJOY MUKHOPADHYAY[1]

[1]Department of Earth and Planetary Sciences, Harvard University (huang17@fas.harvard.edu)

The composition of Bulk Silicate Earth (BSE) provides an important "roadmap" understanding the thermal evolution, mass flow and the structure of Earth's mantle. Athough it has been known since 1960s that the BSE composition is overall not chondritic [1], it is assumed that the refractory elements in the Earth are present in chondritic proportions relative to each other [2], which is the basis of many models about the compositions of BSE and depleted mantle (DM) [e.g., 3].

The ^{147}Sm-^{143}Nd isotopic system has been used as a "backbone" to estimate the compositions of BSE and DM. This is because both Sm and Nd are refractory elements, and all chondrites have essentially the same Sm/Nd ratio (within ±2%) [e.g., 2, 4]. BSE is assumed to have chondritic Sm/Nd and ^{143}Nd/^{144}Nd ratios. However, this assumption is challenged by recent ^{142}Nd studies [4, 5]. Specifically, Boyet and Carlson [4] reported ~20 ppm ^{142}Nd/^{144}Nd difference between Earth and ordinary chondrites. Although this difference could be of nucleosynthetic origin [6, 7], it has also been attributed to either early silicate differentiation of a chondritic Earth, occurred within 30 Myrs after the Earth's formation [4], or to a superchondritic BSE, which has a Sm/Nd ratio 6% higher than the chondritic value [5].

Here we re-examine published data, and found that:

1. There is ~50 ppm ^{142}Nd/^{144}Nd variation in chondrites, and it is correlated with nucleosynthetic anomalies in ^{135}Ba, ^{144}Sm and ^{148}Nd. Consequently, the 20 ppm ^{142}Nd/^{144}Nd difference between Earth and ordinary chondrites must reflect nucleosynthetic origin;
2. Possible nebular processes are unable to significantly fractionate Sm/Nd ratio; consequently, it is unlikely that the Earth accreted from a nebular reservoir with a superchondritic Sm/Nd ratio;
3. Our analyses of the ^{147}Sm-^{143}Nd isotopic systematics of continental crust and DM suggest that BSE, or the accessible portion of BSE under the "hidden reservoir" hypothesis, has a near-chondritic Sm/Nd ratio.

Studies on the characteristics and mechanism of a heavy haze episode in Jiangsu Province, China

X.X. HUANG, T.J. WANG* AND J.L. ZHU

School of Atmospheric Sciences, Nanjing University, Nanjing 210093, China (hxxc829@hotmail.com (*correspondence: tjwang@nju.edu.cn)

Autumn is one of the periods that poor air quality frequently occurs in Jiangsu [1]. In this study, the characteristics and mechanism of a regional haze episode were investigated in late October 2012 over Jiangsu. The analysis was conducted with the observational concentrations of air pollutants (PM_{10}, $PM_{2.5}$, and CO) in 13 cities, visibility data in 5 cities, meteorological elements (relative humidity, wind speed, air temperature, precipitation in surface, upper air soundings, and synoptic situation), fire locations from FIRMS, and trajectories from the numerical models of HYSPLIT. The northern cities suffered more heavily with the highest hourly PM_{10}, $PM_{2.5}$, CO, ratio of $PM_{2.5}$ to PM_{10} exceeding 0.50mg/m^3, 0.45mg/m^3, 3.5mg/m^3, and 0.9, respectively. The lowest hourly visibility was below 5km in the 5 cities. Backward trajectories accompanied with fire spots exhibited that pollutants from large areas of biomass burning during the harvest season mixed with local anthropogenic emissions contributed to this event. The degradation of air quality in northern cities was mainly caused by emissions from biomass burning, while the southern cities were affected by the mixed emissions. Synoptic condition was another factor, especially calm and weak wind, and relatively high temperature before rainfall.

Vanadium Distribution in Environmental Samples Surrounding the Slag Dump in Panzhihua, Sichuan province, P.R.China

HUANG YI[1,2]*, ZHANG WEI[1], NI SHIJUN[1,2], CHEN YING[1] AND ZHONG LICHUN

[1]Department of Geochemistry, Chengdu University of Technology, Sichuan, PRC, huangyi@cdut.edu.cn (* presenting author)

[2]Applied Nuclear technigues in Groscience Key Laboratory of Sichuan Proviance, PRC

Million tons of metallurgical slag bearing abundant vanadium (V) was piled outside along Jinshajiang river, upstream of Yangtze river. Vanadium distribution in water, sediment and soil samples sur-rounding the slag dump was studied. The results showed that from the slag dump to the downstream of the Baguanhe river, vanadium content and the pH value gradually decreased for water samples, and also vanadium content of sediment samples gradually decreased. Soil vanadium near the slag dump is usually higher than the background value of soil in Sichuan province, and the soil with the highest value was collected from the slag dump area. It is apparent that slag piling has brought a certain degree of pollution to the surrounding environment.

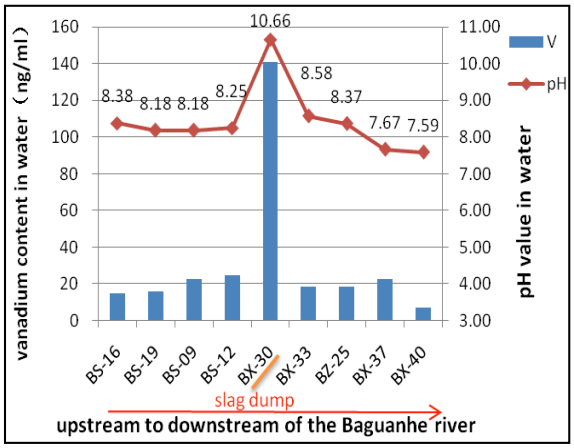

Figure 1. Vanadium concentration and pH values of water samples along the Baguanhe river

A reference Earth model for the heat producing elements and associated geoneutrino flux

Y. HUANG[1]*, V. CHUBAKOV[2], F. MANTOVANI[2], R.L. RUDNICK[1] AND W.F. MCDONOUGH[1]

[1]University of Maryland, College Park, MD 20742, USA (*correspondence: yuhuang@umd.edu; rudnick@umd.edu, mcdonoug@umd.edu)

[2]Università degli Studi di Ferrara/ INFN, Ferrara, Italy (chubakov@fe.infn.it,mantovani@fe.infn.it)

Geoneutrinos are electron antineutrinos emitted by beta-minus decays of naturally occurring radionuclides (e.g., heat producing element (HPEs), namely U, Th and K). The recent geoneutrino experimental results from KamLand [1] and Borexino [2] detectors reveal the usefulness of analyzing the Earth's geoneutrino flux, as it provides a constraint on the strength of the radiogenic heat power and this, in turn, provides a test of compositional models of the bulk silicate Earth (BSE). This flux is dependent on the amount and distribution of HPEs in the Earth's interior.

We have developed a geophysically-based, three-dimensional global reference model for the abundances and distributions of HPEs in the BSE [3]. The structure and composition of the outermost portion of the Earth, the crust and underlying lithospheric mantle, is detailed in the reference model, this portion of the Earth has the greatest influence on the geoneutrino fluxes. The reference model combines three existing geophysical models of the global crust and yields an average crustal thickness of 34.4±4.1 km in the continents and 8.0±2.7 km in the oceans, and the total mass (in 10^{22} kg) of oceanic, continental and bulk crust is 0.67±0.23, 2.06±0.25 and 2.73±0.48, respectively. *In situ* seismic velocity provided by CRUST 2.0 allows estimates of the average composition of the deep continental crust by using new and updated compositional databases for amphibolite and granulite facies rocks, in combination with laboratory ultrasonic velocities measurements. An updated xenolithic peridotite database is used to represent the average composition of continental lithospheric mantle. Monte Carlo simulation is used to predict the geoneutrino flux at selected locations and to track the asymmetrical uncertainties of radiogenic heat power due to the log-normal distributions of HPE concentrations in crustal rocks.

Limitations of isotopic and elemental signatures of oxygenic photosynthesis: A possible solution?

AXELLE HUBERT[1,2]*, FRANCES WESTALL[1], ALEXANDRE SIMIONOVICI[2], CLAIRE ROLLION-BARD[3] AND NATHALIE GRASSINEAU[4]

[1]CBM, CNRS, 45071 Orléans, France (*correspondence axelle.hubert@cnrs-orleans.fr)
[2]ISTerre, Grenoble, France
[3]CRPG, CNRS, 54500, Vandoeuvre les Nancy, France
[4]RHU L, Egham, Surrey TW20 0EX, United Kingdom

The appearance of oxygenic photosynthetic bacteria is recognised to be one of the major processes involved in the rise of oxygen in Earth's atmosphere. This process permitted the development of more complex aerobic lifeforms. However, the timing of the appearance of oxygenic photosynthesis and that of the oxygenation of the Earth are still debated [1] and constraining the event remains a challenge.

Initially, oxygenic photosynthesis must have appeared in very localized zones [2] before having a global influence. Certain factors can influence the isotopic and elemental signatures of early oxygenic photosynthesis at the local level. These include (i) overlapping ranges of ^{13}C isotopes for oxygenic photosynthetic and heterotrophic signatures, (ii) mixing of signatures in complex, multicommunity microbial mats, and (iii) diagenetic reduction of potential redox sensitive transition metals and trace elements by heterotrophs and geochemical processes caused by the predominantly (still) anaerobic environment.

We aim to disentangle the complex isotopic and elemental signatures of photosynthetic bacterial biofilms and cells in sedimentary cherts ranging from 3.5 to 1.9 Ga. We are conducting a systematic *in situ* investigation characterizing individual microbial mats so as to understand the diffrences between fossilized anoxygenic and oxygenic photosynthetic mats. We chose to focus on individual microbial mats as they record the composition and concentration of transition metals and trace elements, as well as C and S isotopic signatures on a very fine, local scale.

We hope to be able to understand the fine scale isotopic and elemental signatures of photosyntheitc oxidation in our samples so as to contribute to the overall delineation of the record of Earth's oxyenation.

[6]Center for Geomicrobiology, Aarhus University

Microorganisms have been repeatedly discovered in environments that do not support their metabolic activity. In a striking example of this, experiments to determine the temperature optima for sulfate reduction in permanently cold Arctic marine sediments revealed that metabolic rates were greatest in sediment that was incubated above 50°C. This response was distinct from that associated with the local cold-adapted microbial community (that catalyzed much lower rates associated with a 20°C optimum) and is explained by the germination of endospores of diverse thermophilic *Clostridiales* that lie dormant in marine sediments but can rapidly mineralize organic matter by hydrolysis, fermentation, and sulfate reduction upon induction at 50°C. Identifying and quantifying misplaced organisms such as thermophilic endospores can reveal rates and vectors of cell dispersal that shape natural microbial diversity and biogeography. In this case, endospore germination experiments that incorporated ^{35}S sulfate radiotracer were combined with a ^{210}Pb sediment age model to enable the estimation of a stable supply of thermophilic bacteria into the sediment at a rate exceeding 10^8 spores per square meter per year. Genomic comparisons indicate that the closest relatives to these and other misplaced thermophilic spores are found in warm subsurface petroleum reservoir and ocean crust ecosystems, suggesting that seabed fluid flow from deep biosphere environments may be transporting thermophiles into the cold ocean. These proposed mechanisms for the passive dispersal of microbial cells may thus connect very different provinces of the biosphere and lithosphere, and could be broadly influencing microbial community composition in the marine environment.

[5] Université du Québec à Montréal, GEOTOP-UQAM, CP 8888, Montréal (Qc), Canada ; (poirier.andre@uqam.ca)

Isotope records of marine seawater composition (e.g. $\delta^{13}C$, $^{87}Sr/^{86}Sr$) display significant variability at the end of the Precambrian, in particular associated with the break-up of the Rodinia supercontinent and spanning the Cryogenian snowball Earth events ca. 716 and 635 Ma. Here we explore the time interval 950–630 Ma to address the long-term evolution of the Neoproterozoic seawater chemistry and climate and to investigate perturbations to the Earth-system over this period. We apply GEOCLIM, a powerful coupled climate-geochemical model to test the effect of the breakup of the supercontinent Rodinia and the emplacement and subsequent weathering of Large Igneous Provinces (LIPs: Willouran-Gairdner, Guibei, Gunbarrel anf Franklin events) on the carbon cycle. The strontium cycle and its isotopes are implemented in the model in order to assess the influence of lithologic and paleogeographic changes on the weathering of continental silicates and climate. To this end, new $^{87}Sr/^{86}Sr$ data from marine carbonates of various Neoproterozoic successions (Northwestern Canada, Eastern Greenland, Svalbard, Siberia and Saudi Arabia) were produced to build a more complete Sr isotope record spanning the Neoproterozoic and to provide initial conditions in our simulations. In addition, Sr and Nd isotopes ratios were measured on Neoproterozoic mafic rocks and Nd isotopes on fine-grained sediments to track the timing of emplacement and weathering of the major LIP relative to glaciations.

Geological history of 4-Vesta: ^{26}Al-^{26}Mg dating on eucrites and diogenites

G. HUBLET[1], V. DEBAILLE[1], J. WIMPENNY[2] AND Q-Z. YIN[2]

[1]G-Time, Université Libre de Bruxelles, Brussels, Belgium, (ghublet@ulb.ac.be)
[2]Department of Geology, University of California, Davis, CA, USA

Eucrites and diogenites are achondrites belonging to a magmatic series coming from 4-Vesta. Eucrites are basaltic rocks, while diogenites are ultrabasic cumulates. We used the ^{26}Al-^{26}Mg chronometer for precise dating of eucrites and diogenites and revealing the geological history of 4-Vesta.

Basaltic eucrite textures suggest a formation and rapid cooling on the surface in lava flows or dikes while cumulative eucrites evidence deeper and slower cooling. This study reveals that those two types of eucrites belong to two different age populations and cannot be used together for external isochrons. Ages obtained for basaltic eucrites suggest a formation of the eucrite crust during a short and ancient period of magmatic activity on 4-Vesta between 4564 to 4563 Ma. Disturbance observed for the $^{26}Mg^*/^{24}Mg$ ratio in plagioclase fraction in one basaltic eucrite (Y-792510) suggest also a metamorphism episode likely related to shock.

Results obtained for the cumulative eucrites show younger ages compared to the basaltic type. This suggests that some inner parts of Vesta were still warm until ~4560 Ma. Ghosh at al. [1] show ^{26}Al decay is probably the heating source for Vesta differentiation and basaltic eucrite magmatic activity, and may have also kept the mantle hot during a few Ma [2], explaining the slow cooling rate evidenced by the younger age of cumulative eucrites.

Finally, our incapacity to date diogenites with the ^{26}Al-^{26}Mg chronometer suggests a younger age for them (< 4560 Ma) Diogenite are thought to be formed in intrusion within the eucrite crust during a second period of magmatic activity on 4-Vesta [3, 4], probably generated by the remelting of the magma ocean cumulates [5, 6]. This remelting cannot be related to the ^{26}Al decay because at this time, the ^{26}Al was completely extinct. A mantle overturn could be a process to explain this remelting event.

Redox controls on diagenetic incorporation of rare earth elements in fossil fish teeth

C.E. HUCK[1]*, T.VAN DE FLIERDT[1], S.M. BOHATY[2], S. HAMMOND[3] AND IODP EXPEDITION 318 SCIENTISTS

[1]Imperial College, London SW7 2AZ UK
[2]Ocean and Earth Science, NOC, Univ. of Southampton, Southampton, SO14 3ZH UK
[3]The Open University, Walton Hall, Milton Keynes MK7 6AA UK

Fossil fish teeth and skeletal debris are considered one of the most robust archives for reconstructing Nd isotope ratios of seawater in the geological past, and have been widely used to fingerprint individual water masses and trace their distribution through time. Little systematic work, however, has been done to verify the robustness of this proxy in marginal settings and under varying bottom-water and sedimentary redox conditions.

IODP Expedition 318 recovered Paleogene drillcores from offshore of the East Antarctic margin (Site U1356; 63°18.61′S, 135°59.94′E). Strata of early Eocene age (~48 to ~49 Ma) deposited in a shelf environment during the warmest period of the Cenozoic - the Early Eocene Climatic Optimum (EECO) - show striking cyclical variations between oxidised and reduced conditions. Since Site U1356 is located proximal to the Tasman Gateway and the EECO is of particular interest for palaeoceanographic reconstructions during the early Paleogene greenhouse, we investigated the robustness of the Nd isotope signal in fish debris deposited during the early Eocene at this site.

Individual fish teeth were picked from the >125µm fraction of washed bulk sediments. Comparison between fully reductively cleaned samples and samples only cleaned with water and methanol yielded the same Nd isotopic composition, and hence the latter cleaning procedure was used for the majority of the samples. All samples were dissolved in HCl, aliquoted for major and trace element analyses, and subjected to a standard two stage ion chromatography. Neodymium isotope ratios were determined using a Nu Plasma MC-ICP-MS and major and trace element data, including rare earth element patterns, were obtained on an Agilent 7500a quadrupole ICP-MS.

Preliminary data show systematic variation in the Nd isotopic composition of fish teeth extracted from reduced and oxidised sediments. We will evaluate these findings in the context of a more comprehensive data set, including main and trace element data, and discuss the implications of varying redox conditions at the sea floor on the incorporation and preservation of seawater Nd isotopes in fossil fish teeth.

Melt-inclusion evidence for a CO_2-rich mantle beneath the western branch of the East African Rift

T.R. HUDGINS[1]*, S.B. MUKASA[2] AND A.C. SIMON[1]

[1]Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI, USA (*correspondence: hudginst@umich.edu)
[2]Department of Earth Sciences, University of New Hampshire, Durham, NH, USA

CO_2 in the mantle may moderate the generation of low silica magmas. Here, we present data from olivine-hosted melt inclusions that are consistent with a carbonated mantle source beneath the western branch of the East African Rift.

Twenty-four samples were collected from the Virunga province of the East African Rift. These rocks are silica-understaturated potassic lavas (kamafugites) with 38-45 wt% SiO_2 and $K_2O/Na_2O>1$. We quantified the abundances of major, minor, and trace elements, as well as the volatiles H_2O, CO_2, F, S, and Cl in olivine-hosted melt inclusions from five whole-rock samples. The H_2O and CO_2 concentrations range from ~0.3 to 2.5 wt% and ~30 to 9,950 ppm, respectively. The CO_2 values are consistent with molecular dynamics simulations for the solubility of CO_2 in MORB and may represent less degassed melt[1]. The melt inclusions have elevated Li concentrations (up to 117 ppm) and B/Be ratios (>10) relative to MORB (Li ~3 to 4 ppm, B/Be ~2 to 4).

Two plausible sources of the volatiles are fluids evolved during paleo-subduction, and fluid exsolved from the melting of a mantle plume. Published Nd, Hf, Sr, and Os data for rocks across the EAR western branch suggest mixing of two metasomatized mantle sources as the source of these magmas, requiring previous fluid-mantle interaction[2]. Elevated Li and B concentrations measured in arc magmas have been used as a fluid tracer to investigate the role of fluid additions to the mantle wedge. As such, volatiles subducted by the closure of the Mozambique Ocean during the Pan-African orogeny are a plausible source for the elevated CO_2 and H_2O. This scenario is consistent with evidence for long-term storage of volatiles in the mantle[3]. Other potential sources include ancient subducted slabs pooled in the lower mantle and fluids released from a partially melting mantle plume. Radiogenic and noble gas isotope studies may be required to fully distinguish the sources of the mantle metasomatism.

Subcontinental lithospheric mantle and mantle plume controls on crustal PGE abundance: A case study of Palaeogene magma conduits from Western Scotland, UK

H. HUGHES, I. MCDONALD, A.C. KERR[1] AND A.J. BOYCE[2]

[1]School of Earth and Ocean Science, Cardiff University, UK CF10 3AT. (*correspondance: HughesH6@cf.ac.uk)
[2]Scottish Universities Environmental Research Centre, East Kilbride, Glasgow, UK G75 0QF.

A strong correlation can be demonstrated between plume magmatism, ancient cratonic lithosphere, and the occurrence of magmatic sulphide Ni-Cu-PGE deposits [1]. Such deposits are typically located proximal to Archaean craton margins. A highly desirable combination of plume-related mafic/ ultramafic igneous systems and Archaean cratons, underlain by their associated subcontinental lithospheric mantle (SCLM) keel, occur within the North Atlantic Igneous Province (NAIP). Significant mineralization has been discovered in the western portion of the NAIP (e.g. Skaergaard and Paleogene macrodykes [2,3]). Therefore, the British Palaeogene Igneous Province (BPIP) is potentially the most prospective PGE province in Western Europe.

This research focuses on the Scottish sector of the BPIP. Isolated platinum group mineral occurrences are documented on the Isles of Rum, Mull and Skye, but with limited assessment of its relationship to the province as a whole. To assess the geochemical inputs of asthenospheric (plume) vs. lithospheric 'reservoirs', a temporal and spatial evaluation of PGE abundance across the region must be adopted. This study incorporates the Paleoproterozoic Scourie dyke swarm, Caledonain lavas and small-scale intrusions, mantle xenoliths, and Palaeogene lavas and magma conduits.

Whole-rock grab samples were analysed for major and trace elements by ICP-OES and ICP-MS and NiS fire assay with ICP-MS analysis to determine PGE and Au abundances. Whole-rock PGE+Au concentrations from the 2.4 Ga Scourie Dyke swarm suggest no major removal of PGE from mantle 'reservoirs' at this time, leaving residual Archaean SCLM as 'fertile'. Permian dyke-hosted lherzolite xenoliths are in support of the shallow mantle remaining 'fertile' during this period, and may have undergone some degree of subduction-related enrichment of Au during Caledonian orogenesis. Lithogeochemical indicators (e.g. Cu/Pd ratio) highlight the occurrence of both S-saturated and -unsaturated magma batches across the BPIP, however there is no clear correlation with MgO, which may infer variable Cu/Pd of parental magmas instead. Pd/Ir suggest variable coeval SCLM contamination.

Dissolved metals in redox-state zero: A gap in thermodynamic databases

W. HUMMEL

Laboratory for Waste Management, Paul Scherrer Institut, 5232 Villigen, Switzerland (wolfgang.hummel@psi.ch)

Dissolution of metals like silver is usually considered solely as oxidative dissolution $Ag(s) \Leftrightarrow Ag^{+} + e^{-}$.

Whereas the solubility of zero-valent mercury is well known [1], experimental data about the solubility of other metals like silver is scarce [2, 3]. The explicit equilibrium

$$Ag(s) \Leftrightarrow Ag(aq)$$

although published and discussed in [2], is not included in any thermodynamic database. The same is true for Hg(aq).

The myth that heavy metals are "insoluble" seems to be so powerful that dissolved metal atoms do not exist in geochemical considerations. This blind spot of chemical equilibrium thermodynamics has consequences: (1) The calculated "solubility abyss" of heavy metals under reducing conditions does not exist. (2) "Unclear differences" in experimental data sets and strange model parameters are due to the ignorance of zero-valent metal species.

(1) In the field of radioactive waste disposal solubility limits of contaminants are important safety issues. In the case of metals like silver, conventional model calculations lead to a "solubility abyss" under strong reducing conditions. There, silver metal is the thermodynamically stable phase and the concentration of dissolved silver virtually drops to zero. This is an artefact due to the omission of Ag(aq).

(2) Experimental determinations of the solubility of silver sulphide, $Ag_2S(s)$, lead to large differences between data sets in acidic solutions. "The reason for this is unclear" [4]. However, these differences can be explained by considering Ag(aq) and assuming that the data sets have been measured under slightly different redox conditions. Measurements of the solubility of gold in water have been interpreted in terms of extremely strong AuOH(aq) complex formation [5]. Assuming a solubility of zero-valent gold similar to Ag(aq) the experiments can be interpreted as governed by the formation of Au(aq).

Experimental data or good estimates for Au(aq), Cu(aq), Ni(aq), Pd(aq), Pt(aq) are needed to fill the database gap.

Structure of carbonate-silicate melts at high P-T conditions using in situ X-ray diffuse scattering

DANIEL HUMMER[1], ABBY KAVNER[2] AND CRAIG MANNING[3]

[1]Department of Earth and Space Sciences, University of California Los Angeles, Los Angeles, CA 90095, (dhummer@ess.ucla.edu)
[2]Department of Earth and Space Sciences, University of California Los Angeles, Los Angeles, CA 90095, (akavner@ucla.edu)
[3]Department of Earth and Space Sciences, University of California Los Angeles, Los Angeles, CA 90095, (manning@ess.ucla.edu)

Carbonatites are an important class of mantle-derived magmas that may play a fundamental role in mantle metasomatism and carbon cycling. To examine compositional dependence of melt structure in the CaO-MgO-CO_2-SiO_2 system, we performed *in situ* X-ray scattering experiments in the Paris-Edinburgh press at HPCAT (Advanced Photon Source) using compositions along the $CaCO_3$-$CaSiO_3$ (Cc-Wo) and $CaCO_3$-Mg_2SiO_4 (Cc-Fo) joins. Both systems exhibit simple eutectic melting over a wide pressure range, with no subsolidus decarbonation reactions [1,2]. Charges were loaded using the setup of Yamada *et al* [3], and held at ~1800 ºC and ~40 kbar while energy dispersive X-ray scattering spectra were recorded at each of eleven scattering angles to achieve reciprocal space coverage up to q=32 $Å^{-1}$.

The presence of both Cc and Wo in quenched charges confirms the retention of CO_2. Pair distribution functions (PDF) reveal local atomic structure of the liquid and, when normalized to the calcite-liquid PDF, provide a measure of silica polymerization. Results suggest that $CaCO_3$ forms an ionic liquid with intact CO_3^{2-} ions, in agreement with previous results [4,5]. Silicate melts show a clear signal at 1.6 Å, corresponding to Si-O in SiO_4^{4-} tetrahedra. Both Wo-bearing and Fo-bearing compositions also show a strong signal at 3.3 Å, corresponding to Si-Si in polymerized silica. Thus, in the presence of carbonate, even liquid orthosilicates contain silica polymers. The extent of polymerization moderately increases with carbonate content along both joins, suggesting that carbonate has a significant influence over the chemistry of molten silicates at mantle conditions.

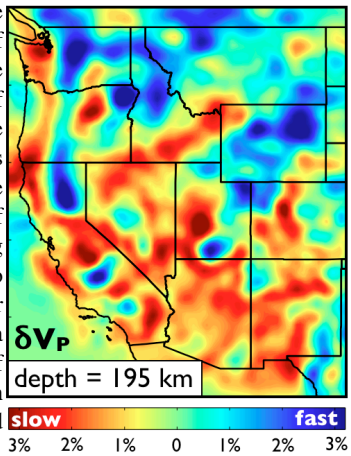
Three styles of delamination found beneath the western United States

EUGENE HUMPHREYS[1]*, BRANDON SCHMANDT[2] AND ALAN LEVANDER[3]

[1]University of Oregon, Eugene Oregon, USA 97403 (*correspondence: genehumphreys@gmail.com)
[2]University of New Mexico, Albuquerque NM, USA 87131
[3]Rice University, Houston Texas, USA 77251

Strong seismic heterogeneity imaged across the western U.S. upper mantle implies the occurrence of segmented subduction, active upwelling associated with Yellowstone, and small-scale convection across most of the area. When put in geologic context, we recognize three types of small-scale convective downwelling. (1) Most of the fast structures are thought to be fragments of Farallon lithosphere emplaced at the base of North America during Laramide-age flat-slab subduction. Their tabular form suggests a delamination style of detachment from North America. Associated magmas probably involves melting of ascending asthenosphere, hydrated basal North America, and Farallon ocean crust. (2) Another type of downwelling is most reasonably explained as a delamiation-style detachment of North American lithosphere. An association with volcanism suggests basalt infiltration and eclogite loading of the delaminated lithosphere, i.e., thermo-chemical convection. (3) A third delamination type is inferred from the young uplift of granitic batholiths that have a geochemical signature for garnet-rich restites.



Examples include delaminations related to the Columbia River Basalt eruptions (involving delamination types 1 and 3, in conjunction with arrival of the Yellowstone plume) and the ignimbrite flareup (type 1), and uplift of the southern Sierra Nevada (3 and maybe 1), Colorado Plateau margin (2) and the Transverse Ranges (1). In many cases, magmatism appearently is an integral part of delamination; it both enables mechanical detachment through the emplacement of lower crustal sills, and caused asthenosphere return flow. A general consequence of these delaminations is a remaking continent by driving mass exchange between continent and underlying mantle, and internal segregation of the continent.

Evolution of chemical and physical properties of mixed arc magmas

MADELEINE C S HUMPHREYS[1], MARIE EDMONDS[2], THOMAS CHRISTOPHER[3] AND RICHARD BROOKER[4]

[1]Department of Earth Sciences, University of Oxford, South Parks Road, Oxford, OX1 3AN, UK (madeleine.humphreys@earth.ox.ac.uk)
[2]Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge, CB2 3EQ, UK
[3]Montserrat Volcano Observatory, Flemmings, Montserrat, West Indies
[4]Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's Road, Bristol, BS8 1RJ, UK

Many intermediate arc magmas arise as a result of mingling between mafic and silicic melts that may be genetically unrelated. Recharge involving mafic melts is commonly cited as the trigger for new or renewed eruptive episodes, and a mechanism for rejuvenating stalled silicic crystal mush in the mid-crust. This process has a profound effect on the chemical and physical properties of the whole volcanic system. Using geochemical microanalysis and textural observations, it is possible to identify distinct compositions of minerals and glass that reflect different elements of the volcanic system. There is abundant evidence of physical and chemical contamination of the silicic magma on the micron-scale during mingling, and entrainment of deeper plutonic material. Disequilibrium reaction textures and overgrowth rims indicate direct contact between crystals from the silicic magma and the mafic melt, including sieved plagioclase, coarse breakdown textures in hornblende and clinopyroxene overgrowth on quartz and orthopyroxene. Anomalous glass compositions overlap with the residual glass of some mafic enclaves, indicating mingling between mafic and silicic melts. Microlite/ microphenocryst compositions overlap with mafic enclave mineral compositions, suggesting incorporporation of mafic crystals into the host magma.

During ascent, the mingled magma experiences volatile exsolution and decompression crystallisation. We discuss and present evidence for the chemical variations that take place in the magma during ascent through the volcanic system, including the controls on changing oxidation state due to degassing and crystallisation, and evidence for the exsolution of a dense brine. We also draw together constraints on the timescales of these processes and consider their effects on the physical properties of the evolving magma. We discuss the implications of these findings for our understanding of andesite petrogenesis and eruption triggering and style.

Clinopyroxene and its relationship to rapdily erupted, carbonate-rich magmas in Calatrava, Spain

EMMA R. HUMPHREYS-WILLIAMS*[1,2] TERESA JEFFRIES[1] AND KEN BAILEY†[2]

[1]Earth Sciences, Natural History Museum London, SW7 5BD (correspondance: e.williams@nhm.ac.uk)
[2]Earth Sciences, University of Bristol, Bristol, BS8 1RJ
†deceased

Rapidly erupted alkaline, ultramafic magmas such as those occuring in intraplate settings offer a unique opportunity to understand lithosphere structure and rock petrogenesis. Such volcanism erupts rapidly from the mantle, entraining a dense load of xenolithic material forming up to 30% of the rock [1]. The discovery of abundant examples of carbonate-rich volcanism containing magmatic carbonate in association with ultramafic silicate glass [2], highlights the role of carbonate and carbon-rich fluids in the formation of these magmas. However, a comprehensive understanding of the petrogenesis of such magmas remains elusive and petrological observations of variably resorbed, originally euhedral crystals are just one indication of a complex magmatic history.

Clinopyroxenes from a rapidly-erupted carbonatitic tuff in Calatrava, Spain have been analysed for their major and trace element composition. Clinopyroxenes are ideal candidates for understanding melting processes as they host a significant quantity of trace elements and the partitioning behaviour is relatively well characterised. The tuff has a wide textural range of clinopyroxene which occurs alongside calcium-carbonate within fresh melilititic silicate glass. Within glassy lapilli, carbonate occurs as globules and also as a matrix between lapilli fragments.

Clinopyroxenes have Mg# 0.68-0.80 and span a wide range of major element compositions. Clinopyroxenes do not overlap with the major element composition of mantle xenolith-derived clinopyroxenes erupted in similar volcanism in Calatrava, suggesting that no clinopyroxene originates from the disaggregation of mantle xenoliths.

Melts calculated to be in equilibrium with a range of clinopyroxenes illustrate the variation of the melt composition before and up to eruption. Our data suggest that large 'xenocrystic' clinopyroxenes relate to the early stages of magma formation. Resorption of once euhedral crystals can be attributed to disequilibrium resulting from changes in composition of the melt prior to eruption.

The influence of urbanisation on forest soils: Comparing variability and mobility of potentially toxic elements and carbon sequestration between urban regions in Scotland and Bulgaria

ANDREW HURSTHOUSE[1]*, VANYA DOICHINOVA[2] AND MIGLENA ZHIYANSKI[2]

[1]School of Science, University of the West of Scotland, Paisley, PA1 2BE, UK (*andrew.hursthouse@uws.ac.uk)
[2]Forest Research Institute, Bulgarian Academy of Sciences, 132 "Kliment Ohridski" Blvd., 1756 Sofia, Bulgaria (doichinova@abv.bg; zhiyanski@abv.bg)

The process of urbanization creates unique urban ecosystems and urbanized soils. Due to high pollution load and the dynamic effect of climate change in the urban environment, green infrastructure comes under increasing stress. The great potential is for urban forest areas to offer a significant contribution in mitigation of CO_2 at a small scale, but little is known about the interaction with urban soils, increasingly recognized as a sink for inputs of urban pollutants. Our study looked at a number of forest soil sites along rural-urban gradiets in Glasgow, Scotland and the Sofia Region, Bulgaria.

We compared soil properties with carbon stocks, nutrient availability and potentially toxic element loads. In urban soils of Sofia carbon stocks varied between 80 - 125 tC ha^{-1} and for Glasgow 76 - 120 tC ha^{-1}, with non-urbanized control sites: 53 - 103 tC ha^{-1} for the Sofia region. The tree carbon stock, was higher in non-urbanized sites, because of higher tree density in these plots. The results for aboveground biomass carbon stock in urban sites varied between 34.5 - 61.7 tC.ha^{-1} for Sofia and 45.2 - 60.8 tC.ha^{-1} for Glasgow and in Non-Urban sites: 33.9 - 67.5 tC.ha^{-1}, and 57.3 tC.ha^{-1} respectively.

We obtained strong correlations between mobile forms of Cu, Zn, Pb, Cd in urban soils and a number of soil parameters (pH, CEC and texture). The mobility related to soil pH (and OM for Cu) agreeing with other work in the cities. The most mobile soil fraction was found for Cd (33%). The assessment of health status of oaks tree vegetation based on indices defoliation of crown and changes in color do not correlate significantly with the bioavailable concentration of PTEs in the soils. Carbon sequestraton relates strongly to management activity and the influence of PTE content is obscured.

Redox and nutrient cycling in a late Mesoproterozoic sea

K.F. HUSBAND[1,2]*, S.W. POULTON[1], R. GUILBAUD[1], A.D. ROONEY[3] AND D. SELBY[4]

[4]Dept. Earth Sci., Uni. of Durham, Durham, DH1 3LE, UK

A growing body of evidence suggests that, during the so-called 'boring billion' (~1.8-0.8 Ga), the global ocean was characterised by widespread euxinia along productive continental margins, with deeper waters that remained ferruginous. In detail, however, evidence for euxinic conditions in continental margin settings is extremely scarce in the early Neoproterozoic (~1.0-0.75 Ga), with most evidence instead suggesting an expansion of ferruginous conditions. In addition, little is known about the detailed nature of ocean chemistry in the late Mesoproterozoic, prior to this apparent change in global ocean chemistry. Ocean redox conditions potentially exert a strong control on nutrient cycling, thus influencing organic carbon production and burial, and, in turn, environmental oxygen levels. However, the lack of detailed studies on late Mesoproterozoic successions means that little is known about redox-driven nutrient feedbacks at this time, and hence controls on environmental conditions towards the end of the 'boring billion' remain poorly understood.

Here, we present an integrated study of Fe-S-C systematics and P cycling in the 1.1 Ga Taoudeni Basin of Mauritania. Earlier in the succession, we find that euxinia was prevalent in mid-depth waters, with deeper waters being ferruginous. However, there is less evidence for euxinia further up the succession and instead ferruginous conditions became more widespread. Ferruginous conditions throughout the succession are commonly characterized by enhanced organic C burial, suggesting that the development of euxinic conditions was not simply driven by organic C availability. To provide further insight, we utilize P speciation and S isotope data, which together shed new light on environmental condtions during this crucial interval that marks the final stages of several hundred million years of apparent environmental stasis.

[2]PerkinElmer LAS (UK) Ltd, Chalfont Road, Seer Green, Beaconsfield, Bucks HP9 2FX , UK. (david.price@perkinelmer.com).

[3]Bureau Veritas Australia Pty Ltd. 58 Sorbonne Cres Canning Vale Perth WA 6155. (alex.christ@au.bureauveritas.com)

Mining operations rely on fast turnaround of precise and accurate analysis of rock and soil sampled from the field. A large mine can supply up to 100,000 samples to the analytical services per month, each requiring extensive sample preparation for analysis by XRF for composition analysis and solution analysis-ICP-MS for trace elements. The latter is typically performed by sample digestion in *aqua regia*, which has cost, health and safety and disposal considerations.

Here we describe methodology and results for the trace element analysis of XRF discs by laser ablation ICP-MS. This methodology removes the solution digestion sample preparation and its associated costs and risks. Furthermore, the sample type is highly stable long-term and can be recalled for repeat analysis without the need for specialist storage.

Overall, the LA-ICP-MS methodology represents improvement in cost, manpower, throughput and risk when compared to solution ICP-MS analysis.

Indirect dating of the Guadalupian-Lopingian Boundary

M.H. HUYSKENS*, Y. AMELIN[1], R.S. NICOLL[1,2] AND I. METCALFE[3]

[1]Research School of Earth Sciences, The Australian National University, 142 Mills Road, 0200 Acton, ACT, Australia. (*magda.huyskens@anu.edu.au)

[2]Geoscience Australia, Canberra, Australia.

[3]Earth Sciences, University of New England, Australia.

The Guadalupian-Lopingian Boundary (GLB) is defined by the first occurrence of the conodont species *Clarkina postbitteri postbitteri* and currently interpreted to be 259.8±0.4 Ma [1]. The Global Stratotype Section and Point (GSSP) for this boundary at Penglaitan, south China has detailed fossil and chemostratigraphy information available, but unfortunately neither magnetostratigraphy nor geochronolgical studies were successful at the GSSP section.

We have correlated the GSSP section to a terrestrial sequence in the southern Sydney Basin, Australia using C-isotope stratigraphy and present high-precision U-Pb geochronology for five samples covering the Wilton Formation to the Erins Vale Formation tied to C-isotopic values [2] of the drill core Bunnerong DDH 1. Based on C-isotope stratigraphy the GLB in the southern Sydney Basin is interpreted to correlate with the boundary between the Thirroul Sandstone and the Woonona Coal. Based on two bracketing U-Pb ages (256.47±0.14 Ma and 258.04±0.54 Ma, 51 m above and 65 m below the GLB respectively) the age of the GLB is interpreted to be ~ 257.5 Ma.

These new dates can be used to constrain the age of the mid-Capitanian mass extinction. This extinction was previously interpreted to coincide with the GLB, but more recent work suggests a prolonged extinction episode in the mid-Capitanian with different biota becoming extinct at different levels. There is no current consensus on placement of the mass extinction. One of the suggestions is that it occurred at the base of the *Jinogondolella granti* zone coinciding with a major sea-level regression [3]. This regression is recorded in the southern Sydney Basin by an erosive contact between the Erins Vale Formation and the Thirroul Sandstone. This regression is dated at ~ 258 Ma.

Assessment of accuracy and precision for IRMS by standard material

JONG-YEON HWANG[1]*, BO-KYONG KIM, WON-SEOK LEE, MIN-SEOB KIM AND JIN-SEOK HAN

[1]Environmental Measurement & Analysis center, NIER, Environmental Research complex, Gyeongseo-dong, Seo-gu, Incheon Metropolitan City, 404-708, KOREA.(*corespondence : hjy6711@korea.kr)

The setup of optimum condition for IRMS

As a result of this study, carbon isotope composition was very precise and accurate in a narrow range as well as a wide range of sample weight. The measured $\delta^{13}C$ value that was within the certified value ± 2σ had the minimum carbon contents in which EMA-P1 and EMA-P2 is 102.107 μg and 116.879 μg, respectively. Although nitrogen and sulfur isotope composition was less precise and accurate than carbon, the nitrogen content(18.650 μg) and sulfur content(27.839 μg) already had been within the certified value ± 2σ. The variation of isotope composition was also investigated by the fractionation factor $\varepsilon_{applied}$ that would explain the stability for $\delta^{13}C$, $\delta^{15}N$ and $\delta^{34}S$ value. We suggest that carbon, nitrogen and sulfur isotope composition need to be determined by considering several factors; accuracy of $\delta^{13}C$ value and precision of $\delta^{13}C$ value, peak height ratio and fractionation factor $\varepsilon_{applied}$.

Discussion of Results

Study on stable isotopes in contaminants is a relatively new concept with high potential of transforming a monitoring-based research paradigm into a more advanced one. In this study, a brand-new stable isotope analyzer was used and accuracy and precision were evaluated using carbon and nitrogen reference materials to establish the optimal analytical condition. And also, we can conclude that the analysis of stable isotopes in environment using a stable isotope analyzer is a promising new method for identifying the sources of contaminants.

Volcanic acid-sulfate analogs for early Mars

BRIAN HYNEK[1,2]*, THOMAS MCCOLLOM[1], KARYN ROGERS[3] AND EMMA MARCUCCI[1,2]

[1]Lab. for Atmospheric and Space Physics, University of Colorado, 3665 Discovery DR, Boulder, CO 80303 USA
[2]Department of Geological Sciences, University of Colorado, 399 UCB, Boulder, CO 80309 USA
[3]Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC 20015 USA

Owing to Mars' prolonged history of volcanism, high heat flow, and copious surface water, we assume abundant hydrothermal systems persisted for significant time periods. Life on Earth may have originated in a similar setting and assessment of putative hydrothermal systems on Mars is paramount to assessing the planet's geochemical history and astrobiological potential. To this end, we have been assessing Earth and putative Mars hydrothermal systems through fieldwork, lab experiments, geochemical modeling, and remote sensing. Fieldwork at active basaltic volcanoes in Central America and Hawaii was used to document geochemical pathways of acid-sulfate alteration and resultant mineralogy. These results were correlated with environmental parameters (T, pH, fluid:rock ratio) to define the controls on alteration pathways. We find that extremely acidic pH and high temperature fumalores rapidly alter the parent lithology into S, amorphous Si, with occasional crusts of gypsum. Moderately acidic (pH of about 4) fumaroles lead to abundant gypsum, natroalunite, Si, and Al-smectites. Mildly acidic and cooler fumaroles produce calcite and gypsum. Correlated laboratory experiments and geochemical modeling on whole basalts and individual mineral components have further defined the controls of acid sulfate alteration over a broad range of conditions and we found that high fluid:rock and temperatures lead to rapid dissolution of primary minerals and the liberated cations lead to a range of sulfates, amorphous Si, and hematite concretions. Remote sensing data from Mars reveals discrete locales of minerals indicative of acid-sulfate alteration and some were undoubtedly hydrothermal in origin. Our terrestrial studies provide a conceptual framework for interpreting the paleoconditions of ancient martian hydrothermal systems, where we are able to use the alteration mineralogy to infer the likely conditions of formation. Further, we have characterized the microbiology within active terrestrial volcanoes. While the hottest and lowest pH sites have minimal biomass, the moderately acidic and cooler fumaroles have diverse endolithic communities of photo- and heterotropic aerobes and anerobes.

High rates of carbon oxidation through dissimilatory manganese reduction in sediment of Ulleung Basin in the East Sea

JUNG-HO HYUN[1], SUNG-HAN KIM[1], JIN-SOOK MOK[1], HYE-YOUN CHO[1], VERONA VANDIEKEN[2] AND BO THAMDRUP[3]

[1/]Hanyang University, Marine Sciences and Convergent Technology, Korea; hyunjh@hanyang.ac.kr
[2]University of Oldenburg, Germany; verona.vandieken@uni-oldenburg.de
[3]University of Southern Denmark; (bot@biology.sdu.dk).

Dissimilatory iron reduction plays an important role in the oxidation of organic carbon in continental sediments, whereas large contributions from dissimilatory manganese reduction are only known from a few locations characterized by a very high Mn content. There are very few experimental studies of these processes in deep sea sediments. As a contribution to filling this gap and obtaining a more detailed understanding of the regulation of the processes in marine sediments, we investigated experimetally the rates and relative importance of terminal electron acceptors in sediment from the slope and floor of the >2000 m deep Ulleung Basin in the East Sea. Our experiments also tested the assumptions behind the methods.

The contributions of Fe and and Mn reduction were detemined in anoxic incubations both indirectly by comparing total carbon oxidation rates from DIC production to the part of DIC production contributed by sulfate reduction, and directly from the accumulation of Fe(II) and Mn^{2+} over time, with corrections for reduction coupled to reoxidation of reduced sulfur species and for the adsorption of Mn^{2+}. Rates obtained by the two methods agreed closely, which indicates that the stoichiometric assumptions behind the incubation approach are correct.

Dissimilatory Mn reduction accounted for ~50% of anaerobic carbon oxidation at the deep basin site, which contained more than 2.5 wt% Mn, while the process was insignificant at the slope site, which was not enriched in Mn. Here, sulfate reduction dominated with ~80% of anaerobic carbon oxidation. Both the the diffusive O_2 uptake in intact cores and the depth-integrated DIC production from anoxic incubations demonstrated very high rates of carbon oxidation in these deep sediments.

Our results add the Ulleung Basin to the very small set of locations where dissimilatory Mn oxidation is important, and demonstrate that this deep basin is a hotspot of benthic mineralization, which can be related to the oceanographic characteristics of the East Sea.

Impact of Fe speciation in the aquifer sediments on ferric (hydr)oxide precipitation at the Changwon research site, Korea

S. P. HYUN*, H. S. MOON, P. YOON, K. HA AND B.-G. CHAE

Korea Institute of Geoscience and Mineral Resources (KIGAM), Daejeon 305-350, Korea (*Correspondence: sphyun@kigam.re.kr)

Ferric (hydr)oxide precipitation can control the mobility of contaminants and redox conditions in an aquifer. The impact of Fe speciation on the kinetics of ferric (hydr)oxide precipitation at the sediment-groundwater interfaces was studied using the sediment samples collected from the KIGAM research site in Changwon, Korea. The research site is on unconsolidated, Quaternary floodplain deposits by the Nakdong River. Sets of sediment samples were collected at varying depths and locations within the research site. The sediment samples were wet-sieved to the sand, silt, and clay fraction, and further used for the Fe speciation characterization. Different pools of Fe present in the sediment samples were selectively extracted using ferrozine, ammonium oxalate, dithionite-citrate-bicarbonate, and hydrochloric acid. Chemical and mineralogical characterization of the sediment samples were performed using X-ray fluorescence, X-ray diffraction, and electron microscopy. Also, Fe distribution between the sediment and groundwater was modeled using the field measured groundwater chemistry data and Fe speciation results.

The results indicate alternating redox conditions along the depth of the aquifer. The alternating redox pattern suggests heterogeneities in the organic matter content and mineral composition within the aquifer, and seasonal and spatial variations in the groundwater table affected by the river water level changes. The different extraction methods resulted in independently varying or even apparently conflicting trends as functions of depth, suggesting the different quantities of Fe in the different pools. The field measured dissolved Fe(II) concentration in groundwater was up to a hundred mg/L with dissolved oxygen between 0.1 to 4 mg/L, depending on the depth and spatial location. This study suggests the potential of ferric (hydr)oxide precipitation upon the infiltration of surface water high in dissolved oxygen, to act as a sink and source of contaminants such as heavy metals and radionuclides, depending on the prevailing geochemical conditions within the aquifer. The results of this study will be used as background information in studying the kinetics of ferric (hydr)oxide precipitation.

Toward a unified method for the quantification of volatiles in magmas via FTIR

KAYLA IACOVINO[1]*, NIAL PETERS[1] AND CLIVE OPPENHEIMER[1]

[1]Dept. Of Geography, University of Cambridge, Cambridge UK (*correspondance: ki247@cam.ac.uk)

Fourier Transform Infrared (FTIR) spectroscopy is a common tool used to quantify dissolved volatiles in melts. The use of this method for the analysis of melt inclusions in particular is crucial to understanding a multitude of volcanic and geochemical processes such as magma storage, crystallization, and degassing. Despite the ubiquitous nature of this technique in the literature, standard methods for the retrieval of dissolved volatile concentrations from IR spectral data are poorly defined and often rely on hand-drawn or assumed straight-line-fit background curves that introduce significant error and variation within data sets. Propogated errors from differences in "acceptable" background curves for a single IR spectrum drawn by a set of individuals (or even by a single individual at different times) can equate to variation in final retreived volatile concentrations on the order of wt%. In an effort to reconcile this problem, we are developing a simple software package capable of retrieving dissolved volatile concentrations (i.e. H_2O, OH, CO_2, and CO_3) from FTIR spectra based on a set of standard peak fitting algorithms. By using spectroscopic first principles to define a volatile-free background spectra, peak heights, and ultimately volatile concentrations, we can eliminate variations between individual researchers that stem from the subjectivity in choosing a "good" background spectrum. In addition, the automation of this procedure by computer eliminates internal variation within data sets and expedites the process of analyzing large data sets.

Our software tool, currently in the early stages of development, will allow for the creation of volatile-free background spectra based on a curve fit to the user-input FTIR data. Subsequently, a calculation of peak heights and ultimately volatile concentrations (based on the Beer-Lambert law, given sample thickness, density, and absorption coefficient) can be performed. Our goal is to make the tool as transparent as possible in order that the user has more control over and understanding of the data transformations being performed. The program, written in Python and released under the Gnu Public License (GPLv3), is currently in alpha. We are now seeking input on the overall design, desired features, and back-end theory/computation.

REE content of phosphogypsum from Romania

AURORA MĂRUŢA IANCU[1]*, DELIA-GEORGETA DUMITRAŞ[1], ESSAÏD BILAL[2], STEFAN MARINCEA[1], CRISTINA GHINEŢ[1], CĂLIN NICOLAE[1] AND MARIA-ANGELA ANASON[1]

Geological Institute of Romania, 1, Caransebes Str., Bucharest, Romania, RO-012271. (*correspondence: aurash83@yahoo.com)

Centre SPIN, Ecole Nationale Supérieure des Mines de Saint-Etienne, 158, Cours Fauriel, F-42023 Saint-Etienne Cedex 2, France (bilal@emse.fr)

Phosphogypsum is a technogenic product remaining after the extraction of phosphoric acid from raw phosphate, mainly apatite. The original phosphate rock contains large amounts of REE, mainly replacing Ca from apatite or included in other phosphate structures. About 70% of the REE contents are stacked in the phosphogypsum obtained after sulfuric attack of the raw phosphate and much less in the case of hydrochloric attack. In Romania, the sulfuric attack through the hemi-dihydrate (HDH) or dihydrate (DH) procedures was extensively used to obtain phosphoric acid at Turnu Măgurele (TM), Valea Călugărească (VC), Năvodari (N) and Bacău (B).

Inductively coupled plasma - atomic emission spectrometry (ICP-AES) analyses performed on selected samples of phosphogypsum from the four deposits showed that the contents in the main REE (cerium, erbium, neodymium, thorium, ytterbium) are specific for the phosphogypsum issued from the processing of sedimentary raw phosphates. The contents are given in the table.

Observation of geoneutrinos in Borexino

A. IANNI[1,*] AND Y. SUVOROV[2]

[1] *correspondance: aldo.ianni@lngs.infn.it
[2] yury.suvorov@lngs.infn.it

Geoneutrinos are electron anti-neutrinos produced by long-lived radioactive isotopes in the earth's crust and mantle. Geoneutrinos can be deteted in kton scale organic liquid scintillator detectors located in underground laboratories. The detection reaction being the inverse-beta decay which has a prompt and delayed signal. These signals are correlated in space and time. The anti-neutrino interacts with a proton from an hydrogen atom and will make a positron plus a neutron. The positron will promptly annihilate; the neutron will thermalize and be captured on hydrogen in some 250 μs. In spite of the strong signature geoneutrino can only be detected in massive low background set-ups designed for low energy (1 MeV) neutrinos. Borexino at the Gran Sasso underground laboratory in Italy has been in operation since 2007 to search for sub-MeV solar neutrinos. The sun is a huge source of electron neutrinos. Observation of solar neutrinos provides a unique tool to study the interior of the sun. At present experimental studies of geoneutrinos are carried out with KamLAND at the Kamioka mine in Japan and with Borexino at Gran Sasso. The first attempt of a geoneutrino measurement was done in KamLAND in 2005. Only in 2010 and 2011 both Borexino and KamLAND observed at more the 4σ C.L. a signal from geoneutrinos. The search of geoneutrinos likewise the one of solar neutrinos for the sun provides a unique tool to probe the interior of the earth. Uranium and thorium from the crust and the mantle make the geoneutrino flux on surface. The energy spectrum of the detected geoneutrinos depends on the abundance of uranium and thorium and on the different beta decays in the two radioactive chains. A spectroscopy determination of the geoneutrino signal can be done. This has been recently shown by Borexino. By means of this analysis the ultimate goal of the geoneutrino search will be the determination of the uranium and thorium content in the mantle. For this purpose a combined analysis of more than one experiment results will be necessary. In this talk we will review the present status of geoneutrino research. We elaborate on the recent results from Borexino and KamLAND. The experimental difficulties and background sources will be discussed.

Influence of osteopontin on apatite formation

C. J. S. IBSEN[1], J. OLSEN[1], D. GEBAUER[2], H. BIRKEDAL[1]

[1] iNANO & Department of Chemistry, Aarhus University, Aarhus 8000, Denmark (*correspondence: hbirkedal@chem.au.dk)
[2] Department of Chemistry, University of Konstanz, Konstanz 78457, Germany

The classical crystallization theories have been shown to be incomplete, particularly in the field biomineralization where non-classical crystallization pathways are widespread [1], including prenucleation clusters in solution as known in $CaCO_3$ and calcium phosphates [2-4]. The picture is even more complicated when additives are also considered. For calcium phosphate biomineralization in vertebrates, phosphate-rich proteins are known to be important. Herein we show how one of these, the calcium binding phosphoprotein osteopontin, drastically modifies the prenucleation behavior during calcium phosphate formation.

The formation of calcium phosphate was investigated by constant pH (8.0) titration of dilute calcium chloride into a sodium phosphate solution [2]. The calcium activity was measured *in situ* using a calcium sensitive electrode.

In the osteopontin-free case, the calcium activity is lower than the added amount reflecting the formation of a bound prenucleation state [2-4]. As the supersaturation increases, an amorphous intermediate is formed which transforms into crystalline apatite upon continued titration. When introducing osteopontin an additional intermediate is observed that remains in dispersion. Both intermediates were stabilized by osteopontin in a dose dependent manner. However, osteopontin did not significantly affect the prenucleation behaviour prior to the formation of the first intermediate.

The initial amorphous phase was HPO_4^{2-}-rich. As more calcium was added, the stoichiometry gradually changed towards stoichiometric amorphous calcium phosphate (ACP), with a distinct increase in the PO_4^{3-}/HPO_4^{2-} ratio at the transition from intermediate 1 to 2. The final apatitic phase was also found to be calcium deficient.

For carbonates, multiple amorphous forms are known, which might influence what polymorph is formed [2]. The observed additive-stabilization of ACP could help unravel the role of additives in biomineral formation, including polymorph selection.

Titanite from the Fish Canyon Tuff: Searching for clues to pre-eruptive magma chamber processes

F. IDDON[1], G. W. MCLEOD[1]* AND T. J. DEMPSTER[2]

[1]Earth & Environment, University of Leeds, Leeds, LS2 9JT, UK (*correspondance: g.w.mcleod@leeds.ac.uk)
[2]Geographical and Earth Sciences, University of Glasgow, G12 8QQ, UK (tim.dempster@ges.gla.ac.uk)

Magma-mixing is thought to be an important mechanism for initiating large-scale pyroclastic eruptions, and as such, may play a key role in the petrogenetic history of such eruptions. However, the fragmental and often glassy nature of pyroclastic deposits, and to some extent the homogenisation associated with emplacement at the surface, may act to mask the details of plutonic level petrogenesis. The deposits rarely display visible evidence of pre-eruptive mixing, and unless there is textural or geochemical alteration of phenocrysts prior to eruption, then evidence of mixing at depth may be very sparse.

Titanite is a geochemically robust accessory mineral that has the ability to serve as a sink for trace elements; the REE and HFSE in particular. Recently, it has been shown that compositional zoning of titanite from plutonic rocks can preserve a record of the changing conditions within a magma chamber, including evidence of magma-mixing processes [1].

This study aims to assess the ability of titanite found in volcanic rocks to preserve evidence of pre-eruptive petrogenetic processes, by conducting a coupled micro-textural and geochemical analysis of titanite from the Fish Canyon Tuff, Colorado, USA. It is thought that thermal rejuvenation of the silicic magma, caused by intrusion of mafic magma at the base of the magma chamber just prior to eruption of the tuff, served as a trigger for eruption [2]. Such an input of mafic magma could induce compositional, temperature, and oxygen fugacity changes in the chamber, to which titanite could respond

Preliminary results, from this ongoing study, show titanite to have compositional zoning with cores preferentially enriched in heavy REE and rims preferentially enriched in light REE; a reflection of the changing compositon of the melt. Dissolution surfaces with inclusions of ilmenite are common, and provide evidence of changing titanite/ilmenite stability; interpreted here to reflect changes in oxygen fugacity brought about by replenishment of the chamber with fresh mafic magma.

Molecular and Micro Element Remote Analysis of Leaves of the Green Plants

A. IGLAKOVA[1], A. KLIMKIN[1], V. PROKOPIEV[2]

[1]Institute of Atmospheric Optics SB RAS, Tomsk, Russia;
[2]Institute of High Current Electronics SB RAS, Tomsk, Russia

Condition of the vegetative ground cover is an important determinant of environmental health. The global scale of this object requires using distant, primarily optical research techniques [1].

In particular, this may be done by measuring the fluorescence spectra and laser plasma emission during leaves surfaces ablation, which allows drawing certain conclusions about the state of photosynthetic apparatus and plant vegetation conditions [2].

This study was carried out by way of remote and laboratory tests, focused on research of fluorescence spectra in photosynthetic apparatus and plasma of green plants optical-induced breakdown under femtosecond laser radiation. Radiation wavelength of 650 ÷ 950 nm, peal energy up to 10 mJ, length 50 ÷ 100 fs [3].

Chlorophyll fluorescence and absorption bands in the light-collecting antenna as well as the leave reaction center with the range of 660 ÷ 800 nm were measured in the radiation spectra. The researched parameters helped to evaluate the current condition of plants photosynthetic apparatus.

Measurements of leaves micro element composition allow finding possible reasons which modify this condition.

Spectra of plasma emission from plant leaves located at 10 meter distance revealed the presence of sensitive spectral lines of atoms and ions of carbon, magnesium, iron, calcium, calcium, and copper. Lines of OH, Swan (C_2), and Cyanogen (CN) were also observed in these spectra.

Veined quartz of the Urals: Structure, mineralogy

M.A. IGUMENTSEVA [1], V.N. ANFILOGOV[2]

[1]Miass,Chelyabinsk region, Institute of Mineralogy, maria@mineralogy.ru
[2]Miass,Chelyabinsk region, Institute of Mineralogy, anfilogov@mineralogy.ru

There are three major groups of the Ural quartz deposits: the Subpolar Urals group, the Middle Urals group and the South Urals one. The Subpolar group is represented by the typical hydrothermal veined deposits. is Zhelannoe - one of the big Subpolar quartz deposit is discribed. It is located in monomineralic quartzy sandstone. The quartz vein may be to 100 meters thick. Rutile, turmaline, zircon and sericite are the major accessory minerals. The chief deleterious constituent in quartz is water, which is located in gas-liquid inclusions. The effective method for H_2O elimination is described. High quality quartz glass may be produced after primary quartz enriching.

The Middle Urals is represented by two giant quartz deposits: Gora Khrustal'naya and Svetlaya Rechka. Gora Khrustal'naya is represented by one quartz body which size is 380X140X160 m. The content of quartz in this body is 98.89%. Quartz deposit was formed on the big massive of quartz-diorite and granite contact. The main accessory minerals are microcline, muscovite, kaolin, hydrogoethite and pyrite. Quartz has giant crystalline structure. The specific enriching technology is described for this quartz deposit.

The South Ural group of quartz deposits is represented by quartz veins disposed in East part of the Ufaleisky gneiss-migmatite complex. Length of quartz vein area is 50 km. There are more than 3000 quartz veins on this area. Granulated quartz is prevalent for this group of deposits. Field spars, micas, rutile, sphene, ilmenite and carbonates are the main accessory minerals. Concentration of impurities in granulated quartz is as the IOTA STD. There is standard technology of quartz enriching for these deposits.

One more type of quartz deposits associated with small Naily gold deposit is vein Tolstikha. It is situated 35 km north from Miass and localized at the contact of small gabbro pluton with the large Talovskii massif of serpentinized dunites, peridotites, and pyroxenites. This is a new economic quartz object. To date, the gold deposit has been mined. The vein is 1000 m along the strike, up to 50 m wide, and is traced up to 450 m deep.

Biogeochemistry of the deep mud-volcano biosphere in the Kumano forearc basin of the Nankai Trough

AKIRA IJIRI[1,2]*, FUMIO INAGAKI[1,2], YUSUKE KUBO[3] AND EXPEDITIONS CK09-01 AND 906 SCIENTISTS

[1]Submarine Resources Research Project, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Monobe B200, Nankoku, Kochi 783-8502, Japan. (*corespondence: ijiri@jamstec.go.jp)
[2]Kochi Institute for Core Sample Research, JAMSTEC, Monobe B200, Nankoku, Kochi 783-8502, Japan.
[3] Center for Deep Earth Exploration (CDEX), JAMSTEC, Showa-machi 3173-25, Yokohama 236-0001, Japan.

Submarine mud-volcanoes are formed by the vertical intrusion of a lower density and deformable materials from deep realm to the seabed. The mud-volcanism transports deep-sourced fluids, elements and hydrocarbons to the seafloor, of which seepages support chemosynthetic benthic life, including microbial communities that mediate anaerobic oxidation of methane with sulfate reduction. However, biogeochemical and microbiological characteristics of the deep realm of submarine mud-volcano have remained largely unknown.

In 2009 and 2012, using the deep-sea drilling vessel *Chikyu*, we drilled one of the most active submarine mud-volcanoes in the Kumano forearc basin of the Nankai Trough, off the Kii Peninsula of Japan, down to 200 meters from the summit (33°67.581N, 136°56.8085E: 1,986.7 m in water depth). Cell count and molecular analysis indicate the presence of relatively small microbial communities (less than 10^5 cells/cm^3) throughout the cored depth. Carbon isotopic compositions of bicarbonate and acetate in the pore water were found to be highly enriched in ^{13}C. High concentrations of hydrogen were also observed, indicating a thermodynamically preferential condition for microbial acetogenesis via CO_2 reduction (i.e., homo-acetogenesis) rather. Radiotracer incubation experiments showed that activities of homo-acetogenesis were 2-3 orders of magnitude higher than those of homo- and acetoclastic methanogenesis.

Consequently, our accumulative biogeochemical and microbiological data indicate that the deep biosphere in the submarine mud-volcano of the Nankai Trough accretionary wedge is characterized by tectonic and sedimentological regimes, and hence different from the previously explored subseafloor biosphere in stratified sediment on the continental margins.

[4]Center for Deep Earth Exploration (CDEX), JAMSTEC, Showa-machi 3173-25, Yokohama 236-0001, Japan.

Integrated Ocean Drilling Program (IODP) Expedition 337 was the first expedition dedicated to subseafloor microbiology that used riser drilling technology [1]. IODP drill Site C0020 is located in a forearc basin formed by the subduction of the Pacific plate off the Shimokita Peninsula at a water depth of 1,180 m. Seismic profiles suggested the presence of deep, coal-bearing horizons at ~2 km subseafloor depth. Our primary objectives during Expedition 337 were to study the relationship between the deep microbial biosphere and the subseafloor coalbed and to explore the limits of life in horizons deeper than ever probed before by scientific ocean drilling. Among the questions that guided our research strategy was: Do deeply buried hydrocarbon reservoirs such as coalbeds act as geobiological reactors that sustain subsurface life by releasing nutrients and carbon substrates? To address this question and other objectives, we penetrated a 2,466 m deep sedimentary sequence with a series of coal layers at ~2 km below the seafloor. Hole C0020A is currently the deepest hole in the history of scientific ocean drilling [1].

During Expedition 337, over 1,700 microbiological and biogeochemical samples have successfully been obtained, for which rigorous contamination controls enable differentiation of contaminants from indigenous microbial communities. We conducted gas chemistry and isotopic analyses using a new mud-gas monitoring laboratory during riser-drilling operation [1], which provided the first indication of biologically mediated CO_2 reduction to methane at the 2 km-deep coalbed layers. The numbers of microbial cells are generally less than 10^3 cells cm^{-3}; however, increase of biomass was observed at the coal layers. Potential rates of organoclastic sulfate reduction are elevated in coalbed-bearing strata.

Studies on the concentration of I-129 and I-131/I-129 ratios in soil samples collected from Fukushima Prefecture

NAOYA INAGAWA[1]*, YASUYUKI MURAMATSU[1]*, TAKESHI OHNO[1], CHIAKI TOYAMA[1], MUTUTO SATOU[2], HIROYUKI MATUZAKI[3],

[1]*Gakushuin University, Tokyo, 171-8588, Japan, naoy1121@yahoo.co.jp (presenting author), yasuyuki.muramatsu@gakushuin.ac.jp (Correspondence),
[2]Fukushima Agricultural Technology Centre , Fukushima, 963-0531, Japan,
[3]University of Tokyo, Tokyo, 113-0032, Japan,

A large amount of I-131 was released from the Fukushima nuclear power plant accident. Radioiodine accumulates in thyroid gland and radiation risk would be enhanced. Therefore, it is necessary to obtain deposition date of I-131 in Fukushima Prefecture. Because of the short half-life of I-131 (8 days), it was below the detection limit after a few months. On the other hand, I-129 released simultaneously with I-131 still remained in soil, due to its long half-life of 1.57×10^7 years. Therefore, I-129 can be used in the estimation of the I-131 depotition. For this purpose, it is essential to obtain I-131/I-129 ratios for calculating the amount of I-131 deposition from the I-129 analysis.

We used Fukushima soil samples in which I-131 had been measured. Iodine was separated by pyrohydrolysis and the evaporated iodine was collected in a trap solution. Stable iodine (I-127) concentrations in the trap solution were measured by ICP-MS. Solvent extraction was performed, and iodine was purified. Silver nitrate was added to precipitate AgI as a target for AMS and the I-129/I-127 ratios were measured by AMS at MALT, the University of Tokyo. For the estimation of I-129 concentrations (Bq/kg) the I-129/I-127 ratios and I-127 concentrations were used.

We obtained concentration (Bq/kg) of I-129 in soil and deposition density (Bq/m^2) for more than 100 samples collected from different locations in Fukushima. It is interested to note that a good correlation was found between the concentrations of I-131 and I-129 in soil samples. This finding suggests the possibility to estimate I-131 levels in soil at the early stage of the accident through the analysis of I-129. We obtained an average I-131/I-129 ratio as $(2.1 \pm 0.7) \times 10^7$, although these are still uncertainties.

We also studied the concentrations of I-129 according to the soil depth. Compared to the depth profile of radiocesium, radioiodine was found to migrate faster into the deeper soil layer.

Mecanisms and kinetics of hydrogen exchange in olivine: A review from experimental and computational studies

J. INGRIN[1]

[1]UMR CNRS 8207, Univ. Lille 1, 59655 Villeneuve d'Ascq, France. jannick.ingrin@univ-lille1.fr

Mobility of hydrogen in mantle minerals and especially olivine has raised interest for its impact on mantle properties for many years. Nevertheless, the mechanisms and kinetics of hydrogen exchange in olivine remain largely misunderstood. We present here a review on the current knowledge of hydrogen kinetics in olivine, highlighted by recent results from experiments [1], [2] and numerical modelling [3]. In forsterite, laboratory's experiments, suggest that incorporation of hydrogen is controlled by the mobility of magnesium vacancies with a diffusion of hydrogen faster than exchange rate along direction [100] and slower in the two other directions. A common kinetics is generally observed for all OH bands, in apparent contradiction with their different origin as highlighted by numerical modelling. In olivine, diffusion of small-polarons is faster than diffusion of hydrogen. These results suggest that diffusion of polarons is anisotropic, with diffusion along [100] probably faster. Theoretical interpretations in connexion with electrical conductivity properties of olivine are discussed.

The nitrogen isotope composition of volcanic fluids

S. INGUAGGIATO[1,2], Y.TARAN[2], T. FRIDRIKSSON[3], S.CALIRO[4]

[1]Istituto Nazionale di Vulcanologia, sezione di Palermo, Via Ugo La Malfa, 153 Palermo Italy (correpondence*: s.inguaggiato@pa.ingv.it)

[2]Instituto de Geofisica UNAM Coyacan Mexico D.F.04510 Mexico (taran@geofisica.unam.mx)

[3]Iceland GeoSurvey grensasvegur 9, 108 Reykjavik (Thrainn.Fridriksson@isor.is)

[4]Istituto Nazionale di Vulcanologia, Sezione di Napoli, via Diocleziano 328, 80124 Napoli, Italy

The main potential sources of nitrogen in volcanic and hydrothermal fluids are (i) the atmosphere; (ii) the upper mantle, including contribution from the subducting plates at the arc settings; (iii) the lower mantle at the hot spot settings; and (iv) the continental crust. The meaningful differences in $\delta^{15}N$ among the four main potential sources of nitrogen make it a useful tracer providing relevant information on the geodynamic environments in which volcanic fluids are generated.

Here we present a large and new data set of nitrogen isotope, $N_2/^{36}Ar$ and $^3He/^4He$ in fluids from more of 20 volcanic systems of different geodynamic setting including subduction zones (Mediterranean volcanoes, Mexico, Central and South America, Kamchatka); spreading zones (Socorro Island) and hotspots (Iceland, Azores, Galapagos). The goals of this work are i) to identify the relationships between the geodynamic setting and the isotopic composition of nitrogen in volcanic fluids; ii) to characterize the lower mantle (fluids with $^3He/^4He$ much higher than MORB values) in terms of $\delta^{15}N$ and iii) to understand the inhomogeneity of $\delta^{15}N$ with respect to the upper mantle.

The preliminary obtained results showed a wide range of $\delta^{15}N$ values, for estimated deep component (ASW corrected), from +7 to -16‰. The fluids related to subduction zones are characterized by values from -5‰ to +7‰, while the very light $\delta^{15}N$ (up to -16‰), were found in some gases of Iceland evidencing an important contribution from the lower mantle. We also discuss some problems related to possible effects of the nitrogen isotope fractionation (N_2-NH_3 system) and to the air correction procedure.

Experimental studies of catalytic properties of Iron II and III modified hydrothermal zeolites

E. IÑIGUEZ[1]*, C. HEMMINGSSON[1] AND N.G. HOLM[1]

[1](*correspondence: enrique.iniguez@geo.su.se)
Department of Geological Sciences, Stockholm University, Sweden

Zeolites are natural minerals formed by condensation of silica, alumina and some metallic hydroxides under hydrothermal systems [1], known by their porous structure and remarkable catalytic properties related to their high surface area, among others characteristics. Moreover, they present high affinity to absorb gases in their crystalline structure (i.e., H_2, N_2, CO_2), decreasing their activation energy barrier promoting recombination of between them [2]. They may occur in hydrothermal systems where constant emission of hydrogen as a product of weathering of the marine lithosphere can react with the dissolved gases in seawater [3]. Hydrothermal systems are considered present since the Hadean when the Earth's seas had formed. Therefore, the interaction of minerals could enhance the nitrogen reduction as well as its subsequent recombination into larger organics [4].

We present results of enhancement of the surface area, porosity proprieties, and acidity of two synthetic iron II and III zeolites and a feldspar - analcime, phillipsite, sanidine - in comparison to the native mineral. These metallic inclusions in the zeolite structure provoke an enlargement of the internal channels and cavities, as well as creating Brønsted acid sites responsible of a stronger adsorption of N_2 o CO_2.

Balance of carbon in the system of geochemically linked mire landscapes

L. I. INISHEVA[1], M. A. SERGEEVA[1], N.V. JUDINA[2]

[1] - Tomsk State Pedagogical University, Tomsk (*correspondence: agroecol@yandex.ru)
[2] Institute of chemistry of petroleum of the Siberian Branch of the Russian Academy of Science, Tomsk

According to V.I. Vernadskiy, migration of chemical elements in biosphere is carried out at direct participation of biogenic matter. The purpose of long-term researches (1996-2011 ye) was studying balance of carbon in bogs. As modeling object for researches it was accepted on territory of Vasyugan mire spurs (West Siberia).

Investigations hade shown, that peat deposits of oligotrophic mires are biochemical active on all structure and the dynamic of biochemical processes is determined by hydrothermal conditions. Process of organic matter transformation in a peat deposit and formations CO_2 is determined by temperature of peatland**.** The greatest concentration of methane in a peat deposit is marked in damp years. As a result of this processes was confirmed with long-term dynamics of gas structure («peepers»-method), carbon balance oligotrophic mires on territory of Vasyugan mire spurs has the following kind.

Position on Landscapes mires	**Receipt of carbon,**	**Allocation of carbon,**	**Deposition of carbon,**
	gC/m^2*year		
Trans accumulative	267.3	97.6	169.7
Transit	235.2	66.9	168.3
Autonomy	158.0	65.2	92.8
Average	**220.0**	**76.6**	**143.6**

Table 1: Carbon balance of Landscapes mires.

In balance of carbon article of the charge determining carrying out of carbon with a drain of mire waters has essential value. According to our results, the average contents of carbon in mire waters, including carbon humid acids, changes from 53 up to 92,5 mg/l with limits 27,8-145 mg/l.

In a result the special kind of mire waters is formed. On the basis of the mathematical model carrying out of organic carbon by mire waters was designed 6,9 g m^2/m^{-1}. But, and in view of losses of carbon with a drain of mire waters, on oligotrophic mires deposition of carbon, and, hence, is observed peat formation process is progresses.

This study was supported by the Russian Foundation for Basic Research, project nos. 5.1161.2011.

Geochemistry of uranium and thorium in soils on the Ditrău Alkaline Massif, Eastern Carpathians, Romania

ADRIANA ION[1,2]*

[1]Geological Institute of Romania, Bucharest, RO-012271, Romania (*adi75riana@yahoo.com)
[2]"Al. I. Cuza" University, Iași, RO-700506, Romania

The rocks of the Ditrău Massif (syenite, nepheline syenite, hornblendite, diorite, monzonite, monzodiorite, granitoid) have naturally higher uranium and thorium contents, making the area ideal for the study of the distribution in soils of these elements. The soil types present in the investigated area, according to the Romanian Soil Taxonomic Classification are: lithosol, redzine, eutricambosol, districombosol, typical luvosol, albic luvosol, ethnic luvosol and aluviosols. Uranium and thorium were analyzed in 70 soil samples collected from an equable points net for all type of representative rocks. U and Th concentration were measured non-destructively using gamma-ray spectrometry with HPGe detector, and the uranium and thorium bearing minerals in soil samples were identified by XRD. The pH values were determined using a digital pH-meter.

U concentrations in the soil varies between 0.5 and 9.3µg g^{-1} (6.18-114.86 Bq/Kg) and Th concentrations from 2 to 51.3 µg g^{-1} (8.12-208.28 Bq/Kg), whereas the Th/U ration in soil ranges from 1.87 to 19.52 µg g^{-1}. The pH varies from 3.6 to 7.3 and it controls the distribution of uranium and thorium in soil. Unlike U which is a mobile element, soluble in the U^{+6} state (oxidizing conditions), Th has low mobility under environmental conditions and reflects source area characteristics. XRD analysis enabled the identification of U and Th as major or trace elements in minerals like zircon, thorite, allanite, monazite, pyroclore, aeschynite, columbit, bastnäsite. The distribution of U and Th in soils is primarily controlled by the distribution of the accessory minerals in bedrocks, and secondly by the physical and chemical stability of these minerals in the pedogenetic process. The soils developed on granitoid rocks that occur in the north-eastern and eastern parts of the massif have the highest thorium content among all types of soils. High uranium contents were determined in soil samples developed on syenite and nephelin syenite. A positive correlation between uranium and thorium occurs in almost all type of soils.

Also, the results indicate an U and Th enrichment in the clay fraction.

The origin of garnet peridotites in the Siberian cratonic mantle from chemical, modal and textural data

D.A. IONOV[1], L.S. DOUCET[1], A.V. GOLOVIN[2]

[1]PRES-Lyon & UMR6524-CNRS, Saint Etienne, France, dmitri.ionov@univ-st-etienne.fr (*presenting author)
[2]Institute of Geology & Mineralogy, Novosibirsk, Russia, avg@igm.nsc.ru

Garnet peridotites, the most common rocks in cratonic mantle, are believed to be variably enriched residues of high-degree melt extraction, but the role and conditions of melting, metasomatism and deformation in their origin continue to be debated. A major problem is that peridotite xenoliths in kimberlites are usually altered during and after their transport to the surface, many are small and heterogeneous. We examine new and published [1-3] chemical, modal and textural data on several dozen large, fresh and homogeneous garnet peridotite xenoliths from the Udachnaya kimberlite in the central Siberian craton to better constrain the origin and evolution of garnet-facies cratonic mantle.

The least metasomatized garnet peridotites are similar in major oxide compositions to low-opx spl harzburgites from Udachnaya (interpreted as pristine melt extraction residues [4]) and were formed by 30–38% of polybaric fractional melting from 7–4 GPa to ≤1–3 GPa. Their whole-rock (WR) Al_2O_3 and Mg#, hence melt extraction degrees, do not vary with depth. Co-variations of modal abundances, major oxides and their ratios in WR indicate that garnet is mainly a residual mineral, which survived partial melting and/or exsolved from high-T opx on cooling, whereas cpx is mainly metasomatic. Modal abundances of garnet can be estimated from WR Al_2O_3; rocks with $Cr\#_{WR} > Cr\#_{gar}$ contain accessory Cr-spinel.

In addition to coarse and sheared peridoties, we identify "transitional" rocks with ≤10% neoblasts at margins of coarse olivine. Such incipient stages of deformation may have been overlooked in previous studies of altered xenoliths in the Siberian and other cratons. Regardless of deformation degrees deformed peridotites show stronger enrichments in Fe, Ti, Ca, REE than coarse peridotites, i.e. deformation is accompanied by metasomatism. Both deformed and coarse peridotites occur near the base of the lithosphere (≥1300°C, 6.8 GPa). P-T estimates define a perturbed geotherm [3]; oxygen fugacity decreases with depth less than inferred previously [3, 5].

Arsenic contamination in an anoxic aquifer in southwest Germany: Assessment and process studies

M. ISENBECK-SCHRÖTER*, M. MAIER, S. AL NAJEM, N. SALM AND C. SCHOLZ

Institute of Earth Sciences, Heidelberg University, INF 236, 69120 Heidelberg, Germany (*correspondence: Margot.Isenbeck@geow.uni-heidelberg.de)

Arsenic groundwater contamination due to the infiltration of arsenic bearing sewage has been assessed analysing groundwater and aquifer material on an abandoned industrial site in the quaternary aquifer in the Upper Rhine Rift, southwest Germany. The contamination plume is about 800 m long, 200 m wide and 20-30 m deep. Detailed studies were performed in order to investigate the redox state and the binding forms of arsenic in the water and in the aquifer material, respectively.

A cross section of four liner boreholes along the plume was drilled and analysed in detail as well as 20 direct push soundings in the center of the contamination. Groundwater was sampled using filtered groundwater wells and the direct push boreholes. The analyses lead to a detailed assessment of the contamination extension and mass. This assessment could also be used to characterize the mobility of both arsenic redox species.

The transport processes in the aquifer were studied more in detail using column experiments with contaminated material under oxic and anoxic conditions. It could be shown that surface complexation and microbial redox processes dominately influence the arsenic mobility under anoxic conditions. The reduction of As (V) to As (III) following iron reduction seems to be the dominating process under the aquifer conditions.

Similar processes have also been observed during field studies with As (V) input into the Cape Cod Aquifer [1]. Both sites are characterized by an iron dominated redox system. They are anoxic due to contamination with sewage of organic contaminants. The sites differ in the geochemical milieu; whereas the contaminated site in the Upper Rhine Valley is a carbonate system, the Cape Cod aquifer is acidic.

We thank the RP Darmstadt, the HIM-ASG and the CDM Smith Consult GmbH for their financial and technical support.

U-Pb dating of Eoarchaean zircons using a NanoSIMS

AKIZUMI ISHIDA[1], NAOTO TAKAHATA[1], YUJI SANO[1], JEAN DAVID[2], AND DANIELE L. PINTI[2]

[1] Atmosphere and Ocean Research Institute, the University of Tokyo (e-mail:ishiaki@aori.u-tokyo.c.jp), [2] GEOTOP, Université du Québec à Montréal

Volatiles, such as hydrogen or sulphur, included in Eoarchaean igneous rocks, have crucial information to reveal about the evolution of the early Earth. Apatite and/or glass inclusions, found in zircon crystals, are expected to preserve primitive information of such volatile elements. NanoSIMS is one of the more powerful tools for micro-scale analyses including precise *in situ* U-Pb dating of zircon.

We performed ^{238}U-^{206}Pb and ^{207}Pb-^{206}Pb zircon dating using a NanoSIMS 50 ion microprobe at the University of Tokyo, with the method developed by our group [1]. The targeted zircons were separated from a tonalite of the Eoarchaean Nuvvuagittuq supracrustal belt, Superior Craton, Canada. The reported U-Pb age of this tonalite is 3661± 4 Ma [2]. Euhedral to subeuhedral zircon crystals were picked up. Some of them have a zoning structure. Glass or apatite inclusions, whose size were 10 to 30 micrometers in diameter, were found in the crystal.

After the correction of common lead, $^{238}U/^{206}Pb^*$ and $^{207}Pb^*/^{206}Pb^*$ ratios of 20 crystals were plotted on Terra-Wasserburg Concordia diagram. They showed a Discordia suggesting recent Pb loss. The intersection of Concordia and Discordia indicates that the age of this rock is 3637 ± 19 Ma, which agrees well with previous study. Now we are trying to measure the volatile compositions of inclusions in theses zircons.

Geo-neutrino measurements with KamLAND

K. ISHIDOSHIRO[1]* (FOR KAMLAND COLLABORATION)

[1]Research Center for Neutrino Science, Tohoku University, Sendai 980-8578, JAPAN
(*correspondence/:koji@awa.tohoku.ac.jp)

KamLAND experiment

The Kamioka Liquid-scintillator Antineutrino Detector (KamLAND) is a 1 kton liquid scintillator surrounded by 53 nuclear reactor units in JAPAN. Following the Fukushima nuclear accident in March 2011, the entire Japanese nuclear industry, which generates > 97% of the reactor neutrino flux at KamLAND, has been subjected to a protracted shutdown. The reactor-off period provides a unique opportunity to measure gen-neutrino with KamLAND.

Geo-neutrino analysis [1]

The data reported here are based on a total live-time of 2991 days, which includes the recent reactor-off period. Assuming a chondritic Th/U mass ratio, we obtain a geo-neutrino flux of $3.4^{+0.8}_{-0.8}$ x10^6 cm^{-2}s^{-1} from ^{238}U and ^{232}Th at the KamLAND location. The geo-neutrino flux translates to a total radiogenic heat production of $11.2^{+7.9}_{-5.1}$ TW from ^{238}U and ^{232}Th. The flux estimation is significantly improved by the reactor-off data. The geodynamical prediction with the homogeneous hypothesis is disfavored at 89% C.L. (Fig. 1) The observed flux is in agreement with the predictions from existing BSE models (geodynamical [2], geochemical [3] and cosmochemical [4]) with in ~ 2σ.

Future prospects

The ability of discriminating between models is limited by the statistical uncertainty. KamLAND contines to measure for getting further statistics. In the future, improved measurements with higher statistics and lower background is desired. Directional geo-neutrino detection is also required to further understand the deep interior of the Earth.

Natural analogue study on long term alteration of bentonite (1) - Geochemistry and clay mineralogy-

TOMOKO ISHII[1], HISAO SATOH[2], KOHEI YAMAGUCHI[2], JIRO ETO[1], TOSHIAKI OHE[3]

[1] Radioactive Waste Management Funding and Research Center, Tokyo, 104-0052 JAPAN(ishii@rwmc.or.jp)
[2] Mitsubishi Materials Corp., Saitama pef.,330-8508 JAPAN
[3] Tokai Univ., Kanagawa pref., 259-1292 JAPAN

In order to evaluate the long-term behavior of the bentonite in geological disposal sites for TRU waste, the prediction of alkaline alteration by cement influences is very important. We conducted geochemical analyses of natural bentonite suffered from Ca-rich groundwater as a natural analogue of bentonite barrier after ~100kyr..

The drilling survey was carried out on geothermal site at a Japanese island arc basin to find similar environment to the bentonite barrier influenced by cement leachates. The hot spring water near the site has high concentration of Ca and pH. We drilled down to GL-250 m, and the tuffaceous bed was recognized in the depth of GL-240m. The sedimentary age of the bed was estimated as 8.2 - 5.6 Ma by analysis of microfossils. Post-sedimental thermal history was estimated to be 20-40 degrees by analysis of stable isotopes. According to whole-rock XRF data, this bentonite could have been altered from basalt-dacite (granite) bimodal igneous rocks. Backscattered electron imaging on the bentoite identified coexisting Na/Ca-smectite and heulandite (Fig.1).

Even in such a Ca-rich condition, Na-smectite still remains without complete conversion to Ca-smectite. Geochronology by fision track dating and ^{36}Cl/Cl suggested about 10Ma for ignesou age and 2Ma for groundwater entrapment. The composition of present groundwater was estimated as the mixture of rainwater and near hot spring water from a result of principal component analysis.

It is inferred that the Na-type smectite could have coexisted with the Ca-type in the bentonite for this geologic time-scale. This natural analogue may suggest a supporting evidence of smectite stability at the repository.

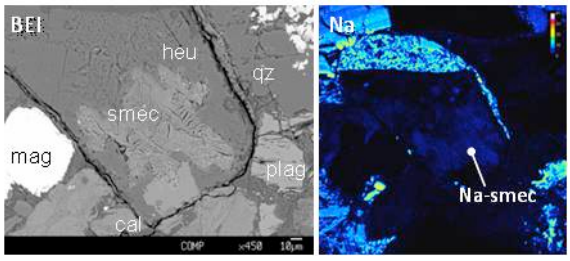

Fig.1 BEI and Na-map of the altered bentonite.

This research is a part of "Development of the technique for the evaluation of long-term performance of EBS (FY2007-2012)" under a grant from the Agency of Natural Resources and Energy , the Ministry of Economy Trade and Industry of Japan (METI).

Re-evaluation of digestion methods for accurate Re-Os isotope and highly siderophile element analyses

AKIRA ISHIKAWA[1,2]*, RYOKO SENDA[2], KATSUHIKO SUZUKI[2] AND CHRISTOPHER W. DALE[3]

[1]Earth Science and Astronomy, The University of Tokyo, Tokyo 153-8902, Japan, akr@ea.c.u-tokyo.ac.jp
[2]IFREE, JAMSTEC, Yokosuka 237-0061, Japan
[3]Earth Sciences, Durham University, DH1 3LE, UK

The current database on highly siderophile elements (HSEs: Re, Au, Ir, Os, Ru, Rh, Pt and Pd) and Os isotopes in geological samples is dominated by isotope dilution methods, coupled with high-temperature sample digestion using inverse aqua regia in closed glass vessels such as Carius tubes (CT) or a high-pressure asher system (HPA). These acid digestion techniques are preferred over traditional flux fusion techniques, such as NiS fire assay, largely due to the ability to measure Re and Os on the same sample aliquot. By contrast, two major limitations - the 'nugget effect' and incomplete digestion - have often been associated with these acid digestion techniques. Recent data suggest that an additional HF step is essential to release HSEs hosted in the silicate portions of certain basaltic materials, necessitating modification of typical digesting procedures.

To address this issue, we systematically conducted analytical tests for CANMET reference material TDB-1 with varying digestion apparatus (microwave, CT, HPA), conditions (temperature, duration, sample size) and protocol (with or without HF desilicification, either before or after aqua regia attack). We found the optimum method for simultaneous determination of $^{187}Os/^{188}Os$ and HSE concentrations used inverse aqua regia to attack 1-2 g of powder over long durations, such as a Carius tube heated to 240˚C for 72 hours, followed by an HF desilicification step after CCl_4 solvent extraction of Os. It is anticipated that extended HPA digestions will also achieve the same effect.

The method provides strong linear correlations on Os versus Ir-Ru-Pt concentration diagrams for repeat dissolutions of TDB-1, reflecting an effect of powder heterogeneity. This is further supported by a linear array on the $^{187}Re/^{188}Os$ and $^{187}Os/^{188}Os$ diagram, yielding a meaningful age of 1230 ± 47 Ma (MSWD=2.1), consistent with the Mesoproterozoic (~1265 Ma) formation of diabase TDB-1. In comparison, excellent reproducibilites for all HSEs were obtained from USGS reference material BIR-1: RSDs for 1-2 g aliquots were 7.4% Os, 4.4% Ir, 1.5% Ru, 5.2% Pt, 1.6% Pd and 0.7% Re (n=8). Thus, BIR-1 might be suitable material for narrowing the confidence intervals of HSE certified values.

Metasomatism recorded in the peridotite overlying metamorphic sole of the the Oman ophiolite: an analog of mantle-wedge events

S. ISHIMARU[1]*, S. ARAI[2], AND A. TAMURA[2]

[1]Dept. of Earth and Environ. Sci., Kumamoto Univ., Kumamoto 860-8555, Japan (*correspondence: ishimaru@sci.kumamoto-u.ac.jp)
[2]Dept. of Earth Sci., Kanazawa Univ., Kanazawa 920-1192, Japan

Mantle peridotites have been modified to various extents at slab-mantle interface within the mantle wedge. To know the details of the event, e.g., which elements and how much amounts?, the materials from the mantle wedge are needed. Ophiolite is a place where we can investigate the slab-mantle interaction, because it has the metamorphic sole, formed at the ophiolite obduction. Its formation is interpreted as an analog of an incipient arc system transformed from the ocean floor.

The Oman ophiolite is quite famous for good exposure and preservation of the oceanic stratigraphy with widespread formation of metamorphic sole. We did systematic sampling at the southern Oman ophiolite from the sole garnet amphibolite to the peridotite up to 110 m above the amphibolite/peridotite boundary, i.e., an analog of slab-mantle boundary. The peridotite is deformed and serpentinized to various degree, and occasionally has mylonitized bands. The peridotite protolith is fertile lherzolite: the Fo content of olivine and Cr# [= Cr/ (Cr + Al) cation ratio] of chromian spinel is 90-93 and 0.11-0.35 (except for the spinels in highly serpentinized peridotite), respectively. The Al_2O_3 contents of clinopyroxenes and orthpyroxenes are high (up to 5.3 and 6.3 wt.%, respectively). Fine pyroxene grains show a low Al_2O_3 content, < 1 wt.%. The peridotites contain amphiboles irrespective of the distance from the amphibolite/peridotite boundary, and the amphiboles are not only tremolite after clinopyroxene but also hornblendes. The incompatible trace-element patterns of clinopyroxene are enriched in LREE and some LILE (Rb, Ba and Sr), and those of hornblendes show similar patterns although some show higher abundances than clinopyroxene.

The peridotites just above the metamophic sole have been cooled as well as extensively hydrated (at least 110 m above the boundary) and enriched in fluid-mobile elements as mantle-wedge peridotites.

REE signatures of accessory minerals from Iron Oxide Copper Gold - skarn mineralization, Hillside, South Australia

R. ISMAIL*, C.L. CIOBANU, N.J. COOK, D. GILES AND A. SCHMIDT-MUMM

Deep Exploration Technologies Cooperative Research Centre, The University of Adelaide, Adelaide, SA 5005, Australia (*correspondence: roniza.ismail@adelaide. edu.au, cristiana.ciobanu@adelaide.edu.au, nigel.cook @adelaide.edu.au, david.giles@adelaide.edu.au, asmumm@gmail.com)

Hillside is an Iron Oxide Copper Gold (IOCG) mineralized system in the Gawler Craton, typified by skarn associations and genetically tied to the ~1.59 Ga Hiltaba Intrusive Suite. Incorporation of REE in skarn and accessory minerals is a valuable tool for understanding evolution of REE-enriched IOCG deposits and their footprints.

Mineralization is hosted within calcic skarns comprising prograde garnet-pyroxene-magnetite and retrograde epidote-actinolite-hematite associations. Early, high-temperature (~750 ºC; Zr-in-titanite geothermometry) pyroxene skarn (I) is tied to strong albitization. Pyrite, present in the calcic skarn (II), is replaced by chalcopyrite during the late-hydrothermal (main Cu-Au ore deposition, III) stage. Titanite, apatite and allanite are abundant throughout all stages of skarn evolution from early-prograde to late-hydrothermal collapse.

REE concentrations and distributions in skarn and accessory minerals were determined by LA-ICP-MS. Whereas skarn minerals are extensively replaced in the main ore stage, accessories are still present, and their REE trends depict all stages of evolution (Fig. 1). Significantly, they record HREE-enrichment in stage III. This can be interpreted as a response to change in the fS_2 character of fluids.

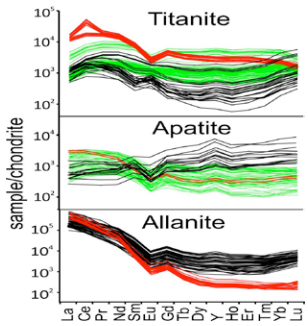

Figure 1 Chondrite-normalized REE+Y plots for accessory minerals. Red - early skarn (I); green - main calcic skarn (II); black - main sulfide deposition (III). Note progressive LREE-depletion and HREE-enrichment during evolution of the IOCG-skarn system.

The data show that REE signatures of accessory minerals from IOCG systems can help monitor development of alteration, and provide a framework for discriminating mineralized from non-mineralized systems in the region.

Mid to Late Holocene decreasing precipitation trends as reflected in $\delta^{18}O$ of speleothems from Apuan Alps (central Italy): Implications for seasonality

[5]School of Earth Sciences, The University of Melbourne, Australia

Changes in insolation related to Earth's orbital variations played a central role in the global-scale changes in climate of the last 11,500 cal yr. A progressive decline in summer temperature since the middle Holocene is well established from pollen and plant macrofossil data in northern and central Europe. The Mediterranean region has also become drier from the Middle Holocene to the present, with a marked precipitation seasonality that is crucial for both Mediterranean ecosystems and societies. Several records show contrasting seasonality patterns between southern and northern border regions of the central Mediterranean during Middle to Late Holocene. In this poster we present $\delta^{18}O$ stalagmite data sets from Corchia and Renella caves (Central Italy), showing long-term trends of increasing values (i.e. reduced rainfall) from Middle to late Holocene, while at secular to millennial scale they present different behavior. This difference is due to the variable recharge conditions related to changes in seasonality. These data can provide a more precise picture of the variations in the seasonality in the Mediterranean area

On the arrangement of sodium atoms around structural units and vibrational properties of a sodium borosilicate glass

S. ISPAS[1]*, L. PEDESSEAU[1,2] AND W. KOB[1]

[1]Laboratoire Charles Coulomb, CNRS UMR 5221, Univ. Montpellier 2, 34095, Montpellier, France (*correspondence simona.ispas@um2.fr, walter.kob@um2.fr)

[2]Univ. Europeenne de Bretagne, INSA, FOTON, UMR 6082, 35708, Rennes, France (laurent.pedesseau@insa-rennes.fr)

We have used first principles simulations in order to investigate the properties of a sodium borosilicate glass of composition 3Na2O-B2O3-6SiO2 (NBS). This composition is similar to that of the glass wool used in our daily life. The study was carried up using first principles molecular dynamics within the density functional theory framework as implemented in the VASP code [1].

In this talk, we will present the analysis of the local environments of the three building structural units of the glass network, namely silicon atoms in 4-fold coordination, and boron atoms with 3- or 4-fold coordination. We will also discuss the local distribution of the Na atoms around the basic structural units. Indeed we have identified their preferential neighborhoods and how the nature of network former and its coordination infer on the shape of these preferential regions of Na atoms.

The vibrational properties have been equally studied, and the contributions of the various species have been identified. We have found that 3- and 4-fold coordinated boron atoms give rise to distinguished spectral features. Moreover, the partial vibrational density of the 3-fold coordinated B atoms has been found to be a weighted sum of 2 specific contributions so-called 3-fold symmetric coordinated B atoms and asymmetric coordinated B atoms.

Different diagenetic behaviors of As, Mo and Sb in Lake Biwa, Japan

TAKAAKI ITAI[1]*, YUIKA HYOBU[1], MICHIO KUMAGAI[2], SHINSUKE TANABE[1]

[1]Center for Marine Environmental Studies (CMES), Ehime University, Bukyo-cho 2-5, Matsuyama, Ehime 790-8577, Japan (*correspondence: itai@sci.ehime-u.ac.jp)

[2]Sigma Research Center, Ritsumeikan University

Lake Biwa, the biggest lake in Japan, is suitable field to study diagenetic behavior of redox sensitive oxyanions, since clear diagenetic accumulation of Mn and As in surface sediment have been observed from entire lake. Redox conditions, evaluated by the depth profiles of solid phase speciation of Mn and As determined by XANES, were significantly varied depending on the sampling location within the lake. Here we show the comparison of depth profile of As, Sb, and Mo in both solid phase and porewater among various redox conditions. Of the seven stations studied, As profiles in porewater showed clear concentration peak in six. The depth of these peaks ranged from 3 to 1 cm below sediment-water interface, and arsenite was the dominant species around the areas where the peaks appeared. The peak values of As in solid phase always appeared 1-2.5 cm above the places where the peaks of porewaters were found. Predominance of arsenate in surface sediments suggested diagenetic accumulation of As, whereas As-S species becomes predominant below As peak areas in porewater. Both Mo and Sb showed cocentration peak in 5 stations. Two stations in which the peaks were not observed are in areas with most reducing conditions where no MnO_2 enrichment was observed even in the top layer (0-5 mm). In the other 5 stations, depth of the peaks in porewater were always in the following order: As>Sb>Mo. Difference in peak depth between As and other 2 elements were 0.75-1.5 cm, whereas difference between Sb and Mo were <0.75 cm. It is well known that these oxyanions have high affinity to Fe (oxy)hydroxides. However, if the dissolution of this phase predominantly controls the solid-water partitioning of these oxyanions, the porewater profile should be similar. Distinctly higher depth of As peak is likely attributed to arsenate reduction to arsenite which enhances the mobility of As. Slight differences in Mo and Sb is possibly due to high affinity of Mo to MnO_2 that reduces more easily than Fe (oxy)hydroxides. Although these relative mobility should change in more sulfidic setting like seawater, such a comparison is rather limited in freshwater sytstem so far, thereby the finding of this study can contribute for better understanding of diagenetic behavior of these elements.

Role of acid mobilization in projected response of soluble iron supply to improvement of air quality in the future

AKINORI ITO[1]*, LI XU[2] AND JOYCE E. PENNER [3]

[1]Research Institute for Global Change, JAMSTEC, Yokohama, Kanagawa 236-0001, Japan (*correspondence: akinorii@jamstec.go.jp)

[2]Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA 92093, USA

[3] University of Michigan, Ann Arbor, MI 48109-2143, USA

Acidification of dust aerosols may increase aerosol iron (Fe) solubility, which is linked to mineral properties (e.g., crystallinity, grain size and impurity content). The mixing of the mineral dust with combustion aerosols can also elevate iron solubility when aerosol loading is low. Here, we use a process-based chemical transport model [1, 2] with improved treatment of Fe in mineral dust and proton-promoted dissolution scheme to investigate the deposition of soluble iron and its response to changes in anthropogenic emissions of both primary particles and precursor gases.

Comparisons of modeled Fe dissolution curves with the measured dissolution rates show overall good agreement under acidic conditions. The improved treatment of Fe in mineral dust and the proton-promoted dissolution scheme results in reasonable predictive capability for iron solubility over the oceans in the Northern Hemisphere. Our model results suggest that iron included in aluminosilicate dust can be released in the form of ferrihydrite colloids, nanoparticles and aqueous species during the long-range transport and thus provide an important bioavailable source of iron to the oceans. As a result of considering both the atmospheric processing of mineral dust and source composition of combustion aerosols, soluble iron deposition to the subarctic North Pacific is projected to respond nonlinearly to changing emissions of fly ash and air pollutant gases (e.g., SO_2, NO_2 and NH_3). These results could have important implications for iron fertilization of phytoplankton growth, and highlight the necessity of improving the process-based quantitative understanding of the response of the chemical modification in iron-containing minerals to environmental changes.

Electronic spin transitions of iron in the Earth’s mantle minerals are of great interest to deep-Earth researchers because their effects on the physical and chemical properties of mantle minerals can significantly affect our understanding of the properties of the deep planet. Polycrystalline samples were synthesized in a multi-anvil apparatus using ^{57}Fe-enriched starting material ((Mg,Fe)O-SiO_2 mixture) at conditions of approximately 22 GPa and 2000 K. Energy dispersive x-ray elemental mapping and electron diffracton study of the sample showed that Fe predominantly presents in the ringwoodite phase γ-$(Mg_{0.75},Fe_{0.25})_2SiO_4$.

The electronic spin states of iron in ringwoodite were studied at high pressures up to 82 GPa using synchrotron Mössbauer spectroscopy (NFS) in a diamond anvil cell (HPCAT, Sector 16, APS, ANL). At ambient conditions, the NFS spectra reveal two non-equivalent iron species $(Fe^{2+})_1$ and $(Fe^{2+})_2$ which can be attributed to octahedral and tetrahedral sites in the cubic spinel structure of ringwoodite, respectively. High-pressure NFS spectra showed the disappearance of the hyperfine quadrupole splitting of the Fe^{2+} ions in both sites at approximately 45-70 GPa, indicating an electronic high-spin to low-spin transition. The spin transition exhibits a continuous crossover nature and is reversible at decompression.

The study was partially supported by RFBR, research projects No. 12-05-31342 and 11-02-00291. The work at the UT Austin was supported by the US National Science Foundation (EAR-0838221) and the Carnegie/DOE Alliance Center (grant DE-FG02-02ER45955). APS is supported by DOE-BES, under Contract no.DE-AC02-06CH11357.

Subseafloor basalts as fungal habitats

IVARSSON, M.[1]* AND BENGTSON, S[1]

[1]Department of Paleobiology and the Nordic Center for Earth Evolution (NordCEE), Swedish Museum of Natural History, Box 50007, Stockholm, Sweden. (*Correspondance: magnus.ivarsson@nrm.se)

The oceanic crust makes up the largest potential habitat for life on Earth, yet next to nothing is known about the abundance, diversity and ecology of its biosphere. Our understanding of the deep biosphere of subseafloor crust is, with a few exceptions, based on a fossil record. Surprisingly, a majority of the fossilized microorganisms have been interpreted or recently re-interpreted as remnants of fungi rather than prokaryotes [1-4]. Even though this might be due to a bias in fossilization the presence of fungi in these settings can not be neglected.

We have examined fossilized microorganisms in drilled basalt samples collected at the Emperor Seamounts in the Pacific Ocean. Synchrotron-radiation X-ray tomography microscopy (SRXTM) studies has revealed a complex morphology and internal structure that corresponds to characteristic fungal morphology. Chitin was detected in the fossilized hyphae, which is another strong argument in favour of a fungal interpretation. Chitin is absent in prokaryotes but a substantial constituent in fungal cell walls.

The fungal colonies consist of both hyphae and yeast-like growth states as well as resting structures and possible fruit bodies, thus, the fungi exist in vital colonies in subseafloor basalts. The fungi have also been involved in extensive weathering of secondary mineralisations. In terrestrial environments fungi are known as an important geobiological agent that promotes mineral weathering and decomposition of organic matter, and they occur in vital symbiosis with other microorganisms. It is probable to assume that fungi would play a similar role in subseafloor basalts and have great impact on the ecology and on biogeochemical cycles in such environments.

Simultaneous measurement of CCN activity and chemical composition of fine aerosols at Noto peninsula, Japan, in autumn 2012

YOKO IWAMOTO[1], KENTO KINOUCHI[2] AND ATSUSHI MATSUKI[1]

[1]Institute of Nature and Environmental Technology, Kanazawa Univ., Kakuma-machi, Kanazawa 920-1192, Japan (*correspondence: iwamoto@se.kanazawa-u.ac.jp)
[2]Graduate School of Natural Science & Technology, Kanazawa Univ., Kakuma-machi, Kanazawa 920-1192, Japan

For the quantitative evaluations of cloud condensation nucleus (CCN) characteristics in the East Asia, CCN activity and chemical composition of atmospheric aerosols in submicrometer size range were measured at Noto Ground-based Research Observatory (NOTOGRO), located at the tip of Noto peninsula, facing the Sea of Japan, in autumn 2012.

In the atmospheric measurement, the CCN efficiency spectra, where CCN number fraction is plotted against the diameter of aerosols, were obtained at four different supersaturation (SS) conditions (0.1%, 0.2%, 0.5% and 0.8%). Hygroscopicity parameters κ [1], which depends on the chemical composition of aerosols, were estimated by the analysis of the CCN spectra. The bulk chemical composition of non-refractory submicrometer-sized aerosols was also measured by an aerosol chemical speciation monitor (ACSM).

The CCN activation diameters of ambient aerosols were clearly larger than those of pure ammonium sulfate under each SS condition. From the relationship between the estimated κ values and the CCN activation diameters, it was suggested that organics contributed to the aerosol mass especially in the size range of less than 100 nm. The contribution of organics observed in this study, based on the analysis of CCN spectra, was more apparent than those for other sites in East Asia [2, 3]. The bulk chemical composition derived by ACSM also indicated the significant mass fraction of organics in the submicrometer size range. The negative correlations between organic mass fraction and cloud droplets' diameters were observed especially under low SS conditions (<~0.2%), suggesting that the initial growth rates of cloud droplets might slow by certain organics.

Clarification for Boron Sorption Mechanism in Coprecipitation with Magnesium Hydroxide

SAYAKA IZAWA[1], CHIHARU TOKORO[2], SHINYA SUZUKI[3] AND KEIKO SASAKI[4]

[1] Waseda University, Tokyo, Japan, izasaya@ruri.waseda.jp
[2] Waseda University, Tokyo, Japan, tokoro@waseda.jp
[3] Waseda University, Tokyo, Japan, Shinya.Suzuki55@gmail.com
[4] Kyushu University, Kyushu, Japan, ksasakime@gmail.com

Although boron is absolutely essential in various industries, especially in glas industry, the high contaminant levels of boron in water are regulated in several countries because of its toxitiy. While ion-exchange resin is commonly used to remove boron from wastewater, it is relatively expensive. In this study, boron removal by coprecipitation method using magneium salt has been investigated. The objective of this study is to clarify how coprecipitation of boron with magnesium hydroxide occurres in order to achieve cost efficient way to treat wastewater.

We carried out three kinds of experimental studies; (i) sorption isotherm formation, (ii) XRD analysis, (iii) NMR analysis. In general, when pH is below 9.2, the predominating species is orthoboric acid, which is less adsorptive because of its low electrical activity[1]. Therefore, we carried out the coprecipitation experiments at pH 10.5 and 0.3 of ion strength. Indeed, we could acheive the best adsorption efficiency of boron to magnesium hydroxide at pH 10.5.

We found that the sorption isotherm was BET type, which suggested that the sorption mecahnism of boron adsorption was changed as the initial B/Mg molar ratio increased. From XRD analysis, the crystal structure of the precipitation corresponded with magnesium hydroxide when the initial B/Mg molar ratio was less than 0.4, wheares uncertain amorphous precipitation and carbonate hydromagnesite were formed when the initial B/Mg molar ratio was larger than 0.4. Formation of the uncertain amophous precipitation indicated that surface precipitation was formed and related to boron uptake to magnesium hydroxide when the initial B/Mg molar ratio was larger than 0.4. NMR analysis showed that boron was adorbed onto the surface of magnesium hydroxide as three-coordinate boron. These results suggested that a part of boron was precipitated or intercalated with uncertain amorphous precipitation as three-coordinate boron during coprecipitation with magnesium hydroxide.

Seeing through the haze: Testing the existence of a Neoarchean bistable organic-rich atmosphere

G. IZON[1,2,*], A.L. ZERKLE[1], M.W. CLAIRE[1], J. FARQUHAR[3], S.W. POULTON[2] AND J. EIGENBRODE[4]

[1] DEES, Univ. of St. Andrews, St. Andrews. KY16 9AL, UK (*correspondence: gareth.izon@ncl.ac.uk, aubrey.zerkle@ncl.ac.uk, m.claire@uea.ac.uk)

[3]Dept. of Geology, University of Maryland, College Park, Maryland 20742, USA (jfarquha@essic.umd.edu)
[4]NASA Goddard Space Flight Center, Code 699, Greenbelt, MD 20771, USA (jennifer.l.eigenbrode@nasa.gov)

The Great Oxidation Event (GOE; ~2.45–2.32 Ga) represents the onset of pervasive atmospheric oxygenation; however, ~2.7 Ga cyanobacterial microfossils and biomarkers [1] coupled with additional geochemical evidence [2], suggests a potentially earlier origin for photosynthetic O_2 accumulation. This temporal disparity implies either localised O_2 production or transient small rises ('whiffs') in atmospheric O_2 [2]. Despite the emerging data, large uncertainties surround the composition and the evolution of the Neoarchean atmosphere.

Analyses of sediments from the Campbellrand-Malmani platform (GKF01; ~2.65–2.5 Ga) suggest localised O_2 production, in a reducing atmosphere [3]. Importantly, within GKF01, large deviations in $\Delta^{36}S/\Delta^{33}S$ correlate with pronounced ^{13}C-depletions in $\delta^{13}C_{Org}$, implying increased sedimentary incorporation of methanogenic carbon [3, 4]. Photochemical model simulations corroborate these data and predict the persistence of a bistable atmosphere poised between clear-skies and hazy conditions, implicating methane as an important component of the Neoarchean atmosphere.

Here, a new multiple S-isotope record from age-equivalent successions in W. Australia, combined with proxies for ocean redox and nutrient availability, will test the envisaged coupling between oceanic and atmospheric chemistry [3] whilst examining the drivers that link the two.

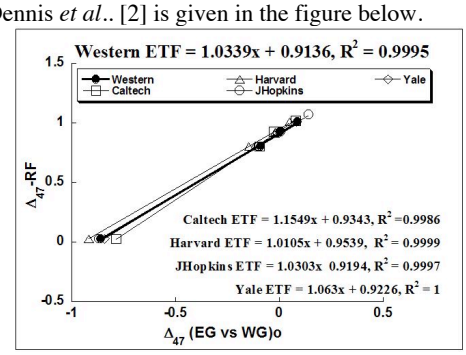
The distribution of rare "clumped" isotopologue species in the carbonate lattice is temperature dependent [1]. Our primary interests lie in exploiting this feature of clumped isotopologue science to explore paleoenvironments. We have established protocols to calibrate the clumped isotope thermometry of CO_2 by defining an absolute reference frame based on CO_2-H_2O equilibration experiments conducted at 10ºC, 25ºC, 50ºC and 1000ºC. A plot of experimental and theoretical equilibration intercepts has yielded an empirical transfer function (ETF) for our lab. A comparison of our ETF with Dennis *et al*.. [2] is given in the figure below.



Application: Seeds from the hackberry tree (*Celtis occidentalis*) precipitate up to 70 wt. % aragonite in their endocarp. Fossil hackberry seeds have been recoved from Holocene deposits across most of N. America and have great potential as a terrestrial paleoclimate proxy. The determination of growth temperature by clumped isotopologue analysis of the seed carbonate is the first application of this emerging field to hackberries. Seed samples were obtained from 4 different locations in N. America with differing climatic conditions. Growth temperatures were calibrated using a regression developed for synthetic carbonates grown from 4 to 45ºC and analysed for clumped isotopologues. This study demonstrates the potential of the isotopologue technique to terrestrial paleotemperature estimates, which can be used to estimate the $\delta^{18}O$ values of plant waters and ancient relative humidity conditions.

Authigenic and exogenic mineral particles in lung tissues.

JABLONSKA M[1], JANECZEK J[2] AND LEŚNIOK M[3]

[1]mariola.jablonska@us.edu.pl;
[2]janusz.janeczek@us.edu.pl
[3]mlesniok@op.pl

Investigation of mineral particles by SEM and TEM in samples of lung tissues from 34 subjects who lived in the urban and industrial region of Upper Silesia, Poland, revealed the occurrence of 15 mineral species. Based on their origin inferred from chemical compositions, structural properties, and morphological features, mineral particles can be grouped into authigenic and exogenic, i.e. inhaled dust particles.

Authigenic biocalcite and Mg-biocalcite (mean-diameter <1.5 μm) are age-related ranging from 5.5 to 64.62 vol.% of mineral matter in dry lungs. They often envelop exogenic particles masking their presence. The biocarbonates formed preferably in lungs of non-smokers. The largest of all mineral particles (mean diameter > 2,5 μm) are bioapatites observed exclusively in lungs of male cigarette smokers and formed in response to pathogenic processes in lungs. Ferrihydrate and goethite are products of redox-driven reactions in lungs.

Mineral composition of exogenic particles reflects the mineral compostion of atmospheric dust particles in the Upper Silesia. The inventory of abundant anthropogenic mineral particles includes: amorphous aluminosilicates, mullite, Fe-oxides, barite, trydymite, REE-phosphates metallic Fe, metal alloys, and (Zn, Fe, Pb)-sulfides. Minerals derived from natural sources and indicative of long-range transport include: micas, feldspars, pyroxenes, and amphiboles. Quartz particles are both natural and anthropogenic.

While the amount of authigenic carbonates increases with age the opposite trend is observed for aluminosilicates, silica, Fe-oxides, and metal alloys in individuals age 70 and older. The amount of barite in lungs of those individuals doubles relative to younger individuals.

Vertical differentation of PM10 concentration and mineral composition in the first 100 m of troposphere related to meteorological conditions in the Sosnowiec urban area, S Poland

JABLONSKA M[1], JANECZEK J[2] AND LESNIOK M[3]

[1]mariola.jablonska@us.edu.pl
[2]janusz.janeczek@us.edu.pl
[3]mlesniok@op.pl

Airborne particulate matter (PM10) was collected in the Sosnowiec city, Upper Silesia conurbation, Poland, at 3 m and 100 m above ground level (a.g.l.) in conjuction with meteorological observations to determine the difference in both PM10 concentrations and mineral composition within the so-called free atmosphere. Samples were examined by the environmental ASEM, ATEM, and X-ray powder diffraction. Particular attention was paid to smog episodes caused by temperature inversion, and responsible for extremaly high concentrations of particulate matter. We found no difference in concentrations and mineral composition of PM10 in samples collected at 3 m and 100 m a.g.l. during smog associated with almost stagnant air. The inventory of PM10 included particles originating from traffic (soot, Pb-chloride) and abundant coal combustion-related particles (soot, glassy aluminosilicates, Fe-oxides, barite, gypsum, Na- and K-chlorides) typical of low emission.

Differentiation of PM10 concentration and mineral composition was observed during inflow of air-masses associated with increased speed of wind. Mineral composition of PM10 at 3 m a.g.l. reflected local sources of anthropogenic pollution, whereas PM10 sampled at 100 m a.g.l. consisted of particles indicative of long-range transport, i.e. derived from natural sources, in addition to anthropogenic particles typical of the Upper Silesia.

Two modes of change in Southern Ocean export production over the past million years

JACCARD, S.L.[1], HAIN, M.P.[2], HAYES, C.T.[3], MARTINEZ-GARCIA, A.[1], ANDERSON, R.F.[3], SIGMAN, D.M.[2] AND HAUG, G.H.[1]

[1]D-ERDW, ETH Zurich, Zurich, Switzerland; samuel.jaccard@erdw.ethz.ch
[2]Department of Geosciences, Princeton University, Princeton, USA
[3]LDEO, Columbia University, Palisades, USA

Export of organic carbon from surface waters of the Antarctic Zone of the Southern Ocean decreased during the last ice age, coinciding with declining atmospheric carbon dioxide (CO_2) concentrations, signaling reduced exchange of CO_2 between the ocean interior and the atmosphere. In contrast, in the Subantarctic Zone, export production increased into ice ages coinciding with rising dust fluxes, thus suggesting iron fertilization of Subantarctic phytoplankton.

Here, a new high-resolution productivity record from the Antarctic Zone is compiled with parallel Subantarctic data over the past million years. Together, they fit the view that the combination of these two modes of Southern Ocean change determines the temporal structure of the glacial interglacial atmospheric CO_2 record, including during the interval of "lukewarm" interglacials between 450 and 800 thousand years ago.

In addition, we present CYCLOPS model runs to separate the implied relative contribution of each parameter to the atmospheric CO_2 budget. Extending this model-based approach holds the promise to quantitatively cross-verify diverse paleoceanographic data, and to refine our mechanistic understanding of the coupling between climate, ocean biogeochemistry and atmospheric CO_2.

N and S isotope fractionation in the terminal electron acceptors during biodegradation of BTEX compounds

CHRIS JACKSON[1]*, BERNHARD MAYER[1] AND LES STEHMEIER[2]

[1]Department of Geoscience, University of Calgary, 2500 University Drive NW, Calgary, Alberta, Canada T2N1N4 (*correspondence: cjjackso@ucalgary.ca)

[2]NOVA Chemicals Research Centre, 2928 16th N.E., Calgary, Alberta, Canada T2E 7K7

The biodegradation of BTEX compounds occurs under varying redox conditions [1]. Anaerobic processes are of particular interest as groundwater is often anaerobic as a result of initial mineralization of BTEX compounds [2]. Isotopic fractionation has been shown to occur for carbon and hydrogen isotopes of benzene during biodegradation [3] and other natural attenuation processes [4]. During the microbial reduction of the terminal electron acceptors (TEA) nitrate, and sulphate, significant isotope fractionation has also been demonstrated [5, 6]. The objective of this on-going project is to assess the extent of N and S isotope fractionation during BTEX biodegradation in laboratory studies and aquifers. Bioactivities of denitrifying and sulphate-reducing bacteria retrieved from a contaminated aquifer are respectively summarized in Table 1.

TEA	Carbon Source	Cells/mL
Nitrate	Benzene	$9.16x10^4$
Nitrate	Toluene	$2.05x10^5$
Sulphate	Benzene	$1.84x10^6$
Sulphate	Toluene	$1.12x10^6$

Table 1: Bioactivity measurements for benzene & toluene degrading bacterial cultures.

In laboratory studies with bacterial cultures growing on a mixed lactate/benzene carbon source, we observed biodegradation of benzene coupled with bacterial sulphate reduction evidenced by decreases of sulphate concentrations from 2500 to 216 mg/L accompanied by increases of $\delta^{34}S$ values from 0.4 to 12.7‰. Further laboratory experiments and groundwater investigations will reveal whether the coupling of isotopic tracers for BTEX and TEA compounds is a suitable approach for separating biodegradation within aquifers from other processes of natural attenuation [4] that affect both concentration and isotopic composition of BTEX compounds.

Noble Gas Recycling and He-Ne-Ar Solubility in Ring Structure-Bearing Minerals

COLIN R.M. JACKSON[1], STEPHEN W. PARMAN[1], SIMON P. KELLEY[2] AND REID F. COOPER[1]

[1]Brown University,. Providence, RI, USA

[2]The Open University, Milton Keynes, Buckinghamshire, UK

There is increasing evidence that significant amounts of noble gases have been recycled back into the mantle. Data on the solution properties of noble gases in geologic materials remain scarce, and thus it is unclear what materials are capable of recycling noble gases and how noble gas recycling is coupled to the recycling of other volatiles.

Towards this end, we have experimentally determined He-Ne-Ar solubility in beryl and cordierite. He-Ne-Ar solubility in beryl and cordierite is very high: 7×10^{-8},1×10^{-7}, 2×10^{-8} in beryl, and 3×10^{-7}, 4×10^{-7}, and 4×10^{-7} in cordierite (list order: He-Ne-Ar, mol g^{-1} bar^{-1}) which are around 10^4 times greater than He solubility in olivine.

Experiments were conducted using an externally-heated pressure vessel (equal parts He-Ne-Ar pressure medium) and analyzed using laser-ablation, noble gas-mass spectrometry. Experiments essentially utilized a constant-source approach, where the minerals diffusivly equilibrated with the imposed fugacity of noble gases present in the pressure medium. Temperatures ranged from 750-800°C, and total pressure ranged from 1.3-1.5 kbar.

Beryl and cordierite were choosen because they possess six-member tetrahedral ring structures in their lattice, and similar lattice structures are present in commonly recycled, hydrothermal minerals (e.g. amphibole, clays, serpentine). These lattice structures are large radius and commonly unoccupied (zero-charge), suggesting they are energetically favorable locations for noble gas dissolution in minerals.

Recent He and Ne solubility determinations for amphibole also indicate that noble gas solubility is correlated with the form of the unoccupied ring structures. Interestingly, the ratio of He to Ne solubility in amphibole is greater than that determined for both beryl and cordierite. Ring structure geometry differs amongst minerals, which may explain why amphibole apparently fractionates He and Ne relative to beryl and cordierite. This suggests that ring structure-bearing minerals may have diagnostic noble gas fractionations. Comparing the expected fractionations of noble gases in subducted materials to the integrated pattern of recycled noble gases in the mantle should yield insight into viable mechanisms for noble gas recycling.

Contrasting origins of an intermediate pluton and a highly silicic pluton, Never Summer Mountains, Colorado, USA

KRISTIN JACOB[1]* AND G. LANG FARMER[1]

[1]University of Colorado, Boulder, Campus Box 399, Boulder, CO 80309, USA
(*correspondence: Kristin.Jacob@colorado.edu)

Field observations, whole-rock major- and trace-element geochemistry, and Sr, Nd, and Pb isotopic data were used to assess the petrogenesis of and relationship between two epizonal plutons: the intermediate Mt Richthofen stock (MRS) and the high-silica rhyolite composition Mt Cumulus stock at the ~28 Ma Never Summer igneous complex, north-central Colorado, USA. The MRS is compositionally zoned from more mafic compositions at the structurally deepest portion of the pluton (55 wt. % SiO_2, ε_{Nd}(T) -2.0, $^{87}Sr/^{86}Sr$(T) 0.7049) to more felsic compositions at the structurally shallowest portion of the pluton (67 wt. % SiO_2, ε_{Nd}(T) -5.6, $^{87}Sr/^{86}Sr$(T) 0.7119). Given the lack of obvious wall-rock assimilation at the level of pluton emplacement, the compositional variations in the pluton most likely reflects differences in the compositions of magmas from which the pluton was assembled. The presence of mafic enclaves in the structurally lowest portion of the pluton reveals evidence for mafic underplating. Aluminum-in-hornblende geobarometry of the structurally lowest rocks yields an emplacement depth of ~3 km. Taken together, we attribute the vertical zonation to mixing of two primary magmas, an early-emplaced felsic end-member with later arriving mafic magmas, which were derived from greater crustal depths and interacted in the upper crust to produce the range of intermediate compositions. In contrast, the MCS is compositionally homogeneous with 77 wt. % SiO_2, ε_{Nd}(T) -5.8, and $^{87}Sr/^{86}Sr$(T) ~0.712. A close fit to a 28 Ma Sr reference isochron reveals that the MCS represent melts derived from an isotopically uniform source and could not have been derived from the adjacent isotopically heterogeneous MRS by upper-crustal differentiation. The Nd isotopic composition of the MCS is similar to that of mafic lower crustal xenoliths entrained in nearby Devonian kimberlites. Rare earth element modeling reveals a good compositional match between the MCS and calculated partial melts of the mafic, garnet-free, two-pyroxene lower crustal granultite xenoliths sampled by the kimberlites. The mafic lower crust is therefore a plausible source for the melts of MCS and early emplaced silicic material associated with the MRS.

An isotopically homogeneous inner terrestrial planet region

S. B. JACOBSEN[1*], M. I. PETAEV[1], S. HUANG[1] AND D. D. SASSELOV[1]

[1]Depts. of Earth and Planetary Sciences and Astronomy, Harvard Univ., 20 Oxford St., Cambridge, MA 02138, USA. (*email: jacobsen@neodymium.harvard.edu)

The well-established variability in isotopic compositions and water contents among various planetary materials in the inner Solar System means that bulk mixing of accreting materials, at least in some regions of the inner Solar System, was limited. We use enstatite chondrites (ECs) to explore a new model for the early evolution of the inner Solar System. In this model, the bulk of the Earth-building material originates inside the orbit of Mars (Oligarchic Growth Zone), which is isotopically homogeneous and identical to Earth and ECs. In contrast, there is a region with significant isotopic heterogeneity from Mars outwards. It is divided by the snowline (~2.7 AU) into two zones: one inside with moderate heterogeneity and another outside with much larger isotopic heterogeneity. Both zones form in a low-mass gap in the disk and therefore could never form larger planets. In this model the planets in the inner, oligarchic growth zone formed essentially dry. The Earth has received its water as a late veneer via very minor contributions from the outer regions beyond the snowline. Despite substantial isotopic variations among different chondrite groups, the isotopic compositions of the Earth's mantle are nearly identical only to ECs. Yet, there is a large chemical difference between Earth and ECs that is explained by different evolution paths from the same precursor, chemically similar to the widely accepted Earth's composition derived from mantle peridotites. This material formed in the isotopically homogeneous inner terrestrial planet region (Oligarchic Zone). The FeO-poor silicates and Ca,Mg sulfides typical of ECs resulted from a local non-nebular sulfidation of this precursor that has also changed the EC's bulk chemical composition. In this model, the identical isotopic composition of Earth and Moon is a logical outcome rather than something that has to be explained away.

Roadmaps for powering the world, U.S., and individual states for all purposes with wind, water, and sunlight

MARK Z. JACOBSON[1]

[1]Department of Civil and Environmental Engineering, Stanford University, Stanford, CA 94305-4020, USA; jacobson@stanford.edu

Global warming, air pollution, and energy insecurity are three of the most significant problems facing the world today. This talk discusses these problems and technical and economic plans to solve them by powering 100% of the world, individual countries, and states for all purposes, including electricity, transportation, industry, and heating/cooling, with wind, water, and sunlight (WWS) together with efficiency measures, within 20-40 years. New specific plans for New York and California are discussed. Relevant papers are at http://www.stanford.edu/group/efmh/jacobson/Articles/I/susenergy2030.html.

Impact of iron limitation on marine unicellular diazotrophic cyanobacteria

V. JACQ[1*], C. RIDAME[1], S. L'HELGUEN[2], F. KACZMAR[1] AND A. SALIOT[1]

[1]LOCEAN, CNRS, UPMC, 75005 Paris, France (*correspondence: violaine.jacq@locean-ipsl.upmc.fr)
[2]LEMAR, CNRS,UBO, IRD, IUEM, 29280 Plouzané, France

Marine diazotrophic cyanobacteria are able to use dissolved dinitrogen (N_2) as nitrogen source for primary production. These cyanobacteria play a key role in the global carbon and nitrogen cycles as they contribute to significantly increase the oceanic N pool and thus primary production and carbon export to deep ocean. Due to the high iron (Fe) content of nitrogenase, the enzyme required for N_2 fixation, and to its low solubility in seawater, Fe is widely suspected as a key controlling factor of the activity of diazotrophic cyanobacteria. Nevertheless, the influence of Fe limitation on the recently discovered unicellular diazotrophic cyanobacteria (UCYN) is poorly understood. To address this knowledge gap, we conducted culture experiments on the UCYN *Crocosphaera watsonii* WH8501 growing under a range of bioavailable Fe concentrations (from 0.017 nM to 2.53 nM). Overall, severe Fe limitation leads to significant decreases in growth rate (-60%), C, N and chlorophyll *a* contents per cell (-70%), N_2 and CO_2 fixation rates per cell (-90%) as well as in cell volume (-60%). Regarding these cellular contents and fixation rates on a volumetric basis we highlight two distinct responses of *Crocosphaera watsonii* depending on the degree of Fe limitation: (i) under low Fe deprivation, cells only reduced their volume while their growth rate, cellular contents and N_2 and CO_2 fixation rates per μm^3 remained maximum, and (ii) when increasing Fe deprivation, cell volume remained unchanged while growth rate, cellular contents and N_2 and CO_2 fixation rates per μm^3 strongly decreased. The half saturation constant for growth with respect to bioavailable Fe of *Crocosphaera watsonii* was 70% lower than that of the large diazotrophic filamentous cyanobacterium *Trichodesmium*. This indicates that UCYN are better adapted to poor Fe environments than large filamentous diazotrophs. Furthermore, the physiological response of *Crocosphaera watsonii* to Fe limitation was different from that shown in a previous study on the UCYN *Cyanothece* sp, indicating potential differences in Fe requirements or Fe acquisition within the UCYN community. Conclusively, our results contribute to a better understanding of how Fe bioavailability can control the activity of UCYN and explain the biogeography of diverse N_2 fixers in ocean.

Geochemical variations in the Central Southern Volcanic Zone, Chile (38-43°S): The role of fluids in generating arc magmas

GUILLAUME JACQUES[1], KAJ HOERNLE[12], HEIDI WEHRMANN[12*], JAMES GILL[3] AND ILYA BINDEMAN[4]

[1]Collaborative Research Center (SFB574), Univ. Kiel & GEOMAR (*correspondence: gjacques@geomar.de)
[2]GEOMAR Helmholtz Centre for Ocean Research Kiel, Germany
[3]University of California, Santa Cruz, USA
[4]University of Oregon, Eugene, USA

We present new major and trace element, volatile and Sr-Nd-Pb-Hf-O isotope data from the Central Southern Volcanic Zone in Chile (CSVZ; 38-43°S). The satellitic and between stratovolcano cinder cones display different geochemical characteristics from the stratovolcanoes. The cinder cone samples have lower HREEs contents and U/Th, Pb/Ce and Ba/Nb ratios, but higher LREE, Nb and Ta abundances, and La/Yb and Nb/Yb ratios. As in the Transitional (T) SVZ (34.5-38°S), S and Cl contents are elevated in some small cinder cones of the CSVZ relative to the stratovolcanoes. They also extend to less radiogenic Pb and Sr isotopic compositions and higher $\delta^{18}O_{olivine}$ compared to the stratovolcano samples, but almost completely overlap in Nd and Hf isotopic composition. These variations are consistent with the lower-volume cinder cones forming through lower degrees of melting as a result of a lower fluid flux from the subducting slab than at the stratovolcanoes. When compared to the TSVZ ([1]Jacques *et al*.., in press), the magmas feeding the CSVZ stratovolcanoes have experienced higher fluid flux released from the subducting slab, resulting in higher degrees of melting and larger magma production.

Microbial transformations of dissolved organic matter in crustal aquifer fluids at North Pond

ULRIKE JAEKEL*[1], JULIE MEYER[2], JULIE HUBER[2], THORSTEN DITTMAR[3] AND PETER GIRGUIS[1]

[1]Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA, (*correnspondence: ulrikejaekel@fas.harvard.edu, pgirguis@oeb.harvard.edu)
[2]Marine Biological Laboratory, Woods Hole, MA, jmeyer@mbl.edu, jhuber@mbl.edu
[3]Max Planck Research Group for Marine Geochemistry, University of Oldenburg, Oldenburg, Germany, tdittmar@mpi-bremen.de

While recent studies have established the existence of a deep subsurface biosphere, little is known about their activity, or their influence on biogeochemical cycles. Near the Mid-Atlantic Ridge, at a site called the "North Pond", deep ocean seawater circulates through the basaltic crust, supplying the aquifer-hosted microbial community with organic matter and electron acceptors. Studies have shown that these crustal fluids contain both oxygen and nitrate, potentially enabling a variety of microbial organic matter transformations that could have implications for the composition and source of dissolved organic matter to the deep ocean. To investigate the transformation of dissolved organic matter (DOM) in crustal aquifer fluids at North Pond, we sampled fluids from CORK (Circulation Obviation Retrofit Kit) observatories. These fluids were incubated at ~ *in situ* pressure and temperature, as well as at atmospheric pressure. Comparative analyses by Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR-MS) generated high-resolution profiles of the molecular composition of DOM, and shed light on the transformations of DOM taking place within these fluids. Molecular analyses of the microbial community and incubations with ^{13}C-labeled substrates further illustrated the potential for these microbial communities to alter the geochemical regime via their collective metabolic activity.

Meteoric ^{10}Be in soils of loessic origin- a case study of Luvisols from Northern France

M. JAGERCIKOVA[1], S. CORNU[1]*, M. MAYOR[1], V. GUILLOU[2] AND D. BOURLÈS[2]

[1]INRA, UR1119 Géochimie des Sols et des Eaux, F-13100 Aix en Provence, France (*correspondence: scornu@aix.inra.fr)

[2]Aix-Marseille Univ., CEREGE, UMR CNRS 7330, BP80, 13545 Aix-en-Provence Cedex 4, France

Meteoric ^{10}Be, due to its high affinity with soil and sediment particles, is a popular tracer in geomorphologic and environmental studies attempting to evaluate the soil production/denudation rates or soil age up to 10^7 years. However, the evolution of the ^{10}Be distribution as a function of depth is poorly known in soils, as has been shown by recent reviews [1, 2]. In this study, we have measured ^{10}Be concentrations of bulk samples and in 0-2 μm (lutum) granulometric fractions in Luvisols profiles developed on loess in Northern France. The three sites differ significantly in ^{10}Be absolute concentrations in bulk samples reflecting probably the past ^{10}Be accumulation in loess parent material. In all profiles, ^{10}Be concentrations in bulk samples show a significant correlation with the lutum content with the maximum ^{10}Be concentrations in the Bt-horizon. This result was surprising, as we expected the maximum concentration of ^{10}Be to appear at the soil surface, since ^{10}Be input occurs at the soil-atmosphere interface. Dominant adsorption of ^{10}Be to the lutum has been corroborated by measurements of ^{10}Be concentrations in lutum fraction and mass balance equation. Nevertheless, an anti-correlation has been observed between ^{10}Be concentrations in lutum and lutum content of the soils, thus outlining the dilution effect of lutum on ^{10}Be concentrations in this fraction. Contrary to the bulk samples, ^{10}Be concentrations in lutum show several maxima coinciding with the shifts in loess grain size distribution (coarse silt/fine silt), probably due to different episodes of pedogenesis occurrence. Finally, in order to quantify ^{10}Be transfers in these soils, a mass balance and numerical modelling approach of diffusion-convection equation has been used.

Were ancient granitoid compositions influenced by contemporaneous atmospheric and hydrosphere oxidation states?

OLIVER JAGOUTZ

MIT, Cambridge MA, USA, jagoutz@MIT.EDU

A fundamental shift in the nature of granitoids occurs at approximately the Archean-Proterozoic boundary. Archean crust is dominated Na-rich tonalite-trondhjemite-granodiorites (TTGs), whereas post-Archean granitoids are characterized by K-rich granodiorite-granite (GG). Due to the HREE depletion commonly found in TTGs indicating the presence of residual garnet, many researchers have proposed that the difference in Na/K is related to the deeper melting depth of the TTG parental liquids.

Here I present a compilation of the relevant experimental data, documenting that no correlation exists between the Na/K of derivative felsic liquids and the pressure of partial melting/fractional crystallization. Instead, the Na/K ratio of the felsic liquid best correlates with the Na/K ratio of the source. This implies that in Archean time the source material of TTG rocks must have been Na/K enriched relative to the modern. Modern granitoids are dominantly formed in a supra subduction zone environment, where a feedback loop exists between subducted materials (oceanic crust and sediments) and arc magmatism. Sea-floor weathering and the Na/K of the altered oceanic crust strongly depends on f(O2) conditions during alteration, which likely changed with earth history. During alteration under oxidized condition K2O is fixated due to the formation of celadonite (K-Mica), wheres during anoxic condition saponite (Na-Smectite) is the stable alteration mineral. I propose that the rise of oxygen at 2600–2400 Ma triggered associated changes in f(O2) seafloor alteration conditions (Jagoutz 2012). The change in the dominant seafloor alteration mineral from reduced to oxidized causes a change in the nature of the arc magma source and provides a possible explanation for the observed transition from TTG-rocks in the Archean to the GG-granitoids in post-Archean times.

Mineral formation and evolution from a first-principles perspective

SANDRO JAHN

GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany (correspondence: jahn@gfz-potsdam.de)

The formation and evolution of minerals is driven by thermodynamics or, more specifically, by the tendency of a usually complex chemical system to reach the lowest energy state at the existing pressure and temperature conditions. Much of what we know about the mineralogy of the Earth's interior stems either from laboratory experiments or from natural samples that at least partly preserved the structure and chemical composition they obtained during their formation. In recent years, computational mineralogy has become a powerful complementary approach to constrain the stability of minerals and their chemistry in the wide range of conditions of the Earth's interior. First-principles simulations that are based on quantum mechanics are especially suited in this respect as they are predictive, accurate and versatile.

In this talk, I will focus on two aspects of mineral evolution: (1) the partitioning of trace elements and isotopes between minerals, melts and fluids and (2) the phase behavior of mantle minerals at high pressures and temperatures. With a number of examples from recent case studies I will illustrate how the most likely incorporation mechanisms of minor elements into minerals are obtained from the simulations and which influence the molecular structure of the fluid or melt has on the partition coefficients. I will present efficient schemes to compute Gibbs free energy differences or element exchange coefficients and conclude with explicit simulations of mineral phase transformations, which sometimes lead to the discovery of previously unknown stable or metastable crystalline phases. All calculations presented here accompany or are accompanied by experimental or analytical work and it is important to stress the new synergies that arise from such collaborations.

Reactive transport modeling of chromium isotope fractionation during Cr(VI) reduction under saturated flow conditions

JAMIESON-HANES, J.H.[1], AMOS, R.T.[1], GIBSON, B.D.[1], PTACEK, C.J.[1] AND BLOWES, D.W.[1]

[1]Dept. of Earth and Environmental Sciences, University of Waterloo, Waterloo, ON, Canada (jhjamies@uwaterloo.ca, ramos@uwaterloo.ca, bgibson@uwaterloo.ca, ptacek@uwaterloo.ca, blowes@uwaterloo.ca)

Hexavalent chromium (Cr(VI)) is a very mobile groundwater contaminant most often derived from industrial processes such as tanning and electroplating, but also from naturally occurring geological sources. Reduction of Cr(VI) to the sparingly soluble Cr(III) is a common method of groundwater remediation, and is accompanied by a significant isotope fractionation. During reduction the remaining Cr(VI) pool becomes enriched in the $^{53}Cr/^{52}Cr$ ratio; the degree of this enrichment depends on the reductant, the mechanism of Cr removal, and is potentially influenced by transport processes [1].

Several laboratory experiments were conducted using organic carbon and zero-valent iron to treat Cr(VI) under both static and saturated flow conditions. In addition to traditional aqueous geochemical measurements, MC-ICP-MS analyses were made to determine the Cr isotope composition of the dissolved Cr(VI). Results from the analogous batch and column experiments exhibited different Cr isotope trends, suggesting that transport processes may play a role in the overall fractionation factor. The experiments were simulated using the reactive transport model MIN3P in order to further explore the influence of transport. Modeling results indicated that the interpretation of Cr isotope fractionation during reduction can be complex, particularly where multiple removal mechanisms may exist. Overall, the simulations were able to provide further insight into the isotope fractionation associated with the Cr removal processes.

Structural and geochemical evidence for the origin of felsic microgranular enclaves and porphyry granite, Itu Rapakivi Batholith, SE Brazil

VALDECIR DE ASSIS JANASI[1], GIOVANNA DOS SANTOS PEREIRA[1] AND ADRIANA ALVES[1]

[1]Instituto de Geociências, Universidade de São Paulo, Rua do Lago, 562, 05508-080, São Paulo, Brazil, vajanasi@usp.br (corresponding author); gsp.santos@gmail.com; adrianaalves@usp.br.

The 590 Ma Salto Granite Pluton, part of the post-orogenic Itu Rapakivi Batholith (590-580 Ma), SE Brazil, is interpreted on the basis of structural data as a westward-tilted magma chamber, whose main portion consisting of red coarse-grained hornblende-biotite granite is capped by a cupola of pink inequigranular biotite leucogranite with miarolitic cavities. This main unit was invaded by a body of zoned rapakivi granite which varies from a porphyritic facies dominated by fine-grained matrix (porphyry granite) to a cumulate granite in the eastern deeper portions. Abundant felsic microgranular enclaves (*fme*) with ellipsoidal shape and dimensions up to 4 m occur within both the red granite and the rapakivi granite, and are interpreted as products of recharge by new inputs of slightly hotter magma that broke up and froze within mushy portions of the chamber in advanced state of crystallization.

Whole-rock geochemistry helps recognize the identity of the three main magma pulses that constituted the pluton. Relative to the main body, the porphyry-rapakivi granite unit is on average slightly less felsic (0.3-0.4 wt% MgO), and has higher Ca, Ba and Sr. The *fme*, on the other hand, besides being distinctly less felsic (0.4-0.7 wt% MgO), are characterized by higher Rb and U, and lower Sr/Ba, Ba/Rb and Th/U. REE patterns ($(La/Yb)_N$= 14-18), ($^{87}Sr/^{86}Sr)_t$ (0.7058-0.7074) and εNd_t (-10.0 to -10.6) do not discriminate the units, revealing the broadly cogenetic nature of all magma inputs. Very small (<3 cm) mafic microgranular enclaves (2.3-2.9 wt% MgO) had their chemical composition strongly transformed by reaction with the host granite magmas; although they are indicative that basic magmas participated in the genesis of the granites making up the pluton, these probably did not reach the exposed portions of the Salto chamber.

Change in water circulation of the Bering Sea recorded by authigenic neodymium isotopes in sediments from the Bering Slope over 500 ka BP

KWANGCHUL JANG[1*] AND YOUNGSOOK HUH[1]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul 151-747, Korea, wkdrhkd3@snu.ac.kr (*presenting author), yhuh@snu.ac.kr

The Bering Sea is located in the nothernmost part of the Pacific Ocean, joining with the Arctic Ocean. Because of its proximity to the polar region which is sensitive to climate change, reconstructing the paleoenvironmental changes of this region is important. We analyzed the neodymmium isotope ratios in Fe-Mn oxide coating of marine sediments from the Bering Slope (site U1345; water depth 1008 m) recovered during the Integrated Ocean Drilling Project (IODP) Expedition 323. The ε_{Nd} value (n = 80) for the last 150 kyrs was relatively constant at an average value of -3.0 ± 0.8, which is slightly higher than the values of the Bering Strait (-4 to -6) [1]. We observed some deviations from the average ε_{Nd} value. According to the tentative age model [2], trends toward unradiogenic value were observed during deglacial periods. The Yukon River whose pathway was blocked by sea ice during cold periods may have increased its input of unradiogenic material to the Bering Sea upon melting of sea ice during deglacial periods. Seasonal sea ice and brine formation may have facilitated the sinking of this unradiogenic water mass. A radiogenic ε_{Nd} peak was observed in MIS 4. It may be interpreted as enhanced sinking of the Kamchatka-sourced radiogenic water as suggested by Horikawa *et al*. [2010].

[6]University of California Berkeley, USA, kim.handley@berkeley.edu

In-situ bioremediation studies have shown that adding electron donor to groundwater stimulates the activity of metal- and sulfate-reducing bacteria, profoundly impacting the cycling and speciation of redox-sensitive elements such as iron and sulfur, and changing the redox status of contaminants such as U(VI) to insoluble U(IV) products. While numerous studies have examined the impact of bioreduction in laboratory-based studies, very few have examined Fe and S speciation changes at the molecular to pore scales *in situ* in a biostimulated aquifer. In this study, we used in-well columns to obtain direct access to sediment speciation at different time points during a bioremediation experiment at the Old Rifle site, CO, transitioning dominantly from iron-reducing to sulfate-reducing regime.

We investigated Fe and S speciation at the molecular scale using X-ray absorption spectroscopy (XAS). Chemical extractions of reduced sediments revealed the rates of Fe(II) and sulfide formation. Bulk Fe EXAFS showed a significant change of Fe redox status with ongoing bioremediation. Results provide evidence for the reduction of the entire S pool to monosulfide and elemental sulfur. The speciation of FeS grain coatings that appear under sulfate-reducing conditions was probed using electron microscopy and micro-XAS. Results showed elemental sulfur accumulating in the coatings which appear to also concentrate uranium.

REE microdistribution in laterite from Madagascar

E. JANOTS[1], F. BRUNET[1], A. BERGER[2], F. BERNIER[1], M. MUNOZ[1], M. LANSON[1], N. TRCERA[4] AND E. GNOS[3]

[1]ISTerre, UJF-CNRS, Grenoble, France, janotse@ujf-grenoble.fr
[2]Institut of Earth Sciences, University of Bern, Switzerland
[3]Museum de Geneve, Switzerland
[4]Synchrotron SOLEIL, Gif-sur-Yvette, France

Despite of relatively low REE concentrations, laterites are attractive as REE ion-adsorption deposit because REE are sorbed on mineral surfaces (readily leached) and HREE are enriched in comparison to LREE. However, in laterites, the REE distribution is difficult to assess due to the small size of the host phases and their low REE concentrations. We present here an innovative approach to determine the microscale REE distribution by combining geochemical data (whole-rock elementary and isotopic composition) with high-resolution in-situ techniques including FE-SEM, EMP and synchrotron μ-XRF and μ-XAS (LUCIA beamline at SOLEIL, France). The investigated laterite developed by weathering of tonalitic rock in Madagascar. The weathering profile includes from bottom to top: fresh tonalite, saprolite, oxidized-soil layer and top-soil. Bulk-rock composition reveals REE-mobility along the profile. REE are significantly leached from the top-soil and they accumulate in the oxidized layer, which is also enriched in Mn^{4+} and other redox sensitive elements. In this oxydized soil, all REE concentrations are 3-4 times the bed-rock concentrations, but Ce reaches 9 times the bed-rock concentration. In all studied samples, electron images and XRF mapping indicate that the main Ce portion is hosted by REE-phosphates, which belong to the rhabdophane group in the saprolite and to the alunite-jarosite group in the oxidized-soil and top-soil. The CeIII/CeIV ratio in these minerals (determined from the Ce_LIII edge XANES) reflects that of the bulk-rock values. The highest Ce concentrations are localized in porous zones enriched in Mn-oxide of the oxidized-layer. Although cerianite and alunite-jarosite minerals appear as the main REE-hosts, Mn-oxides also contain significant REE amount. In comparison, clay-rich domains show low Ce concentrations. Our in-situ results confirm that phosphates are crucial REE-carriers in common laterites.

Protolith and metamorphism of Moldanubian HP granulites – a geochemical perspective

V. JANOUŠEK*, J. FRANĚK AND S. VRÁNA

Czech Geological Survey, Klárov 3, 118 21 Prague 1, Czech Rep. (*correspondence: vojtech.janousek@geology.cz)

Petrogenesis of voluminous, widespread and chemically nearly uniform felsic Moldanubian HP granulites in the Variscan orogenic root of the Bohemian Massif remains controversial. Previous studies of the best exposed Blanský les Granulite Massif (BLGM) showed that it originated by ~340 Ma HP–HT metamorphism of mid-Ordovician–Silurian [1] acid metaigneous rocks of Saxothuringian provenance [2]. Such refractory protoliths would suffer only limited chemical modification (mainly loss of U, Th, and Cs [2,3]).

Carefully selected samples from rare relict (S1) felsic–intermediate BLGM granulites help to constrain the peak mineral assemblage (Grs-rich Grt, Ky, mesoperthite) giving pressures of ~20–23 kbar (GASP barometry), higher than any previous estimates ([4] for review) and, together with geothermometric data from the same domain (~ 950 °C, see also [5]) support the early eclogite-facies history.

The other samples show small-scale mineral disequilibria (several mineral generations, zoning in mineral grains and various reactions related to HT decompression), contain large proportion of pre-Variscan (>400 Ma) inherited Zrn, preserve ~470 Ma Rb–Sr whole-rock errorchrons and show largely undepleted whole-rock geochemical signatures. This implies only a limited melt participation at the peak conditions [2,3].

We propose that the felsic Saxothuringian crust rich in heat-producing elements was deeply subducted [6,7] and relaminated to the base of the Moldanubian crust. After thermal incubation, rheological weakening with a limited partial melting triggered gravitational instability and ascent of the orogenic lower crust [3,8]. The mantle contaminated by the passage of the crustal material produced characteristic K-rich magmas with crust-like Sr–Nd–Pb isotopic signatures, closely related with HP granulites in space and time [9].

The Selva Negra: A Favourable Setting for Alkalic Au Mineralisation

NICHOLAS H. JANSEN[1], PETE HOLLINGS[2] AND F. MARTINEZ-LEGORRETA[3]

[1]CODES, ARC Centre for Excellence in Ore Deposits, Private Bag 126, Hobart, Tasmania 7001, Australia
[2]Geology Department, Lakehead Univeristy, 955 Oliver Road, Thunder Bay, Ontario, P7B 5E1, Canada
[3]SRK Consulting Mexico, Lava Street, #2, Int. 6, Cañada de La Bufa, 98619, Guadalupe, Zacatecas, Mexico

The Selva Negra volcanic rocks are located in Chiapas State, southeastern Mexico, in a complex triple junction between the North American, Caribbean, and Cocos plates. The Chiapanecan Volcanic Arc, which hosts the Selva Negra complex, activated around 3 Ma when slab flattening in central Mexico caused volcanism on the Pacific coast to change from parallel to the Middle American Trench to approximately 30º oblique to the trench. Volcanic activity was focused along northwest-oriented faults that extend from the Caribbean and North Amercian plate boundary and likely acted as magma conduits during periods of extension.

The Selva Negra rocks occur at the northwest end of the coeval calc-alkaline arc and at the furthest point from the trench (300-330 km). They comprise widespread alkaline and LILE-erniched monzodiorite to diorite intrusions with a crystallization age of ~1.0 Ma (zircon U-Pb), trachyandesite volcanic rocks and rare basalt flows. The radiogenic isotope data suggest that the ascending magmas interacted with the thick crust (~50 km) through MASH processes. The Selva Negra rocks likely resulted from a combination of low degree partial melts of a heterogeneous mantle enriched in LILE and LREE and crustal contamination.

Alkaline magmatism is commonly associated with Au-rich deposits and several key geological parameters are favourable for their formation including rifted arc terranes, back-arc sites, extensional and post-subduction settings are [1, 2, 3]. In the case of the Selva Negra, slab flattening and the complex triple junction has refocused the magmatism 30º oblique to the trench allowing low degree partial melts and alkaline intrusions to occur at the furthest extension inland and creating a favourable setting for mineralising intrusions. Au-rich mineralisation has been intersected within the Selva Negra but remains largely underexplored.

Microbial and redox evolution in the Neoproterozoic of Australia

A. J. M. JARRETT[1*], S. W. POULTON[2], M. GIORGIONI[1], AND J. J. BROCKS[1]

[1]Research School of Earth Sciences, The Australian National University, Canberra, ACT 0200. (* correspondance: amber.jarrett@anu.edu.au)

[2]School of Earth & Environment, University of Leeds, LS2 9JT, United Kingdom.

Availability of oxygen and a stable redox environment may have been major factors in the evolution of the Ediacaran biota [1]. Therefore, much research is focused on tracing the co-evolution of life and the redox state of marine environments through the Neoproterozoic. The Centralian Superbasin in Australia is one of the few places in the world where it is possible to study body fossils, redox conditions as well as molecular fossils in sediments ranging from the ~850 Ma Bitter Springs Formation to the Cambrian. The thick siliciclastic or evaporitic successions were deposited in a marine intracratonic basin and include evidence for two Snowball Earth events.

Here we provide first insights into the redox state of the Centralian Superbasin using Fe speciation data. In mid-shelf or deeper waters, our results document a major transition from a predominantly unstable ferruginous water column to a marine basin persistently oxygenated by at least 580 Ma. Therefore, the Centralian Superbasin became oxygenated at a time similar to other major basins worldwide [2].

We also complement the redox record with biomarker data from ~850 Ma to 570 Ma successions. We speculated that the transition from unstable redox conditions to persistently oxic conditions would also mark a transition to eukaryotic dominated ecosystems. Despite excellent organic preservation and the presence of abundant bacterial biomarkers, we did not find any evidence for a complementary increase in eukaryotic biomass. Thus, although oxygenated mid-shelf environments significantly predate the Ediacaran biota in Australia, eukaryotes such as algae and sponges did not become a dominant part of these oxic marine ecosystems for at least 20 Ma after full oxygenation [3, 4]. Therefore, the rise of eukaryotes to ecological dominance in the Neoproterozoic was not solely dependent on the availability of a stable oxygenated water column.

Sealing time: Numerical simulation of water-rock interaction in volcanic systems

JASIM A.[1]*, WHITAKER F.[1], RUST A.C.[1] AND SCOTT T.B.[2]

[1]School of Earth Sciences, University of Bristol (*alia.jasim@bristol.ac.uk)

[2]University of Bristol, Interface Analysis Centre

Clogging of porosity around active volcanos influences fluid flow paths, degassing processes and rock strength, altering the response of the volcano to deeper perturbations as well as meteoric recharge events. Water-rock interactions in systems characterised by significant gradients in temperature and pressure lead to the destabilisation of primary igneous minerals and precipitation of secondary phases. The objective of this research is to use RTM to provide a rigorous foundation for the development of a conceptual model describing the complexity of the interactions between circulating hydrothermal fluids and andesitic country rock.

Preliminary 1D simulations using TOUGHREACT permit identification of key controls, quantitative evaluation of their effects and interactions between different controls. The modelling is constrained using data from the well-studied andesitic composite Soufrière Hills Volcano (SHV) on Montserrat. Temperature is a key control on reaction kinetics and, in combination with effective reactive surface area (RSA) of component minerals, controls the evolution of mineralogy and porosity over time. Moreover we can evaluate key feedbacks between the effects of this paragenesis on permeability and the flow of fluids supplying reactants and removing alteration products. RTM simulations offer answers to questions such as; how long does the plagioclase take to disappear from the andesite? What is the rate of change of the porosity? Key challenges are better understanding of RSA and kinetics of reactions. Preliminary results allow us to start thinking about the effects of water-rock reactions in altering transport of mass and heat and implications for volcanic response and slope stability.

This work contributes to building a holistic understanding of volcanic systems within the framework of the VUELCO project (Volcanic Unrest in Europe and Latin America: phenomenology, eruption precursors, hazard forecast, and risk mitigation).

The "boring billion": An exciting time for early eukaryotes!

E.J. JAVAUX[1]*, J. BEGHIN[1], J-P. HOUZAY[2] AND C. BLANPIED[3]

[1]Dept Geology, Uni. of Liège, Liège, 4000, Belgium (*correspondence: ej.javaux@ulg.ac.be)
[2]Fluids and Geochemistry Dpt, TOTAL, Pau, France
[3]Projets Nouveaux, TOTAL, Paris, France

The so-called 'boring billion' (~1.8-0.8 Ga) was characterized by a stratified ocean with anoxic ferruginous deep water, euxinic mid-water-column layer or wedges, and oxygenated shallow-water. These conditions are thought to have delayed eukaryotic diversification by limiting nutrient availability.

Here, we present a new, exquisitely preserved and morphologically diverse assemblage of organic-walled microfossils from the 1.1 Ga Taoudeni Basin of Mauritania. The assemblage includes diverse protists (ornamented and process-bearing acritarchs), possible multicellular xanthophyte algae, unidentified microfossils including smooth sphaeromorphs, prokaryotic filamentous sheaths and filaments, as well beautifully preserved microbial mats. Several taxa are reported for the first time in Africa.

This new microfossil assemblage, and others documented during the "boring billion", evidence the early and worldwide diversification of eukaryotes. Stem eukaryotes appeared before or at the start of that time, had evolved a cytoskeleton, a nucleus, multicellularity, and diversified in mostly (but not only) shallow-water settings. Between 1.2 and 0.75 Ga, a major diversification of crown group eukaryotes occurred at the supergoup level, with key biological innovations such as cell differentiation, sexual reproduction, and eukaryotic photosynthesis by primary and secondary endosymbioses. Soon after the boring billion, a second diversification occurred but within supergroups, together with the evolution of eukaryotic biomineralisation and predation, and later on in the Ediacaran, tissue and organ-grade multicellularity.

Thus, the chemical state of the mid-proterozoic ocean does not entirely explain the pattern and timing of eukaryotic diversification, started well before the onset of global ocean ventilation around 0.8 Ga.

To better understand the paleobiology and paleoecology of early (stem or crown, aerobie or anaerobie) eukaryotes, we combine our morphological, microchemical and ultrastructural studies of microfossils, with high-resolution paleoenvironmental and paleoredox characterization.

The genesis of Enstatite Chondrites and the Earth.

MARC JAVOY [1*] AND JAMES CONNOLLY [2]

[1]Institut de Physique du Globe de Paris mja@ipgp.fr
[2]ETH Zurich, (james.connolly@erdw.ethz.ch)

The multielemental isotopic convergence between the Earth's Mantle and Enstatite Chondrites (E Chondrites) likely results from a large scale high temperature isotopic equilibrium within the same isotopically homogeneous medium (« mother nebula »). High temperatures insured nearly total isotopic homogeneisation, the residual differences between E chondrites and Earth being due to a temperature gradient inside the mother nebula, and/or cooling of a zone where E chondrites appear after the main accretion episode of the Earth. The mother nebula resulted from the high temperature (1550-1650K) processing of a mixture of solar gas with concentrated (150 ±20 times), dehydrated, and partially reduced CI dust, resulting in volatile (S, Na) and transitional (Si, Mg, Fe, Ni) elements' enrichment and refractory (Al, Ca REE, actinides) elements depletion. The dust-gas proportion and the condensation temperatures are, respectively, constrained from the isotopic compositions of nitrogen and silicon. The mother nebula genesis likely took place during the Sun's T Tauri phase. An appropriate location is the « dust chemical reactor » around 1AU, described in recent studies of T Tauri stars [1]. This also agrees with the idea that terrestrial planets accreted dominantly from a 0.7-1UA circumsolar annulus [2]. At 10^{-3} atmospheres the condensation sequence of such compositions reproduces the chemical and mineralogical composition of « primitive » EH3 Chondrites around 1150 K, and Earth's bulk compositions at 1280-1420K, with large variations of the volatile (S, Na) contents and moderate changes of the Mg/Si ratio. The enhanced (Si +Mg)/O ratio of the dust-enriched mixture and the corresponding increase in oxygen uptake by the condensates, explain the very low oxygen fugacities observed, especially in the E chondrites' temperature domain.

Revisiting land to ocean fluxes

CATHERINE JEANDEL[1] AND ERIC H. OELKERS[2]

[1]LEGOS (CNRS/UPS/IRD/CNES) Observatoire Midi-Pyrénées, 14 Ave Edouard Belin 31400 Toulouse France
[2]GET (CNRS/UPS/IRD) Observatoire Midi-Pyrénées, 14 Ave Edouard Belin 31400 Toulouse France

A large number of diverse observations reveal that substantial lithogenic material dissolution occurs at the land-ocean interface, a key area targeted by the GEOTRACES international program (www.geotraces.org).

1) The compositions and distribution of numerous elemental tracers and isotopic systems including Co, $^{143}Nd/^{144}Nd$, $^{232}Th/^{230}Th$, $^{30}Si/^{28}Si$, $^{56}Fe/^{54}Fe$ in the oceans can only be accurately interpreted by taking account of a substantial input to seawater from lithogenic material from the continental shelf or margins [1].

2) Closed-system laboratory experiments show that a significant fraction of river transported material dissolves into seawater over the time scale of days to months, releasing elements and isotopes to the fluid [2].

3) A recent study demonstrated that particulate material dissolution is the dominant source of Sr to the waters the Borgarfjörður (Iceland) estuary (Jones *et al*., in prep).

These observations suggest that from 0.5 and 10% of the mass contained in river transported particulate material is released to seawater during the first days to months following its arriving to the oceans. As the total particulate material flux to the world's oceans exceeds the corresponding dissolved load flux by as much as a factor of 30, particulate dissolution at the continental margins may be the dominant source of many of the elements present in the oceans [3].

To assess the significance of particulate dissolution on ocean chemistry, we have estimated the total global flux to seawater of a suite of elements originating from riverine transported particulate material by taking account of the average composition and mineralogy of continental and volcanic sourced particulates, together with the published dissolution rates for these minerals, measured surface areas of representative particulate materials, and mineral saturation indexes computed using PHREEQC. Results indicate that particulate material dissolution is a significant contributor to the global flux of major elements (e.g. Si, Ca, and Sr) to the oceans, and can dominate the fluxes of some critical trace elements and nutrients.

Magmatic processes beneath Furnas volcano, São Miguel, Azores

A. J. JEFFERY[1], R. GERTISSER[1], B. O'DRISCOLL[1], A. PIMENTEL[2] AND J. M. PACHECO[2], S. SELF[3]

[1]School of Physical and Geographical Sciences, Keele University, Keele, Staffordshire, ST5 5BG, UK. (*correspondence: a.j.jeffery@keele.ac.uk)
[2]Centro de Vulcanologia e Avaliação de Riscos Geológicos, Universidade dos Açores, 9501-801 Ponta Delgada, Açores, Portugal
[3]Department of Earth and Environmental Sciences, The Open University, Milton Keynes, MK7 6AA, UK

Furnas, São Miguel, Azores is an oceanic-island caldera volcano characterised by mafic to silicic, metaluminous to peralkaline magmas, and a range of eruption styles that imply significant variation in pre- and syn-eruptive processes. Here, we investigate these processes and provide insights into the magma plumbing system of Furnas by targeting selected units within the volcano's stratigraphy. These include the products of two older caldera-forming events, namely the Povoação Ignimbrite (PI) (30,000 ^{14}C y B.P.) and an ignimbrite interpreted to represent the second caldera-forming eruption (~12,000 ^{14}C y B.P.), as well as the younger, sub-plinian eruptions (< ~5,000 ^{14}C y B.P.) of the Upper Furnas Group (UFG), Furnas A-J.

The UFG spans a compositional range from metaluminous to mildly peralkaline trachyte, with agpaitic indices (AI) between 0.73 and 1.13. Mineralogical assemblages of the UFG include alkali-feldspar, clinopyroxene, Ti-magnetite ± biotite, ilmenite and apatite, though phenocryst contents are typically low (< 5 vol.%). Ba and Sr concentrations are 5-115 and 2-51 ppm, respectively, whilst Nb and Zr contents are 177-303 and 1010-1498 ppm, respectively. A pronounced negative Eu anomoly (Eu/Eu* = 0.15) is present in all UFG samples. Rare cognate syenite nodules are present in Furnas J, comprising alkali-feldspar, clinopyroxene, amphibole, Fe-Ti oxides and apatite. The PI is trachytic and metaluminous (AI = 0.95-0.98), with no Eu anomaly. The mineral assemblage is similar to the UFG, but Ba and Sr contents are significantly higher (287-308 and 85-88 ppm, respectively), whilst Nb and Zr are notably lower (133-140 and 810-860 ppm, respectively) than in the UFG.

We discuss the geochemical variation of silicic magmatism at Furnas, and highlight the role of plagioclase and alkali-feldspar fractionation, alongside formation of a syenitic mush zone, in the derivation and shallow crustal evolution of Furnas magmas, as well as the temporal development of oceanic island, peralkaline magma systems.

Constraining Rates of Ocean Processes Using Tracers

W.J. JENKINS[1]

[1]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA 02543 USA

The marine environment is controlled by a complex interplay of physical, chemical, biological, and geological processes occuring over a vast array of time and space scales. Deconvoluting these processes is necessary to gain any quantitative understanding of how the ocean works and is a challenging task. Much of what we know about oceanic biogeochemical processes (and their rates) comes from the interpretation of the distributions of tracers combined with simple physical laws. Progress in measurement techniques have lead to numerous new tracer tools, including transient-, radioactive-, age-, and "steady state" tracers that have lead to remarkable insights into oceanic processes.

While we have advanced from the halcyon days of one-dimensional advection-diffusion models, we still struggle with some fundamental challenges arising from the nature of tracers and their observations. Among these are the fact that individual tracers, based on their *in situ* behavior and their boundary conditions in space and time, provide a specific, skewed measure of the ocean. Recognizing factoring in this bias is an important step forward for tracer oceanographers. Another important consideration is that the tracers' boundary conditions and/or *in situ* behavior may not be completely defined or understood, so inclusion of these uncertainties into the confidence assigned to the results of our interpretation. Finally, we have to deal with the reality that tracer observations are usually sparse in both space and time. Although all of the above conspire to make life difficult for tracer geochemists, valuable insights can still be gained, and advances in tracer diagnostic methodologies hold considerable promise. Among the relatively new methods include Optimum Multi-Parameter Analysis (and the related Total Matrix Inversion), Transit-Time Distribution Analysis, and Age Tracer Contour Inverse Method. In this overview, I will attempt to compare these methods and tracers and point to future directions where progress may be made.

The competing roles of sulfide saturation, magma mixing and degassing during the petrogenesis of convergent margin magmas

F. JENNER[1*], E. H. HAURI[1], R. ARCULUS[2], J. A. MAVROGENES[2], H. ST.C. O'NEILL[2] AND T. H. E. WHAN[2]

[1]Carnegie Institution of Washington, Department of Terrestrial Magnetism, Washington DC 20015-1305, U.S.A (*correspondence: fjenner@ciw.edu)

[2]RSES, Australian National University, Canberra, Australia

The point at which the silicate melt becomes saturated with a sulfide phase in an evolving magmatic system depends on the initial S content and oxidation state of the parental melt. Because of their more oxidized character, evolving convergent margin magmas usually reach sulfide saturation at a more advanced stage of their evolution than mid-ocean ridge basalts (MORB). Sulfide saturation may be initiated by stabilization of magnetite: the so-called "Magnetite Crisis", identified in the near-arc, Manus Backarc Basin submarine volcanic systems. Here we report new major and trace element data for submarine volcanic glasses from the magma-starved southern Valu Fa Ridge (SVFR), the current location of the propagating tip of backarc basin spreading of the Eastern Lau Spreading Centre in the Lau Basin, SW Pacific. The change of Cu/Se, Ag/Se and Cu/Ag with indices of evolution also indicate a Magnetite Crisis, demonstrating this process is not a localized phenomenon. In contrast, chalcophile element contents of submarine glasses from the more active Central Valu Fa Ridge (CVFR) are more scattered, which may be due to magma chamber recharge, resulting in illusion of sulfide saturation prior to the appearance of magnetite as a crystallizing phase. The systematics of chalcophile and volatile element abundances of Valu Fa Ridge samples are inconsistent with partitioning of Cu, Ag and Au into an exsolved Cl-rich brine or vapor phase during differentiation or degassing. The occurrence of volcanogenic hydrothermal sulfide deposits along the Valu Fa Ridge indicate that Cu, Ag and Au were likely leached from the host rocks during circulation of hydrothermal fluids post dating magmatic solidification, and accounting for the similarity of hydrothermal sulfide deposits in both the Manus and the Lau backarc basins.

Reactive transport in bentonite: Experiments and modelling

A. JENNI[1*], U. MÄDER[1] AND R. FERNÁNDEZ[2]

[1]RWI, University of Bern, Institute of Geological Sciences, Bern, Switzerland (*correspondence: andreas.jenni@geo.unibe.ch, urs.maeder@geo.unibe.ch)
[3]Universidad Autonóma de Madrid, Departamento de Geología y Geoquímica, Madrid, Spain (raul.fernandez@uam.es)

Bentonite plays a key role in many engineered barrier concepts for nuclear waste repositories. Gradients in chemical composition, temperature, and water potential drive reactive transport in bentonite when acting as a barrier. Subsequent mineral reactions may influence the long-term performance of the material and are thus investigated.

The experimental approach consists of a compacted, saturated bentonite cylinder subjected to a confining pressure. In addition to chemical diffusion, an infiltration pressure leads to advective transport of an infiltrate through the cylinder [1]. As long as hydraulic conductivity (set by P_{inf} and P_{conf}) is slow compared to kinetics of phase reactions, this approach imitates a long-term diffusion-only reactive transport scenario.

Comparison of reactive transport at room temperature with an expected repository temperature of 140°C reveals that the same mechanisms operate: ion exchange in smectite, and gypsum dissolution.

Substantial differences of break-throughs and break-outs of anionic and neutral tracers, all non-reactive in this system, can be explained by anion exclusion from the smectite interlayer, where no advection is expected.

Therefore, the chosen model consists of a double porosity approach [2]: the "microporosity" domain (diffusion only), where chemistry is determined by charged smectite basal sheet surfaces and Donnan equilibrium, and the "macroporosity" (charge balanced, advective and diffusive transport). This multi-component model fits the experimental data and explains the substantial differences in tracer break-through behaviour.

Origin of the Neoproterozoic zircon inheritance in the Arabian Shield

HEEJIN JEON[1]*, MARTIN WHITEHOUSE[1] AND KHALID KADI[2]

[1]Swedish Museum of Natural History, Stockholm, Sweden (*correspondence: heejin.jeon@nrm.se)
[2]Saudi Geological Survey, Jeddah, Saudi Arabia

The Arabian Shield is the largest area of Neoproterozoic juvenile crust on Earth and consists of several oceanic island arc terranes. There is rare exposed old (pre-Neoproterozoic) crust in the shield and to date, no evidence of it at depth. However, many studies have reported pre-Neoproterozoic zircon inheritance from igneous and sedimentary rocks and even from ophiolites, whose origin is ambiguous. The cores are variously interpreted to have been inherited from the Khida (sub)terrane, the only continental terrane in the shield, attributed to the 'contaminated' nature of the shield by sedimentary incorporation, or to have survived subduction and transport through the mantle.

While pre-Neoproterozoic zircon core studies have been focused on determining their source(s), Neoproterozoic ones only slightly older than the host-rocks have received little attention, despite their abundance. The Neoproterozoic cores may have the same origin as the pre-Neoproterozoic ones or may be derived from another source: wall rocks, recycled materials of the juvenile arc crust, undetected older crust underneath the shield, or the mantle. In either case, new U-Pb and O isotopic data of the Neoproterozoic zircon inheritance gives insights into the evolution of the Arabian Shield

About 10 granite and sandstone samples were collected along an E-W transect across six terranes in the Arabian Shield. Zircon cores were dominantly targeted (>100 analyses) for U-Pb analysis with several rim spots in each sample for both inheritance and crystalline ages. The studied granite and sandstone were emplaced or deposited at ca. 640–610 Ma (Cryogenian–Ediacaran) and slightly older cores (mostly <800 Ma, Cryogenian) were found. The cores are clearly distinguished by discordant zoning and sometimes by different Th/U ratios from the surrounding rims. Corresponding stable O isotopic data help to determine origin of the cores in the Arabian Shield, most components of which are juvenile and newly formed. Thus, the new data of the Neoproterozoic zircon inheritance will contribute to understanding the formation processes and compositions of the terranes in the Arabian Shield.

Measurement of soil loss affected by rainfall and slopes with different rocks and slopes from Andong, Korea

JEONG GYO-CHEOL[1]*, LEE JUN-JEONG[2], NAM KOUNG-HOON[3], AND CHOO CHANG-OH[4]

[1]Andong National University, Andong, Korea(*correspondence: jeong@andong.ac.kr)
[2]InForworld, Seoul, Korea (jklee8103@paran.com)
[3]Andong National University, Andong, Korea (namsoil@naver.com)
[4]Andong National University, Andong, Korea (mineralogy@hanmail.net)

Since several factors such as the movement pattern of soil mass, intensity of rainfall, surface relief, soil mineralogy, or geology can affect the process of soil loss or landslide[1], it is not easy to predict them in the field. Here, we present some important factors that affect the behaviors of soil loss related to rock types, slopes, rainfall, and mineralogy. In recent years, there has been growing increase in annual rainfall in Korea and it is interesting to mention that more than 90 % of the total rainfall is recorded during the summer ranging from June to September, possibly due to climate change over the world. As a result, especially soil erosion or soil loss on natural slopes by such torrential rains became a matter of some concern on the rise. We investigated the characters of soil loss in four sites with different slope angles: two sites are gneiss, other two sites are sedimentary rocks, respectively.

Based on XRD data, constituent minerals in soils are quartz, feldspars, and clay minerals such as illite, kaolinite, and vermiculite. Soils tended to be much coarser as erosion proceeded, and especially the amount of fine particles (0.1~0.01 mm) decreased by 10 % while that of coarse particles (1.0~10 mm) increased drastically by more than 30~40 %. The rate of soil loss becomes high while the slope is steeper. As the process of soil erosion repeats, the grain sizes in soil tend to be coarser, which in turn acts as weakening the strength of the moisture holding ability in soil.

This study was supported by the GAIA Project (RE201202051), Ministry of Environment, Korea.

The distribution map of lead isotope compositions for galena from ore deposits in South Korea

Y.-J. JEONG [1], C.-S. CHEONG [1], H.J. CHO [1], J.Y. CHOI [1], Y.M. AN[1], D.B. SHIN [2], S.J. KIM[3 A] AND J.J. HWANG [3]

[1]Korea Basic Science Institute, Daejeon 305-333, Korea (hero0123@kbsi.re.kr)
[2]Department of Geoenvironmental Sciences, Kongju National University, Kongju 314-701, Korea.
[3]Division of Conservation Science, National Research Institute of Cultural Hertage, Daejeon 305-380, Korea

In this study, we report the distribution map of lead isotope compositions for galena from ore deposits(n=91) in the southern part of the Korean peninsula with new and published data. The ore deposits are mostly skarn and hydrothermal-type deposits formed in close relation to the Mesozoic magmatic activities. The lead isotope compositions plot around the growth curve of the upper crust and orogene in the plumbotectonic model.

The comprehensived lead isotope data of this study indicated may be subdivided into four discrete zones that were reconized by geological consideration and statistical analysis for the ore lead composition.

Zone I geotectonically comprises the Gyeongsang basin in South Korea. Their $^{207}Pb/^{204}Pb$ ratios were characteristically low for the given $^{206}Pb/^{204}Pb$ rations, suggesting an involvement of reservois with low time-intergrated U/Pb and Th/U ratios such as the mantle or low crust. Zone II covers the northeastern Yeongnam massif and eastern Taebaeksan basin, lead isotopic composition of those had the most radiogenic in South Korea($^{206}Pb/^{204}Pb$ = 18.66–20.48, $^{207}Pb/^{204}Pb$ = 15.71–16.07, $^{208}Pb/^{204}Pb$ = 37.73–40.46). Zone III corresponds to the middle and southwestern parts of the Precambrian Yeongnam massif, the western part of Cambro-Ordovician Taebaeksan basin, and the Okcheon metamorphic belt. Galenas of these deposits showed the less radiogenic signature and limited variations in lead isotopic composition. The lead isotopic difference between zone II and zone III could be ascribed to the spatially-selective involvement of highly radiogenic crustal materials represented by the basement rocks($^{206}Pb/^{204}Pb$ up to 76) in the northeastern Yeongnam massif. Zone IV comprises the Gyeonggi massif of Precambrian craton in central parts of the Korean peninsula.

Such distribution map of lead isotope composition in South Korea may be useful of application for mining exploration, estimation of ancient artifacts, and environmental tracer.

Halogens in basalts of the Azores, Canaries and Tristan da Cunha

L.D.A. JEPSON[1*], R. BURGESS[1], V.A. FERNANDES[2], D. MURPHY[3] AND C. BALLENTINE[1]

[1]School of Earth, Atmospheric and Environmental Sciences, University of Manchester, Oxford Road, Manchester, M13 9PL, UK (*correspondence: lisa.abbott@postgrad.manchester.ac.uk)

[3]School of Natural Resource Sciences, Queensland Institute of Technology, Brisbane, Australia

The halogens (Cl, Br, I) are moderately volatile elements that exhibit incompatible behaviour during melting, and are hydrophyllic - in addition, iodine is strongly fractionated by biological processes. Although the halogens share similar geochemical properties to the noble gases, the heavy halogens in particular have been underutilized as tracers, because of the analytical difficulties related to determining their low abundances in geological materials.

Olivine and pyroxene mineral separates from basalts have been analysed from Tristan da Cunha, Canaries, and Azores ocean island groups. The halogens are assumed to be mainly sited in fluid (Canaries) and melt (Tristan, Azores) inclusions observed within the mineral phases; noble gases were liberated by a combination of crushing and stepped heating. Only bulk molar halogen ratios are quoted here.

The Tristan da Cunha basalts show Br/Cl and I/Cl ratios that extend from the range previously determined for MORB samples up to the high values characteristic of marine pore fluids, with maximum values of Br/Cl = 3.4×10^{-3} and I/Cl = 4.1×10^{-3}. This range is interpreted to represent a mixing trend between MORB and a subducted marine pore fluid or I-rich sediment signature, in the source of the Tristan da Cunha basalts.

Initial results show that the Azores basalts have a similar range in I/Cl ($9.92\text{-}253 \times 10^{-6}$) to MORB, with the Br/Cl values offset to slightly higher values ($0.62\text{-}4.22 \times 10^{-3}$). There appears to be some variation between islands, observed in the I/Cl values – with the samples from Graciosa having the highest I/Cl and Br/Cl ratios.

Crushing analyses show that the Canaries basalts have a similar range in Br/Cl ($0.456\text{-}1.07 \times 10^{-3}$) to MORB, but extend to much higher I/Cl values ($94.5\text{-}15500 \times 10^{-6}$). The data overlap with unpublished data from marine sediments. Analyses indicate the presence of a fluid component, which is not seen in the other OIBs.

Reducing uncertainty in the climatic interpretations of speleothem $\delta^{18}O$

CATHERINE N JEX*[1,2,3], S.J. PHIPPS[4,5], A. BAKER[2,3] AND C. BRADLEY[6]

We explore two principal areas of uncertainty associated with paleoclimate reconstructions from speleothem $\delta^{18}O$ ($\delta^{18}O_{spel}$): i. potential non-stationarity in relationships between local climate and larger-scale atmospheric circulation; and ii. routing of water through the karst aquifer. Using a $\delta^{18}O_{spel}$ record from Turkey, the CSIRO Mk3L climate system model and the KarstFOR karst hydrology model, we confirm the stationarity of relationships between cool season precipitation and regional circulation dynamics associated with the North Sea – Caspian Pattern since 1ka. Stalagmite $\delta^{18}O$ is predicted for the last 500 years, using precipitation and temperature output from the CSIRO Mk3L model and synthetic $\delta^{18}O$ of precipitation as inputs for the KarstFOR model. Interannual variability in the $\delta^{18}O_{spel}$ record is captured by KarstFOR, but we cannot reproduce the isotopically lighter conditions of the 16th to 17th Centuries. We argue that forward models of paleoclimate proxies (such as KarstFOR) embedded within isotope-enabled general circulation models are now required.

Carbon and Sr fluxes of river waters from a karstic and a granitic terrain in the Yangtze River system

HONGBING JI*[12] AND YONGBIN JIANG[2]

[1]The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: hongbing.ji@yahoo.com)

[2]Department of Environmental Engineering, Civil and Environmental Engineering School, University of Science and Technology Beijing, Beijing 100083, China

Two typical subtropical watersheds were chose in the Yangtze River, which have similar latitudes and climate, but distinct differences in basin lithologies. These features provide a good natural laboratory in which to investigate weathering processes, carbon and Sr fluxes in river waters. Total erosion rates, dissolved inorganic carbon flux and CO_2 uptake were 28.0 t km^{-2} yr^{-1}, 2.9×10^5 mol km^{-2} yr^{-1} and 2.3×10^5 mol km^{-2} yr^{-1} for the granitic terrain and 70.2 t km^{-2} yr^{-1}, 11.9×10^5 mol km^{-2} yr^{-1} and 6.4×10^5 mol km^{-2} yr^{-1} for the karstic terrain, respectively. These results indicated the karstic area plays an important role in uptake of CO_2 and DIC flux along the Yangzte River Basin. Our results revealed that the chemical erosion rate and Sr flux in the karstic terrain are twice and six times that of the granitic terrain. This indicates that the intensive carbonate weathering in the karstic area can provide much more Sr flux than that of silicate weathering in the granitic area. Our results support the conclusion the process of a non-steady state of rock cycling (e.g., the uneven distribution of dolomite through geological time) has an important meaning in elemental cycle and the global climate change (buffer effect).

Zircon U-Pb age and Hf isotope constraints on the petrogenesis of the Alpine Periadriatic intrusions

W.-Q. JI[1]*, F.-Y. WU[1], M. TIEPOLO[2], A. LANGONE[2], AND R. BRAGA[3]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (*correspondence: jiweiqiang@mail.iggcas.ac.cn)

[2]C.N.R.-I.G.G.-Pavia, 27100 Pavia, Italy

[3]University of Bologna, Italy

The origin of the Tertiary Periadriatic magmatism, developed along the Alpine Chain and its relationship with tectonic evolution of the Alpine Orogeny is still controversial. Integrated zircon U-Pb age and isotope study is an effective method to decipher petrogenesis of granite and crustal evolution in orogenic belt. Here we carried out zircon LA-ICPMS U-Pb and Hf isotope analyses on granitoid rocks from the major Periadriatic intrusions of the Western and Central Alps, including the plutons of Biella, Miagliano, Novate, Bergell and the Adamello batholith.

The dated granitoid rocks of different lithologies from the Biella pluton, yield identical ages of 30.5–30.1 Ma and similar $\varepsilon_{Hf}(t)$ values of -5.9–-1.8. The Miagliano tonalite gives an age of 32.6 ± 0.5 Ma and $\varepsilon_{Hf}(t)$ value range from -5.2 to -1.3. The Novate pluton yields ages in the range of 26.5– 23.5 Ma with $\varepsilon_{Hf}(t)$ values vary from -8.5 to -2.5. The tonalites and the granodiorites from the Bergell plutons are dated at 32.1–30.3 Ma and 31.3–30.3 Ma, respectively. Their zircon $\varepsilon_{Hf}(t)$ values vary from -5.0±0.5 to -3.2±0.3. In the Adamello batholith, the trondhjemites from Corno Alto pluton (43.2–43.0 Ma) and the tonalites from southern Re di Castello Unit (43.3–42.9 Ma) are coeval. Both units exhibit relatively high $\varepsilon_{Hf}(t)$ values (5.0±0.6 – 7.7±0.3). Whereas the tonalite from Presanella pluton of north Adamello yield a young age (33.9±0.4 Ma) and low $\varepsilon_{Hf}(t)$ values (-7.5±0.4).

The new data, combined with literature data, support two main stages of magma generation in the Alpine Orogen are at 43–40 Ma and 33–30 Ma. These two stages are associated with two contributions of juvenile materials during partial melting of magma source. We tentatively propose that the oldest rocks of the Periadriatic magmatism (Adamello batholith) may be related to removal of a thickened mountain root resulting from previous subduction. Partial melting at this stage was generated by the upwelling of asthenosphere, while subsequent northward magmatism of the Adamallo batholith was ascribed to slab rollback. Then the ignition of the younger magmatism (33–30 Ma) along the Periadriatic Lineament is induced by slab breakoff.

Tetraether biomarker records for the last 60 kyr from a loess-paleosol sequence in the western Chinese Loess Plateau

GUODONG JIA[1]*, ZHIGUO RAO[2], JIE ZHANG[1], ZHIYANG LI[1], AND FAHU CHEN[123]

[1]State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China (*correspondence: jiagd@gig.ac.cn)
[2]Key Laboratory of Western China's Environmental Systems (Ministry of Education), Lanzhou University, Lanzhou, China

In this study we present records of glycerol dialkyl glycerol tetraethers (GDGT)-derived proxies for the last 70 kyr from the Yuanbao LPS, western CLP. Temperature record reconstructed from the cyclization and methylation index of branched tetraethers (CBT-MBT) displays that the onset of deglacial warming at ~20 kyr BP precedes the strengthening of summer monsoon, which is in agreement in timing with previous CBT-MBT temperature records from the southeastern CLP. The maximal deglacial warming of ~10 °C is slightly higher than those in the southeastern CLP, perhaps due to the higher latitude and farther inland of the study site. The late Holocene temperature of ~8 °C is consistent with present mean air temperature from spring to autumn, not including winter temperature and suggesting that the growth of GDGT-producing bacteria in winter is retarded by the low temperature, and hence contributing insignificantly to its annual production. The branched/isoprenoid tetraether (BIT) Index shows higher values in the glacial loess and lower values in the Holocene paleosols, with a steady decreasing trend since the early Holocene. The decreasing trend could suggest that archaea production exceeded that of the branched GDGT producing bacteria since the early Holocene, but other possibilities, such as preferential degradation of isoprenoid GDGTs or upward increase in living archaea relative to bacteria in the paleosol profile, cannot be fully excluded. Our results thus demonstrate the need of future study on regional calibration of the CBT-MBT temperature proxy, microbial community structure in soil column and differential degradation of GDGT molecules.

A dustier world since MIS12 inferred from Sr and Nd isotopes of sediments in the western Philippine Sea

FUQING JIANG[1*], MARTIN FRANK[2], TIEGANG LI[1], TIAN-YU CHEN[2], YU ZHOU[1] AND ANCHUN LI[1]

[1]Institute of Oceanology, Chinese Academy of Sciences, Nanhai Road 7, 266071 Qingdao, P.R.China (*correspondence: fqjiang@qdio.ac.cn)
[2]GEOMAR Helmholtz Centre for Ocean Research Kiel, Wischhofstrasse 1-3, 24148 Kiel, Germany

Asian dust deposition in the tropical Pacific has supplied essential nutrients (e.g. Fe) to fuel bioproductivity and allows reconstruction of East Asian continental paleoclimate. Here we report a high-resolution record of dust supply to the tropical northwest Pacific over the past one million years derived from the analysis of radiogenic Sr and Nd isotopes in the marine sediments of core MD06-3050, located on Benham Rise in the western Philippine Sea.

The down-core variability of the Sr and Nd isotopic composition of the lithogenic fraction documents climatically induced changes in sediment supply from two isotopically distinct end-members: (1) Eolian dust from Asia and (2) volcanic matterial from the Luzon islands. The dust flux over the past one million years was closely coupled to glacial-interglacial climate cycles and showed a pronounced 100kyr periodicity. Eastern Asia has become overall dustier since MIS12 (0.47 Ma) as reflected by a marked increase of the average Asian dust flux from 0.27 to 0.45 g/(cm^2·kyr). The "dustiest" conditions occurred during MIS12, MIS10 and the LGM. We suggest that this reflects increasing aridity of the Asian continent and an enhancement of the atmospheric circulation forced by changes in the eccentricity of the Earth's orbit. The higher dust flux may have amplified the internal feedbacks of the climate system and may thus serve as an explanation for the strong 100kyr glacial/interglacial cyclicity of the Late Quaternary.

Karsting mode and its features in YINGMAI-2 of North Tarim Basin, China

JIANG HUA, SUYUN HU, ZECHENG WANG AND RUIJU WANG

(PetroChina Research Institute of Petroleum Exploration & Development, Beijing 100083, China)

Distinctive heterogeneity of reservoir and its complex formation mechanism of marine carbonate rocks was focused in the fields of oil and gas exploration in China. Applying 3D seismic attributes, cores, imaging loggings and thin sections, etc, combined with fluid inclusions analysis and tectonic recovery techniques, reservoir characteristics and its formation mechanism were researched. It was concluded that it is not karst reservoir in YINGMAI-2 area, while it is reservoir controlled by faults. Reservoir space includes fracture and pore-fracture which was not or partly not filled with calcites. Furthermore, distribution of reservoir was controlled by faults. Through studying structure activities and fluid inclusion salinity, it was recognized that two types of fault-controlling karst happened, they were surface water karsting downward along faults and hydrothermal fluid upward along faults. The former was constructive for reservoir, while the latter was destructive. Based on the research, it was concluded that it was not enough to find karst crust type reservoir during oil and gas exploration, more types of reservoir should be concerned; fault-controlling karst could become prospecting fields.

Stability analysis on hydrocarbon secondary migration pathway

JIANG LIN[123]*, BAO DONGMEI[1], HONG FENG[123], HAO JIA-QING[12] AND FAN YANG[4]

[1]Research Institute of Petroleum Exploration & Development, CNPC, Beijing 100083, China jianglin01@petrochina.com.cn (*)

[2]State Key Laboratory of Enhanced Oil Recovery, Beijing 100083, China

[3]Key Laboratory of Basin Structure and Hydrocarbon Accumulation, CNPC, Beijing 100083, China

[4]School of Earth Sciences and Technology, China University of Petroleum (east China), Qingdao 26658, China

In order to accumulate in effective trap, hydrocarbon generated form source rocks has to go through a certain distance of secondary migration, therefore the process of hydrocarbon secondary migration has a great influence on hydrocarbon accumulation rate, eventually. The secondary migration process of crude oil can be divided into two types such as piston pattern and advantage pattern, the secondary migration of nature gas is an intermittent migration process composed by two basic migration ways of piston pattern and advantage pattern. The difference of secondary migration pattern leads to the differences of the migration pathway stability between crude oil and nature gas. The study used dye kerosene and nitrogen to conduct physical simulation experiment of secondary migration process respectively, discussing secondary migration pathway stability of crude oil and nature gas through way of more than once filling, and analysis its formation mechanism in view of the difference of physical characteristics of oil/gas/water and the relation of the difference between reservoir rock and oil/gas/water. The result indicates that the crude oil can change the rock wettability, and will not only alternate the free water located in the center of rock pores, but also replace the water adsorbed on the surface of porous rocks in secondary migration process. So crude oil could form a fairly stable migration pathway in the process of secondary migration, and its transport efficiency is higher. Natural gas can not change the wettability of porous rocks like crude oil does; natural gas form a relatively stable dynamic migration pathway in the process of secondary migration, the loss amount is larger while migrating.

Formation of hydroxylapatite with different morphologies and implication for biomineralization

SHU-DONG JIANG[1], QI-ZHI YAO[2] AND GEN-TAO ZHOU[1*]

[1]School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, P. R. China (gtzhou@ustc.edu.cn)

[2]School of Chemstry and Materials Science, University of Science and Technology of China, Hefei 230026, P. R. China (qzyao@ustc.edu.cn)

Living organisms are capable of inducing and controlling the crystallization and deposition of a wide variety of minerals, but the vertebrates mainly utilize the calcium phosphates in constructing their mineral phases in both normal circumstances in bone, dentin, and tooth enamel and in pathological ectopic mineral deposits. The predominant form of the mineral in all situations is hydroxyapatite. Morphological control during mineral crystallization is one of the prominent hallmarks of biomineralization. A general consensus is that organisms can employ some of biological or organic molecules to produce crystals with special morphologies. Herein, hydroxyapatite (HAP) was synthesized in the absence of any biological or organic molecules at room temperature. The results show that different phosphate concentrations leads to the hydroxyapatite with various morphologies. However, the porous flower-like spheres are always obtained at the different concentrations of Ca^{2+}. Moreover, the initial precipitate is always an unstable amorphous calcium phosphate (ACP) at all different PO_4^{3-} concentrations used, and the generation of the HAP with various morphologies may have experienced the dissolution of the initial ACP, and then the recrystallization and self-assembly of HAP. Contrary to the common believe that crystal morphology control of biominerals is generally achieved by biological or organic molecules, our results suggest that PO_4^{3-} concentration may also play an important role in the different morphogenesis of HAP. The dependence of HAP morphology on phosphate concentration suggests that in biomineralization biological genetic and physicochemical factors can cooperatively influence the formation of HAP with unusual morphologies and hierarchical structures. As such, this provides a deep insight into biomineralization mechanism.

Engineered crumpled graphene oxide nanocomposite for environmental application

YI JIANG, WEI-NING WANG, JOHN D. FORTNER* AND PRATIM BISWAS*

Department of Energy, Environmental, and Chemical Engineering, Washington University in St. Louis, MO, 63130, United States (*Correspondence: jfortner@seas.wustl.edu; pbiswas@wustl.edu)

Graphene oxide (GO), with large specific surface area, strong hydrophilicity, and broad (chemical) functionalization possibilities, holds great promises for surface modification of engineered nanoparticles (ENPs). A one-step aerosol-based method, which utilizes evaporation-induced confinement force to crumple GO and thus effectively encapsulate ENPs, has been demonstrated to synthesize various GO-based binary and ternary nanocomposites, such as GO-magnetite (GOM), GO-TiO_2 (GOTI), and GO-TiO_2-Magnetite (GOTIM).

The as-synthesized quasi-spherical, core-shell nanostructured composites, with controllable size and functionality, have demonstrated outstanding water-stability. GOTI exhibited enhanced photocatalytic activity compared to bare TiO_2 due to increased lifetime of photo-induced holes and electrons; and reactive oxygen species, such O_2-·, H_2O_2, and OH·, have been identified by employing various radical scavenging experiments. GOM and GOTIM are ready to be magnetically recovered by one handheld magnet. Regarding nano-environment interfacial interactions, QCM-D is utilized to study deposition kinetics of GO-coated ENPs onto different model surfaces. The proposed facile aerosol-based method enables the encapsulation of nearly all pre-synthesized NPs by graphene oxide; and thus opens up many more possibilities in environmental applications, such as pollutant degradation and sensing, groundwater remediation. The potential impacts on the environment by examining the stability of the material will be examined. The compatibility with biological systems will also be discussed.

Rapid high amplitude variability in Baltic Sea hypoxia during the Holocene

TOM JILBERT[1] AND CAROLINE P. SLOMP[1]

[1]Department of Earth Sciences (Geochemistry), Faculty of Geosciences, Utrecht University, P.O. Box 80.021, 3508 TA Utrecht, The Netherlands.

Hypoxia (oxygen <2ml/L) is widespread in the modern Baltic Sea and has occurred intermittently throughout the Holocene. Previous studies based on the occurrence of laminated sediments have shown that during the Holocene Thermal Maximum (HTM) and Medieval Climate Anomaly (MCA), hypoxic conditions were present in the deep basins of the Baltic Sea. However, high-resolution, quantitative reconstructions of past hypoxia are lacking. Here we present sediment records of molybdenum enrichment (Mo/Al), organic carbon content (C_{org}) and the ratio of organic carbon to total phosphorus (C_{org}/P_{tot}) which facilitate the first detailed comparison between modern and past hypoxic conditions in the Baltic Sea. We show that the previously identified intervals of widespread hypoxia were in fact characterized by multiple centennial-scale hypoxic events, interrupted by periods of more oxic conditons. This rapid high amplitude variability in hypoxia intensity was likely forced by climatic oscillations – which influence the ventilation rate of the Baltic Sea – and amplified by positive feedbacks in the P cycle, which control export productivity. We show that the modern hypoxic event has a similar intensity to the most extreme past events, implying a maximum potential intensity of both hypoxia and productivity in the Baltic Sea. However, modern hypoxia intensified more rapidly than any past event, confirming the role of anthropogenic nutrient loading in forcing this coastal marine system into its current hypoxic state.

Crystallization of schwertmannite from Na-rich solutions

AMALIA JIMÉNEZ[1], ANGELES FERNÁNDEZ-GONZALEZ[1*] AND MANUEL PRIETO[1]

[1]University of Oviedo, Spain, mafernan@geol.uniovi.es*

Schwertmannite is a ferric oxyhydroxysulphate ($Fe_8O_8(OH)_{5.5}$ $(SO_4)_{1.25}$) formed in acid waters that may play a key role in the removal of toxic elements from aqueous solutions. It is generally accepted that this metastable phase is transformed into goethite and jarosite-like compounds, which infer changes in the chemical composition of aqueous solutions. Here, the objective is studying the crystallization of schwertmannite from sodium-rich solutions at ambient temperature and its stability during aging processes. For this purpose, a set of experiments was carried out by mixing $Fe_3(SO_4)_2$ (0.16M) and NaOH (0.5M) parent solutions which were kept at constant stirring (250 rpm) for specific reaction periods (1, 7, 14 and 21 days) at 25ºC. Nature of the solids were characterized by X-Ray Diffraction (XRD) and Scanning Electron Microscopy (SEM). The surface of the solids was analyzed by X-ray photoelectron spectroscopy (XPS) and the binding energies of $Fe2p_{3/2}$, S2p, Na1s, and O1s core levels were obtained to determine the chemical state of the species.
A colloidal mixture of dark brown colour is obtained at the beginning of the reaction, which changed to brown-reddish colour at the end of the period of reaction (21 days). Changes of colour in the mixture are associated with the evolution of the nature of solids as the aging process progresses. XRD reveal that the solid obtained in the early stage of experiments (1day) seems to be amorphous and evolves to a poorly crystalline phase. This phase matches with the pattern of schwertmannite which was recognized as a mineral in spite of its poor crystalline character (Bigham *et al*. 1994). Any other phases have not been identified in these diffractograms. SEM images show grains of higher size (≈ 50 μm) coexisting with grains of lower dimension (< 5 μm) in the entire aging process. All the particles displaying a shapeless morphology. The overall XPS spectra reveal the presence of sodium on the surface of schwertmannite. The binding energies obtained for Na, Fe, S and O suggest that sodium is adsorbed on the surface of the precipitates but a chemical bond is not established with iron, sulfur or oxygen. Thus, sodium has not been incorporated in the crystal structure of schwertamannite, which remains stable throughout the entire aging process at the experimental conditions used in the present work.

Evidence for the microbial in situ conversion of oil to methane in the Dagang oilfield

NÚRIA JIMÉNEZ[1], MINMIN CAI[12], NONTJE STRAATEN[3], BRANDON E L MORRIS[1], JUN YAO[2], HANS H RICHNOW[1] AND MARTIN KRÜGER[3].

[1]Helmholtz Centre for Environmental Research (UFZ), 04318 Leipzig, Germany
[2]School of Civil & Environment Engineering. University of Science and Technology Beijing, P. R. China
[3]Federal Institute for Geosciences and Natural Resources (BGR), 30655 Hannover, Germany

The microbial degradation of hydrocarbons in oil reservoirs affects the quality and economic value of recovered petroleum products. Recent studies suggest that anaerobic biodegradation may play a significant role in situ and the biodegradation of residual oil constituents under methanogenic conditions has been reported. Methane, like other gases, may aid in oil viscosity reduction and enhance flow characteristics through the reservoir matrix. In addition, methane may be used as a energy source.

The aim of this study was to assess the ability of indigenous microbial communities from a thermophilic oil reservoir (Dagang oilfield, China) to produce methane from crude oil under environmental conditions. The isotopic composition of reservoir fluids (H2O, CO2, CH4) was analyzed, and GC-MS fingerprinting was applied to assess the oil composition in the reservoir. Microbial cell numbers were assessed by qPCR. Microcosms with 13C-labelled hydrocarbons were inoculated with production and injection waters to characterize these processes in vitro.

Analysis of oil samples confirmed that the majority of the oils from Dagang are highly weathered. Geochemical data from reservoir oil, water and gas are consistent with in situ biogenic methane production linked to aliphatic and aromatic hydrocarbon degradation. The bulk isotopic discrimination between methane and CO2 was in accordance with previously reported results for methane formation during hydrocarbon degradation. Degradation experiments revealed that autochthonous microbiota is capable of producing heavy methane from 13C-labelled n-hexadecane or 2-methylnaphthalene,. Microbial numbers in oil/water samples from production wells were abundant and the communities diverse, including methanogenic Archaea and hydrocarbon-degrading bacteria. In summary, the investigated areas of the Dagang reservoir may have significant potential for testing the viability of in situ conversion of oil to methane as an enhanced recovery method.

Occurrence of aerobic and methanogenic oil biodegradation in a water-flooded oil field

N. JIMÉNEZ[1]*, M. CAI[2], Y. JUN[2], M. KRÜGER[3] AND H.H. RICHNOW[1]

[1]UFZ, Permoserstraße 15, 04318 Leipzig, Germany (*Correspondence: nuria.jimenez-garcia@ufz.de)
[2]University of Science and Technology Beijing - No. 30 Xueyuan Road, Haidian District, Beijing, P. R. China
[3]BGR, Stilleweg 2, 30655 Hannover, Germany

Water flooding is a secondary oil recovery method intending to enhance oil recovery by increasing the pressure in the oil-bearing strata. However, it can accelerate microbial oil degradation processes leading to a reduction of its quality (by changing its viscosity, sulfur content, etc.). In undisturbed subsurface oil reservoirs biodegradation is thought to be primarily anaerobic, as oxygen is practically unavailable, and methanogenesis may play a predominant role. Nevertheless, injection waters could be an oxygen source, causing alterations in the indigenous microbial communities. The conversion of oil to methane might be of interest because it does not require the supply of additional electron acceptors and methane could be recovered using the existing production infrastructure. On the other hand, aerobic oil biodegradation can involve the production of biosurfactants and other oil-releasing agents, which might favor oil production.

Oil biodegradation was investigated in a highly degraded water-flooded oil reservoir [1]. Isotopic composition of its gases was consistent with a biological origin ($\Delta\delta^{13}C$ between CH_4 and CO_2 ranging from 32 to 65‰). The reservoir contained an active microbial community, rich in syntrophic bacteria and methanogenic archaea, able to produce $^{13}CH_4$ and $^{13}CO_2$ ($\delta^{13}C$ up to 550‰) from ^{13}C-labelled hydrocarbons *in vitro*. Additional laboratory experiments, using production waters, showed oil biodegradation potential not only under methanogenic but also under aerobic conditions. In both cases biodegradation paterns similar to those observed *in situ* were found*: n*-alkanes, *n*-alkyltoluenes and *n*-alkylbenzenes were removed before PAHs and biomarkers. Degradation decreased with increasing alkylation and ring number. A selective removal of some compounds like steranes or alkylted naphthalenes was observed. Further experiments will focuse on studying biosurfactant production by indigenous oil degrading communities.

Geochemical studies of the weathering profile developed on the Pegmatitic terrain in Awo mining district, Southwestern Nigeria.

M.T. JIMOH[1]*, A.T BOLARINWA[2] AND O. ARANSIOLA[1]

[1]Department of Earth Sciences, Ladoke Akintola University of Technology, Ogbomoso, Oyo State, Nigeria. (*correspondence: jimohmustapha@yahoo.com)
[2]Department of Geology, University of Ibadan, Nigeria.

This study on geochemistry of the weathering profile developed on pegmatite in Awo mining district describes mobility of elements from the bedrock to the top soil. The report is targeted at obtaining the concentration of the major, trace and rare earth elements in the weathered profile revealing the degree of weathering. The pegmatite which intrudes the syenite and migmatite gneiss belongs to the NE/SW trending type.

The samples collected from the B-horizon were air dried, sieved with size of 75 mesh and analysed using X-ray Fluorescence Spectrometry (XRF) analytical technique of the digested samples at ACME Laboratory, Ontario, Canada.

The result of the major, trace and rare earth elements of the weathered soil revealed that Mg, Ca, Na and K have been extremely weathered and massively depleted. The mass percentage of these elements are Mg (-84.3%), Ca (-99.2%), Na (99.9%) and K (-96.0%). The Chemical Index of Alteration (CIA) for the soil samples 1 to 9 are 97%, 97%, 97%, 96%, 96%, 95%, 97%, 97% and 98% respectively; this shows high degree of weathering which indicate that Kaolinite is the clay mineral found in the mining site.

The analysis also shows that there is high abundance of rare metals typified by Ta (3 ppm), Nb (25.6ppm), Cs (26.3ppm), and Sn (36.7ppm), this reveals that the precambrian pegmatite of the study area rare metal bearing.

Integrated C and Cl isotope modeling of chlorinated ethenes degradation

BIAO JIN,[1] STEFAN B. HADERLEIN,[1] AND MASSIMO ROLLE[1,2]

[1]Center for Applied Geosciences, University of Tübingen, Hölderlinstr. 12, D-72074 Tübingen, Germany
[2]Department of Civil and Environmental Engineering, Stanford University, 473 Via Ortega, 94305 Stanford, CA, USA

We propose an integrated method to predict the evolution of carbon and chlorine isotope ratios and we apply the new approach to chlorinated aliphatic hydrocarbons dechlorination. The carbon and chlorine isotopic changes are explicitly simulated by tracking the cleavage of isotopically different C-Cl bonds of the combined carbon-chlorine isotopologues. To illustrate the proposed modeling approach we compare our method with the currently available method, in which carbon and chlorine isotopologues are treated separately. Our approach is self-consistent and provides an accurate description of dual-isotope effects regardless of the extent of the isotope fractionation and physical characteristics of the experimental system. We further applied the new approach to reproduce published experimental results on dehalogenation of chlorinated ethenes both in well-mixed systems and in situations where mass-transfer limitations control the overall rate of biodegradation. Our integrated dual isotope modeling approach is proved to be most advatageous when isotope fractionation factors of carbon and chlorine differed significantly and for systems with mass-transfer limitations, where both physical and (bio)chemical transformation processes affect the observed isotopic values.

Hydrochemical and stable isotopic assessment of water quality and its variations in rice-growing areas in East China

ZANFANG JIN, FEILI LI AND LINGXIAO CHEN

College of Biol. & Environ. Engineering, Zhejiang Univ. of Tech., Hangzhou 310032, China (jinzanfang@zjut.edu.cn)

Nitrate contamination of surface-water and groundwater is a common occurrence worldwide. In drinking water, nitrate in excess of 10 mg N/L may be toxic for infants and may be responsible for increases in stomach cancer for other. The nitrogen-stable isotopic composition of nitrate has been extensively used for the identification of nitrogen sources and transformation pathways in hydrologic studies. The West Lake is a typical shallow lake located in Hangzhou city, China. East of the West Lake is on the verge of the downtown, the other three sides are surrounded by small hills. The West Lake has been in the risk of eutrophication and ecosystem degradation. Here, we have analyzed the dissolved anions in the West Lake, with the immediate goals of describing water quality and identifying the sources of nitrate in the West Lake.

All the samples were taken in the West Lake on April 4, 2012. The average pH value of water was 6.95, and all samples was weakly acidic. The average DO concentration of the surface water was 7.43 mg L^{-1}. The surface water was aerobic. The average BOD_5 and COD_{Cr} concentration of the samples was 3.0 mg L^{-1} and 13.5 mg L^{-1}, respectively. Low BOD values and COD values reflect low burden of organic pollution in the West Lake. TP concentrations remained at a low level, was 0.075 mg L^{-1} concentrations was low and was 0.29 mg L^{-1}. NO_3^--N concentration in the samples was higher than NH_4^+-N concentrations, was 1.66mg L^{-1}. The average TN concentration was 2.48 mg L^{-1}. It was found that 75% of the surface water samples in the West Lake had higher TN concentration than the statutory limit (1.5 mg L^{-1}) for surface water (GB3838-2002). TN was the major contaminant. The $\delta^{15}N_{NO3}$ values for the samples from the West Lake ranged from 5.8‰ to 12.0‰. It was probable that the sources of NO_3^--N were rainfall, manure applied to land, and agricultural fertilizer.

Table1: Water quality of the West Lake and the Environmental guideline of national quality standards for surface waters, China (GB3838-2002) (mg L^{-1}).

	Concentration/Ave.	Standard deviation		GB3838-2002/IV
DO	7.43	0.42		3.0
pH	6.95	0.04	≥	6~9
BOD_5	3.0	1.0	≤	6.0
COD_{Cr}	13.5	5.1	≤	30.0
TP	0.075	0.02	≤	0.1
TN	2.48	0.47	≤	1.5
NO_3^--N	1.66	0.29	≤	10.0
NH_4^+-N	0.29	0.23	≤	1.5

Halogen partitioning behavior at Earth's mantle conditions

B. JOACHIM, I. LYON, A. PAWLEY, T. HENKEL, L. RUZIE, P. CLAY, R. BURGESS AND C. J. BALLENTINE

School of Earth, Atmospheric and Environmental Sciences, University of Manchester, M139PL Manchester, United Kingdom (bastian.joachim@manchester.ac.uk)

Halogens have, because of their incompatibility, the potential to act as key tracers of volatile transport processes in the Earth's mantle. Combining Mid Ocean Ridge Basalt (MORB) [1] and Ocean Island Basalt (OIB) [2] bulk halogen concentrations with experimentally determined halogen partition coefficients (this study) allows us to investigate the halogen content and variance in different mantle reservoirs.

As starting material, we used a primitive mantle composition simplified to four components (CaO, MgO, Al_2O_3 and SiO_2), to which defined small amounts of halogens (~0.2 wt%) were added. Partition experiments were performed for 5 h at 1.0 to 2.5 GPa and 1500-1600°C.

Samples contain forsterite grains or a mixture of forsterite and orthopyroxene grains with a side length of up to 150 μm embedded in a MORB-like melt. Euhedral crystal shapes and the fact that no halogen concentration gradients are detectable within the crystals or melt indicate that experiments were performed at equilibrium conditions.

In all experiments, compatibilities of Br, Cl and F are ordered with $D_{Br}^{mineral/melt} < D_{Cl}^{mineral/melt} < D_F^{mineral/melt}$; e.g. $D_{Br}^{fo/melt}$ was determined to 0.128 at 1600°C ($D_{Cl}^{fo/melt} = 0.202$, $D_F^{fo/melt} = 0.259$; Uncertainties: ~20%). Our data combined with results of recent studies [3,4] show that fluorine and chlorine partitioning into forsterite increases by about two orders of magnitude between 1300°C and 1600°C and does not show a pressure dependence. Chlorine partitioning into orthopyroxene shows a similar temperature effect ($D_{Cl}^{opx/melt}$ = 0.905(81) at 1600°C and 2.3 GPa) but decreases significantly with increasing pressure.

By using natural bulk Cl concentrations in basalt [1,2] and assuming accumulated fractional melting [5], we are able to estimate bulk Cl concentrations of MORB (3-5 μg/g) and OIB (25-50 μg/g) source regions. Data suggest that the MORB source region is 80-95% more depleted in chlorine relative to the OIB source region.

Advanced Antineutrino Estimation

G. R. JOCHER[1], S. USMAN, S. T. DYE AND J. G. LEARNED

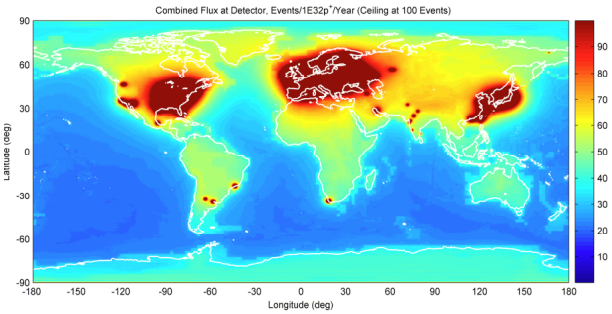
[1]IAI, 15020 Conference Center Drive, Chantilly, VA, 20151 USA (correspondence: gjocher@integrity-apps.com)

Geoneutrinos are emitted via Uranium and Thorium decay within the Earth's crust and mantle, and, when observed by current antineutrino detectors can provide great insights into the inner geological workings of the Earth. Unfortunately though, these valuable geoneutrino measurements are nearly always obscured today within larger datasets populated by various types of unwanted background. Common approaches to this statistical quandary, such as trying to identify and filter out geoneutrinos from the background, are largely unsatisfactory and suboptimal. In this paper we attempt to combat this problem three ways.

First we introduce a novel mixture-distribution Bayesian estimator capable of operating in extremely low Signal to Background Ratio (SBR) environments. We show how, under real world conditions, an antineutrino signal obscured 100 times over by background (0.01 SBR) can still yield great quantities of information about a source if a moderate understanding of the obscuring background is available.

Secondly, we show how exploitation of the energy and direction vector of individual antineutrino measurements can offer far more information than that available by counts only. We show that crust-geoneutrinos can be segregated statistically from mantle-geoneutrinos in this manner.

Thirdly, we demonstrate the use of Cramer-Rao Lower Bounds for optimal detector placement. We evaluate the entire surface of the Earth and find the best spots to place a detector to study geoneutrinos and theta$_{12}$ oscillations.



Lastly we model the entire Earth, and combine all the above methods into a large Monte Carlo simulation showing how four oceangoing antineutrino detectors, strategically placed around the world, can reduce geoneutrino flux uncertainty by 50%, and antineutrino theta$_{12}$ oscillation uncertainty by 80% within just 1 year.

Ge/Si variations in the deep sea deduced from microanalyses of giant spicules of the sponge *Monorhaphis chuni*

K.P JOCHUM[1]*, M.O. ANDREAE[1], J.A. SCHUESSLER[2], X.H. WANG[3], B.STOLL[1], U.WEIS[1] AND W.E.G. MÜLLER[3]

[1]Max Planck Institute for Chemistry, 55020 Mainz, Germany (*correspondence: k.jochum@mpic.de)

[2]German Research Centre for Geosciences GFZ, Potsdam, Germany

[3]Institute for Physiological Chemistry, Universitätsmedizin Mainz, Germany

The exceptional longevity of the deep-sea sponge *Monorhaphis chuni* and the stability of their giant spicules provide the potential that they can be used as paleoenvironmental archives spanning the last 13 ka. To track secular variations of the geochemically similar elements Si and Ge [1] in the East and South China Sea, we used femtosecond-LA–MC-ICP-MS at GFZ and LA-ICP-MS at MPI for the high-resolution *in-situ* determination of Si isotope ratios and Ge and other trace element concentrations, respectively, in cross sections of giant spicules.

Significant variations in Si isotope ratios (δ^{30}Si: from -1.9 to -3.7 ‰) and Ge concentrations (0.21-0.29 μg g^{-1}) were observed in the largest spicule collected so far (SCS-4, 2.7 m long) from a depth of 2100 m. No obvious trend in Si isotope variability could be identified in smaller and presumably younger spicules. To convert the Si isotope and Ge data into respective seawater concentrations, we used the inverse relationship of Si(OH)$_4$ in seawater and δ^{30}Si in the sponge [2] as well as the linear relationship between Ge/Si in the sponge and the Ge concentration in the seawater [3]. Present-day Ge/Si is uniform and about 0.7 μmol mol^{-1}. In contrast, there are significant changes of Ge/Si in the time interval corresponding to the Younger Dryas event 11 – 13 ka BP, where Ge/Si is about 0.55 μmol mol^{-1}. A high value of 0.8 μmol mol^{-1} was observed at the Holocene optimum around 6 ka BP. The Ge/Si pattern compares well with the results of previous studies on diatomaceous opal obtained from South Atlantic cores [4] and supports the idea of secular changes of whole ocean Ge/Si.

Kinetic isotope effect in the atmospheric reaction of the methane clumped isotopologue $^{13}CH_3D$ with OH and Cl

L. M. T. JOELSSON[1], R. FORECAST[1], S. ONO[2] AND M. S. JOHNSON[1*]

[1]Copenhagen Center for Atmospheric Research, CCAR, Department of Chemistry, University of Copenhagen, Copenhagen, Denmark

[*]Corresponding author msj@kiku.dk

Methane, as the long lived greenhouse gas with the second largest radiative forcing [1], has a significant impact on Earth's climate. Atmospheric methane abundance has undergone a critical growth from pre-industrial levels of 400-700 ppb to above 1750 ppb around year 2000, where the growth seemed to level out [1]. The recent trend, however, shows renewed growth [2]. The causes for these changes are not well known. Methane has an array of natural and anthropogenic sources. The study of clumped isotopes has proven useful for determining sources of atmospheric gases, since the formation temperature give each source contains a characteristic distribution of stable isotopes. Removal processes such as oxidation often prefer one isotopologue over another and thus shift the isotopic composition of atmospheric samples relative to the source. By characterizing the kinetic isotope effects of the sink reactions, the composition of the source can be determined.

Oxidation of methane by OH and Cl was studied experimentally in the photochemical reactor at Copenhagen Center for Atmospheric Research [5]. OH was formed from photolysis of ozone in the UV region and subsequent reaction with H_2O. Cl_2 was photolysed to obtain Cl radicals. A synthesised sample of pure $^{13}CH_3D$ was used along with natural abundance CH_4. Under the course of reaction several infrared spectra were recorded with a Bruker IFS 66v/s Fourier Transform Infrared spectrometer. The spectra were analysed using the non-linear least squares algorithm MALT [6].The kinetic isotope effect α was obtain from the data points by linear regression as:

$$\alpha=\log([^{13}CH_3D]_{t=0}/[^{13}CH_3D]_t)/\log([^{12}CH_4]_{t=0}/[^{12}CH_4]_t)$$

We present the first results of this study.

The sensitivity of biological processes to changes in temperature is described in terms of Q_{10}, the fractional increase in metabolic rate per 10°C increase in temperature [1]. This value is greater in heterotrophs than autotrophs (e.g. [2,3]). Consequently, faster bacterial respiration rates in a warmer ocean may result in more efficient remineralisation of organic matter at shallower sinking depths with major implications for carbon and nutrient cycling. We find support for this in a series of reconstructed carbon isotope depth profiles based on well-preserved planktonic foraminifera assemblages from Tanzania and Mexico from the warm Eocene epoch. Our results suggest relatively sharp $\delta^{13}C$ gradients in the upper water column which supports hypotheses that invoke high metabolic rates in a warm Eocene ocean leading to more efficient recycling of organic matter and reduced burial rates of organic carbon [4]. We examined these ideas using a GENIE model that incorporates temperature sensitivities of primary producers and respiring bacteria, i.e. different Q_{10} values.

[3]Department of Geosciences, Princeton University, NJ.

For Cd and fixed N in the ocean, there are important similarities in the depth profiles of both dissolved concentration and stable isotopic composition (δ^{114}Cd, and δ^{15}N-NO_3^-). Both elements are biologically assimilated in surface waters and regenerated from sinking organic matter in the ocean interior. Preferential uptake of the lighter isotopes during biological assimilation typically leads to an increase in both δ^{114}Cd and δ^{15}N-NO_3^- in surface waters, and the isotopic signal of nutrient uptake in high latitude waters is subducted into water masses (such as Subantarctic Mode Water) that ventilate the mid-depths at low latitudes. Against this background of similar behaviour due assimilation and regeneration, differences between δ^{114}Cd and δ^{15}N-NO_3^- are expected in regions of active nitrogen fixation and denitrification, as these processes lower and raise the δ^{15}N-NO_3^-, respectively, while they should not directly affect δ^{114}Cd. Paired analyses of dissolved δ^{114}Cd and δ^{15}N-NO_3^- from the US GEOTRACES North Atlantic transect appear to show the expected distinction due to nitrogen fixation. Dissolved δ^{114}Cd increases from deep water into the permanent thermocline and then more sharply into the surface, due to biological assimilation, while δ^{15}N-NO_3^- decreases from deep water into the permanent thermocline, which has been interpreted as resulting from the remineralization of low δ^{15}N material from nitrogen fixation in low latitude surface waters.

Here, we use the difference between δ^{114}Cd and δ^{15}N-NO_3^- profiles in the North Atlantic to quantify the amount of low-δ^{15}N-NO_3^- 'newly fixed' nitrogen in the water column. δ^{114}Cd is used to calculate the δ^{15}N-NO_3^- profiles expected in the absence of nitrogen fixation, and the differences between this and the observed δ^{15}N-NO_3^- profiles are used to calculate the fraction and concentration of newly fixed N that has been oxidized to NO_3^- in the Atlantic interior.

Structure and fate of Zn-bearing green rust nanominerals in slightly acidic mine drainage crossing a steep redox boundary

C. A. JOHNSON[1*], G. FREYER[2], M. FABISCH[2], M. MURAYAMA[1], K. KÜSEL[2] AND M. F. HOCHELLA JR[1]

[1]Virginia Tech, Blacksburg, VA, USA, (*correspondence: cjohns49@vt.edu, hochella@vt.edu, murayama@vt.edu)
[2]Friedrich Schiller University Jena, Jena, Germany, (maria.fabisch@uni-jena.de, kirsten.kuesel@uni-jena.de)

The fate and transport of inorganic contaminants in mine drainage systems are strongly dependent on pH and redox conditions. As drainage water crosses geochemical gradients, changes to the transporting particle and/or the contaminant speciation will dictate how the contaminant continues to be transported and how bioavailable it is. In order to gain insights into these processes, we examined water and sediments directly taken from a mine drainage outflow environment. Our field site is a former uranium mine near Ronneburg, Germany, where water outflow from the underground mine at pH 6 crosses a steep redox boundary. Contact with oxygen causes dramatic changes in the mineralogy of suspended particles that interact with metal(loid)s in the water and sediments. After careful sample preparation, we use analytical transmission electron microscopy to characterize the nanoscale structure and elemental composition and compare with measurements from standard bulk techniques.

The suspended particles in the anoxic mine outflow consist primarily of nanometer-thin pseudo-hexagonal Zn-bearing green rust platelets ($(Fe^{2+})_6Fe^{3+}_2(OH)_{18}\cdot 4H_2O$) co-precipitated with amorphous silica. Green rusts have been found previously in groundwater systems, but are difficult to track due to rapid oxidation in aerated water. Zinc is the contaminant of second-highest concentration in the outflow. Once these particles cross the redox boundary, they undergo oxidative dissolution and rapidly co-precipitate with silica to form aggregates of spheroidal iron oxide nanoparticles. Some aggregates settle to the streambed where they get larger and grow needles, many of which are nanocrystalline goethite.

In this ongoing study, we show why knowledge of the formation, transformation, reactivity, and dissolution of nano-components are important in understanding the behavior and evolution of environmental systems.

Quantifying the isolation performance of CO_2 reservoirs: Requirements, results, and challenges

JAMES W JOHNSON[1]

[1]Schlumberger-Doll Research, 1 Hampshire St, MD A-139, Cambridge, MA 02139, USA, *jwjohnson@slb.com*

Transitioning the technical focus of CO_2 flood operations from the efficient extraction of hydrocarbons (CO_2 EOR) to the secure emplacement of CO_2 (+/- EOR) involves significant paradigm shifts for the oilfield services industry. Most important among these are new requirements to predict and monitor the fate of isolated (un-recycled) CO_2, which in turn requires baseline site (versus solely reservoir) characterization. Meeting these requirements demands the development of new modeling, monitoring, and characterization techniques. The isolation performance of engineered (and natural) CO_2 reservoirs is largely controlled by multiphase CO_2 migration, dynamic CO_2 mass partitioning among physical/chemical sinks, and reservoir/seal permeability evolution, all of which are strongly dependent upon specific integrated processes and system properties. These correlations can be quantified through reactive transport modeling, within which the operative processes of multiphase flow, geochemical mass transfer, and geomechanical deformation are explicitly integrated. In particular, important structural, compositional, and integrated-process constraints on CO_2 migration, mass partitioning dynamics, and permeability evolution can be identified, and the dependence of isolation performance (CO_2 capacity, footprint, and containment) on such migration, dynamics, and evolution can be assessed. In this paper, I will review the conceptual framework, present results obtained from applying this modeling approach to field projects, and discuss current challenges.

Manganese-oxidizing photosynthesis before the rise of cyanobacteria

The evolution of oxygenic photosynthesis was a singularity that fundamentally transformed our planet's core biogeochemical cycles and redox state. Here we probe the geological record for clues of the evolutionary pathway to light-driven water oxidation. One attractive hypothesis from the perspective of modern photo-assembly of the water-oxidizing complex posits a Mn(II)-oxidizing photosystem as a precursor to oxygenic photosynthesis [1,2]. We tested this hypothesis by exploring early Paleoproterozoic manganese deposits (up to 17 wt. % Mn) to test this hypothesis, captured in the 2415 ± 6 Ma Koegas Subgroup from scientific drill cores retrieved by the Agouron Drilling Project in South Africa. We utilized a novel X-ray absorption spectroscopy microprobe to make redox maps of these deposits at a 2μm scale to understand their petrogenesis and textural context. Coupled to light and electron microscopy and C isotopic measurements, we determined that all of the Mn is hosted in Mn(II) carbonate minerals produced from early diagenetic reduction of Mn-oxides with organic matter. To determine whether the Mn oxidant was molecular oxygen or a Mn-oxidizing photosystem, we examined two independent redox proxies sensitive to low levels of environmental oxygen—multiple sulfur isotopes analyzed using whole-rock IRMS and texture-specific SIMS techniques, and the presence of redox-sensitive detrital grains. Both proxies indicate O_2 was < $10^{-5.7}$ atm [3]. Kinetic calculations reveal that these maximal levels are several orders of magnitude too low to explain the observed Mn enrichments. The 2.415 Ga Mn deposits therefore provide strong geological evidence for an early, transitional Mn-oxidizing photosystem before the evolution of oxygenic photosynthesis.

In situ immobilization of Pb using a natural Mn oxide by-product amended to contaminated soil

K.L. JOHNSON[1]*, C.M. MCCANN[2], J. TOURNEY[1], R.J. DAVENPORT[2], S.A. ROBERTSON[1], N.C. FINLAY[1], N.D. GREY[2], M. WADE[2] AND K. HUDSON-EDWARDS[3]

[1]School of Engineering and Computing Sciences, Durham Univ., Durham, DH1 3LE, UK (*correspondence Karen.johnson@durham.ac.uk)
[2]School of Civil Engineering and Geosciences, Newcastle Univ. Newcastle, NE1 7RU, UK (clare.mccann@newcastle.ac.uk)
[3]Department of Earth and Planetary Sciences, Birkbeck Univ. London (k.hudson-edwards@bbk.ac.uk)

Natural Mn oxide (NMO)-coated sand byproducts from the water treatment industry were assessed as a potential remediation amendment for in situ immobilization of Pb in contaminated soils. Sorption of Pb by the NMO was found to be pH dependent in aqueous batch experiments and qmax was calculated. The viability of NMO amendment as a remediation strategy was determined through a 10 month outdoor lysimeter trial using naturally Pb contaminated soils mixed with 10 % by weight NMO. After 10 months available pore-water Pb did decrease but bioaccessibility data was equivocal and at odds with other literature e.g. [1],[2].

Our data, the first to explore the use of natural manganese oxides in contaminated soils suggests that it is difficult to establish a statistically significant reduction in available Pb concentrations and we suggest that this is due to the highly heterogeneous nature of Pb contamination in industrially contaminated soils. However, our electron probe X-ray mapping shows Pb immobilization on the Mn oxide coating of the sand grains, which were Pb free prior to their addition to the soils. Amendment of the Pb contaminated soil with NMO had no effect on gross microbial functioning as assessed by respiration, potential denitrification and nitrification rates. In addition, 454 pyrosequencing showed that NMO amendment did not alter soil microbial community structure or diversity. We conclude that NMO byproducts could be used as an effective soil amendment for the treatment of sites contaminated with Pb.

North Pacific SST variability and drought in Southwestern North America since 854 AD

K.R. JOHNSON[1*], S. MCCABE-GLYNN[1], C. STRONG[2], M. BERKELHAMMER[3], A. SINHA[4], H. CHENG[5] AND R.L. EDWARDS[5]

[1]Dept. of Earth System Science, Univ. of California, Irvine, CA 92697 (*correspondence: kathleen.johnson@uci.edu)
[2]University of Utah, Salt Lake City, Utah 84112
[3]CIRES/ATOC, University of Colorado, Boulder, CO 80309
[4]California State University, Dominguez Hills, CA 90747
[5]University of Minnesota, Minneapolis, MN 55455

Climate models predict increasing aridity in Southwestern North America (SWNA) as storm tracks intensify and shift poleward under global warming. However, precipitation in SWNA also exhibits significant natural variability, which has been linked to Pacific and Atlantic sea surface temperature (SST) regimes and the associated atmospheric circulation patterns. The North Pacific, in particular, is known to influence decadal precipitation variability in this region over the 20th century, yet little is known about its role in past droughts and pluvials. Here we present a new record of North Pacific SSTs and SWNA drought from 854 to 2007 A.D. derived from stable isotope ($\delta^{18}O$ and $\delta^{13}C$) and trace element (Mg/Ca, Sr/Ca) variations in a stalagmite (CRC-3) from Crystal Cave, located in the southern Sierra Nevada Mountains, CA (36.59°N; 118.82°W; 1,386 m). Crystal Cave drip water reflects the mean $\delta^{18}O$ of precipitation falling over the cave, which is largely controlled by moisture source region and storm track, with lower values reflecting transport from the North Pacific and higher values reflecting transport from the tropical Pacific. Storm tracks are influenced by North Pacific SST patterns and we find that CRC-3 $\delta^{18}O$ values are strongly correlated with SST anomalies in the Kuroshio Extension region in particular and we use this relationship to reconstruct KE SSTs from 854 to 2007 A.D.. A moderate correlation between $\delta^{13}C$, Mg/Ca, and Sr/Ca suggests that these proxies are linked to prior calcite precipitation, which is thought to reflect local effective precipitation. Comparison of the KE SST reconstruction with last millennium tree-ring records indicate only weak coherence between KE SST and SWNA droughts, with only some occurring during periods of warm KE SSTs, as seen in the instrumental record. $\delta^{13}C$, Mg/Ca, and Sr/Ca are, however, significantly correlated with tree ring records of drought. Through this novel multi-proxy approach, we demonstrate how records of large-scale ocean-atmosphere dynamics and local hydroclimate may be obtained from individual speleothem samples.

Carbon dioxide is the main component of the atmospheres of Mars and Venus, and the early Earth. Photochemistry in these atmospheres is based on the UV photolysis of CO_2 ; fractionation in CO_2 photolysis impacts the isotopic composition of the photoproduct CO and O_2. For the first time, an accurate model of fractionation in CO_2 photolysis has been made, using the time-dependent methodology, yielding the temperature and isotopologue dependent CO_2 absorption cross sections: $^{16}O^{12}C^{16}O$ (626), 627, 628, 636, and the clumped species 638. The calculations reproduce experimental absorption cross sections at low resolution without scaling intensity. The main results are: a) The accurate description of the temperature dependence of the CO_2 UV absorption cross section has a large impact on catalytic HOx radical concentrations in CO_2 atmospheres. b) CO_2 photolysis in the modern mesosphere has a ^{13}C fractionation exceeding 300 per mil. This, together with $CO_2 + O(^1D)$ exchange, may generate a significant CO_2 clumped isotope anomaly. c) In a CO_2 atmosphere, CO_2 photolysis produces mass independent fractionation (MIF) in the Ox reservoir. This, combined with a sink of oxygen to the surface of Mars and/or space, may impact the oxygen isotope distributions found in the Martian meteorite ALH84001 and the 'Black Beauty' meteorite NWA 7034.

Composition, formation, and role of the Si-rich surface layer during olivine dissolution

NATALIE C. JOHNSON[1*], KATE MAHER[2], DENNIS K. BIRD[2] AND GORDON E. BROWN JR[123]

[1]Department of Chemical Engineering, 381 North-South Mall, Stauffer III, Stanford University, Stanford CA 94305 (*correspondance: nataliej@stanford.edu)

[3]Stanford Synchrotron Radiation Lightsource, 2575 Sand Hill Rd, Menlo Park CA 94025 (gordon.brown@stanford.edu)

Olivine ($(Mg,Fe)_2SiO_4$) dissolution in the presence of water and supercritical CO_2 results in the fomation of a Mg-depleted, Si-rich surface layer. The Si-rich layer may play a role in limiting olivine carbonation kinetics, but little is known about its mechanism of formation and chemical composition. This study probes the Si-rich layer by reacting olivine with a ^{29}Si-spiked CO_2-containing aqueous solution at 60°C and 100 bar, followed by analysis of the mineral products using ion microprobe depth profiling and TEM imaging of cross-sections. After 19 days of unmixed reaction, TEM imaging coupled with energy dispersive spectroscopy (EDS) revealed an amorphous Si-rich layer, 30-40 nm thick, with an average composition of $MgSiO_3$ [Figure 1]. The location of the Si-rich layer is visible in the image as a vertical stripe slightly lighter in color and in the plot as sharp drops in both the Mg:Si and O:Si ratios. Depth-profiling with the ion microprobe indicates that ^{29}Si penetrates >100 nm into the mineral surface. Combined TEM and SIMS results suggest that, under these conditions, the Si-rich layer forms due to a dissolution/reprecipitation mechanism.

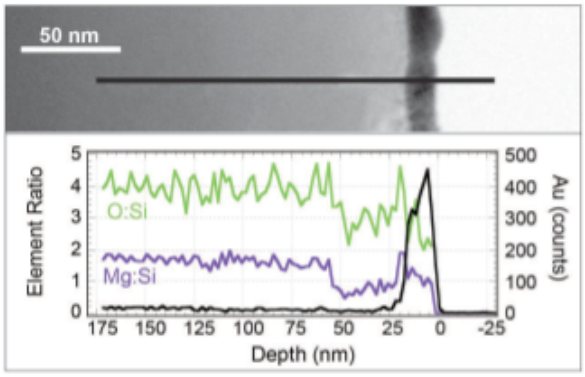

Figure 1: Scanning transmission electron microscopy image and results from an EDS line scan (location of scan marked by black line on image). Gold (black line in plot) was used to protect the mineral surface during cross section preparation.

[2](http://iodp.tamu.edu/scienceops/expeditions/antilles_volcanism_landslides.html)

Island arc crust has a bulk composition that is approximately basaltic, but continental crust has a bulk andesitic composition. It is has been suggested, however, that island arc crust is layered, with an upper portion that has a silicic composition similar to bulk continental crust, and a lower, mafic portion, that may be lost during transition from arc crust into continental crust. Testing of this model requires observations of clear trends in time and space that reflect the growth, evolution and differentiation of island arc crust.

Evolution of an arc centre also has geohazard implications. For example, if early activity is characterised by mafic volcanism and an absence of shallow magma storage, large-volume explosive eruptions are less likely to occur. The probability of tsunami-forming flank collapses may also increase as the crust thickens and a large, composite edifice forms. Large collapse events may also feedback into volcanic activity by releasing the confining pressure above a magma chamber, leading to the ascent of fresh, less evolved magmas, and a period of increased activity.

It is difficult, however, to test these and other models of the life cycle of an arc centre because erosion, collapses, later eruptions, etc., all obscure and destroy the subaerial record; e.g., ~75% of erupted material on Montserrat (Lesser Antilles) since 1995 has been transported to the Caribbean Sea. The best records of the evolution of arc centres are, therefore, preserved in nearby marine sediments. During IODP340 we recovered a complete sedimentary record from site U1396. This site (~30 km SW of Montserrat) comprises hemipelagic carbonate interspersed with >150 visible tephra layers extending back ~4.5 Myr (the oldest dated rocks on the island are only 2.6 Ma). We also obtained high-recovery records of collapse events from the east of the island at sites U1394 and U1395.

We present preliminary data from these IODP sites that reveal new information concerning the evolution of this arc volcanic centre.

Neoproterozoic ocean chemistry and redox evolution as inferred through sulfur isotope records

DAVID T. JOHNSTON[1]

[1]Dept. of Earth and Planetary Sciences, Havard University, 20 Oxford St., Cambridge MA 02138: johnston@eps.harvard.edu

The classic geochemical approach to reconstructing the net oxidation state of the ocean-atmosphere system is via tracking changes in the C, S and Fe cycles. Rebuilding the Neoproterozoic ocean-atmosphere and searching for the presumed second great rise in atmospheric oxygen has appropriately employed a similar approach. For example, work on the carbon cycle documents large perturbations in the marine DIC, however the interpretation of these anomalies and the links to redox budgets remain contraversial. In parallel, great success has been gained through the pervasive application of Fe-based methods, which now appropriately serve as a backdrop to Neoproterozoic storylines, but record a more basinal and less globally integrated signal. Parallel work on the sulfur cycle ($^{34}S/^{32}S$) carries interest, but often suffers from a lack uniqueness in its interpretations—that is, biological and abiological processes can be hard to distinguish from one another and quantifying seawater sulfate concentrations remains elusive.

Similar to changes in global oxidation state, the role for the S cycle in Neoproterozoc ocean is not clear. A dominant electron acceptor in modern seawater, there is a thermodynamic expectation for sulfate to play a major role in anaerobic remineralization, especially given persistent anoxia in Neoproterozoic deeper water masses. However, thousands of shale analyses reveal strikingly low pyrite contents from both oxic shelves and deeper water facies, and only fleeting indications of euxinia asociated with elevated organic carbon loading mark the Neoproterozoic. Viewed in parallel with pre-Sturtian sulfate evaporites and beautiful Marianoan barite cystal fans, the role of the S cycle gains added mystery. In hopes of gaining insight into the Neoproterozoic S cycle, here I present multiple sulfur isotope data from sulfides and sulfates from numerous Neoproterozoic basins. With ^{33}S, the opportunity exists to 1) differentiate between primary and burial diangenetic signals, 2) discern distillation from changes in biological isotope effects, and 3) uniquely track changes in classic measures of pyrite burial over long-timescales. This dataset is further viewed in light of new microbial data and modern marine sediment analyses, which together provides an independent perspective on later Proterozoic ocean-atmosphere oxygenation.

The isotopic composition and controls on modern seawater sulfate

DAVID T. JOHNSTON[1], BENJAMIN GILL[2], ANDREW MASTERSON[1], ERIN BEIRNE[1] AND WILLIAM BERELSON[3],

[1]Dept. of Earth and Planetary Sciences, Havard University, Cambridge MA 02138: johnston@eps.harvard.edu
[2]Dept. of Geosciences, Virginia Tech, Blacksburg, VA 24061
[3]Dept. of Earth Sciences, USC, Los Angeles CA 90089

The isotopic composition of seawater sulfate carries great utility for informing rates of modern biogeochemical cycling and tracking changes in oxidant budgets on geological timescales. These applications, and numerous others, lean on the the analysis of modern seawater sulfate. Through decades of great work, it is broadly understood that the sulfate reservoir carries a long residence time (~ tens of millions of years), with the oxygen in sulfate turning over much more quickly (~ one million years). With this context, the modern ocean should carry a homogeneous isotopic composition. However, recent and quite provocative work suggests that oxygen minimum zones host a cryptic sulfur cycle (implicating potential effects on the isotope compostion of both S and O in sulfate), while in parallel, experimental work on oxygen isotope exchange with S-bearing intermediates suggests that interpretations of $^{18}O/^{16}O$ in sulfate may also may also require updating.

To address these questions, we present ~ 200 measurements of modern seawater sulfate ($^{34}S/^{32}S$ via SO_2 and $^{18}O/^{16}O$ via CO) through 10 vertical, 1-D profiles in different ocean basins with variable nutrient regimes. To complement these measurements, we targeted 4 of the profiles (BATS, SAFE and 2 profiles through oxygen minimum zones) for high precision ^{33}S and ^{36}S measurements generated via SF_6. With this, we first revisit decades of work on ^{18}O and ^{34}S to place these data on a common scale (V-CDT and relative to SF_6), alleviating small but important differences in inferred compostions. The resultant isotopic compositon of seawater sulfate ($^{34}S/^{32}S$. $^{33}S/^{32}S$, $^{36}S/^{32}S$, $^{18}O/^{16}O$) allows for a series of major questions to be revisited. Of particular interest are: 1) Does the cryptic S cycle exist at a measurable scale? 2) What biogeochemical information is locked within the $^{18}O/^{16}O$ of sulfate? 3) What are the implications for the state of the marine sulfur cycle as a whole (is the modern cycle in steady-state or imbalanced)? We thank K. Casciotti, D. Capone, W. Homoky and A. Knapp for assistance in sample collection.

Iron geochemistry in redox-dynamic coastal wetlands: Consequences for trace element cycling in the environment

SCOTT G. JOHNSTON

Southern Cross GeoScience, Southern Cross University, Lismore NSW 2480, Australia (*correspondence: scott.johnston@scu.edu.au)

Many acidic coastal wetlands in eastern Australia contain abundant reactive iron species within their sediments due to oxidation of bioauthigenic pyrite. Redox fluctations occur periodically within these wetlands due to changes in hydrology that are driven by natural climate variations, anthropogenic drainage and wetland remediation practices. These redox fluctuations drive complex iron geochemical cycling in the environment, influencing the bio-mineralisation, mobilisation and redistribution of iron species and co-associated trace elements. Here, we employ case-studies to explore iron redox transformations and trace element cycling within these wetlands at a variety of spatial and temporal scales. We examine the consequences for sediments, surface water and groundwater quality.

Remediation of acidic, Fe-rich wetlands via inundation with seawater can lead to mobilisation and redistribution of As and extreme enrichment of poorly crystalline Fe(III) (hydr)oxides (~40% Fe w/w) in redox-interfacial sediments. This results from a complex interplay between tidally controlled hydrology, landscape topography, sediment geochemistry and macroporosity. Highly heterogenous intertidal sediments also contain organic-rich micro-niches, where sulfate reduction occurs alongside As-bearing, pedogenic jarosite. We examine this spatial pairing of thermodynamic opposites by reacting S(-II) with As-bearing jarosite under a range of pH conditions. We quantify the corresponding iron mineral transformations and co-associated arsenic mobilisation, re-partitioning and speciation.

Anthropogenic drainage of Fe-rich acidic wetlands can also cause off-site impacts on estuarine sediments and recieving waters. Impacts include; tidally modulated discharge of low pH (~3) and metal-rich waters; elevated reactive-Fe, trace elements and REE's in downstream sediments and porewaters; drastically altered sedimentary sulfur geochemistry and; enhanced trace elements in some estuarine plant species.

We also explore how large, seasonal flood events in Fe-rich coastal wetlands can drive landscape-scale reductive mobilisation of Fe into floodplain surface waters. Anthropogenic drainage of these anoxic, C and Fe^{2+}-rich waters influences the subsequent magnitude and intensity of large-scale (>40 km) riverine hypoxic events.

The Paleoproterozoic Rooiberg Group, Kaapvaal Craton, South Africa: New insights into the formation of silicic large igneous provinces (SLIPs)

OLUTOLA O. JOLAYEMI, JAMES ROBERTS AND NILS LENHARDT

Department of Geology, University of Pretoria.

With an estimated erupted volume of 300,000 km^3[2] and areal extent of ca. 200,000 km^2, the Paleoproterozoic (2.06 Ga) silicic volcanics of the Rooiberg Group (Kaapvaal Craton) in northern South Africa form one of the largest and oldest silicic large igneous provinces (SLIPs) known. These rocks can be sub-divided into four formations[1]: the Dullstroom, Damwal, Kwaggasnek and Schrikkloof Formations. Despite the uniqueness of these rocks and their scientific importance regarding the formation of SLIPs worldwide, the Rooiberg Group received little attention in the past. Therefore, a geochemical and petrological study was initiated to further investigate the petrogenesis of the Rooiberg Group, provide constraints on the magma forming processes and to come up with an explanation for the wide extent of its rhyolitic lava flows.

The Loskop Dam area, Mpumulanga province, ca. 120 km east of Pretoria, and one of the type localities for the Rooiberg Group, was found suitable as study area because of its good outcrop conditions and the fact that most of the formations can be found here.

The studied rocks vary from dacites to rhyolites. Comparison of major, trace andrare earth elements of the Rooiberg Group with other SLIPs around the world show remarkable similarities thus suggesting similar magma sources for the different SLIPs.

Diffusion of titanium in forsterite

M.C. JOLLANDS [1]*, H.ST.C. O'NEILL [1], J. HERMANN [1] AND C. SPANDLER [2]

[1]Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia (*correspondence: mike.jollands@anu.edu.au)

[2]School of Earth and Environmental Sciences, James Cook University, Townsville, QLD 4811, Australia

Titanium diffusion in cubes of synthetic, pure forsterite has been determined as a function of chemical activity, oxygen fugacity (fO_2), crystal orientation, temperature and time at 1 atmosphere. Experimental run products were analysed using both LA-ICP-MS with a scanning rectangular beam, and EPMA in line profile mode. Experiments were conducted between 1300-1500°C, and diffusivity was shown to be positively temperature-dependent.

The experiments consistently produce non-Fickian diffusion profiles that do not fit an error function, hence diffusivity was determined from penetration distance of above-background Ti into the cubes.

In order to fix chemical activity in a three component system (SiO_2, MgO, TiO_2), the sources of Ti were four different three-phase buffers (forsterite–qandilite-periclase, forsterite–qandilite-geikielite, forsterite–geikielite-karooite, forsterite-karooite-enstatite). These were powdered and coupled to polished [001], [010] and [100] crystal faces. In all experiments, a strong positive dependence of diffusivity on silica activity was observed, with fastest diffusion in the presence of enstatite and slowest diffusion in buffers containing periclase. This result agrees with those of Ni, Co and Y diffusion in forsterite [1,2], suggesting Ti is predominantly diffusing on the M site.

Oxygen fugacity was fixed using either CO_2/CO mixtures or air, and experiments were run between $fO_2=10^{-0.7}$ and 10^{-12}. A large negative dependence of diffusivity on fO_2 is observed (slower diffusion in more oxidising conditions), possibly related to the Ti^{4+}/Ti^{3+} transition. In addition, Ti solubility at the buffer-crystal interface increases as fO_2 decreases.

Diffusion is anisotropic; fastest along the *c* axis and slowest along the *a* axis. Contrasts between these findings and a recently presented data set in the same system [3] are currently being investigated.

[3]Geological Survey of Japan, AIST, Japan

A series of nationwide geochemical maps of element concentrations using catchment outlet stream sediments (<180 μm) have been created by Geological Survey of Japan, AIST, in Japan [1]. The original purpose of this project was environmental assessment. Recently, the geochemical database is also applied to determinate producing area of food and tracking of human migration in archaeology. For such purposes, we have started to determine $^{87}Sr/^{86}Sr$ ratios in stream sediments of whole Japan because isotope fractionation is much smaller than concentration variation.

As a first step, we investigated appropriate grain sizes of stream sediments for the $^{87}Sr/^{86}Sr$ mapping project because it is unknown whether the fine sediments (<180 μm) are also suitable for the above purposes or not. The stream sediments were collected from two river systems. They were sieved into 6 fracions (1000─500 μm, 500─300 μm, 300─180 μm, 180─125 μm, 125─75 μm, and <75 μm), and each size fraction was measured for $^{87}Sr/^{86}Sr$ ratios by thermal ionization mass spectrometry (TIMS; VG Sector 54). The results indicate that $^{87}Sr/^{86}Sr$ ratio in <180 μm fraction shows the most representative value of bedrocks in the catchment area.

Secondly, we created the $^{87}Sr/^{86}Sr$ geochemical map using stream sediments (<180 μm) in Shikoku Island and the Kii Peninsula in Japan, to investigate the factors controlling spatial distribution of the $^{87}Sr/^{86}Sr$ ratios [2]. The $^{87}Sr/^{86}Sr$ ratios range from 0.705 to 0719. The variation correponds to the distributions of geological units. For example, underlaying Neogene-Cretaceous accretionary complexes in the southern part of this area show the highest values (0.718-0.719), while the other regions covered by the older accretionary complexes have the lower isotope ratios. The fact suggests that detrital materials derived from the Asian continent having high $^{87}Sr/^{86}Sr$ ratio were supplied to the fore-arc basin during the Neogene and Cretaceous ages. From the results, we concluded that newly created $^{87}Sr/^{86}Sr$ maps reflect geochemical features of source rocks faithfully.

Grain boundaries and transient porosity as fluid pathways for reaction front propagation

LAURA JONAS[12], TIMM JOHN[1], HELENE E. KING[1], THORSTEN GEISLER[3] AND ANDREW PUTNIS[1]

[1]Institut für Mineralogie, Universität Münster, Germany
[2]Institut für Mineralogie, Geologie und Geophysik, Universität Bochum, Germany (Laura.Jonas@rub.de)
[3]Steinmann-Institut für Geologie, Mineralogie und Paläontologie, Universität Bonn, Germany

We used the pseudomorphic replacement of Carrara marble by calcium phosphates as a model system to study the influence of different fluid pathways for reaction front propagation induced by fluid-rock interaction. Grain boundaries present in the rock as well as the transient porosity structures developing throughout the replacement reaction enable the reaction front to progress further into the rock as well as to the center of each single grain until transformation is complete. Hydrothermal treatment of the marble using phosphate bearing solutions led to the formation of OH-apatite and β-TCP; the formation of the latter phase was probably promoted by ~0.6 wt.% Mg in the parent carbonate phase. Completely transformed single grains show a distinctive zoning, both in composition and texture. Whereas areas next to the grain boundary consist of nearly pure OH-apatite with a coarse porosity, areas close to the center of the single grains have a high amount of β-TCP and a very fine porous microstructure. The use of the isotope ^{18}O as a chronometer for the replacement reaction makes it possible to reconstruct the chronological development of the calcium phosphate reaction front. Raman analysis revealed that the incorporation of ^{18}O in the PO_4 tetrahedron of OH-apatite results in the development of distinct profiles in the calcium phosphate reaction front perpendicular to the grain boundaries of the marble. Through the use of the ^{18}O chronometer, it is possible to estimate and compare the time effectiveness of the different fluid pathways in this model system. The results demonstrate that the grain boundaries are an effective pathway enabling the fluid to penetrate the rock more than one order of magnitude faster compared to the newly developing channel-like porosity structures, which act as pathways towards the center of single mineral grains. Thus, after only short reaction durations, it may be possible for the fluid to progress relatively large distances along the grain boundaries without developing broad reaction fronts along the path.

Mineralogical effects on microbial diversity and accumulation in subsurface communities

AARON A. JONES* AND PHILIP C. BENNETT

The University of Texas at Austin, Austin, TX 78712, USA, (*correspondence: aaajones@utexas.edu)

The rocks and minerals that comprise the subsurface lithology; each have properties that will potentially benefit specific microbial communities, especially those uniquely adapted to take advantage of these surfaces. We present experimental evidence that microorganisms colonize rock surfaces according to the rock's chemistry and the organism's metabolic requirements and tolerances. We investigated this phenomenon using laboratory reactors, which allowed microbial colonization of assorted surfaces by both a pure culture of the sulfur-oxidizing bacteria (SOB) *Thiothrix unzii* and a diverse mixed environmental sulfur-metabolizing microbial inoculant collected from Lower Kane Cave, WY, USA. Variations in microbial community structure on each surface were characterized and quantified by SEM, total biomass accumulation measurements, and high-throughput 16S rRNA sequencing.

We found that the combination of mineral properties such as buffering-capacity, nutrient content and aluminum content; as well as cell wall electronegativity, and competitive exclusion control biomass density and diversity of microbial communities attached to rock and mineral surfaces. Diversity analysis reveals that nearly identical communities, primarily composed of neutrophilic SOB, colonize a variety of carbonate surfaces. This resulted in aggressive dissolution of the carbonate minerals, producing a characteristic weathered surface texture. In contrast, a variety of silicate surfaces accumulate highly dissimilar communities with abundant acidophilic microorganisms colonizing only non-buffering quartz. Nutrient rich minerals consistently accumulated substantial biofilms. Nutrient poor and potentially toxic aluminosilicates accumulated very sparse, but highly diverse biofilms composed of a relatively large relative abundance of microorganisms that have been shown to have the ability to neutralize toxic aluminum. Also, Gram-positive bacteria are almost completely excluded from colonization of carbonate surfaces, but are abundant on all of the silicates.

Additionally, members of the genus *Thiothrix* (often found in mid-ocean ridge environments) show an affinity for basalt in both pure and mixed cultures, where it competitively excludes other SOB. These results suggest that adaptations to specific rocks are retained despite displacement of the organism in time and space from an ancestral rock habitat.

Is Diamond a repository of mantle helium and noble gases ?

ADRIAN P JONES[1] AND SUDESHNA BASU[1]

[1]Dept Earth Sciences, University College London, Gower S., London WC1E 6BT;
email adrian.jones@ucl.ac.uk; sudeshnabg@yahoo.com

The high $^{3}He/^{4}He$ ratios observed in some oceanic island basalts has been explained by the presence of a primordial undegassed reservoir, a model now often considered untenable. Other geodynamic models have been suggested but need further testing [1]. Considering the very high $^{3}He/^{4}He$ in diamonds from pipes, and a range spanning six orders of magnitude varying with location, age and history, we propose that diamonds can be an important repository of helium and other noble gases in Earth's mantle. Residence times of billions of years are implied from preserved internal zonation. This work has evolved from combining our review of noble gas data for natural diamonds [2], with recent data and perspectives for Earth's deep carbon through time [3]. The mantle, at depths > 150 km along continental and oceanic geothermal gradients is in the diamond stability field [4]. Considering the low solubility of C and incompatibility of noble gases in mantle silicates and oxides, diamonds trapping large amounts of noble gases can crystallize within a large volume of Earth's mantle in the presence of carbonate or methane. The true amount of diamond crystallizing will be much larger than that actually erupted [5]. The noble gases can be released when diamonds graphitize or oxidize, and the mobility of a variety of small degree melts may be the rate-limiting step. It will be important to investigate the solubility of noble gases in diamond forming melt at mantle conditions.

Phosphorus is an essential nutrient for life, and aquatic microorganisms have strict P requirements for cellular structure, energy, function, and replication. We examined the physiological capacity of a microbial community to cope with extreme P limitation. This community lives in the surface waters of Lake Matano, an ultra-oligotrophic, stratified, ferruginous, ancient lake situated on Sulawesi Island, Indonesia. Based on dissolved nutrient concentrations in the surface waters, the elemental composition of microbial biomass, alkaline phosphatase enzyme assays, metagenomic analyses, and C-fixation assays with and without added P, we show that biomass production is P limited in the surface waters (0-100 m). The planktonic microbial community has responded to the extreme scarcity of available P through increased bulk C:P ratios (>1000), an order of magnitude higher than the Redfield ratio of 106:1. Such high C:P ratios are in part explainable by a lack of detectable phospholipids in the microbial biomass. Instead, abundant and structurally diverse betaine and glycolipids substitute for phospholipids, reducing the cellular P demand of the Lake Matano microbial community. With this observation, we show that this ability is not restricted to autotrophic organisms[1] but is universally distributed among different microbial taxa stressed by extremely low concentrations of available P. Such extreme P limitation in Lake Matano suggests that ferruginous conditions in general may lead to P limited ecosystems. This is consistent with previous work indicating P limitations on primary production during ferruginous Precambrian ocean chemistry[2].

Microbial phosphate release from marine sediments: Transcriptomics and geochemistry

D.S. JONES*, B.E. FLOOD AND J.V. BAILEY

[1]Dept. of Earth Sci., University of Minnesota, Minneapolis, MN 55455, USA (*correspondance: dsjones@umn.edu,)

Hydrolysis of intracellular polyphosphate (polyP) by benthic marine microorganisms is a potentially significant mechanism for phosphorus (P) flux from sediments to the water column. Additionally, polyP utilization by large sulfur (S) bacteria has been linked to phosphogenesis in episodically anoxic marine settings. Here, we combined incubations of sediment-hosted microbial communities with geochemical measurements and comparative metatranscriptomics in order to identify important polyP accumulating organisms in different marine environments and compare their activities under distinct redox conditions. We incubated sediments from two locations: (i) methane-seep sediments near Barbados that included a *Thiomargarita*-like bacterial biofilm; and (ii) sulfidic Santa Barbara Basin (SBB) sediments with no visible S oxidizing bacteria. P release from sediments of both localities was observed under anoxic conditions (Fig. 1), with and without additions of sulfide and acetate. Following incubations, sediments were immediately preserved for RNA extraction and sequencing. Metatranscriptomic analysis of the Barbados incubations revealed that, based on rRNA and *rpoB* transcripts, active microbial populations included diverse representatives of the Methanosarcinales, Bacteroidetes, and Delta-, Gamma- and Epsilonproteobacteria. However, based on identification and taxonomic classification of polyP kinase and exopolyP-ase transcripts, only certain gamma- and epsilonproteobacteria appeared to be metabolizing polyP under incubation conditions. Comparative analysis of metatranscriptomes from Barbados (where S bacteria were abundant) with metatranscriptomes from SBB (rare S bacteria) will provide insight into the identities and activities of key marine polyphosphate-metabolizing organisms, and further define their contributions to the global P cycle.

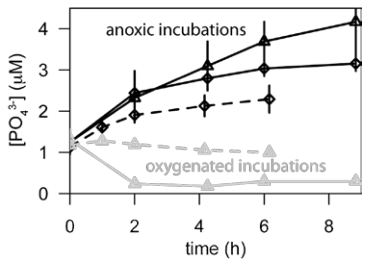

Figure 1: Dissolved phosphate changes during incubation experiments with marine sediments from Barbados (dashed lines) and the Santa Barbara Basin (solid lines).

Daily geochemical monitoring of volcanic rivers: A tool for eruption prediction?

MORGAN T. JONES[1*], ATHANASIOS GKRITZALIS-PAPADOPOULOUS[2], MARTIN R. PALMER[2], MATTHEW C. MOWLEM[2] AND SIGURÐUR R. GISLASON[1]

[1]Institute of Earth Sciences, Sturlugata 7, 101 Reykjavík, Iceland (* correspondence: morgan@hi.is)

[2] National Oceanography Centre, University of Southampton, European Way, SO14 3ZH, UK

The exsolution of volatiles and magma degassing can have a profound impact on the behaviour of volcanic systems and eruption style and frequency. Measuring volcanic degassing has traditionally focused on atmospheric emissions. However, volatiles can become dissolved in proximal water bodies en route to the surface, thus the monitoring of rivers draining active volcanoes can be integral to understanding the state of the volcano and potentially be used as a tool for predicting changes in activity or imminent eruptions. This method of monitoring is hampered by the dependence on spot-sampling due to financial and equipment constraints.

Recent advances in the design of osmotic samplers now allow for the continuous collection of water, providing a daily-averaged sample for weeks to months without the need of electricity or human supervision [1]. Deployment and testing of these osmotic samplers has been conducted in the rivers draining Mýrdalsjökull glacier and Katla volcano in southern Iceland. Preliminary results suggest that daily-averaged samples are able to track changes in volatile and metal concentrations over days to months. Results are used in conjunction with continuous monitoring of conductivity and temperature by the Icelandic Meteorological Office to highlight the differences in glacial, meteoric, volcanic and spring sources to the river chemistry from season to season. We envision that this form of sampling and monitoring can provide vital information on the behaviour and activity of volcanoes, and with further data become a potential method of eruption forecasting.

This work is funded as part of the EU collaborative project FUTUREVOLC, "a European volcanological supersite in Iceland: a monitoring system and network for the future".

Effects of sediment porosity and particulate organic carbon on Fe, S and U cycling in Naturally Reduced Zones (NRZs) of a contaminated aquifer

M.E. JONES[1]*, N. JANOT[2], J.R. BARGAR[2] AND S. FENDORF[1]

[1]School of Earth Science, Stanford University, Stanford, CA 94305, USA (*correspondence: mejones@stanford.edu)

[2]SLAC National Accelerator Laboratory, Menlo Park, CA 94025, USA

Previous studies have illustrated the importance of Naturally Reduced Zones (NRZs) within saturated sediments as a source of reduced organic compounds and hydrogen, providing electron donor for subsurface microbial respiration. NRZ's are typically characterized by low permeability and elevated concentrations of organic carbon and trace metals. However, both the formation of NRZs and their importance to the overall aquifer carbon remineralization is not fully understood.

Within NRZs the hydrolysis of particulate organic carbon (POC) and subsequent fermentation of dissolved organic carbon (DOC) to form low molecular weight dissolved organic carbon (LMW-DOC) provides electron donors necessary for the respiration of Fe, S, and in the case of the Rifle aquifer, U. Rates of POC hydrolysis and subsequent fermentation have been poorly constrained and rates in excess and deficit to the rates of subsurface anaerobic respiratory processes have been suggested.

In this study, we simulate the development of NRZ sediments in diffusion-limited aggregates to investigate the physical and chemical conditions required for NRZ formation. Effects of sediment porosity and POC loading on Fe, S, and U cycling on molecular and nanoscale are investigated with synchrotron-based Near Edge X-ray Absorption Fine Structure Spectroscopy (NEXAFS. Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT-ICR-MS) and Fourier Transform Infrared spectroscopy (FTIR) are used to characterize the transformations in POC and DOC. Sediment aggregates are inoculated with the natural microbial biota from the Rifle aquifer and population dynamics are monitored by 16S RNA analysis.

Overall, establishment of low permeability NRZs within the aquifer stimulate microbial respiration beyond the diffusion-limited zones and can limit the transport of U through a contaminated aquifer. However, the long-term stability of NRZs and the colocated U is unknown and requires further study.

Boron cycling in the Central Andean subduction zone: Evidence for recycled components

ROSIE JONES[1*] LINDA KIRSTEIN [1], RICHARD HINTON[1], SIMONE KASEMANN[2], TIM ELLIOTT[3] AND VANESA LITVAK[4]

[1]School of GeoSciences, University of Edinburgh, UK r.e.jones-3@sms.ed.ac.uk (* presenting author)
[2]Department of Geosciences, University of Bremen, Germany
[3]Department of Earth Sciences, University of Bristol, UK
[4]Departamento de Ciencias Geológicas, Universidad de Buenos Aires, Argentina

Subduction zones, such as the active Andean margin, form large recycling systems and are the main producers of new continental crust. Some of the material which enters the subduction zone, including terreginous and pelagic sediment and oceanic crust, is recycled to the continental crust via arc magmatism, and some re-equilibrates with the mantle. Boron has been identified as an ideal tracer for mass transfer in subduction zones, especially of recycled slab compents (eg. [1, 2]). The study area is located within the Pampean flat slab segment (~27º - 33ºS) of the southern Central Andes. This segment is currently volcanically inactive due to the low angle at which the Nazca plate currently subducts beneath the South American plate. This low angle has been attributed to the subduction of the Juan Fernandez Ridge, a volcanic seamount, which began intersecting the Andean continental margin during the early Miocene (~18Ma) [3]. Volcanism terminated in the region during the late Miocene (~6Ma).

A suite of Eocene – Miocene arc volcanic rocks were sampled from the southern Central Andes (28º to 32ºS). Whole rock major- and trace-element data indicate variable contamination of the magmas during this interval but the source of the contamination remains enigmatic. New *in situ* analyses of boron concentrations and isotope ratios in pyroxene and zircon hosted melt inclusions were measured by SIMS, in order to identify contributions to Central Andean arc magmas from the subducting slab and sediments. This new data has been combined with high resolution, U-Pb zircon dating to provide insight into the petrogenetic evolution of magmas along the margin.

Average boron concentrations and isotope ratios obtained for the three Miocene samples are distinctly higher ([B] = 111.7 ±9.0 ppm, $\delta^{11}B$ = 4.47 ±0.86 ‰ (2σ)) than those obtained for the four Eocene – Oligocene samples ([B] = 76.3 ±15.9 ppm, $\delta^{11}B$ = -0.09 ±1.01 ‰ (2σ)). This suggests Central Andean arc magmas received a greater influence from slab derived fluids after the intersection of the Juan Fernandez Ridge and subsequent shallowing of the Nazca plate. This work demonstrates boron isotope ratios can be used in combination with high resolution U-Pb dating and major and trace element geochemistry to provide new insights into arc processes in changing geodynamic settings.

Microbially mediated phosphogenesis 2 Ga ago

LAURI JOOSU[1]*, AIVO LEPLAND[23] AND KALLE KIRSIMÄE[1]

[1]University of Tartu, Tartu, Estonia. (*correspondence: lauri.joosu@ut.ee)
[2]Geological Survey of Norway, Trondheim, Norway.
[3]Tallinn University of Technology, Tallinn, Estonia.

Modern phosphogenesis is typically associated with high productivity upwelling systems where apatite (Ca-phosphate) precipitation is mediated by large sulphur bacteria [1]. They live in the upper few centimetres of sediment at oxic/anoxic interface and thrive in close association with a consortium of anaerobic methane oxidising archaea and syntrophic sulphate-reducing bacteria.

Paleoproterozoic Zaonega Formation in the Onega Basin, Karelia, Russia, is a c. 1500 m thick succession of organic-rich sedimentary rocks interlayered with mafic tuffs and lavas, containing several P-rich intervals in its upper part. Microsructure of these P-rich intervals exhibit apatitic laminae and particularly nodules up to several hundred μm in size. Individual apatite particles in P-rich lamellas and nodules occur as cylindrical apatite aggregates 0.5-4 μm in diameter and 1-8 μm in length. Cross-sections of cylindrical apatite particles reveal a thin outer rim whereas the internal parts consist of small anhedral elongated crystallites.

The sizes and shape of the nodules are similar to those of giant sulphide-oxidising bacteria known in modern and ancient settings [2, 3]. Individual apatite cylinders and aggregates have shapes and sizes similar to the methanotrophic archaea ANME-1 and ANME-2 that inhabit microbial mats in modern seep/vent areas where they operate in close associations with sulphur-oxidising microbial communities [4]. Moreover apatite in the Zaonega Formation is found in organic rich sediments exhibiting strongly negative $\delta^{13}C_{org}$ values (-37 to -34 per mil) which is interpreted to reflect the occurrence of methanotrophic biomass. We conclude that modern-style phosphogenesis, mediated by sulphide-oxidising bacteria living in consortia with methanotrophs, was established at least 2 Ga ago in response to the oxygenation of the Earth.

Rare earth element signatures of metal-rich hydrothermal ferromanganese deposit in the South-West Pacific

PIERRE JOSSO[12,*], EWAN PELLETER[1], OLIVIER POURRET[2], YVES FOUQUET[1], JOEL ETOUBLEAU[1], SANDRINE CHERON[1], CLAIRE BOLLINGER[3] AND THE SCIENTIFIC PARTIES

[1]Ifremer c/Brest, Laboratoire de Géochimie et Métallogénie, Plouzané, France (email: pierre.josso@ifremer.fr)
[2]HydrISE, LaSalle Beauvais, Beauvais, France
[3]IUEM, UMS 3113, Plouzané, France

A metal-rich hydrothermal ferromanganese deposit was discovered in the south-west Pacific during a French cruise [1]. The deposit formed at ridge axis and is hosted by pyroclastic rocks (e.g., hyaloclastite, tuffite, pumice). Mineralogical and geochemical investigation shows evidence of vertical zonation with depth. From top to bottom, we distinguished highly Ni-enriched manganese oxyhydroxides (Ni up to 4.6%) then iron oxyhydroxides ± nontronite with low metal concentrations, and barren nontronite. Here, we report rare earth element (REE) data for Fe-Mn oxyhydroxides and nontronite samples. All samples exhibit very low REE abundance (ΣREE: 12.6 – 92.7 mg/kg) and relatively low middle REE / heavy REE ratios (Nd_n/Yb_n= 0.52 – 2.13). This signature is characteristic of low temperature hydrothermal Fe-Si-Mn mineralization [2]. All samples have a slight negative Eu anomaly while the Ce negative anomaly is well developed (Ce/Ce*: 0.04 – 0.89) and negatively correlated with Mn/Fe ratio (Mn/Fe: 0.14 – 80). This opposite correlation might implicate a strong mineralogical control of Ce content in Fe-Mn oxyhydroxides possibly related to pH [3]. This observation is to be qualified as the lack of correlation between the ΣREE and Mn/Fe ratio leads to think of the differential state of the phase's crystallinity as a control factor of the REE fractionation rather than its mineralogical nature [2].

Volcanoes, asteroid impacts and mass extinctions: A matter of timing

FRED JOURDAN

Western Australian Argon Isotope Facility; JdL Centre & Dept of Applied Geology; Curtin University, GPO Box U1987, Perth WA6845. Australia.

The history of life on Earth is punctuated by large mass extinction events, with five large ones occurring in the Phanerozoic and several smaller ones occurring between them. Isotopic and elemental chemistry shows that the extinctions are somehow linked to drastic climate changes.

The Cretaceous-Palaeogene (K-Pg) extinction event is well-documented, but controversy as to whether this was caused by an asteroid impact or the Deccan Traps has raged for many years [1,2], in particular because both events are demonstrably synchronous witht the K-Pg boundary [3].

One important question is wether other significant extinction events were caused by impact, volcanism or the combination of both? To test these hypothese, impacts and/or volcanic eruptions *must* be exactly synchronous with a mass extinction.

Quality-filtered age compilations show that whereas at least six large volcanic province – mass extinctions pairs have been recognized (including the newly added Kalkarindji – Middle Cambrian extinction pair at 510 Ma; [4]), only one asteroid – mass extinction pair has been demonstrated [5]. A possible synchronicity between extinction and impact candidates can be tested using precise geochronology. For example, our $^{40}Ar/^{39}Ar$ data on the Siljan Impact structure [6] show that the impact occur several million years before the Frasnian-Fammenian boundary (~376 Ma). New data on Popigai and Chesapeak Bay [7] show that the two events are older than the mid-Eocene extinction. Some impact events (Rochechouart [8]; Araghuaina [9]) have ages that make them time-compatible with a major extinction levels, but there small sizes (20-40 km) rule out any possible link.

At the face value of the current age database, large outpouring of lava is a more recurent kill factor in the evolution of life than large impacts. Nevertheless, and largely understudied, is the potential of impact cratering events to have fostered life evolution [e.g., 10].

Controls on methane cycling in the Baltic Sea

B.B. JØRGENSEN[1*], G. REHDER[2] AND BALTIC GAS TEAM[3]

[1]Center for Geomicrobiology, Aarhus University, 8000C Aarhus, Denmark (*correspondence: bo.barker@biology.au.dk)

[2]Department of Marine Chemistry, Leibniz Institute for Baltic Sea Research Warnemünde, Germany (gregor.rehder@io-warnemuende.de)

[3]www.balticgas.net

The Baltic Sea is an ideal model to understand the environmental factors controlling methane production and methane cycling in coastal marine sediments. Salinities range from marine to nearly limnic, temperatures vary seasonally, and the stratified water column leads to widespread anoxia. During the BONUS+ project, BALTIC GAS, an international group of researchers studied sediment geophysics, free gas distribution, methane fluxes and organic carbon mineralization to determine the constraints on methanogenesis and methane emission to the water column and atmosphere.

The entire Baltic Sea region was ice-covered during the last glaciation, and modern methanogenesis primarily takes place in organic-rich sediments from the past <10,000 years. Sub-surface methane fluxes are highly dependent on the thickness of these Holocene sediments. In fact, the geographic distribution of dissolved methane and free gas can only be understood in the light of post-glacial geology as revealed by seismic-acoustic mapping combined with targeted coring and geochemical analyses. When Holocene deposits exceed a theshold thickness of 6-10 m, the methane partial pressure builds up to form gas bubbles. The underlying post-glacial clay, in contrast, may be a sink for methane.

Ebullition of free gas appears to be insignificant in the main Baltic Sea basins, yet hotspots with outgassing associated with pockmarks have been found by multibeam bathymetry, mostly in the Polish and Russian sectors. Outgassing also occurs in the most eutrophic coastal zone. Enhanced ebullition was not found associated with the low sulfate concentrations in the Bothnian Bay. Elevated methane concentrations in the bottom water are confined to the anoxic basins and methane is retained and oxidized in the chemocline of the water column. The Baltic Sea basins are thus generally robust towards methane emission to the atmosphere, although studies during extreme water level fluctuations are still lacking.

Hierarchy of two drivers of soil organic matter biodegradation: microbial habitat properties versus microbial communities

S. JUAREZ[1], N. NUNAN[1], V.POUTEAU[1], T. LERCH[2] AND C. CHENU[1]

[1]UMR Bioemco AgroParisTech, CNRS INRA, 78850 Thiverval Grignon France (juarez@grignon.inra.fr, chen@grignon.inra.fr)

[2]UMR Bioemco, UPEC, Créteil France

Soil microbial communities live in a complex 3-D framework in which a range of habitats with a variety of properties exists. The importance of these habitat properties relative to the intrinsic properties of microbial communities in the regulation of soil organic matter decomposition is still unclear.

In order to uncouple effects linked to microbial habitat properties from ones linked to microbial communities, we sterilized 6 contrasted soils and performed to crossing inoculations. Each soil microbial community was extracted from its native soil by a saline solution, and inoculated in each on the six different sterilized soils. During the incubation, we measured C mineralisation as well as the microbial communities structures. Microbial habitat was the dominant determinant of SOC decomposition and of microbial community structure.

A human health risk assessment (HHRA) for a former landfill located at Cerdanyola del Vallès (Catalonia, Spain) was performed to evaluate the present risk of the identified receptors in the area and to the receptors of a the future urban planning. A former clay extraction activity in the area caused the existence of three 40m-deep holes which were aftewards filled with several types of industrial waste during the 80's. After landfill closing in 1995 several sudies have been performed to assess the effect of the landfilled wastes to the environment. The innovative aspect of HHRA in this study was based on direct measurements of volatile organic compounds (VOC) in the urban air (immission concentrations around landfill), fluxes from the subsoil and surface emission.

Therefore, 130 VOC were identified and 70 quantified (odor, toxic and irritant compounds) in outdoor air at 4 urban sites located close to the landfill. The emission flux of the same compounds was determined in 5 points on the surface of the landfill, and soil gas composition at 5m-deep was also evaluated in the edge of the landfill. VOC were adsorbed into multi-sorbent tubes and analyzed by means of TD–GC–MS.

Several potential scenarios were defined for the HHRA: 3 for the current situation and 4 for the future situation (recreative area with sorrounding buildings). USEPA methodology for HHRA was followed and toxicity values from IRIS database were used. Admissible risk was obtained in all scenarios due to low emissions. Effect of landfill on inmission air measurements was calculated to be negligible.

The use of direct mesurement of contaminants in air and emission fluxes allowed a more accurate HHRA with respect to the typical approach.

Enhancing the performance of GC-IRMS for small biomarker samples

DIETER JUCHELKA[1], JENS RADKE[2] AND ANDREAS HILKERT[3*]

[2] Thermo Fisher Scientific, 28199 Bremen, Germany (jens.radke@thermofisher.com)
[3] Thermo Fisher Scientific, 28199 Bremen, Germany (andreas.hilkert@thermofisher.com)

The combination of Gas Chromatography with Isotope Ratio Mass Spectrometry (GC-IRMS) was introduced in 1988, opening the wide field of compound specific isotope analysis (CSIA). It combines the high purification efficiency of GC with the utmost precision of isotope ratio mass spectrometry.

Today compound specific isotope analysis of the main bioelements and their major isotopes ^{13}C, ^{15}N, ^{18}O and ^{2}H is a standard tool in many laboratories and is used in a wide range of applictions. Consequently, this analytical tool is extending into new areas of research, in which smallest sample size at high precision is a must.

The development of more sensitive IRMS systems with optimized GC combustion and high temperature conversion interfaces is also related with modern sample introduction techniques, choice of GC columns, advanced GC technology, conversion technology and interfacing to the IRMS as well as data handling. New challenges in sample size and separation concern the improvement of sensitivity and GC resolution combined with full automation for higher sample throughput.

We will discuss in this presentation the neuralgic points in the GC-IRMS system with application examples on biomarkers and other important biomolecules linked to improvements in sample introduction techniques, GC- and reactor technology.

Partitioning of sulfur between silicate melts and volatile phases as function of fO_2: Clues from old models for a new reference framework

PEDRO J. JUGO

Department of Earth Sciences, Laurentian University, Sudbury, Ontario P3E 2C6, Canada (pjugo@laurentian.ca)

The partitioning of sulfur between silicate melts and coexisting volatile phases is a key parameter to understand igneous processes such as massive S degassing in explosive eruptions (e.g. Mount Pinatubo, June 1991) and the formation of porphyry deposits (which in addition to Cu, Mo, and Au, are S anomalies). It is well-established that the S content at sulfide saturation (SCSS) in a silicate melt increases exponentially with increasing fO_2 regardless of whether the system is anhydrous or the melt is in equilibrium with a hydrous phase [1, 2, 3, 4]. It is also well-established that only S^{2-} and S^{6+} species are significant in silicate melts [5], whereas S^{4+} species (in addition to S^{2-} and S^{6+}) are significant in volatile phases [6]. Thus, the stability of S^{4+} species in the volatile phase is an essential parameter controlling S partitioning. Early studies of S behaviour between volatile phases and silicate melts [7, 8] have been used extensively to describe a "sulfur solubility minimum" that has no relevance to SCSS because the experiments in those studies lacked sulfides as run products. However, those experimental studies provide useful reference models when the data are recast in a more appropriate framework (i.e. to express S partitioning between the input gas and the silicate melt). The results show that, at atmospheric pressure, a S partitioning maximum exists at fO_2 conditions that may be attributed to S^{4+} dominance in volatile phases at low pressure (and that overlap the fO_2 range corresponding to the S^{2-} to S^{6+} transition in silicate melts at high pressure). Linking the two types of data (SCSS at high P and $D_S^{gas/melt}$ at atmospheric P) provides a useful model to understand S mass transfer from silicate melts into volatile phases during volatile exsolution and degassing resulting from magma ascent and decompression.

Natural type-C olivine fabrics in garnet peridotites in North Qaidam UHP collision belt, NW China

H. JUNG[1*], J. LEE[1], B. KO[1], S. JUNG[1], M. PARK[1], Y. CAO[1] AND S.G. SONG[2]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul 151-747, Republic of Korea (*correspondence: hjung@snu.ac.kr).

[2]School of Earth and Space Sciences, Peking University, Beijing 100871, China.

Water is known to change the lattice-preferred orientation (LPO) of olivine, which significantly affects seismic anisotropy in the Earth's upper mantle. Research into the LPO of olivine in the deep interior of the Earth has been limited due to inadequate specimens. We report both the water-induced LPOs of olivine and the presence of large quantities of water inside olivine, enstatite, and garnet in garnet peridotites from the North Qaidam ultrahigh-pressure (UHP) collision belt in NW China. We show that the [001] axis of olivine is aligned subparallel to the lineation and that the [100] axis is strongly aligned subnormal to the foliation. This alignment is a known feature of type-C LPO of olivine formed experimentally under water-rich conditions (≥700 ppm H/Si) at high pressure and temperature. Enstatite possessed an LPO with the [001] axis aligned parallel to the lineation and the [100] axis aligned normal to the foliation. FTIR analysis of this specimen revealed that olivine contained concentrations of water up to 1130 ± 50 ppm H/Si in clean areas, whereas olivine, enstatite, and garnet contained considerably more water, i.e., 2600 ± 100 ppm H/Si, 5000 ± 100 ppm H/Si, and 21000 ± 200 ppm H/Si, respectively, when exsolved inclusions were visible. Confocal micro-Raman spectroscopy of these exsolved inclusions revealed that they were composed of hornblende and amphiboles. Straight dislocations were also commonly observed in olivine and are characteristic of olivine that had been experimentally deformed under hydrous conditions. These observations suggest that the type-C LPO of olivine in the North Qaidam UHP belt formed under water-rich conditions.

[3]Jeju Special Self-Governing Province Development Corporation, Jeju, South Korea

Hydrochemistry data of groundwater were collected in the Gosan area, southwestern coastal part of Jeju Island, South Korea. In the western part of the study area, an impermeable clay-rich layer (Gosan Formation) locally overlies the basaltic aquifer. The Robust PCA method (ROBPCA) was used to investigate hydrochemical characteristics. The results show that principal component 1 effectively distinguishes the groundwater samples recording varying degrees of agricultural contamination. Groundwater samples whose chemistry is controlled by agricultural contamination are restricted to the eastern part of the study area, while uncontaminated water is predominantly obtained in the western part where the Gosan Formation occurs. Groundwater samples from wells near the edge of the Gosan Formation show a seasonal fluctuation of water quality (i.e., from uncontamination in a dry season to agricultural contamination in a wet season). This study suggests that groundwater below the marginal part of an impermeable layer is seasonally contaminated by a temporal extension of the pollution front during the wet season, even though the impermeable layer plays a role as a natural barrier to protect groundwater from the infiltration of surface contaminants.

PANGA: A new tool for the evaluation of noble gas data

M. JUNG[1]* AND W. AESCHBACH-HERTIG[1]

[1]Institute of Environmental Physics, Heidelberg University, 69120 Heidelberg, Germany (*correspondence: michael.jung@iup.uni-heidelberg.de)

In recent years, several new models for the description of dissolved noble gases in groundwater have been developed, because the more traditional models did not yield good results for certain data sets [1]. The oxygen depletion model was proposed in response to the observation that the classical models yielded too low temperatures for some aquifers [2]. To overcome specific problems related with unrealistically high temperature estimates of the closed-system equilibration model, a Monte Carlo-based evaluation method was developed [3].

In order to adapt and simplify the evaluation process, we created *PANGA*, a new software for the analysis of noble gas data sets. Its basic features are comparable to *Noble* [4], but it also includes more recent excess air models and provides additional features like fast Monte Carlo fitting (up to several 100,000 fits per minute) and the subsequent depiction and evaluation of the results in one- and two-dimensional histograms as well as the possibility to interactively explore the χ^2 space of noble gas fits, enabling the user to identify problems like local minima in the χ^2 surface.

Comparison tests have shown that *PANGA* is able to reproduce *Noble's* results very well. The analysis of several data sets showed that Monte Carlo results, especially parameter uncertainties, differ considerably from the original fit results in a number of cases. Therefore, it is recommended to perform Monte Carlo evaluations in all cases, especially if any kind of problematic behavior occurs, like parameters approaching physical boundaries or unrealistically high temperature estimates or uncertainties.

Pharmaceutically active compounds (PhACs) are a matter of growing concern because they might produce potentially harmful effects on ecosystems and human health. The incomplete removal of some PhACs during conventional waste water treatment represents the main source in surface and ground waters. As a result, groundwater quality can be deteriorated by the presence of PhACs. Thus, understanding their fate in the aquifer is a key environmental issue.

In this work, a multicomponent reactive transport modeling will be used to investigate the fate of the PhACs in an urban aquifer which main recharge source is the polluted River Besòs in Barcelona (Spain). River Besòs flow is heavily dependent on seasonal rainfall and it receives large amounts of effluents from waste water treatment plants. Therefore, a wide range of PhACs may be present in groundwater at similar levels or even higher than the River Besòs.

Prior inspection of the collected data suggests different behavior of the PhACs in the aquifer. As an example, ibuprofen, gemfibrozil, sulfadiazine and bezafibrate present a significant removal in when river water infiltrates the aquifer, with elimination rates ranging between 60–80%. However, other PhACs such as carbamazepine are highly persistent with elimination rates that usually below 10%. It is important to understand and quantify the different attenuation behavior of PhACs to know whether the groundwater of Besòs River Delta can be use to other purposes, such as supply ones, apart from street cleaning and water plant.

Chromium chemistry in natural waters, Iceland

HANNA KAASALAINEN[1]*, ANDRI STEFÁNSSON[1], INGVI GUNNARSSON[2] AND STEFÁN ARNÓRSSON[1]

[1]Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavik, Iceland, (*correspondence: hannakaa@hi.is)

[2]Present address: Reykjavik Energy, Bæjarhalsi 1, 110 Reykajvik, Iceland

Chemistry of Cr and Fe was studied in non-thermal and geothermal waters in Iceland. Chromium (Cr) is typically present at low concentrations (<1 μg/l) in natural waters, but elevated concentrations have been observed in waters with low pH values, e.g. acid mine drainage, and in association with industrial activities. Chromium occurs in two oxidation states, Cr(III) and (VI), these being characterized by different (bio)chemical behaviour and solubility. As Cr(VI) is known to be toxic but Cr(III) an essential micronutrient, it is important to determine the two oxidations states. Iron (Fe) is known to play an important role in the chemistry of Cr through adsorption on and incorporation in Fe containing minerals, and by affecting the distribution of Cr species. In natural waters, iron is present in two oxidation states (Fe(II) and (III)) and understanding its chemistry is complicated by fast oxidation kinetics, importance of colloidal forms and low solubility in the pH range of most natural waters (pH>6).

Samples were collected from non-thermal surface and spring water, surface geothermal water and geothermal well discharges, and analyzed for their major and trace element composition. Chromium and Fe speciation was determined in selected samples. The sampled waters showed wide range of composition with temperature, pH and total dissolved solids in the range of 0-184°C, 2.0-9.6, and 35-4030 mg/l, respectively. The total dissolved Fe and Cr concentrations were between <1 μg/L to 360 mg/L and <0.01 and 660 μg/L, respectively. The highest concentrations were associated with steam-heated acid-sulfate waters with the lowest pH values, whereas the concentrations in neutral to alkaline waters were low, typically <1 μg/L Cr and <100 μg/L Fe.

The main processes controlling Cr chemistry were found to depend on the water pH and rock leaching. At a low pH, Cr(III) becomes released into solution through leaching of Cr-containing minerals contained in basaltic rocks. At neutral to alkaline pH, Cr leaching from rock is limited and Cr(III) concentrations may be further reduced and controlled by solubility of Cr(III)-Fe(III) mineral phases. However, Cr(VI) mobility is enhanced associated with decreasing importance of mineral surface complexation. Indeed, Cr(VI) was frequently found to dominate over Cr(III) at pH>6 in concentrations of a few μg/L.

Deformation mechanisms in Martian Shergottites

KACZMAREK M.-A.*[12], GRANGE M.[1], REDDY S.M.[1], AND NEMCHIN A.[1]

[1]Department of Applied Geology, The Institute for Geoscience Research, Curtin University of Technology, GPO Box U1987, Perth, WA 6845, Australia

[2]Now at University of Lausanne, Institute of Earth Sciences, UNIL Mouline, Géopolis, CH-1016 Lausanne, Switzerland (*correspondence: mary-alix.kaczmarek@unil.ch)

Nakhla and Zagami are both clinopyroxene-rich basaltic shergottite, with some Fe-rich olivine. The microstructure, the preferred orientation of pyroxene using Electron Backscatter Diffraction (EBSD) method and the gochemistry are combined to study subsamples of both Zagami and Nakhla to decipher deformation processes that have occurred on Mars.
