Nakhla displays a granular texture, essentially composed of augite, fayalite, plagioclase and magnetite. Our Zagami sample, formed by olivine, plagioclase, and whitlockite is part of the “coarse grained” portion of Normal Zagami texture [1, 2] with long prism of clinopyroxene underlying a weak preferrential orientation. Complete maps of both Zagami and Nakhla samples and detailed maps of clinopyroxene single grains were obtained with EBSD. Both samples show a strong preferred orientation of clinopyroxene and CPOs display several point concentrations on <001> axes within a girdle. The relationship between the microstructure and CPOs inferred the possible activation of (100)[001] and (010)[100] slip systems. Moreover, the several point concentrations on clinopyroxene <001> axis might correspond to twinning.

Geochemical maps of clinopyroxene single grains highlight chemical zoning from augite core to pigeonite rims. Phases indexation with the EBSD is concordant with the geochemistry and highlights no variation in the slip system from cores to rims, suggesting either no variation of deformation during the evolution of the geochemical system, or a late deformation event. Inspection of clinopyroxene single grains show that Nakhla clinopyroxenes have almost no internal deformation, rather than Zagami clinopyroxenes showing complicate microtexture with possible activation of several slip systems.

Our results suggest a composite deformation related to magmatic deformation (preferred orientation and prismatic clinopyroxene) and to the shock event (single grain internal deformation and twinning).

Bioavailability of nanoparticulate iron derived from atmospheric mineral dusts

ENIKÖ KADAR[1], JONATHAN J. POWELL[3] AND ZONGBO SHI[2]

[1]Plymouth Marine Laboratory, Prospect Place, the Hoe, Plymouth PL1 3DH, UK email: enik@pml.ac.uk
[2]School of Geography, Earth and Environmental Sciences, University of Birmingham, B15 2TT, U.K email: z.shi@bham.ac.uk
[3]Biomineral Research Section, Medical Research Council - Human Nutrition Research, Elsie Widdowson Laboratory, Fulbourn Road, Cambridge CB1 9NL email: Jonathan.Powell@mrc-hnr.cam.ac.uk

We have studied the composition, Fe dissolution/Fe lability, particle aggregation/size distribution, surface topology and zeta potential (i.e. colloidal stability) of Fe-rich nanoparticles (NPs) formed during simulated atmospheric processing of dust in contact with seawater under a range of environmentally realistic conditions typical in oceanic waters to shed light on putative relationships between NP structure and water parameters. These laboratory studies showed that: (i) despite the close resemblance in micromorphology, NPs formed from mineral dusts have distinct aggregation behaviour from ferrihydrite NPs; (ii) the relatively stable and mondosiperse aggregates of NPs formed during simulated cloud processing of mineral dust become more polydisperse and unstable in seawater; (iii) exopolymeric substances (EPS) extracted from phytoplankton seem to "stabilise" the aggregates of dust derived NPs; iv) dissolved Fe concentration from NPs, is consistently higher in seawater in the presence of EPS and is also affected by sunlight; v) EPS-mediated Fe uptake may be responsible for enhanced bioavailability in phytoplankton.

To test the hypothesis that nanoparticulate Fe is more bioavailable than the bulk analogue we have grown marine microalgae on synthetic nano-iron substrates. Algal growth was significantly enhanced when the nanomaterials were added in equimolar concentration compared to Fe-EDTA in the optimised algal growth medium (f/2). NP addition influenced cellular fatty acid composition compared to control treatments, but this was significant only in haptophytes. The NP uptake mechanism proposed is via secretion of an extracellular matrix that binds NPs through which Fe is bioavailable via fagocytotic membrane processes and/or NP dissolution. The implications of the use of such engineered nanomaterials as Fe substrate in algal culture are discussed.

Determination the step of karst formation using GPR and Raman Spectroscopy Methods, South East Anatolia, Turkey

SELMA KADIOGLU[12] AND YUSUF KAĞAN KADIOĞLU[2]

[1]Ankara University Faculty of Engineering Department of Geopgysical Engineering, Ankara, Turkey
[2]Ankara University Earth Sciences Application and Research Center, Ankara, Turkey (kadi@ankara.edu.tr)

Ground Penetrating Radar (GPR) is used to identify the relatively shallow subsurface features at scale from centimeter up to meter. In this study dissolution of soluble rocks (Karst) including limestone and dolomitic limestone are examined using GPR and Raman spectroscopy methods around Adiyaman City in East Anatolia Turkey. Karstification led to form sinkholes, caves, and underground drainage systems. Rainwater becomes acidic as it comes in contact with carbon dioxide in the atmosphere and the soil. As it drains into fractures in the rock, the water begins to dissolve away the rock creating a network of passages. The step of the karst formation towards the inner parts of the surface of the limestone is determined using 250 and 500 Mhz GPR antenna. GPR attribute volumes is sensible and suggests that the formation of the cavities along the fracture packets exist over cavity floors elsewhere but that there is also variation in fracture intensity and in orientation over the whole system. The matrix consolidation and dissolution of the rocks are observed through the processing of the radar data.
The microscopically examination and Confocal Raman spectroscopy determination studies show the degree of the dissolution is increased towards the crack and aid to form ankerite, siderite, limonite, hydrous carbonate-sulfates, vermiculite clay minerals with rare amount of albite and pyrite.

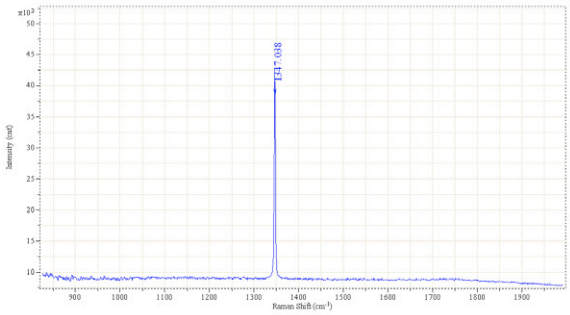
Diamond Bearing Mantle Xenoliths in Alkaline Basalts: Karacadağ Volcano, South East Anatolia, Turkey

YUSUF KAĞAN KADIOĞLU[12]

[1]Ankara University. Faculty of Engineering Department of Geological Engineering, Ankara, Turkey and kadi@ankara.edu.tr

[2]Ankara Uni. Earth Sciences Application and Research Center, Ankara, Turkey

Small Diamond crystals are determined by Raman spectroscopy within the mantle xenoliths from alkali basalts in Karacadağ Volcanic province South East Turkey. The peridotite mantle xenoliths are in the compositions of dunite and pyroxene bearing dunite and they are ranging from 1 cm up to 30 cm in size. The purpose of this contribution is to review the nature of the latest Cenozoic alkaline magmatism with respect to the geochemistry of mantle xenoliths. Diamond bearing Peridotite xenoliths in basalts of Karacadağ provide snapshots of the lithospheric mantle beneath particular regions at the time of their eruption and hence are crucial direct evidence of the nature of the mantle beneath regions. The diamond bearing peridotite mantle xenoliths suggests that these diamonds might be cogenetic with old rock provinces in the subcontinental mantle and then erupted with the latest events of the alkaline magmatism.



Raman Shift value of the diamond crystals within mantle xenolites of Karcadağ Basalts

HSE and S-Se-Te fractionation in components of enstatite chondrites

YOGITA KADLAG[1] AND HARRY BECKER[1]

[1]Institut für Geologische Wissenschaften, Freie Universität Berlin, Germany. yogita@zedat.fu-berlin.de, hbecker@zedat.fu-berlin.de

Enstatite chondrites show distinct fractionations of the highly siderophile elements (HSE) that may reflect volatility control or other types of partition processes [1, 2]. To investigate the origin of the fractionation of the HSE, S, Se and Te in enstatite chondrites, we have separated the components from the unequilibrated enstatite chondrites (EH3) Sahara 97072 and Kota Kota: magnetic, slightly magnetic and nonmagnetic components in five different grain size fractions, matrix, chondrules, CAIs (Ca-Al rich inclusions) and dark inclusions. Samples were analyzed following established techniques [2, 3].

Magnetic components of both meteorites (and the chondrule fraction of Sahara 97072) are enriched in HSE, S, Se and Te compared to the bulk rocks. Au is more enriched relative to the PGE and Re in the magnetic fractions, compared to non-magnetic fractions. In contrast, S, Se and Te in the magnetic fractions are always depleted compared to the HSE. The CAI fraction and a dark inclusion from Sahara 97072 are depleted in all elements (0.3*bulk) and show a similar abundance pattern as CI chondrites. Magnetic fractions display higher Re/Os (0.08-0.19) than most non-magnetic fractions, which have Re/Os lower than Re/Os of CI chondrites.

The relative enrichments, depletions and element fractionation in the components allow some preliminary conclusions: (1) Because metal rich components display strong enrichment of Au and Pd relative to refractory HSE, but depletion of Te-Se-S (with ratios relatively close to CI), the different groups of moderately volatile elements in metal rich components are decoupled. (2) In non-magnetic silicate rich fractions, Se and S are less depleted than HSE and Te, likely reflecting low-pressure metal-silicate-sulfide partitioning [4,5].

Transformation of Silver Nanoparticles: From the Sewer to the Fly Ash

R. KAEGI[1], A. VOEGELIN[1] AND B. THALMANN[1]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland (*correspondence: ralf.kaegi@eawag.ch)

Silver-nanoparticles (Ag-NP), used in textiles and cosmetics, will eventually be discharged to the municipal sewer system. We have shown that Ag-NP are efficiently transported along the sewer channel without substantial loss to the biofilm [1]. In the wastewater treatment plant (WWTP), partially sulfidized Ag-NP attach to the wastewater biomass and are removed from the wastewater stream. In parallel, the sulfidaton reaction proceeds and the Ag-NP are almost completely sulfidized when leaving the WWTP via the surplus sludge [2]. Ag_2S is very recalcitrant to oxidation as shown in a recent study where digested sludge was stockpiled for several weeks under oxic conditions [3].

In Switzerland sewage sludge is exclusively incinerated, in Germany about 50% with an increasing trend towards thermal sewage sludge disposal and on a EU level, about one third of the sewage sludge is incinerated. In order to allow for later phosphorus (P) recovery, sewage sludge has to be incinerated in monocombustion facilities. Until an economic and ecologic process for P recovery from sewage sludge ashes (SSA) has been found, the majority of the SSA are stored in separate deposits, although in Germany, a small fraction (5%) of the SSA is directly used as fertilizer.

X-ray fluorescence (XRF) analysis of fly ashes collected from monocombustion (fluid bed) facilities revealed Ag concentrations of ~10 mg/kg. X-ray absorption spectroscopy (XAS) analysis showed that Ag in the fly ash was dominantly Ag_2S. This result is in contrast to a recent study concluding that Ag_2S transforms into Ag(0) during the combustion [4], which would possibly have far reaching consequences regarding the direct application of SSA in agriculture. The differences are most likely caused by different combustion conditions between the two studies. We will further investigate the the fly ash samples using electron microscopy to assess whether silver is present in the form of nanoparticles.

Sulfur and halogen fluxes at mid-ocean ridges: Estimations based on gas compositions in MORB vesicles

T. KAGOSHIMA[1]*, Y. SANO[1], N. TAKAHATA[1] AND B. MARTY[2]

[1]AORI, Univ. Tokyo, Chiba, Japan (*correspondence: kagoshima@aori.u-tokyo.ac.jp)

[2]CRPG, CNRS, Nancy, France

Since S and halogens (F and Cl) form various compounds on the Earth's surface, their geochemical cycles are important issues in the Earth's evolution. Though fluxes of S and halogens at MORs have been estimated using compositions of chilled margins of MORB glasses characterised as those of silicate melts derived from the upper mantle, they may be somewhat overestimated [1]. Plausible estimations based on compositions of volcanic gases released as hydrothermal fluids are necessary. We characterised gas and melt compositions retained respectively in vesicles and solids of MORB glasses and estimated MOR fluxes of S and halogens.

We analyzed MORB glasses collected at 2 sites on East Pacific Rise, 2 sites on Mid-Atlantic Ridge and 2 sites on Central Indian Ridge. After extractions of gases in vesicles by the frozen crushing method [2], concentrations of ^{3}He were measured using a VG-5400 and those of S and halogens were measured using an ICS-2100. Concentrations of S and halogens in solids were measured using a NanoSIMS. We calculated relative molar ratios ($S/^3He$, $F/^3He$ and $Cl/^3He$) and estimated MOR fluxes of S and halogens calibrating against the known ^{3}He flux (527 mol/yr [3]).

For vesicle components, global averages of $S/^3He$, $F/^3He$ and $Cl/^3He$ are $(4.2\pm1.6)\times10^7$, $(1.4\pm0.7)\times10^6$ and $(2.6\pm1.0)\times10^7$. For bulk components, they are $(0.3–1.2)\times10^{10}$, $(1.6–6.5)\times10^9$ and $(0.7–3.0)\times10^9$, respectively. Using these ratios and the known ^{3}He flux, MOR fluxes were estimated to be $(2.2\times10^{10}–6.6\times10^{12})$ mol/yr for S, $(7.1\times10^8–3.4\times10^{12})$ mol/yr for F and $(1.4\times10^{10}–1.6\times10^{12})$ mol/yr for Cl. Assuming the continuous degassing from the solid Earth, formations of atmosphere and ocean can not be achieved by the low MOR fluxes estimated based on vesicle compositions. The amount of S accumulated on the surface are calculated to be 50 times lower than its surface inventory, and halogens are calculated not to be accumulated because of dominant influxes at subduction zones. This implies a possibility that the elements were significantly degassed in the early Earth.

Evaluating possible risks and benefits of nanopesticides application

M. KAH[1]*, S. BEULKE[2], K. TIEDE[2] AND T. HOFMANN[1]

[1]Department of Environmental Geosciences, University of Vienna, Austria
(*correspondence: melanie.kah@univie.ac.at)
[2]Food and Environment Research Agency, York, UK

Deliberate application of nanoparticles as plant protection products within agricultural practices could result in one of the rare intentionally diffuse inputs of engineered nanoparticles into the environment. The anticipated new or enhanced activity of nanopesticides will inevitably result in both new risks and new benefits to human and environmental health. It is unclear whether the current regulatory framework is adequate for the evaluation of these new products.

A literature review [1] was carried out with the objectives (i) to explore potential applications of nanotechnology within the pesticide formulation sector, (ii) to identify possible impacts on environmental fate, and (iii) to analyse the suitability of current exposure assessment procedures to account for their novel properties within the EU regulatory context. Nanopesticides encompass a great variety of products and cannot be considered as a single category. Nanopesticides can consist of organic ingredients (e.g., active ingredient(s), polymers) and/or inorganic ingredients (e.g., metal oxides) in various forms (e.g., particles, micelles). Studies on the environmental fate of nanopesticides are scarce. Possible effects of nano-formulations on the fate of the active ingredient can be complex and reported results are often contradictory.

The current level of knowledge does not appear to allow a fair assessment of the advantages and disadvantages that will result from the use of some nanopesticides. A great deal of work will be required to successfully combine analytical techniques that can detect, characterize and quantify the active ingredient and adjuvants emanating from nano-formulations, and also to understand how their characteristics evolve with time, under realistic conditions.

A more robust risk assessments framework for nanopesticides is urgently needed. In this context, priority for research are to (i) identify the assumptions currently applied that are not valid in the case of nanopesticides, (ii) evaluate the points or situations in which differences may impact significantly on the exposure assessment outcomes, and (iii) refine or adapt current assessment protocols as required.

Characterizing magma migration dynamics beneath Mt. Etna using combined kinetic and thermodynamic (MELTS) modelling

MAREN KAHL*[1 2], SUMIT CHAKRABORTY[2], FIDEL COSTA[3] AND MASSIMO POMPILIO[4]

[1]SEE, The University of Leeds, UK
(*correspondence: M.Kahl@leeds.ac.uk)
[2]GMG, Ruhr-University Bochum, Germany
(Sumit.Chakraborty@rub.de)
[3]EOS, Nanyang Technological University, Singapore
(fcosta@ntu.edu.sg)
[4]INGV - Sezione di Pisa, Italy (pompilio@pi.ingv.it)

Characterizing the routes of magma migration beneath active volcanoes is important to understand the dynamic processes in sub-surface magma plumbing systems. We present a method that combines kinetic (diffusion) and thermodynamic (MELTS) modelling of the chemical stratigraphy preserved in zoned olivine crystals to constrain the nature and dynamics of magma storage and migration beneath Mt. Etna. We used 180 olivine crystals erupted during several episodes between 1991 and 2008. The compositional and zoning record preserved in these crystals reveal five different olivine populations (i.e. Fo_{79-83}, Fo_{75-78}, Fo_{73-75}, Fo_{70-72} and Fo_{65-69}). These can be explained as the result of multistage magma mixing and magma exchange between at least four different magmatic environments (M_0 containing olivine of Fo_{79-83}; $M_1$with Fo_{75-78}, M_2 with Fo_{70-72} and M_3 with Fo_{65-69}). Two dominant magma migration routes (M_0-M_1; M_1-M_2) have been identified in the majority of the studied eruption products and thus might represent major pathways for magma transfer. Kinetic modelling of the compositional zoning observed in the olivines reveal that most of the timescales related to the transfer of magma between the environments M_0-M_1 as well as M_1-M_2 is less than three months, though a minor population of longer timescales ranging up to 3 years was also found. Combining these results with thermodynamic modeling using the MELTS thermodynamic database [1], we aim to characterize the ambient intensive variables (e.g. P, T, fO_2) along the two most prominent magma transfer routes (i.e M_0-M_1; M_1-M_2). Comparison of the obtained results with compositions of other mineral phases (i.e. Cpx, Plag and Ti-Mt) allows elucidating the P-T-fO_2-H_2O-time history of the magmas before eruption.

Geochemical and mineralogical properties of harzburgite and dunite in Margı (NE Eskisehir) Area

ASUMAN YILMAZ AND MUSTAFA KUŞCU SÜLEYMAN

[1]Aksaray Üniversitesi Mühendislik Fakültesi, Jeoloji Mühendisliği Bölümü (asuman27@hotmail.com
[2]Demirel Üniversitesi, Mühendislik Fakültesi, Jeoloji Mühendisliği Bölümü

Study area which located in the Izmir-Ankara suture zone is found Tavsanlı zone peridotites. Harzburgites which is a host rock of magnesite have been subject to severe serpentinization. Dunite consists of mostly olivine, very few orthopyroxene and opaque mineral chromite. Harzburgite contains olivine, orthopyroxene, serpentine, talc, opaque mineral magnetite and chromite. Chrysotile, lizardite are common and antigorite is a small amount serpentin mineral according to the XRD. Rock has sieve / network-glass clock texture because of widespread serpentinization. REE (Rare Earth Elements) values oh these rocks have positive La, Nd, Eu, Ho, Tm, Lu and negative Pr, Sm, Gd, Er, Yb anomaly by chondrites / normalized distribution and show rather depleted according to the chondrite. Can be said that mineral transformation temperature reaches amphibolite facies according to the mineral association.

Raduzhnoe – epithermal breccia-hosted deposit (Northern Caucasus, Russia)

E.N. KAIGORODOVA[1]

[1]Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry, Russian Academy of Sciences, Staromonetny per., 35, Moscow, Russia (katmsu@mail.ru)

The **Raduzhnoe deposit** is situated in the central part of North Caucasian Mountains within Jurassic depression zone, related with extensional-transtentional tectonic regime, forming horst and graben structures. Intensive tectonic and magmatic activity was associated with the closure of the Tethys Ocean and the Andean type of subduction. Block movements began in the Early Jurassic (Pliensbachian). Jurassic volcanic formations are represented by Aalenian basalt-rhyolite and Bajocian basalt-porphyry-trachytic formations. Rhyolites are the most common volcanic rocks at this area. Epimagmatic hydrothermal activity related to rhyolites led to: broad development of processes of silicification of host rocks, less their kaolinization, carbonation, sulphidation, baritization, chloritization, the widespread expression of alkaline metasomatism.

The ore occurrences are confined to the PZ granite ledge and zones of intense brecciation. Composition of the breccias is quite diverse. Breccias have been changed in a varying degree during gas-hydrothermal activity. Ore minerals which have been identified at Raduzhnoe are native gold, calaverite, dyscrasite, proustite, sulfides. Au content reaches up to 215 g / t, Ag and 4000 g / t.

At the deeper levels of the breccias the pyrite content increases and galena, sphalerite and chalcopyrite appear. Polymetallic mineralization is mainly associated with hydrothermally altered basement granites and Pliensbachian sandstones. Gold and silver are being in a finely dispersed state in sulfides.

Thus, at the Raduzhnoe there are allocated two types of mineralization: gold-silver (low-sulfidation gold-sylver type) and gold-silver-containing polymetallic (low-sulfidation silver-gold-base metal type) [1]. Probably gold-silver-polymetallic mineralization is earlier process and is associated with developing of the global Jurassic polymetallic belt of the North Caucasus. Gold-silver subtype of mineralization is more recent, local and related to the final (solfatara) stage of volcanism.

Origin of secondary REE minerals in grusified Karkonosze granites, SW Poland

BARTŁOMIEJ KAJDAS[1]* AND MAREK MICHALIK[1]

[1]Institute of Geological Science, Jagiellonian University, Kraków, Poland; (*correspondence: xszerlit@gmail.com)

Primary monazite-(Ce), which is one of the most common accesory mineral in Karkonosze granites, is absent in grusified granites from Głębock, Kowary Średnie and Miłków. In the grusified granites muscovite–thorite or cheralite–xenotime-(Y) pseudomorphs after primary monazite-(Ce) are present. Instead of monazite-(Ce) in grusified granites secondary rhabdophane-(Ce), florencite-(Ce), cerianite-(Ce), rhabdophane-(La) and rhabdophane-(Nd) are present.

Small (about 5 μm) automorphic crystals of rhabdophane-(Ce) and florencite-(Ce) occur inside sericitised plagioclases often along clevage planes of primary feldspar. Cerianite-(Ce) occurs as thin veins or as clusters of crystals impregnating rims of the grains of grus. Rhabdophane-(La) and rhabdophane-(Nd) crystals are usually small, xenomorphic and fill large cracks inside the grains of granitic grus.

Decomposition of primary monazite-(Ce) might be the result of the activity of hydrothermal fluids [1], which could be also the main factor of the development of microcracks in granite that led to the development of grus. REE released from the decomposed monazite-(Ce) crystalized as secondary rhabdophane-(Ce) and florencite-(Ce). Chemical analysis of primary monazite-(Ce) from Karkonosze granite and secondary rhabdophane-(Ce) and florencite-(Ce) shows, that ratios of REE in primary and secondary REE phosphates are very similar.

Secondary cerianite-(Ce), rhabdophane-(La) and rhabdophane-(Nd) crystallisation could be caused by low temperature weathering, oxidizing fluids [2].

Decomposition of primary REE minerals and multistage crystalisation of secondary REE minerals in grusified granites indicates that process of grusification *sensu stricto* was proceded by activity of hydrothermal fluids, which developed microcracks in the rock and caused brakedown of primary minerals including REE phosphates. Similar observations were obtained in grusified Tatra granites [3].

Addressing the nanoscale complexity of mineral-water interfaces in MD simulations: Effects of the substrate compositional disorder on the properties of surface species

ANDREY G. KALINICHEV[1]*, NARASIMHAN L.[1] AND BRICE F. NGOUANA W.[1],

[1]Laboratoire SUBATECH (UMR-6457), Ecoles des Mines de Nantes, 4 Rue Alfred Kastler, La Chantrerie, 44307, Nantes Cedex 3, France (*kalinich@subatech.in2p3.fr)

Thermodynamic, structural and transport properties of hydrated clays and clay-related materials for many geochemical, environmental, and technological applications are routinely studied by computational molecular modeling techniques. However, simulated system size limitations often impose a considerable quasi-periodicity on the distribution of the tetrahedral and octahedral site substitutions in the T-O-T clay layers. Such quasi-periodicity is then typically propagated further even if larger models are later constructed by simply multiplying the smaller ones, and the effects of this imposed structural ordering on the calculated properties of the interfaces is not obvious.

Here we report the results of molecular dynamics simulations with a new set of larger-scale muscovite and montmorillonite models which were systematically constructed to introduce as much structural disorder in the distributions of the Al/Si and Mg/Al substitutions as possible. The effects of such disorder on the local structural and dynamic properties of the interfacial and interlayer water and hydrated ions are then carefully quantified and analyzed for a number of typical monovalent and divalent cations.

The time- and space- averaged properties of the hydrated interfaces and interlayers, such as atomic density profiles, radial distribution functions, and surface diffusion coefficients, are observed to be not particualrly sensitive to the specific details of the substrate disorder. However, local effects of the disordered distribution of charge-substituted sites in clay layers can be substantial and can influence the strength of the ionic and molecular adsorption at a specific surface site, the structure and dynamics of the interfacial hydrogen bonding network around it, and the molecular mechanisms of its local rearrangement.

Putting age into the equation: A new look at microbial distribution in subseafloor sediments

JENS KALLMEYER[1]

[1]Helmholtz Centre Potsdam, GFZ German Research Centre For Geosciences Telegrafenberg, 14473 Potsdam, Germany, kallm@gfz-potsdam.de

At any given depth cell abundance in subseafloor sediments varies by up to six orders of magnitude between sites. To a large extend this variability correlates with mean sedimentation rate and distance from land. This relationship can therefore be used to predict subseafloor cell abundance.

Usually, decrease in subseafloor microbial abundance at each site can be described by a logarithmic function. However, at some sites, e.g. IODP Exp. 320, Site U1334 from the equatorial Pacific Ocean, cell distribution strongly deviates from this trend and cannot be described by a simple equation.

In order to better understand why cell distribution at some sites exhibits such unusual patterns it is necessary to take a closer look at sedimentation rates and therefore sediment ages as well. The sites that were drilled by IODP Exp. 320 and 321 recovered a continuous Cenozoic record of the paleoequatorial Pacific by coring above the paleoposition of the highly productive equatorial upwelling zone at successive crustal ages on the Pacific plate. Although some of the unusual cell distribution is caused by strong geochemical gradients and diagenetic alteration fronts, the significant differences in sedimentation rates between within and outside the upwelling zone appear to be a major cause for the strong deviations in cell abundance from the expected logarithmic decline with depth.

Subseafloor microbial communities have to subsist without fresh supply of organic matter, which becomes increasingly recalcitrant with increasing age. When assigning ages to cell count data from different oceanic regions, these cells vs. age correlation show less variability between sites than correlations vs. depth.

These observations suggest that subseafloor microbial abundance is controlled by organic matter reactivity, which is largely controlled by sediment age. Using age instead of depth models might provide important clues about the finer details of subseafloor cell abundance, especially in areas that have not fitted into previous models.

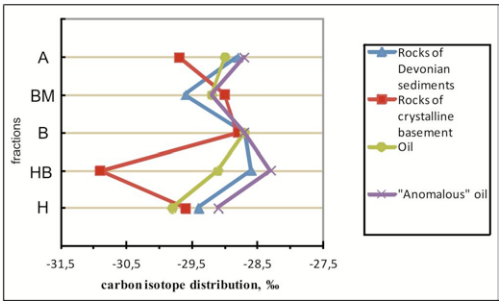
Biogenic or abiogenic hydrocarbon source of Melekes Depression

A.I.KAMALEEVA* AND E.M.GALIMOV

Vernadsky Inst. of Geochemistry and Analytical Chemistry RAS, Kosygin 19, Moscow, 119991 Russia (*correspondence: adelya-kamaleeva@yandex.ru)

The question of hydrocarbon origin is an important problem in Tatarstan, where some of the geologists suggest the existence of abiogenic hydrocarbon “inflow” to sedimentary oil fields. Core samples for the study of the organic matter were taken from Devonian sediments (DS), as well as from the rocks of the crystalline basement (CB). The oil was taken from the main productive complexes of seven fields within the studied areas and from the so-called "anomalous" boreholes of the Romashkinskoye supergiant field, where the inflow of deep hydrocarbons is possible. The distribution of the isotope ratios of carbon between different fractions was studied in oil and extracted bitumoids of rocks by the method [1].

In the studied oil the sufficiently common type of carbon isotope distribution by fractions was found (Figure). This type of oil consists of the sapropelic type of organic matter and mixed type, which is formed by a certain percent of humus and aquahumus materials. The "anomalous" oil completely coincides with other samples of oil. So there is no reason to assume for them any other source of hydrocarbons. Bitumoids extracted from the organic matter of DS, with a few exceptions, are of the same genetic type as the studied oil.



Bitumoids extracted from the rocks of CB carry traces of thermal and hydrothermal effects missing in the oil of sedimentary strata [2]. Therefore, they may be the product of thermal alteration of sedimentary naphtides but cannot be primary with regard to the last one. Thus, the biogenic hydrocarbon source of Melekes Depression is proved.

The evolving nature of terrestrial crust from the Hadean, through the Archaean, into the Proterozoic

BALZ S. KAMBER[1]

[1]Geology Department, Trinity College Dublin, Ireland

The ancient rock and mineral records show that Hadean crust could persist for 500-700 Ma. Notwithstanding the general longevity of evolved crust, the well-established major Precambrian time boundaries remind us that terrestrial geology did not proceed in a uniform manner. The Hadean-Archaean boundary witnessed the near-complete destruction of the Hadean crust. This crust was chemcially diverse, and at least the zircon bearing magmas formed at relatively low T and had interacted with the hydrosphere. Opinions diverge as to whether these attributes imply plate tectonics. Advocates of the existence of Hadean continental lithosphere have yet to propose a plausible mechanism by which this lithosphere was destroyed. Those who appeal to internal differentiation of largely basaltic crust, aided by volcanic resurfacing, can appeal to the episodic collapse of early planetary crustal lids to explain the disappearance of Hadean crust.

Regardless of this unresolved debate, agreement exists that the entire Archaean record is dominated by greenstone-granitoid terrains. The much-improved greenstone belt geochronological database demonstrates that most of these edifices grew vertically, by repeated eruptions of new volcanic sequences on top of older ones. Although they do not represent oceanic crust, the existence of subduction and subductable oceanic lithosphere can be inferred from a variety of observations, ranging from granitoid geochemistry to diamond inclusions. It is thus proposed that the Archaean represents the era of three types of plates: continental and oceanic lithosphere as well as prominent oceanic plateaus.

The Palaeoproterozoic rock record differes in many ways. Greenstone belts have disappeared, platform sediments have become abundant and the first very high-P rocks are preserved at the Earth's surface. These phenomena reflect a change in the mechanical stength of the continents, which increased due to less internal heat production and redistribution of K, Th and U. However, the disappearance of komatiites and the unexpected lack of increase in extent of mantle depletion from 2.7 Ga to 2.0 Ga argue for mantle reorganisation. It is here proposed that a mechanical and thermal boundary layer existed in the mantle transition zone until the end of the Archaean. This led to severe depletion in the upper mantle, promoted build up of heat plumes and prevented recycling of oceanic plates into the deep mantle. Accordingly, the onset of deep recycling is dated by the ca. 2 Ga 'age' of OIB sources.

A first-order deep time reconstruction of the marine Sr/Ba ratio from microbial carbonate

BALZ S. KAMBER[1], THOMAS F. NAEGLER[2], ELIZABETH C. TURNER[3], GREGORY E. WEBB[4] AND CHLOÉ PRETET[5]

[1]Geology Department, Trinity College Dublin, Ireland
[2]Geological Sciences, University of Bern, Switzerland
[3]Earth Sciences, Laurentian University, Sudbury, Canada
[4]Earth Sciences, The University of Queensland, Australia
[5]Earth Sciences, University of Geneva, Switzerland

The upper crust is enriched in Sr and Ba where they occur at a mass ratio of ca. 1.25. The dissolved river load has a Sr/Ba of ca. 1.8, whereas residual weathering profiles have a Sr/Ba of ca. 0.9, showing that Sr is more easily released. In our estuarine transects both elements behave conservatively. Once in the ocean, the fates of Ba and Sr diverge sharply. Sr has a long residence time and is homogenously distributed whereas dissolved Ba concentration in seawater is very low and varies systematically with depth [1] (very depleted in the shallow ocean and more enriched at depth). The overall depletion and the depth structure are explained by Ba-removal as biogenic marine barite in organisms and its partial re-release at depth. Hanor [2] predicted that this type of barite formation may not have been constant through time and that marine Ba could be a proxy for sulphate concentration.

Our data from Holocene microbial carbonate faithfully record the very high but variable Sr/Ba (400-1,200) of very shallow seawater. In situ LA-ICP-MS of partly dolomitised samples clearly indicate that dolomitisation greatly increases the Ba content and our deep time reconstruction was conducted on best preserved calcite only. The reconstruction shows a very clear first-order Sr/Ba topology. The ratio remained very high (>>200) back to 555 Ma, decreased rapidly throughout the Proterozoic to 2-5 until the Great Oxygenation Event, before which it was quite constant at 10. This evolution is interpreted as a three step increase of marine sulphate levels. A second-order control on the shape of the Sr/Ba topology can be inferred from the absolute Sr and Ba concentrations in the microbial carbonate, which, for Sr, was much lower for most of the Precambrian but increased strongly after the Marinoan. This is important as it suggests a much reduced nutrient load to the Precambrian ocean with wide implications for other deep time studies (e.g. Mo in shale) that assume variable removal but constant supply of metals.

PGE-Au potential of sulphide-saturated melts from the subcontinental lithosphere

V. S. KAMENETSKY[1], R. MAAS[2], R.O.C. FONSECA[3], C. BALLHAUS[3] AND A. HEUSER[3]

[1]University of Tasmania, Hobart, TAS 7001, Australia; Dima.Kamenetsky@utas.edu.au
[2]University of Melbourne, VIC 3010, Australia
[3]Universität Bonn, Bonn 53115, Germany

The origin of platinum element metal (PGE) enrichment in large magmatic nickel sulphide deposits is controversial; both primary magmatic and hydrothermal processes have been invoked. Irrespective of their exact mode of deposition, the ultimate source of such extreme enrichments of these rare metals must be PGE-enriched parental silicate melts capable of reaching sulphide saturation and efficient PGE capture in immiscible sulphide liquids. Direct observation of coexisting primary silicate and sulphide melts at the onset of silicate-sulphide liquid is impossible because of intense magmatic processing up until ore deposition. Here we report the discovery of Fe-Ni sulphide melt globules highly enriched in noble metals (Pt, Pd, Os, Ir, Au, Ag; total 150 ppm) within an unusual high-Mg andesitic glass dredged from the southern Mid Atlantic Ridge [1]. The composition of this primitive glass (8.2 wt% MgO, Mg# 67.1 mol%) indicates derivation of its parental silicate melt from a garnet pyroxenite mantle source with pronounced 'continental' isotopic (Pb, Sr, Nd, Hf, Os, O) signatures [1]. We infer that the chemical properties of this melt, notably high SiO_2 (57.3 wt%) and Ni (310 ppm) contents, promoted sulphide saturation at low pressures in a purely oceanic setting and propose that this unique example, with its likely origin in the continental lithospheric mantle, may be a useful analogue for magmatic PGE enrichment and incipient Ni-PGE- sulphide melt generation within large Ni-PGE magmatic sulphide systems.

A two-stage scenario for the formation of the Earth's mantle and core

E. KAMINSKI[1]* AND M. JAVOY[2]

[1]Institut de physique du globe de Paris, 75005 Paris, France, (*correspondence: kaminski@ipgp.fr)
[2]Institut de physique du globe de Paris, 75005 Paris, France, (javoy@ipgp.fr)

Various geophysical constraints on the deep Earth point to a chemically heterogeneous mantle. Based on such constraints, Bulk Earth compositions inferred from Enstatite chondrites (E-Earth composition) predict that, whereas the Primitive Upper mantle (PUM) had a pyrolitic composition, the Primitive Lower mantle (PLoM) was enriched in Fe and Si and depleted in Mg, Ca and Al relative to PUM. We will explain how, in E-Earth formalism, this chemical heterogeneity can be related to the formation and differentiation of the Early Earth, and mantle Si and Fe variations reflect variations in the efficiency of Si and FeO dissolution in the metal phase during core formation, through the reaction $SiO_2+2Fe_{metal}=Si_{metal}+2FeO$ which increases progressively the fO_2 of the silicate. In the simplest and most direct scenario of homogeneous accretion, we calculate by mass balance the composition and the mass fraction of the metallic extract in equilibrium with a pyrolite. The O, Si and Ni contents of this metal extract correspond to a silicate-metal equilibrium at high pressure (50±5 GPa) and high temperature (3500±500ºC), in line with a giant impact scenario. The mass of pyrolite produced during that stage is significantly smaller than the mass of the Bulk Silicate Earth. Mass balance calculations then yield the composition of the proto-core and the proto-mantle prior to the giant impact. We obtain that the core of the proto-Earth was almost devoid of oxygen, hence formed under lower pressure and temperature conditions, in agreement with an early differentiation of planetesimals in the early solar system. In such a two-stage scenario of Earth's core formation, no massive silicate differentiation is required to create a pristine mantle heterogeneity. The concentration of lithophile elements in the Primitive Lower mantle, notably Ca, Al, U and Th, can then be constrained using RLE ratios in E-chondrites and in the upper mantle.

New minerals in the primary, deep-seated carbonatitic association

FELIX V. KAMINSKY[1]* AND RICHARD WIRTH[2]

[1]KM Diamond Exploration Ltd., West Vancouver, Canada
*correspondence: felixvkaminsky@aol.com
[2]GeoForschungsZentrum, Potsdam, Germany

In one of newly studied diamonds from the Juina area, Brazil, several new polymineral inclusions of the carbonatitic association were identified. The hosting diamond belongs, like most of the diamonds from this area, to the Deep Earth. The composite carbonate-halide-phosphate inclusion consists of magnesite, dolomite and mixed-anion phosphate micrograins along with nanograins of eitelite, halite, sylvite, phlogopite, spinel and pentlandite. The inclusion has a 'negative' shape, typical for syngenetic inclusions in diamond. The mineral assemblage comprising this inclusion belongs to the carbonate-chloride line of the primary, deep-seated carbonatitic association, which has been established among inclusions in diamond in our earlier works [1, 2]. Three new minerals for this association were identified in this inclusion: magnesite, eitelite and a mixed-anion phosphate, $Na_4Mg_3(PO_4)_2(P_2O_7)$. The presence of magnesite, within this new mineral association, provides evidence for its stability in the diamond stability field, which was earlier questioned; magnesite had been suggested to decompose with the formation of ferropericlase and diamond. Eitelite, $Na_2Mg(CO_3)_2$, has been identified previously in alkaline-carbonatitic rocks of the Khibini Massif, Kola Peninsula, Russia [3]. The mixed-anion phosphate, $Na_4Mg_3(PO_4)_2(P_2O_7)$, has not previously been observed in the natural environment before. This mineral contains an admixture of FeO (up to 6 at.%). In other carbonatitic inclusions, Fe-phosphate $Fe_2Fe_5(P_2O_7)_4$, and aluminium fluoride AlF_3 were identified. They were found in the natural environment for the first time as well. The carbonatitic inclusions most likely originated as a high-density fluid (HDF) micro-inclusions, encapsulated in diamond during its initial growth. Such inclusions are fully miscible under mantle conditions and subsequently crystallize as polyphase mineral inclusions, during ascent of diamond to the Earth's surface.

Sampling a natural CO_2 reservoir, Green River, Utah

NIKO KAMPMAN[1], MIKE BICKLE[1], HAZEL CHAPMAN[1], ALEX MASKELL[1], JIM EVANS[2] AND ANDREAS BUSCH[3]

[1]Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge CB2 3EQ (correspondence: nkam06@esc.cam.ac.uk)
[2]Department of Geology, Utah State University, 4505 Old Main Hill Logan, UT 84322-4505 16
[3]Shell Global Solutions International, Kessler Park 1, 2288 GS Rijswijk, The Netherlands

We present the initial results from a scientific drilling project to recover core and high pressure fluid samples from a natural CO_2 reservoir near Green River, Utah. We use this as an analogue to investigate fluid-flow and CO_2-fluid-mineral interactions with caprocks and fault zones likely during anthropogenic storage of carbon dioxide

Diamond drilling of drill-hole CO_2W55, adjacent to the CO_2-degassing Little Grand normal fault, recovered core from two major CO_2 reservoirs in the Entrada and Navajo Sandstones, and from the intervening Carmel Formation caprock. The well encountered CO_2-charged fluids in the basal sandstones of the Entrada Sandstone, in open fractures in the footwall damage zone of the fault penetrating the Carmel Formation, and throughout the Navajo Sandstone. Downhole wireline fluid sampling to recover high-pressure CO_2-charged fluids during drilling, and analytical methods to measure their dissolved CO_2 content and pH on-site, are presented and discussed. Measurements of CO_2 concentrations, fluid chemistry and isotope ratios from the drill-hole fluid samples are used to constrain fluid-fluid mixing, fluid-rock reactions and dynamics of CO_2 migration within the fault damage zone. Fluid-mineral reactions predicted from fluid geochemistry are compared to petrological, mineralogical, geochemical and petrophysical measurements from the reservoir and caprock core, and the implications for reservoir alteration and caprock performance are discussed.

Here, we report on the accumulation of high levels of cyanide as free cyanide, complexed cyanide, iron-cyanide, and thiocyanate in sediments of the non-polluted Delaware Great Marsh (up to 230 μmol kg^{-1}). Free cyanide at concentrations which are toxic to aquatic life (up to 1.92 μmol L^{-1}) were detected in sediment pore-waters, and the concentration of total (free and complexed) cyanide in the pore waters was found to be as high as 6.94 μmol L^{-1}. The presence of hydrogen cyanide in the salt marsh sediments is attributed to processes associated with decomposition of cord grass *Spartina alterniflora* roots. The formation of iron-cyanide complexes and their adsorption onto sedimentary organic matter provide a temporary sink of cyanide, but the ultimate cyanide sink is associated with the formation of thiocyanate by reaction with sulphide oxidation products, principally polysulfides, formed by reaction with by Fe(III) minerals. The formation of thiocyanate by this pathway detoxifies two poisonous compounds, polysulfides and hydrogen cyanide, in the salt marsh sediments [1]. Thiocyanate is stable under anoxic conditions, but diffuses freely through sedimentary pore waters to upper oxic sediment layers, where it may be oxidized by biologically assisted processes either to carbonyl sulfide and ammonia or to cyanate and hydrogen sulfide. Thiocyanate was also detected at concentrations up to 288 nmol L^{-1} in the water column of Lake Rogoznica (Croatia) [2] and up to 274 nmol L^{-1} in the water column of Fayetteville Green Lake (NY). Here, thiocyanate appears to be produced in the sediment and diffuse towards the chemocline, where it is consumed by abiotic or biologically enhanced oxidation.

Petrogenesis and tectonic setting of the Nasrand granitoid pluton, southeast of Ardestan

ALI KANANIAN*, ZAHRA HAMZEHIE, FATEMEH SARJOUGHIAN AND JAMSHID AHMADIAN

Kananian@Khayam.ut.ac.ir 1 zahra.hamzei@ut.ac.ir Fsarjoughian2@gmail.com, jamshidahmadian@yahoo.com

The Nasrand pluton of Oligo-Miocen age, which is located in south-east of Ardestan, intruded into Eocene volcanic rocks of the Urumieh-Dokhtar magmatic belt. This pluton consists mainly of granite and granodiorite, and has been intruded by a series diabase dikes. The nasrand plutonic rocks are metaluminous, with mineralogical and geochemical characteristics of I-type calc-alkaline to high-K calc-alkaline granite. They are characterized by enrichment of LREE and LILE, depletion of HREE and HFSE, negative anomalies of Ti, Nb, P, Ba, and positive anomalies of U, K, Th, Rb, Ba, associated with high Ba/Nb ratio and interpreted to reflect emplacement of the plutonic rocks in an active continental margin. The Nasrand granitic pluton and its diabase dikes were all derived from partial melting of the lower continental crust, but it seems that the granitic rocks are slightly more fractionated than diabase dikes and may be modified by assimilation of upper crustal materials.

Keywords: Ardestan, I type granite, calc-alkaline, diabase dikes, active continental margin.

Mineralogical, petrographical and geochemical investigation of Tefenni-Burdur chromite occurences

ALEV KAN BOSTANCI[1], DEMET KIRAN YILDIRIM[1], MUHITTIN KARAMAN[1], ANIL SENA SERT[1] AND MURAT BUDAKOĞLU[1]

[1]Istanbul Technical University, Department of Geological Engineering, 34469, Istanbul, TURKEY

The lithological units are consist of Late Jurassic – Early Createaous aged Yeşilova ophiolites, Upper Cenonian aged Kızılcadağ ophiolitic melange, Pliyo-Quaternary aged Niyazlar Formation and Quaternary aged alluvions in the investigation area.

Yeşilova ophiolite consist of tectonites, ultramafic and mafic cumulates, isotropic gabbros, plagiogranites and basalts from bottom to top. Yeşilova ophiolite in which sheeted dike complex and pillow lavas are not seen, represents an ophiolite group with missing row character.

In the bottom of the Yeşilova ophiolite there are tectonics ,which is composed of harzburgite, dunite, serpantinized harzburgite and dunite, serpantinite and chromite masses with dunitic envelope. Tectonites are mostly serpantinized in parts where mafic dikes are dense and along tectonic lines. Tectonites are cut by many mafic dikes.

According to the metamorphic paragenesis determined in the oceanic crust rocks forming Yeşilova ophiolite, it is metamorphised in P/T situations which does not reach the sub limit of greenschist facies.

Upper Cenoniyen aged Kızılcadağ ophiolitic melange takes place tectonically on Yeşilova ophiolite. Tectonic boundry between these to units is nearly horizontal.

Role of submicron-sized particles on the ^{134,137}Cs migration in Fukushima

M. KANEKO[1], Y. NAKAMATSU[1], T. OHNUKI[2], K. NANBA AND S. UTSUNOMIYA[1]

[1]Dept. Chemistry, Kyushu University, Fukuoka 812-8581, Japan (utsunomiya.satoshi.998@m.kyushu-u.ac.jp)
[2]ASRC, Japan Atomic Energy Agency, Tokai, Japan
[3]Dept. Environmental Management, Fukushima University

In the vicinity of Fukushima Daiichi Nuclear Power Plant (FDNPP), ^{137}Cs ($T_{1/2}$ = 30.07 y) and ^{134}Cs ($T_{1/2}$ = 2.062 y) have great contribution to the radiation dose. Although the initial distribution of radionuclides derived from FDNPP accident have been reported to date, there are limited knowledge on micron- and submicron-scale distribution and migration of ^{134,137}Cs in the surface and sub-surface environments. In order to understand the fundamental mechanism of ^{134,137}Cs retention and migration in the contaminated area in Fukushima, Cs speciation in various environmental samples (soils, aerosol and groundwater) is investigated, which were collected from severely contaminated area in Fukushima.

In the soil samples, the vertical profile of ^{134,137}Cs distribution revealed that >98% of ^{134,137}Cs remained within top 5 cm. Sequential extraction of the contaminated soils revealed that most ^{134,137}Cs was strongly bound to high-affinity site of clay minerals such as illite and montmorillonite, while upto 20% of ^{134,137}Cs was present as an ion exchangeable form, suggesting that elution of ^{134,137}Cs from soil minerals would be minimal in the surface environment in Fukushima. In the size fractionation experiment, ~78% of ^{137}Cs was distributed in the colloid region (<1 μm) and the concentration was as high as ~3,000,000 Bq/kg. The ^{137}Cs radioactivity of airborne particles collected in Iitate was measured to be 12.2, 15.7, and 11.8 mBq/m^3 for the size fractions of <0.4, 0.4-2.5, and >2.5 μm, respectively. ^{134,137}Cs were under the detection limit in the groundwater samples. These results clearly indicate that ^{134,137}Cs have not migrated to the groundwater system until one year after the accident, and the airborne Cs-particles were mainly derived from suspension of the fine fraction of the contaminated soils, namely Cs-bearing clay minerals.

The present study strongly suggests that the migration of ^{134,137}Cs in the surface and sub-surface environment is not governed by the adsorption-desorption cycle but by the behavior of Cs-adsorbed submicron-sized particles. Therefore, the unique physico-chemical property of Cs-bearing colloids should be taken into account for predicting the future behavior of ^{134,137}Cs in the surrounding environments in Fukushima.

A Ni porphinoid, coenzyme F430 is the prosthetic group of methyl-coenzyme M reductase, which catalyse a final step of methanogenic reactions in all methanogenic pathways including CO_2 resuction, acetate fermentation and methylotrophic pathyways[1]. F430 is unstable, hence native F430 will not be persisting in sediments through a geologic time scale. Given its unique structure, functionality and lability, F430 can be a robust biomarker for a quantitative estimation of *in situ* activities of living methanogens.

Conventionally F430 was analyzed photometrically using HPLC or off-line MS [2]. Recently we have developed a high sensitive detection of F430 by a HPLC-MS/MS. This sensitivity (femto mol level) is 10^4 to 10^5 times higher than the conventional photometric dection and only 10^2 to 10^4 methanogen cells are required for quantification of F430 in environmental samples. Our analyses indicated that concentration in paddy field ranges between 9870 and 253 fmol/g which is 1-2 orders of magnitude higher than those in marne sediments off Japan, ranging between 100 and 7 fmol/g, and 1910 fmol/g from Peru Margin (68 mbsf).

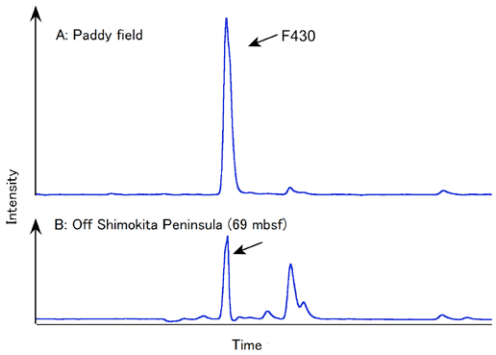

Fig. 1. HPLC-MS/MS chromatograms of derivatized F430 from a paddy field and marine sediment.

Biomineralization of Strontianite ($SrCO_3$) by *Proteus mirabilis*

SERKU KANG[1], YUMI KIM[2], AND YUL ROH[3]*

[1]Chonnam National University, Gwangju, Korea, (chodang02@naver.com)
[2]Chonnam National University, Gwangju, Korea, (yumddalki@hotmail.com)
[3]Chonnam National University, Gwangju, Korea, (*correspondence: rohy@jnu.ac.kr)

Microbially induced mineralization of carbonate minerals has drawn much attention in recent decades because of its practical applications such as atmospheric CO_2 fixation through mineral carbonation and solid phase capture of toxic radionuclide or metal contaminants (i.e., ^{90}Sr, ^{60}Co and Cd). The objectives of this study were to investigate the potential for microbially induced precipitation of strontianite ($SrCO_3$) using microorganisms enriched from rhodoliths and to identify mineralogical characteristics of the bio-precipitates.

Carbonate forming microorganism (CFM) was enriched from rhodoliths and aerobically cultured at 25°C in D-1 medium containing 30 mM Sr-acetate. The microorganisms were analyzed by 16S rRNA gene DGGE analysis to confirm microbial diversity. Mineralogical characteristics of the bio-precipitates were determined by XRD, TEM/SEM-EDS analyses.

A 16S rRNA sequence analysis showed the CFM was mainly *Proteus micrailis* [1]. The growth of CFMs gradually increased for 16 days (OD_{600} = 2.613) and then decreased until 22 days (OD_{600} = 2.016) of incubation. Medium pH in the biotic group increased from acidic at first (pH = 5.3) to alkaline condition (pH = 8.6). The pH changes might induce favorable geochemical condition for Sr-carbonate precipitation. In the abiotic group, neither growth of microorganism nor changes in pH were detected.

The enriched microorganisms mediated the precipitates in D-1 medium containing 30 mM Sr-acetate. The bio-precipitates were identified strontianite ($SrCO_3$) by XRD analysis. SEM-EDS analyses showed that the precipitates were round in shape, and around 60 ㎛ in size, and composed of C, O and Sr. TEM-EDS analyses showed that the Sr-carbonate minerals were irregular in shape, 60~70 nm in size, and composed of C, O, and Sr.

These results indicate that the CFM induce the precipitation of strontianite ($SrCO_3$) by biological processes. Therefore, CFM such as *Proteus micrailis* may play one of important roles in Sr immobilization in Sr-contaminated water and CO_2 fixation in natural environments.

Pb, Sr, Nd, Hf isotope geochemistry of South Arch lavas: Origin of the upstream side Hawaiian arch volcanism

T. KANI[1]*, B. B. HANAN[2], R. KINGSLEY[3] AND J.-G. SCHILLING[3]

[1]Kumamoto University, Kumamoto 860-8555, Japan (*correspondence: kani@sci.kumamoto-u.ac.jp)
[2]San Diego State University, San Diego, CA, USA (bhanan@mail.sdsu.edu)
[3]GSO, University of Rhode Island, RI, USA

South Arch volcanic field is located on the crest of a broad swell surrounding the Hawaiian Islands, 200 km south of Kilauea, along the peripheral edge of the radially dispersing mantle plume stream, diverted to the NW by the migrating Pacific lithospheric plate.

Pb, Sr, Nd and Hf isotope compositions of 14 alkali basalts collected at water depths > 4 km by JAMSTEC Kaiko and Shinkai dives (K217 and S697), distinguish these magmas from shield tholeiites, rejuvenated stage, and North Arch lavas. Pb isotope compositions of South Arch lavas are more radiogenic compared to North Arch and rejuvenated lavas, but similar to Kea lavas, confirming plume compositional influence on the upstream plume periphery is stronger than downstream. In Pb-Sr-Nd multi-isotope binary plots the data clusters, with little variation, and no apparent correlation. The $^{87}Sr/^{86}Sr$ is lower and the ε_{Nd} higher than Hawaiian shield tholeiites indicative of a depleted source. Plots of ε_{Hf} against ε_{Nd}, $^{87}Sr/^{86}Sr$ or $^{206}Pb/^{204}Pb$ define trends oblique to the mantle array. The variation is in ε_{Hf} essentially at constant ε_{Nd}, $^{87}Sr/^{86}Sr$ or $^{206}Pb/^{204}Pb$. These relationships cannot be explained by seawater or sediment contamination, but could result from metasomatism. The results suggest that the South Arch basalt source consists of metasomatised oceanic lithosphere and plume components. The isotope characteristics of the South Arch lavas could be interpreted to represent metasomatised Pacific lithosphere, residue of a MORB-related melting event at ~100 Ma, modified by plume fluids and melts. Alternatively, the South Arch mantle source may be ancient recycled oceanic lithosphere, part of the Hawaiian plume.

Diagnosing the hydroclimate influences on soil water $\delta^{18}O$: Precipitation $\delta^{18}O$, evaporation, or moisture transport?

LISA KANNER[1]*, NIKOLAUS BUENNING[1], LOWELL STOTT[1], AXEL TIMMERMAN[2], DAVID NOONE AND LISA SLOAN[4]

[1]University of Southern California, Los Angeles, CA, USA lkanner@usc.edu, buenning@usc.edu, stott@usc.edu (*presenting author)
[2]University of Hawaii, Honolulu, HI, USA, axel@hawaii.edu
[3]University of Colorado, Boulder, CO, USA, dcn@coloradu.edu
[4]University of California - Santa Cruz, Santa Cruz, CA, USA, sloan@ucsc.edu

The stable oxygen isotopic composition of soil water that is incorporated into paleoclimate proxies is often assumed to be the same as precipitation $\delta^{18}O$ in order to obtain information about past hydroclimate variations. For example, the $\delta^{18}O$ of soil water, when taken up by tree roots, is transferred to the $\delta^{18}O$ of xylem water and eventually incorporated into the tree cellulose. Thus, implicit in the use of cellulose $\delta^{18}O$ as a proxy for precipitation $\delta^{18}O$ is that evaporative influences on soil water $\delta^{18}O$ do not overprint the precipitation $\delta^{18}O$ signal.

In this study, we use an isotope-enabled land surface model (IsoLSM) to diagnose environmental influences on soil water $\delta^{18}O$ across seasonal to interannual timescales. An unpeturbed control simulation from 1979-2004 reveals that in many semi-arid regions, such as the southwest United States, the $\delta^{18}O$ of xylem water is only partially related to the $\delta^{18}O$ of precipitation. At these locations, both evaporation and upward moisture fluxes in the soil water column contribute to variations in xylem water $\delta^{18}O$. For typical soil water profiles that are more depleted at depth, soil water tagging simulations reveal that in years with lower precipitation, an upward flux of deep soil moisture can lead to isotopically depleted xylem water. Consequently, this depleted cellulose $\delta^{18}O$ signal may be misinterpreted as reflecting more istopically depleted precipitation or enhanced rainfall due to an inferred "amount effect". Thus, where these soil moisture transport processes are dominant, there is a positive correlation between xylem water $\delta^{18}O$ and relative humidity, even though a decrease in relative humidity would be expected to enrich surface water $\delta^{18}O$. Furthermore, sensitivity experiments demonstrate that for these semi-arid regions, the seasonal cycle in xylem water $\delta^{18}O$ is not driven by the isotopic composition of precipitation but instead by ground evaporation.

Crystal structures of two oxygen-deficient calcium aluminum silicate perovskites from NMR and powder X-ray diffraction

M. KANZAKI[1]*, X. XUE[1], Y. WU[2] AND S. NIE[2]

[1]Institute for Study of the Earth's Interior, Okayama Univ., Misasa, Tottori 682-0193 Japan (*Correspondence: mkanzaki@misasa.okayama-u.ac.jp)
[2] School Earth and Space Sciences, Peking Univ., China

Several high-pressure phases along the $Ca_2Si_2O_6$-$Ca_2Al_2O_5$ join have been reported to occur with oxygen-deficit perovskite structures [1], but their detailed crystal structures remained undetermined. We have successfully determined the crystal structures for two of these phases: a $Ca_2AlSiO_{5.5}$ phase synthesized at 7 GPa and 1500 °C, and a $Ca_2Al_{0.8}Si_{1.2}O_{5.6}$ phase synthesized at 11 GPa and 1500°C, both in a multi-anvil press. Here we report these results.

^{29}Si MAS NMR and ^{27}Al 3Q MAS NMR revealed one tetrahedral Si peak and one octahedral Al peak for the $Ca_2AlSiO_{5.5}$ phase, and two Si (one tetrahedral and one octahedral) peaks and one octahedral Al peak for the $Ca_2Al_{0.8}Si_{1.2}O_{5.6}$ phase.

The crystal structures were solved with an ab initio structural determination technique (using the program FOX) from synchrotron powder X-ray diffraction data (measured at BL19B2, SPring-8) using information from NMR as constraints, and were further refined using the Rietveld method (RIETAN-FP). The space groups for both phases were found to be *C2/c*. The crystal structure of the $Ca_2AlSiO_{5.5}$ phase consists of double-layers of perovskite-like AlO_6 octahedra and double-layers of SiO_4 tetrahedra, stacked alternatively in the [111] direction of cubic perovskite, forming an 8-fold superstructure. That of the $Ca_2Al_{0.8}Si_{1.2}O_{5.6}$ phase is made of triple-layers of perovskite-like AlO_6-SiO_6-AlO_6 octahedra and double-layers of SiO_4 tetrahedra, also stacked alternatively in the [111] direction, forming a 10-fold superstructure. The double-layers of SiO_4 in both phases are similar, having deficient oxygens at the middle with one terminal oxygen (not bonded to other Si/Al) for each SiO_4 tetrahedron. These structures are related to the merwinite ($Ca_3MgSi_2O_8$) structure, which consists of alternating single layers of MgO_6 octahedra and double-layers of SiO_4 tetrahedra. This series of oxygen-deficit peroviskites provide additional insights into the local structural environments of Al- and Fe^{3+}-containing $CaSiO_3$ perovskite.

Estimates of atmospheric CO_2 in the Neoarchean-Paleoproterozoic

YOSHIKI KANZAKI* AND TAKASHI MURAKAMI

Department of Earth and Planetary Science, the University of Tokyo, Tokyo 113-0033, Japan (*Correspondence: kanzaki@eps.s.u-tokyo.ac.jp)

The weak luminosity of the younger Sun requires the early Earth to have more greenhouse effects than those today. The candidates for such greenhouse effect gases are CO_2 and CH_4 in the Neoarchean and the Paleoproterozoic. The quantification of CO_2 and CH_4 levels in the Neoarchean-Paleoproterozoic is a crucial issue, because the multiple glaciation events at ~2.9 Ga and ~2.4-2.2 Ga are considered to have been caused by the transitions of CO_2 and CH_4 levels.

Paleosols record vestiges of weathering by CO_2 and therefore have given estimates of atmospheric CO_2 levels. However, the CO_2 levels estimated from paleosols are less than those estimated by the climate model. Therefore, CH_4 is considered to have had a significant role as greenhouse effect gas. Because the CO_2 levels have been usually discussed indicating the contemporary CH_4 levels and vice versa, it is important to validate or assess the CO_2 levels extracted from paleosols so far. In this study, another method was developed to re-evaluate CO_2 levels from paleosols.

The new method estimates CO_2 levels operating in weathering profiles in 3 steps: (1) estimation of cation concentrations in porewater at the time of weathering from the loss amounts of cations in paleosol profiles, (2) estimation of pH in porewater at the time of weathering from likely secondary minerals in paleosols (kaolinite and smectite with no carbonates), and (3) CO_2 estimation from a charge-balance equation in porewater for dissolved CO_2 species (carbonic acid, bicarbonate ion and carbonate ion) and cations, using the estimated cation concentrations and pH. Application of the new method to modern weathering profiles has revealed that the new method reproduces modern soil CO_2 levels reasonabley well, confirming the validaty of the method.

Applyng the new method to the Neoarchean-Paleoproterozoic paleosols, the CO_2 levels were calculated to be > 100 PAL at ~2.8-2.4 Ga and < 100 PAL at ~2.3-1.8 Ga. The calculated levels of CO_2 throughout the above eras were sufficient to keep the average surface temperature of the Earth more than the freezing point of water. These results indicate (i) the general decreasing trend of CO_2 throughout the Neoarchean-Paleoproterozoic and (ii) that it would have been more difficult to make the Earth a Snowball than previously thought.

Delineation of recharge patterns and nitrate contamination using stable isotopes of water, ^{3}H-^{3}He, and CFCs in an agricultural basin

DUGIN KAOWN[1]*, DONG-CHAN KOH[2], YOON-YEOL YOON[2], HEEJUNG KIM[1], JIN-YONG LEE[3] AND KANG-KUN LEE[1]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul 151-747, Korea (*correspondence: dugin1@snu.ac.kr)

[2]Korea Institute of Geoscience and Mineral Resources, Groundwater Resources Group, 30 Gajeong-dong, Yuseong-gu, Daejeon 305-350, Korea (chankoh@kigam.re.kr)

[3]Department of Geology, Kangwon National University, Chuncheon 200-701, Korea (hydrolee@kangwon.ac.kr)

Haean basin in Yanggu (Korea) shows a bowl-shaped topography and the drainage system shows a simple dendritic pattern. Stable isotopes of groundwater, ^{3}H-^{3}He, and chlorofluorocarbon (CFCs) combined with hydrogeochemical data were applied to delineate groundwater residence time, recharge patterns and nitrate contamination of groundwater in the agricultural basin. The study area is consisted of forests (58.0%), vegetable fields (27.6%), rice paddy fields (11.4%) and fruit fields (0.5%). Thus, most of residents in the study area practice agriculture. The concentration of NO_3-N in groundwater showed 0.2 ~ 15.2 mg/L in June, 2012 and 0.4 ~ 14.8 mg/L in September, 2012. Nitrate concentrations were higher in the downgradient area than in the upgradient area due to the land use pattern and topography. The values of $\delta^{18}O$ and δD showed that groundwater is derived mainly from summer precipitation and the evidence of evaporation was observed in some wells in the paddy fields. The apparent groundwater ages using ^{3}H-^{3}He and CFCs are ranged from 7 to 10 years in the upgradient area and from 15 to 30 years in the downgradient area. The apparent groundwater age corresponds to the different nitrate concentrations in the upgradient and downgradient area. The NO3-N concentration in recently recharged groundwater showed 3-15 mg/L while the NO3-N concentration in 30 years old groundwater showed less than 3 mg/L. The reconstructed ^{3}H input and initial ^{3}H were used to estimate groundwater mixing. A conceptual model of groundwater flow using measured apparent ^{3}H-^{3}He and CFCs age will be developed to understand the hydrological processes of the study area.

SHRIMP U–Pb zircon dating, geochemical and petrographical characteristics of calc-alkaline Early Miocene Şapçı volcanics around Balıkesir (W Turkey)

D. KAPLAN[1], Z. ASLAN[1]* AND B.CHEN[2]

[1]Balıkesir Univ., Dept. Geol. Engn., Balıkesir,Turkey (*correspondence: zaslan@balikesir.edu.tr)

[2]Peking Univ., Dept. Geol. Engn., Beijing 100871, Peoples R China (binchen@pku.edu.cn)

Tertiary volcanic rocks are widespread in the Biga Peninsula of western Anatolian region (Turkey), and related to a collision tectonics in origin [1]. One of them, the Şapçı volcanics crop out in the northwest of Balıkesir. The volcanics consist of tuffs and lava flows in andesite and trachyandesite compositions. The rocks show microlitic, hyalo-microlitic, microlitic-porphyritic and fluidal textures. Modal minerals of the rocks are plagioclase (An_{30-49}), hornblende, biotite, Fe-Ti oxide and accessory apatite and zircon.

The SHRIMP U–Pb zircon dating from the lava yielded ages between 22.72 ± 0.19 and 22.97 ± 0.23 Ma, which are regarded as the crystallization age. The Şapçı volcanics have a composition of 60.09-66.45 % SiO_2, 0.47-0.60 % TiO_2, 14.64-16.38 % Al_2O_3 and 2.75-4.00 % K_2O. Petrochemically, they have high-K calc-alkaline characteristics, and exhibit similar features of volcanic arc setting. Besides, the trace element compositions are indicative of subduction-related volcanism. The volcanics have high large ion lithophile elements (LILEs) contents and low high field strength elements (HFSEs) contents compared to N-type Mid-Ocean Ridge Basalt (MORB), and have a high ratio of La/Yb, Zr/Nb. Chondrite normalized rare earth element (REE) patterns are concave upwards with $(La/Lu)_{CN}$ = 6.72–21.84, indicating significant fractional crystallization during the evolution of the volcanics. Furthermore, some trace element ratios indicate that the role of a subduction component and/or crustal contamination in the genesis of the Şapçı volcanics.

Sedimentary rocks as old as 3.8 billion years, such as Precambrian banded iron formations (BIFs), offer a unique archive of key past chemical and biological processes. Yet, post-depositional alterations such as diagenesis can alter these sediments and make accurate interpretation of primary processes challenging. Fe(II)-oxidizing bacteria have been proposed as key contributors to BIF deposition. One main challenge to this proposition is to understand how temperature/pressure diagenesis transforms biogenic Fe(III)(hydr)oxides formed by these bacteria.

We present diagenetic experiments of the transformation of precursor Fe(III) minerals associated with microbial biomass. Mixtures of ferrihydrite (biogenic ferric oxyhydroxide mineral proxy) and glucose (microbial biomass proxy) were incubated in gold capsules at 1.2 kbar and 170ºC. Key BIF minerals are produced by electron transfer from organic carbon to Fe(III) minerals during this diagenesis. Ferrihydrite transforms to hematite, magnetite, and siderite. Silica-coated ferrihydrite mixed with glucose yields hematite and siderite. Spheroidal siderite, a structure found in IF, forms depending on the Fe(III):C ratio of primary ferrihydrite-biomass sediment. Our results thus suggest that post-depositional BIF mineralogy does not directly archive the oceanic or atmospheric conditions during their lithification. Furthermore, we argue that spherical to rhombohedral siderite structures in deep-water Fe-oxide IF can be used as a biosignature for photoferrotrophy, whereas massive siderites reflect high cyanobacterial biomass loading in highly productive shallow-waters.

The platinum group and precious metals contents of Muğla-Ortaca Area Chromites

SALIH BURAK KARABEL[1], LOKMAN GUMUS[1], DEMET KIRAN YILDIRIM[1], SERENA UZASCI SULTANYAN[1], MURAT BUDAKOĞLU[1] AND MUSTAFA KUMRAL[1]

[1]Istanbul Technical University, Department of Geological Engineering, 34469, Istanbul, TURKEY

The study area is located in Menteşe Region, which is called Taurus belt, Southwest of Turkey. Structural units in the area are Menderes Massive, Western Taurus Nappes, Beydağları Autochthonous and Antalya Nappes.

In general, region consists of from bottom to top allochthonous units, peridotite nappe and alluvium. Allochthonous units, include Jura aged limestone interlayered with calciturbidite. The Upper Cretaceous aged complex consist of limestone with micritic texture and marn which is formed intermediate layers.

The peridotitic unit is composed of serpentinite, serpentinized dunite, dunite and harzburjite and it is Cretaceous aged. Also Quaternary alluvium is located at the top of the peridotites.

In this study, in order to determine the geochemical and petrographic characteristics (ore and rock) major, trace and rare earth elements were analyzed around Muğla-Ortaca.

The distribution of platinum group elements for Zimparalik shows according to geochemical analyses that Pt content is between 10 ppb and 147 ppb, Pd content is between 6 ppb and 54 ppb and Ir content is between 12 ppb and 131 ppb. In additon, Au content is between 24 ppb and 135 ppb in this area.

The samples from Yemislik show that Pt content changes between 30 ppb and 138 ppb, Pd content is approximately 8 ppb, Ir content changes from 10 ppb to 100 ppb and also Au content reaches to 205 ppb.

Geophysical constraints on the water content in the lunar mantle and its implications for the origin of the Moon

SHUN-ICHIRO KARATO[113]

[1]Yale University, Department of Geology & Geophysics, New Haven, CT, USA

Although the Moon was considered to be “dry”, recent measurements of hydrogen content in some of the lunar samples showed a substantial amount of water comparable to the water content in the Earth's asthenosphere. However, the interpretation of these observations in terms of the distribution of water in the lunar interior is difficult because the composition of these rocks reflects a complicated history involving melting and crystallization. In this study, I analyze geophysically inferred properties to obtain constraints on the distribution of water (and temperature) in the lunar interior. The electrical conductivity inferred from electromagnetic induction observations and the geodetically or geophysically inferred Q are interpreted in terms of laboratory data and the theoretical models on the influence of water (hydrogen) on these properties. Both electrical conductivity and Q are controlled by defect-related processes that are sensitive to the water (hydrogen) content and temperature but less sensitive to the major element chemistry. After a correction for the influence of the major element chemistry constrained by geophysical observations and geochemical considerations, I estimate the temperature-water content combinations that are consistent with the geophysically inferred electrical conductivity and Q. I conclude that the lunar interior is cooler than Earth (at the same depth) but the water content of the lunar mantle is similar to that of Earth's asthenosphere. A possible model is presented to explain the not-so-dry Moon where a small degree of water loss during the Moon formation is attributed to the role of liquid phases that play an important role in the Moon forming environment.

Four types of olivine from orangeites of Kostomuksha-Lentiiro area (Russia, Finland)

A.V. KARGIN, A.A. NOSOVA AND E.V. KOVALCHUK

Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry of the Russian Academy of Sciences, Russia, Moscow, kargin@igem.ru

Mineral characteristics of alkaline ultramafic rocks of the Kostomuksha-Lentiiro area suggest their orangeitic rather than lamproitic nature. The orangeites are divided into three types by their macrocryst assemblages: Ol-Phl-Cpx, Ol-Phl and Phl-Carb. The Ol-Phl-Cpx orangeites of Lentiiro contain four generations of unaltered olivine that vary in composition and origin.

Olivine I is large (3-2 mm) typically rounded zoned macrocrysts. Core composition is Fo 92 with the highest content of NiO (0.33-0.37 wt. %) and the lowest CaO (0.03-0.04 wt. %). This olivine is interpreted as a xenocryst derived from depleted mantle peridotite.

Olivine IIa is represented by euhedral and subhedral phenocrysts (commonly 0.15-0.3 mm). Olivine IIa and rims of olivine I and III have the same composition - Fo 88-89 with high content of CaO (0.10-0.42 wt. %), and moderate contents of NiO (0.14-0.35 wt. %) and MnO (up to 0.07-0.21 wt. %), which is consistent with fractional crystallization trend of olivine from orangeites. This olivine crystallized from orangeitic melt at 950-960°C (content of Ca and Al [1]).

Olivine IIb is observed as microphenocryst in a groundmass (< 0.1 mm). It is Fo 86-87 with the highest content of CaO (1.19-1.40 wt. %). This olivine is the product of late-stage crystallization of evolved kimberlitic melt.

Olivine III forms medium size (commonly 1.0-1.5 mm) rounded zoned "tablet"-shaped crystals [2]. Core of olivine III is Fo 82-83 with the lower content of CaO (0.03-0.05 wt. %), NiO (0.12-0.17 wt. %) and high MnO (up to 0.40 wt. %). This generation is interpreted to represent either early stage crystallization of megacryst assemblage [3] or a product of metasomatic interaction between mantle peridotite and protokimberlitic melt [2].

6Geological Survey of Namibia, P.O. Box 2168, Windhoek, Namibia (khhoffmann@mme.gov.na)

Neoproterozoic response to, and recovery from, a postulated greenhouse state following global glaciation represents an acute test of feedbacks within the Earth system to maintain an equable environment. One explanation for the severe environmental change predicts progressive build-up of pCO_2 during extreme glaciation, and rapid melt back and influx of atmospheric CO_2 into the ocean [1]. A boron isotope study of post-glacial carbonates from Namibia identified a temporary ocean acidification (pH ~7), potentially linked to oceanic uptake of carbon dioxide [2]. $\delta^{44}Ca$ (0.4 to 1.3‰) and $\delta^{26}Mg$ (-2.1 to -1.4‰) excursions in Neoproterozoic carbonate profiles elucidate the recovery of the Earth System from such an ocean acidification event and elevated greenhouse gas concentrations in the glacial aftermath. Both isotope patterns indicate an enhanced weathering influx following the glaciation demise, and increase in global temperature and precipitation in the greenhouse aftermath. This enabled the ocean to return to normal pH after climatic amelioration. Differences in time-development of the Ca and Mg isotope patterns reflect a change from carbonate- to silicate-dominated weathering flux and suggest primary dolomite formation during "cap dolostone" sedimentation. Differences in the magnitude of both isotope patterns across the palaeocontinental margin of the Congo Craton suggest a local influence potentially overprinting and amplifying the global pattern. Thus, extreme regional signals can lead to an overestimate of the global chemical weathering flux.

Tungsten species in natural ferromanganese oxdies related to its different behavior from molybdenum in oxic ocean

TERUHIKO KASHIWABARA[1] AND YOSHIO TAKAHASHI[2]

[1]Japan Agency for Marine-Earth Science and Technology (JAMSTEC), teruhiko-kashiwa@jamstec.go.jp*
[2]Hiroshima University, ytakaha@hiroshima-u.ac.jp

Different concentrations of Mo and W in oxic ocean attribute to their different distributions at the seawater/ferromagnanese oxide interface. Recent studies also revealed large isotopic fractionation of Mo on ferromagnanese oxides, which leads to the utility of Mo isotope systems as a paleoredox proxy. In contrast to extensive attentions on Mo, chemistry of W at the solid/water interface is pooly understood. The aim of this study is to reveal the W species in natural ferromanganese oxide, which affects its different behaviors from Mo in modern oxic ocean.

Conventionally, it has been difficult to obtain high quality fluorescence XAFS spectra of trace amount of W because of interferences of intense scattering and/or fluorescence from other predominant elements, such as Fe, Mn, Ni, Cu, and Zn. Here, we applied wavelength dispersive XAFS method, where Bent Crystal Laue Analyzer was used in front of detector to selectively extract fluorescence X-rays of W [1].

We revealed that the W species are in distorted *Oh* symmetry in natural ferromanganese oxides. The host phase of W is suggested to be Mn oxides. We also found that the W forms inner-sphere complexes in hexavalent state and distorted *Oh* symmetry on both synthetic ferrihydrite and δ-MnO_2. It is known that Mo forms a distorted *Oh* inner-sphere complex on Mn oxides and a *Td* outer-sphere complex on ferrihydrite, and the host phase of Mo in natural ferromanganese oxides is δ-MnO_2 [2]. Therefore, the different behaviors of W and Mo at the seawater/ferromanganese oxide interface can be caused by (i) the stability of inner-sphere complexes on the Mn oxides and (ii) mode of attachment (inner- or outer-sphere) on Fe oxyhydroxides. In addition, preferential adsorption of lighter W isotopes is expected based on the molecular symmetry of the adsorbed species, implying the potential significance of the W isotope systems as paleo redox proxy similar to Mo [3].

Future calamity of Arsenic poisoning in the groundwater of Thoubal and Bishnupur districts of Manipur (India)

A. K. CHANDRASHEKHAR [1]*; S. H. FAROOQ[2]; D. CHANDRASEKHARAM[1] AND P. THAMBIDURAI[1]

[1]Department of Earth Sciences, IIT Bombay, Mumbai - 400076. (*correspondance: kashyapglm27@gmail.com)
[2]School of Earth, Ocean and Climate Sciences, Indian Institute of Technology Bhubaneswar, Bhubaneswar-751013, (hilalfarooq@gmail.com)

Above 10 μg/L (WHO 2001) concentration of arsenic in the drinking water lead to carcinogenic, cardiovascular disease, neurotoxicity and diabetes in the human. Arsenic poisoning in the groundwater is growing threat to a very large portion of Indian population. Along with the West Bengal, many areas of Uttar Pradesh, Jharkhand, Bihar, Chhattisgarh and Assam have been reported with higher concentrations of arsenic in the groundwater. To know the extent of arsenic poisoning in parts of Manipur a study has been carried out and 26 groundwater and samples were collected for analysis. More than 57% samples recorded arsenic > 10μg/L while this concentration in the surface waters samples is negligible. The highest concentration of arsenic (535 μg/L) was registered from Ngangkha Lawai Mamang Leikai area of Bishnupur district which is fifty fold of the (WHO 10 μg/L) limit for arsenic and tenfold of Indian permissible limit (50 μg/L).

In previous study the highest concentration of arsenic 200 μg/L[2] was reported in the same area of Bhishnupur district. Whereas in present study the highest concentration of arsenic is (535 μg/L) which is nearly three fold of previous study. This study shows that the arsenic concentration in groundwater is increasing with time. If situation continues, the groundwater may become higly pollutted with arsenic and may become a major cause of concern to the population of this region.

In this study the presence of arsenic free water on the surface and contaminated groundwater at subsurface levels indicates the existence and functioning of arsenic release mechanism within the aquifer sediments [3].

Role of aggregates formed during process stabilization in a production of methane in biogas reactors

M. KASINA[1,2]*, A. KLEYBÖCKER[1], M. MICHALIK[2], M. LIEBRICH AND H. WÜRDEMANN[1]

[1]Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, 14473 Potsdam, Germany (Hilke.Wuerdemann@gfz-potsdam.de)
[2]Institute of Geological Science, Jagiellonian University, Kraków, Poland;

To optimise the co-digestion of sewage sluge and rape seed oil a fast increase in the organic loading rate and the addition of CaO was tested in an experimental setup. The process stability was increased by aggregate formation. Theses aggregates were extracted and subjected to detailed characterization using SEM-EDS, XRD, FTIR and optical microscopy. The aim of this study is to describe the aggregates in terms of their morphology and mineral composition, as well as to find the answer about the role of microorganisms in their formation. The relationship between Calcium and organics components like long-chain fatty acids (LCFA), polysaccharides and proteins and microorganims was investigated to get a more detailed inside into biofilm formation that is known to favour syntropic acetate oxidation and methane formation.

The aggregates differed in size (from 0.5 mm up to 0.5 cm), shape (usually rounded) and porous inner structure (different pore size) and showed a bipartite structure. In each part organic material containing calcium was the main component (LCFA-Ca).

Adsorption effects as well as precipitation of insoluble salts of LCFA and Ca formed an outer cover of aggregates and offered interfaces within the aggregate as well. The aggregates formation was stimulated by CaO addition and had a positive impact on growths of synthrophic consortia. Due to the high concentrations of short-chain organic acids phosphate accumulating bacteria (PAO) took up acids like acetate and propionate and released phosphate which precipitated with cations present in the sludge. Iron and aluminium phosphates were more common than calcium phosphates. Therefore we assume that calcium added during experiments mainly precipiated with LCFA as a strengthening material for aggregates. It was noted that precipitation of LCFA decreased their toxicity and obviousloy, activity of PAO and syntrophic consortia increased the pH inside the aggreagates and created favourable conditions for methan production. Therefore, an stable biogas production was observed although the pH and the H_2 concentration in the liquid phase of the sludge were below optimum.

Experimental study of mineral-microbial interaction to investigate the effects of CO_2 storage

MONIKA KASINA[1]*, DARIA MOROZOVA[1], LINDA PELLIZZARI[1], ANDREA KASSAHUN[2] AND HILKE WÜRDEMANN[1]

[1]Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, 14473 Potsdam, Germany, (Hilke.Wuerdemann@gfz-potsdam.de)

[2]Dresden Groundwater Research Centre e.V., 01217 Dresden, Germany

The influence of biological processes on the composition of reservoir sandstones the interactions between fluids and minerals are monitored during exposure to CO_2 in long-term experiments. Samples from the core deposit were incubated with fresh reservoir fluids as inoculum for indigenous microorganisms in a $N_2/CH_4/H_2$-atmosphere at a temperature of 80ºC and a pressure of 40 bars for half a year. Afterwards the samples were exposed to supercritical CO_2. Incubation was performed under lower temperature than in situ conditions to create more favourable growth conditions for microorganisms.

Analyses of the downhole fluids taken from a reservoir well using genetic fingerprinting methods (PCR SSCP and DGGE) revealed different DNA sequences indicating the presence of H_2-oxidising, biocorrosive thermophilic bacteria, thiosulfate-oxidising bacteria as well as some microorganisms similar to representatives from other deep environments, which have not been cultivated previously. Given a high temperature (120 – 127°C) and high salinity (up to 420 g/l) of fluids, the cells were difficult to detect because of very low numbers. The analysis of rock and fluid material from the long-term experiment after 11 and 31 months of incubation with CO_2 indicated the dissolution of major minerals and cements present in the sandstones, and secondary precipitation of new mineral phases such as quartz, albite, gypsum, halite, iron oxides and clay minerals. Changes in organic acid concentration and the release of organic components might indicate a metabolic activity of microorganisms or a mobilisation due to CO_2 exposure.

Slight indication of microbial activity like EPS formation was detected: Calcofluor white staining of carbohydrates indicates the presence of biofilms. We assume that changes observed in the samples until now were related mainly to CO_2 exposure and fluid-rock interaction. In the next steps, samples will be fed with H_2 to enhance microbial growth and molecular biological analyses will be used to characterise the changes in the biocenosis due to CO_2 and H_2 exposure.

What caused the rise of atmospheric O_2?

JAMES F. KASTING

Dept. of Geosciences, 443 Deike, Penn State University, University Park, PA 16802 (jfk4@psu.edu)

Oxygenic photosynthesis appears to have evolved well before O_2 levels increased in the atmosphere, at around 2.4 Ga. This has led to numerous suggestions as to what may have kept O_2 suppressed and then eventually allowed it to rise. These suggestions include changes in the recycling of carbon and sulfur relative to water (or hydrogen), a switch from dominantly submarine to dominantly subaerial volcanism, gradual oxidation of the continents and a concomitant decrease in reduced metamorphic gases, a decline in deposition of banded iron-formations, a decline in nickel availability, and various proposals to increase the efficiency of photosynthesis. Several of these different mechanisms could have contributed to the rise of O_2, although not all of them are equally effective. To be considered successful, any proposed mechanism must make predictions that are consistent with the carbon isotope record in marine carbonates, which shows relatively little change with time, apart from short-lived (but occasionally spectacular) excursions. The reasons for this constancy are explored here, but are not fully resolved. In the process of making these comparisons, a self-consistent redox balance framework is developed which will hopefully prove useful to others who may work on this problem and to astronomers who may one day try to decipher spectral signatures of oxygen on Earth-like exoplanets.

Melting of FeO-SiO_2 system at high pressure and the fate of subducted banded iron formations

CHIE KATO[1]*, RYUICHI NOMURA[1] AND KEI HIROSE[1,2,3]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan (*Correspondence: kato.c.ab@m.titech.ac.jp)
[2]Earth-Life Science Institute, Tokyo Institute of Technology, Tokyo, Japan
[3]Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology, Yokosuka, Japan

Large amount of banded iron formations (BIFs) is thought to have subducted into the deep mantle. Because of their high density, BIFs may have fallen down toward the core mantle boundary (CMB) region and might cause the ultra-low velocity zones (ULVZs) [1]. BIFs would be composed of FeO and SiO_2 in the mantle because its oxidation state is close to iron-wustite. FeO and SiO_2 form a simple binary eutectic system above 16 GPa [2]. Its eutectic temperature must be lower than the melting temperature of FeO, which is estimated to be about 3,500 K at the CMB pressure [3]. Since temperature at the CMB is most likely over 3,500 K, subducted BIFs may have melted there. In order to understand the fate of the subducted BIFs, we have conducted high-pressure melting experiments on FeO-SiO_2 binary system, using laser-heated diamond-anvil cell techniques. Results at 47 GPa demonstrate that eutectic composition is extremely FeO-rich only with < 3 wt% SiO_2. Dense FeO-rich melt should have segregated downward, while buoyant SiO_2-dominant solid residue may have recycled upward. Such FeO melt accumulating between the core and mantle could have formed Fe-rich lowermost mantle and O-rich topmost core.

Experimental studies of partial melting at the contact between limestone and pelitic gneiss

M. KATO[1]*, Y. HIROI[2] AND M. ARIMA[3]

[1]Chiba University, Chiba 263-8522, Japan (*correspondence: andkysil@gmail.com)
[2]Chiba University, Chiba 263-8522, Japan
[3]Yokohama National University, Yokohama 240-8501, Japan

Continental crust is much more diverse than oceanic crust in composition. To evaluate the significance of partial melting for interaction between such diverse lithologies during high-grade metamorphism, we performed high-pressure experiments of partial melting at the contact between limestone and pelitic gneiss, which are characteristic lithologies in Gondwana fragments such as the Highland Complex of Sri Lanka and the Lützow-Holm Complex (LHC) of East Antarctica [1].

The rock fragments of limestone from Japan were loaded in a sealed Pt capsule with powdered garnet-sillimanite gneiss from the LHC. H_2O or NaCl aqueous solution were also added to the capsule. Experiments were performed at 900 °C, 800 MPa, and 100 hours with a piston-cylinder, high-pressure apparatus at the Yokohama National University.

At the contacts between limestone and partially molten garnet-sillimanite gneiss (garnet + spinel + peraluminous liquid), different mineral assemblages are formed depending on the composition of solution as follows.

H_2O: Wollastonite, clinopyroxene, plagioclase, biotite, and subaluminous to peraluminous liquid.

NaCl aqueous solution: Clinopyroxene, plagioclase, scapolite, and metaluminous liquid.

The results show that clinopyroxene, scapolite, plagioclase, and metaluminous liquid could be formed by the melting reaction between limestone and garnet-sillimanite gneiss when NaCl aqueous solutions are involved. We attempt to disuss the origin of clinopyroxene-scapolite-bearing calc-silicate granulites that have been reported from many high-grade metamorphic terrains including Antarctica [2], Sri Lanka [3], southern India [4] based on our experimental results.

Mineralization rates of organic carbon in freshwater vs marine environments and implications for carbor burial efficiencies

SERGEI KATSEV[1], SEAN A. CROWE[2], MATTHEW KISTNER[1] AND JIYING LI[1]

[1]Large Lakes Observatory, University of Minnesota Duluth, (skatsev@d.umn.edu)

[2]NordCEE, University of South Denmark, (sacrowe1@gmail.com)

The mineralization and burial rates of organic carbon in aquatic sediments influence the global carbon cycle and over geological time scales determine the atmospheric CO_2 and oxygen levels. As organic matter descends through the water and then sediment columns, its reactivity towards mineralization decreases. In marine environments, the decrease in organic carbon reactivity was described as a power-law function of carbon age, sometimes referred to as Middelburg power law. The relationship extends over time scales spanning eight orders of magnitude and is largely independent of temperature, exposure to oxygen, concentration of sulfate, and other factors that have been suggested to affect carbon mineralization rates. In contrast, no relationship of this kind was suggested in freshwater where conditions are typically more variable. Using a compilation of data from large lakes, we show that the reactivity of autochthonous organic carbon in fresh water decreases with time according to a similar power-law. The similarity suggests that mineralization rates of organic carbon are determined primarily by intrinsic factors rather than the characteristics of the enviroment. It also suggests that carbon mineralization by sulfate reduction is not fundamentally faster than by methanogenesis, with a particular implication that carbon mineralization rates in oceanic sediments 0.5Ga ago, when sulfate concentrations were low, were not particularly different from today. Our results indicate that carbon reactivity is higher in presence of oxygen, consistent with the enhanced preservation of carbon in anoxic sediments. Using the obtained relationships for oxic and anoxic mineralization rates, we calculate the theoretical burial efficiencies as a function of oxygen exposure time, which match the previously reported observational trends. In contrast to the effect of oxygen, the effect of temperature on specific (per carbon atom) carbon mineralization rates appears to be minor, suggesting that climate-related warming of lake sediments may not lead to increases in specific rates of carbon mineralization.

Highly sensitive and precise analysis of stable chlorine isotope ratio by continuous-flow isotope ratio mass spectrometry

SHINSUKE KAWAGUCCI AND UTA KONNO

Subsurface Geobiology Advanced Research Project (SUGAR), Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2-15 Natsushima-cho, Yokosuka 237-0061, Japan, (kawagucci@jamstec.go.jp)

Recent advancements in continuous-flow isotope ratio mass spectrometry (CF-IRMS) enable us to determine stable isotope ratios with only subnanomolar quantities. However, the current CF-IRMS methods for stable chlorine isotope ratios ($\delta^{37}Cl$) of CH_3Cl had required more than several hundreds nano-mole CH_3Cl. We thus develope a CF-IRMS system for the $\delta^{37}Cl$ analysis that combines a sample processing procedure largely based on the highly sensitive method for the $\delta^{13}C$ analysis of CH_3Cl with the IRMS setting for the $\delta^{37}Cl$ analysis of CH_3Cl.

The newly developed system successfully reduces sample requirements (>0.6 nmol-CH_3Cl) to less than one hundredth of that required by the previous CF-IRMS systems while maintaining comparable precision in the $\delta^{37}Cl$ determination (±0.1 ‰, 1σ). This system is also able to determine carbon isotope ratio for CH_3Cl with comparable precision (±0.3 ‰, 1σ, >0.3 nmol-CH_3Cl) to the previous study. δ^{37}Cl-SMOC and δ^{13}C-VPDB values of CH_3Cl in commercial tank were determined to be -6.8 ± 0.1 ‰ and -46.9 ± 0.3 ‰, respectively.

The gas emitted from the leaves of *Myrica rubra* was collected near a harbor of Tokyo Bay (35°19.1'N, 139°39.0'E) using the vial method reported previously. On a dry weight basis, *Myrica rubra* was found to emit CH_3Cl with a flux of 3.1–3.9 ng-CH_3Cl/g-leaves/hour, whereas no CH_3Cl was detected in the empty vials. The $\delta^{37}Cl_{SMOC}$ and $\delta^{13}C_{VPDB}$ values of the leaf-emitted CH_3Cl ranged from -4.9‰ to -2.9‰ (n=4) and from -112.7‰ to -108.0‰ (n=4), respectively. The newly developed system is applicable not only to atmospheric CH_3Cl, but also to any chlorine in liquid and solid samples when appropriate treatment such as silver chloride precipitation and its methylation is combined.

Reconstruction of pH and PCO2 by boron isotopes of unaltered ammonoids & nautiloids and the expected high alkalinity during the Cretaceous

KAWAHATA, H.[1,], FUKUSHIMA, A.[1], MORIYA, K.[2], SUZUKI, A.[3] AND ISHIKAWA, T.[4]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, kawahata@aori.u-tokyo.ac.jp
[2]Waseda, University
[3]AIST, a.suzuki@aist.go.jp
[4]JAMSTEC, t-ishik@jamstec.go.jp

The reconstruction of pCO2 during the geological time is required in order to predict the future environments. Boron isotopic ratio is an excellent proxy for pH and the relevant partial pressure of carbon dioxide in the seawater (PCO2). By using P-TIMS method, we conducted the high precision analysis of delta 11B (+/- 0.1 per mil reproducibility) of unaltered aragonite shells of ammonoids and nautiloids mainly in the Cretaceous and in Jurassic (70-162 Ma), which were expected to be much warmer due to higher PCO2. So far, difficulty of fresh biogenic carbonate during these periods has produced no reliable reconstruction data using foraminiferal delta 11B before Cenozoic era. Our careful assessment of secondary alteration was conducted by 1) Determination by X-ray diffraction (XRD), 2) Observation of microstructures of the nacreous layers by SEM, and 3) Measurement of trace element contents. Positive correlation between delta 11B and delta 18O (temperature) of biogenic aragonites in 80 and 86 Ma revealed that relatively deeper dwellers within the surface ocean showed lower delta 11B values, which corresponded to lower pH. It is observed in the modern vertical water column. The reconstructed maximum PCO2 levels at late Cretaceous (80 Ma and 86 Ma) are 1,750 and 1,540 ppm, respectively. This is moderately high, coinciding with the suggestion by Breecker *et al*. (2010). Abundant deposition of biogenic carbonate during the Cretaceous requires the enhancement of alkalinity, which could be raised by 20% relative to modern value. This is indirectly supported by seawater-rock interaction in Oman ophiolite around 100Ma. Both terrestrial and ocean environments have strong buffering mechanism for pH and PCO2 levels in moderate time scale.

Supercontinent cycle and 2nd continents

It has been thought that granitic crust, having been formed on the surface, must have survived through the Earth's evolution because of its buoyancy. Recent geological studies have suggested that a significant amount of crustal material has been lost from the surface due to delamination, continental collision, and subduction at oceanic–continental convergent margins (von Huene and Scholl 1991; Yamamoto *et al*. 2009; Ichikawa *et al*. 2013a). If so, then the subducted crustal materials are expected to be trapped in the mid-mantle due to the density difference from peridotitic materials induced by the phase transition from coesite to stishovite (Kawai *et al*. 2013). In order to study the effect of the subducted granitic materials floating around the mantle transition zone, we conducted two-dimensional numerical experiments of mantle convection incorporating a continental drift with a heat source placed around the bottom of the mantle transition zone. We found that the addition of heat source in the mantle transition zone considerably enhances the onset of upwelling plumes in the upper mantle, which further reduces the time scale of continental drift. The heat source also causes massive mechanical mixing, especially in the upper mantle. The results suggest that the heat source floating around the mantle transition zone can be a possible candidate for inducing the supercontinent cycle (Ichikawa *et al*. 2013b).

[3]Kyushu University, Fukuoka 812-8581, Japan.
[4]Natl. Inst. Genetics, Mishima 411-8540, Japan.
[5]Natl. Inst. Basic Biology, Okazaki 444-8585, Japan.
[6]Tokyo Inst. Technology, Tokyo 152-8550, Japan.

Recent molecular analysis of microbial communities in subseafloor sediment indicates that phylogenetically diverse bacteria utilize organohalides as the electron acceptor: e.g., diverse 16S rRNA and reductive dehalogenase-homologous (*rdhA*) genes related to the member of *Dehalococcoides* have been detected by PCR from organic-rich deep subseafloor sediments (Futagami *et al*., 2009, 2013). Incubation experiments also demonstrated the biological degradation of organohalides (e.g., trichloroethene), indicating that organohalides support anaerobic microbial respiration in sedimentary habitats that are generally poor in bio-available electron acceptors.

To gain molecular insight into the largely unknown subseafloor reductive dehalogenation processes, we studied metagenomic pools obtained from five sediment core samples (i.e., 0.7, 5, 18, 48, 107 m in depth) at Site C9001 off the Shimokita Peninsula of Japan during the *Chikyu* Shakedown Cruise CK06-06 in 2006. From all samples examined, we detected phylogenetically remarkably diverse *rdhA*-homologous genes that affiliate to novel specific clusters, indicating that molecular characteristics of subseafloor *rdhA*-homologous genes are evolutionary and functionary more diverse than those previously expected from the modern surface biosphere (e.g., anthropogenic habitats). Consistently, the frequency of *rdhA*-homologous genes in the subseafloor metagenomic pools was found to be statistically high as compared to those in genomic sequences of over 1,800 isolated species. Interstingly, however, no or very little differences in phylogenetic distribution of *rdhA*-homologous genes were observed between five pools, suggesting that the genes are spatially evenly distributed in sediment regardless of the formation age ranging from modern to Pleistocene.

Contrasting behaviour of monazite and zircon during partial melting and fluid infiltration: An example from the Ryoke metamorphic belt, Japan

TETSUO KAWAKAMI[1]

[1]Department of Geology and Mineralogy, Kyoto University, Japan, t-kawakami@kueps.kyoto-u.ac.jp

Behaviour of monazite and zirocn in the pelitic and psammitic migmatites are investigated in the low P/T type Ryoke metamorphic belt at the Aoyama area, Japan where regional metamorphic terrane is thermally overprinted by later granite intrusions.

Monazite grains in migmatites yield a CHIME age of 96.5±1.9 Ma mainly in the core, and rims and patchy domains yeild 83.5±2.4 Ma. The age of ~97 Ma is interpretd to represent the timing of monazite growth during prograde regional metamorphism. Some monaizte includes PbO-rich phases at the core/rim boundary where sharp chemical and age zonings are observed, suggesting the contribution of interface-coupled dissolusion-precipitation mechamism. Patchy young domains could represent the result of fluid-related Pb loss through mircocracks. Therefore, ~80 Ma overprint on migmatites represents the wide and combined effect of thermal input and fluid activity on the monazite grains caused by the ~80 Ma granite intrusions [1].

On the other hand, zircon in the same area records 90.3±2.2 Ma alone except for inherited ages at the core. Between inherited core and the metamorphic rim, a thin, dark-CL annulus containing <2 μm melt (glass) and nano-granite inclusions is commonly developed, suggesting the presence of melt during the rim growth. In diatexites, the annulus is further truncated by the brighter-CL overgrowth, suggesting the resorption and regrowth of the zircon after peak metamorphism. This kind of zircon rim probably crystallized during the solidification of the melt in migmatites, and yeilds 90.3±2.2 Ma. Therefore, zircon records the timing of partial melting event but not the fluid infiltration event during the ~80 Ma contact metamorphism [2].

Using the difference of growth timing of monazite and zircon, the duration of metamorphism higher than the amphibolite facies grade is estimated to be ca. 6 Myr [2], similar to ~5 Ma estimated by [3]. This duration of high-temperature metamorphism is difficult to be attained by the intrusion of a single granite sill (3 km thick), and requires additional granite intrusions [4] or alternative heat source.

Chemical fractionation of slab-derived supercritical fluids can play an important role in elemental transfer from subducting slab to the mantle wedge and arc magmatism [1]. Synchrotron radiation X-ray fluorescence (XRF) analysis is conducted to know elemental partition between aqueous fluids and high magnesian andesite melt with Kawai-type large-volume press at BL04B1, SPring-8, Japan. Incident X-ray is a white beam with energy ranging from 20 keV to 150 keV. During heating at a given pressure, synchrotron XRF spectra are collected from the melt and the aqueous fluid with help of X-ray radiography under HT-HP [2]. The spectra show characteristic X-ray peaks of the doped elements (Cs, Ba, Rare Earth Elements (REE)) superimposed on a continuous X-ray background. A series of experiments has been carried out to obtain partition coefficients between them at 1000-1200 °C and 0.5 - 2.2 GPa. The results suggest that (Na, K)Cl in aqueous fluids have large effects on the partition as previous studies [3]. Two slab-derived components: a melt and a fluid component are suggested to explain trace element characteristics of basalts and basaltic andesites in the Mariana arc [4]. Both components are characterized by enrichment of alkali and alkali earth elements. In addiiton to these, the melt component has immobile elements such as REE [4]. Such features can be explained if the fluid component is a Cl-rich aqueous fluid [3]. We suggest that slab-derived components have compositional features consistent with a Cl-rich aqueous fluid and a melt, which can be formed through a separation of a slab-derived supercritical fluid [1].

Difficulty of the self-replication of prebiotic RNA molecules

K. KAWAMURA[1]*, Y. MARUOKA[1], K. HAMAHIGA[1] AND N. KONAGAYA[2]

[1]Department of Human Environmental Studies, Hiroshima Shudo University, Hiroshima, Japan (*correspondence: kawamura@shudo-u.ac.jp)
[2]Department of Nutritional Sciences, Yasuda Women's University, Hiroshima, Japan

Difficulties of RNA formation

The RNA world hypothesis is supported by the discovery of ribozyme, the simulations of RNA formation under the primitive earth environments, and *in vitro* selection of a variety of functional RNA molecules. However, there are several drawbacks regarding the formation and replication of entirely prebiotic RNA molecules. First, the efficient pathway of formation of RNA monomers under the primitive earth conditions is not yet clarified. Second, the cylization of short oligonucleotides [1], such as dinucleotides and trinucleotides, inhibits the accumulation of long RNA. This was partially solved by addition of intercalators [2]. Third, although it is true that RNA molecules preserve genetic information and enzymatic function *in vivo*, these functions are not yet elucidated for the RNA molecules formed entirely prebiotic conditions. It is known that the template-directed synthesis of oligoguanylate from activated nucleotide monomers proceeds on a polycytidylic template [3]. However, other combinations of activated nucleotide monomers on a complementary polynucleotide template proceed with very low efficeincy.

Results and Discussion

We have attempted screening to enhance the efficency of the template-directed formation of oligonucleotides. The screening was carried out in the presence of intercalator, polypeptides, metal ions, and naturally-occuring minerals. In addition, the template-directed reaction was carried out at temperature below 0 ºC. Although the efficieny of the template-directed reaction was slightly enhanced in the presence of intercalator, that was generally reduced in the presence of polypepetides, metal ions, and minerals. Furthermore, the influence of very low temperatures was not also deteceted. These results imply the fact that the replication of RNA molecuIs consisting of entirely prebiotic materials would be very difficult.

Reactive transport modelling of mineral trapping of CO_2, revised by water sampling data at Nagaoka CO_2 storage site

YUKO KAWATA*, ZIQIU XUE AND SAEKO MITO

Research Institute of Innovative Technology for the Earth (RITE), 9-2 Kizugawadai, Kizugawa-shi, Kyoto 619-0292, Japan (*correspondence: kawatayk@rite.or.jp)

Carbon dioxide capture and storage (CCS) in saline aquifer is one of the global warming countermeasure technologies. A part of injected CO_2 will be stored by reacting with formation water and reservoir rock forming minerals over many years, which is more stable for CO_2 trapping. Conducting reactive transport simulation is needed to evaluate CO_2 mineralization. However, some geochemical input data for kinetic mineral dissolution/precipitaion calculation has high uncertainty. We have attempted to revise the geochemical data by matching the geochemical simulation results with sampled formation water composition, to make more realistic model for long term CO_2 behavior prediction . A series of trial runs would be needed to gain a good match, and so we used 1-D radial model for simulation-time saving. If a field-scale model is used, we have to consider lots of geological uncertainties simultaneously, which should make the study too complicated and time consuming.

Formation water was sampled twice after CO_2 injection from the observation well OB-2 at the depth of 1118m at the Nagaoka site. The concentration changes of HCO_3^-, Ca, and Si from the first run to the second run was chosen for matching data, because only calcite is a carbonate mineral in the initial mineral composition referring to Mito *et al*. [1]. 1-D radial model was constructed with TOUGHREACT, based on the previous study. Since the reservoir pressure is already stable, CO_2 dissolved water moves mainly by the gravity effect, which can't be expressed in 1-D radial model. Instead, the diffusion coefficient was adjusted by considering HCO_3^- concentration. We selected reactive surface area (RSA) for varying geochemical parameter, and the initial data was based on the experimental results using reservoir rock powder. Finally, RSA value was modified to 0.015 times of the initial model, then a good matching result was obtained. This result is reasonable because the sandstone of Nagaoka site has some conglomerate, and thus should have the narrower contact area with formation water than expected. Subsequently, we performed long term CO_2 behavior simulation with this matched model.

Hydrogen isotope exchange between insoluble organic matter and water in chondrite parent bodies

Y. KEBUKAWA[12]* AND G. D. CODY[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington, Washington DC, 20015, USA (*ykebukawa@ciw.edu)
[2]Department of Natural History Sciences, Hokkaido University, Sapporo 060-0810, Japan

The high deuterium enrichment in insoluble organic matter (IOM) in chondrites has largely been attributed to small molecule chemistry prior to IOM, specifically ion-molecule reactions at low temperature interstellar medium (ISM) [1]. The hydrogen isotope (D/H) ratio of IOM tends to decrease as alteration proceeds [2]. While water in carbonaceous chondrites is more depleted in D [3]. Thus, the decrease in D/H ratio of IOM could be attributed to the hydrogen isotope exchange between D-enriched IOM precursor and D-depleted water, which could have occurred during and/or after the formation of IOM.

Cody *et al*. [4] proposed that IOM in chondrites may have formed through the polymerization of interstellar formaldehyde after the planetesimal accretion, in the presence of liquid water. Our recent study successfully enhanced production of IOM analog materials from formaldehyde in the presence of ammonia [5]. Using this formaldehyde polymer as an IOM analog we have conducted kinetic hydrogen isotope exchange experiments, starting with (1) deuterated formaldehyde polymer and normal water, and (2) normal formaldehyde polymer and deuterated water, both as a function of temperature. The three-dimensional diffusion rate control model was found to fit well the changes in the D/H ratio with time. The apparent activation energies and the frequency factors were obtained by the apparent rate constants for each temperature with the Arrhenius equation. Using these kinetic expressions, hydrogen isotope exchange profiles were estimated for time and temperature behavior, based on the assumption that the kinetic rate low is valid over all temperatures. We will discuss the δD variation observed in various chondrites, and the IOM grain size effects, based on our hydrogen isotope exchange kinetics.

Lithospheric control of plume impact: Evidence from dyke geochemistry

JAKOB K. KEIDING[1]*, ROBERT B. TRUMBULL[1], THOMAS M. WILL[2], HARTVIG E. FRIMMEL[2], MIRIAM WIEGAND[3] AND ILYA V. VEKSLER[1]

[1]GFZ German Research Centre for Geosciences, Germany (*correspondence: jakob@gfz-potsdam.de)
[2]University of Würzburg, Germany
[3]Karlsruhe Institute of Technology, Germany

Dyke swarms in continental flood basalt (CFB) provinces carry more information about the magmatic systems than coeval lavas since they often are less differentiated and less prone to removal by erosion. Moreover, dykes directly record the site of magma emplacement whereas eruptive vents for CFB lavas are rarely known and can be distant from the sampling site. Here we report on ~250 samples from the Early Cretaceous Henties Bay Outjo dyke swarm (HOD) in NW Namibia, which is the best exposed major dyke swarm associated with South Atlantic rifting and breakup. The goals of this research are to assess the geochemical variability of dyke magmas, to determine the composition of the mantle source and physical conditions of melting, and to understand the influence of the continental crust and lithosphere on magma composition, ascent and emplacement. And finally, we are interested in the time-space variation of these parameters.

Chemical and isotopic compositions distinguish three end-member magma groups in the HOD. In order of decreasing abundance these are: (a) crustally-contaminated tholeiites, with "spiky" trace element patterns and enriched isotope ratios ($^{87}Sr/^{86}Sr_i$ = 0.710-0.712, εNd_i = -2 to -7) very similar to the main series of Etendeka flood basalts, (b) MORB-like tholeiites with relative flat trace element patterns and depleted isotope ratios ($^{87}Sr/^{86}Sr_i$ = 0.704-0.705, εNd_i = +2 to +6), and (c) alkaline, trace element enriched basalts ($^{87}Sr/^{86}Sr_i$ = 0.7055-0.7059, εNd_i = 0 to -2). In general, dykes in the southern part of the HOD (lat. 20-23º) are more diverse and more primitive. Neither picritic nor alkaline dykes have been so far observed to the North (lat. 17-20º). Interestingly, the most primitive dykes (MgO > 6 wt.%), with the highest magmatic temperatures (1350°C) and the greatest apparent depth of melting (highest Zr/Y and Dy/Yb ratios) occur in the southern area although the proposed plume impact is farther north (Walvis Ridge). The dyke diversity may be controlled more by crustal permeability than differences in magma source.

Biogeochemical Mechanisms Underlying the Manganese Dependence of Litter Decomposition

Climate change is predicted to impact the organic and inorganic composition of foliar litter, and global warming may increase soil microbial and enzymatic activity, with uncertain consequences for litter decomposition rates and pathways in soils. Recent work has identified the bioavailability of key resources (e.g, assimilable C or inorganic nutrients) as the main control of litter decomposition rates. A particularly strong correlation was established between manganese (Mn) content in needle litter and litter decomposition rates across a variety of boreal forest ecosystems, suggesting that Mn is an essential component of the decomposition pathway. There is good reason to assume that this is due to the critical role of Mn(III)-ligand complexes acting as potent oxidizers in the enzymatic breakdown of lignin. Here we related changes in Mn form and distribution to lignin transformation over the course of a 7-year litter decomposition experiment in an old growth forest ecosystem. Soft-ionization mass spectrometry, FTIR and X-ray absorption spectroscopy analyses of fresh needles, litter at different decomposition stages, and mineral soil show that the formation of oxidative Mn species is well correlated with lignin decomposition. Spatially-resolved synchrotron-FTIR and X-ray microprobe imaging revealed that microorganisms colonizing individual needles redistribute and transform reduced Mn(II) present in the vascular system of fresh needles into oxidative Mn(II/III) forms at the sites of lignin decomposition. These mechanistic insights suggest that Mn bioavailability and form are important parameters for improved model predictions of litter decomposition rates in forest soils. The response of ecosystem Mn fluxes to rising temperatures and CO_2 concentrations and, specifically, its implications for litter decomposition rates will be discussed.

Trace element systematics of pyrite from submarine hydrothermal vents

M. KEITH[1]*, F. HÄCKEL[1], K.M. HAASE[1], U. SCHWARZ-SCHAMPERA[2], R. KLEMD[1] AND S. PETERSEN[3]

[1]GeoZentrum Nordbayern, Univ. Erlangen-Nuernberg, Erlangen, 91054, Germany (*correspondence: Manuel.Keith@gzn.uni-erlangen.de)
[2]Federal Institute for Geosciences and Natural Resources, Hannover, 30655, Germany
[3]Geomar, Helmholtz-Zentrum fuer Ozeanforschung, Kiel, 24148, Germany

Submarine hydrothermal sulfide deposits occur at mid-ocean ridges, island arcs, and in back-arc basins. It is believed that the different wall rocks and potential magmatic volatiles [1] influence the metal budget of the hydrothermal fluid and the composition of the sulfide precipitates to variable degrees.

Pyrite is the dominating mineral in these precipitates and thus, the trace element composition of pyrite may reflect the different metal sources. However, the physicochemical composition of the fluid phase and processes such as phase separation [2] largely control the solubility and transport of metals and hence, metals enriched in the wall rock or magmas may not necessarily be concentrated in the sulfides.

Here we report on a systematic study of major and trace element concentrations on pyrites from active and inactive hydrothermal fields including the Indian and Mid-Atlantic Ridges, the Tonga-Kermadec arc, Lau back-arc, and the central Okinawa Trough. Preliminary results indicate that the pyrites show significant variations in their trace element contents irrespective of the surrounding host rocks. Pyrites from single locations have highly variable concentrations of elements like Cu, Sb, Ag, Au and Co that are most likely related to fluid evolution and changes in fluid compositions. Elements like Sb, Ag and Au have a characteristic affinity to As and Pb in pyrite, Cd correlates closely with Zn. High temperature (>240°C) As-Cu-pyrites are often enriched in Co and Au, while Ni seems to be unaffected by temperature variations. The incorporation of Co and Ni into pyrite is wall rock-independent. Bismuth appears to be enriched in pyrites from settings associated with sediments [3] and Mo may be concentrated due to seawater mixing [4].

These results indicate the complexity of trace metal contents in pyrite as a function of the physicochemical composition of the fluid phase rather than their source.

Clumped isotope geochemistry of travertine carbonates in the 22-95 °C temperature range

KELE S[1]*, BERNASCONI SM[2], KLUGE T[3], JOHN CM[3], MILLÁN MI[2], MECKLER AN[2], ZIEGLER, M[2], BREITENBACH SFM[2], CAPEZZUOLI E[4], ÖZKUL M[5] AND GÖKGÖZ A[5], DEÁK J[6]

[6]Gwis Ltd, Dunakeszi, Hungary

The formation temperature of carbonates can be estimated using both the conventional carbonate-water paleothermometry and the newly developed clumped isotope method of [1]. However, there is still a large uncertainty in the published clumped-isotope based temperature calibrations.

In this work recent travertines forming from natural springs and wells between 22 and 95 ºC from Hungary, Turkey and Italy were studied for stable- and 'clumped' isotopes. Clumped isotope data showed an excellent correlation with temperature indicating equilibrium precipitation close to the spring orifice. Δ_{47} values decreased with increasing distance from the springs, which may be related to kinetic isotope fractionation due to CO_2 degassing in the different depositional sub-environments (e.g. channel, terrace-pool, cascade).

All vent travertine samples show a strong Δ_{47}-temperature relationship (r^2>0.9) defining an empirical equation with a slightly lower slope (i.e. lower temperature sensitivity) than that of Ghosh *et al*. [1]. This empirical calibration significantly extends the calibration range of the clumped isotope thermometer to temperatures of 95 ºC and can be used to derive the oxygen isotope composition of travertine-depositing waters from ancient deposits to reconstruct glacial-interglacial variations in meteoric water compositions and the paleohydrological regimes of the study areas.

Some less conventional processes in subduction zones

P.B. KELEMEN

LDEO, Columbia University, (peterk@ldeo.columbia.edu)

Emplacement of buoyant, felsic material from subduction zones into hanging wall crust may be as important as foundering of dense lithologies from the base of the crust. Building on the ideas of Hacker *et al*. (EPSL 2011), we've proposed an end-member, uniformitarian model in which continental crust forms and evolves via accumulation of buoyant, felsic material ascending from the upper crust of the subducting plate in arc-arc or arc-continent collisions (Kelemen & Behn, submitted).

More generally, fore-arc sediments can be thrust into arc crust during subduction erosion, buoyant material can be subducted to great depths and then ascend along a "subduction channel", or diapirs may rise through the hot mantle wedge beneath arcs. The latter process can efficiently recycle components from subducted sediment (greywacke, pelite, carbonate; Behn *et al*. Nature Geoscience 2011), and play a key role in global geochemical cycles. Interaction between metasedimentary diapirs and mantle peridotite may form a variety of hybrid rocks, melts and fluids.

It is more challenging to understand accumulation and transport of partial melts of subducting basalt, where these comprise a substantial geochemical component in arc lavas (e.g., W Aleutian primitive andesites). Perhaps, reaction between SiO_2-rich melt and peridotite forms an impermeable carapace of pyroxenite, beneath which melt accumulates to sufficient thickness to form diapirs (e.g., Ringwood 1975).

Diapirs may slow or stop near the crust-mantle boundary. An intriguing observation in some areas (Mt Shasta, W Aleutians) is the spatial juxtaposition of primitive magmas (Mg# ~ 0.7) with very different MgO and H_2O contents, and thus different temperatures. Perhaps hydrous, cool, primitive andesites and dacites commonly pond and equilibrate with the mantle just below the base of arc crust, while hotter primitive basalts rise rapidly through this region in cracks or porous conduits of focused flow.

Reaction-driven cracking

P.B. KELEMEN

LDEO, Columbia University, (peterk@ldeo.columbia.edu)

Hydration, carbonation, and oxidation of volatile-poor lithologies are essential to the rheology of oceanic plates, the structure of subduction zones, global geochemical cycles, and possible capture and storage of CO_2. There's plenty of energy. Mantle olivine plus H_2O or CO_2 contains 5% of the energy density (J/m^3) of petroleum fuels (Kelemen and Hirth EPSL 2012). Negative feedbacks (fluid consumption fluid, falling diffusivity, increasing solid mass, decreasing solid density, crystallization in pore space, armouring of surfaces) make these processes self-limiting under many conditions. Yet, fully hydrated (serpentinite) and carbonated (listvenite) peridotites demonstrate that reaction can proceed to completion in some cases. Cracking due to stress from volume change can maintain or increase permeability and reactive surface area (MacDonald & Fyfe Tphys 1985). In systems far from equilibrium, reactions can produce kilobars of differential stress to fracture rocks, though the effect of confining pressure is uncertain. In natural samples that underwent reaction-driven cracking, the surface energy density on newly formed fractures corresponds to a strain energy density produced by kilobars of stress, consistent with thermodynamic estimates (Kelemen & Hirth EPSL 2012).

Devolatilization and melting may cause earthquakes and hydro-fracture, if fluid/melt production is rapid and permeability is low. Again, disequilibria in natural systems have energy densities ~5% of petroleum. Reaction of eclogite melt with peridotite could form an impermeable pyroxenite carapace, beneath which a column of interconnected melt grows until buoyancy leads to magma fracture. Volume change due to rapid fluid evolution from cooling melt, or from warming rocks, can cause fracture if relaxation (porous flow, viscous deformation) cannot keep pace. Shear-heating could cause rapid fluid production and fracture in localized shear zones. If fluid pressure reduces effective stress, heating will slow. With different time scales for thermal evolution and reaction progress, such instabilities could be oscillatory.

A statistical approach to the volcanic – plutonic connection

BRENHIN KELLER*, BLAIR SCHOENE, KYLE SAMPERTON, MELANIE BARBONI, JEFF GRONEWOLD AND JON HUSSON.

Princeton University, Geosciences, Princeton, USA, (cbkeller@princeton.edu * presenting author)

The geochemical relationship between volcanic and plutonic rocks - whether the two are geochemically identical, or if the choice between eruption and intrusion is correlated with magma chemistry - represents a major unanswered question in igneous petrology. In one endmember scenario, felsic to intermediate plutons are proposed to represent the unerupted crystal mush from which crystal-poor eruptible melts are extracted. At the other end of the spectrum, it is argued that a nearly the entire volume of magma is evacuated during large silicic eruptions, and that the probability of eruption versus intrusion is instead largely a function of magma flux.

In the first scenario, parental magmas originating at depth experience substantial fractionation during volcanic melt extraction, leading to complementary volcanic and plutonic reservoirs. In the second endmember scenario, volcanic/plutonic fractionation is negligible, but geochemical differences on average between volcanic and plutonic rocks are still possible if high- and low-flux melts have distinct geochemical characteristics that are correlated with the eruptibility of a magma.

We have compared the geochemistry of ~300,000 volcanic and plutonic rocks by Monte Carlo analysis in order to produce maximally representative average compositions that reflect the influence of meaningful physical processes. The results indicate that while volcanic and plutonic rocks in general show remarkably similar major element trends, intermediate to felsic plutonic rocks, for a given silica content, display clear enrichments in Sr and Ba and depletions in Zr, Hf, and HREEs relative to their volcanic equivalents. More subtly, intermediate volcanic rocks are found to exhibit small but distinct enrichments in FeO and depletions in K2O relative to equivalent plutonics. These results suggest that, in the first endmember scenario above, volcanic/plutonic fractionation of plagioclase must be a key factor; while for the second scenario to hold, average water content must differ substantially between extrusive and intrusive equivalents. Further examination of trace element systematics combined with geochemical modelling allows for the discrimination between the influence of late stage crystal fractionation, versus the influence of water to suppress plagioclase relative to the ferromagnesian minerals and to delay the crystallization of most silicate minerals relative to zircon saturation.

Sulfur isotope systematics of geothermal fluids, Krafla, Iceland

N.S. KELLER[1], A. STEFÁNSSON[1], S. ONO[2] AND J. GUNNARSSON ROBIN[1]

[1]Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavík, Iceland (nic@hi.is)

[2]Department of Earth Atmospheric and Planetary Sciences, MIT, Cambridge, MA, USA

Sulfur is among the major components in geothermal systems. It is present in various oxidation states ranging from sulfide (S^{-II}) to sulfate (S^{+VI}) and present in solid phases and fluids (water and vapor). The source of the various sulfur compounds and the processes affecting their chemistry and fluxes are complex and in many respects not fully understood. In an effort to study the complex geochemistry of sulfur in this system, we obtained new chemical and isotopic data for fluids sampled from the Krafla field, NE Iceland, an active volcanic geothermal system. High-temperature well fluids discharging water and/or steam were collected having enthalpies ranging from 852 to 2774 kJ/kg. The fluids were analyzed for various sulfur compounds including, H_2S, SO_3, S_2O_3 and S_2O_3 in the water phase and H_2S and SO_2 in the vapor phase and for sulfur isotopes including ^{32}S, ^{33}S, ^{34}S and ^{36}S on H_2S and SO_4 in the water phase and H_2S in the vapor phase. For the sulfur isotope analysis the various sulfur oxidation states were sequentially precipitated as ZnS and $BaSO_4$, converted to Ag_2S and analyzed by Fluorination-GC-IRMS.

The observed concentrations in the waters were SO_4 = 5.1-280 ppm, H_2S = 27.6 to 120 ppm and S_2O_3 = 0-39.1 ppm. The concentrations in the vapor were H_2S = 46-2617 mg/kg condensate. No other sulfur phases were detected. The $\delta^{34}S$ in SO_4 and H_2S in the waters were +3.4 to +13.4‰ and -1.8 to -0.2‰, respectively, and H_2S in the vapor were +0.1 to +1.3‰. The $\Delta^{33}S$ and $\Delta^{36}S$ follow the theoretical value for mass-dependent fractionation in all cases.

The results indicate that the $\delta^{34}S$ for H_2S in the total discharged fluid are very close to 0.0‰, suggesting magmatic origin, either through magma degassing and/or magmatic sulfide leaching. The $\delta^{34}S$ ratio between H_2S in the water and vapor is considered to reflect boiling temperatures. For SO_4, the positive isotope shift observed may be explained by H_2S oxidation to SO_4 and/or SO_4 originated from the surface either through meteoric water and/or sulfate mineral leaching and/or mixing of these two different sources.

The relationship between fO_2 and calc-alkaline affinity of arc magmas

K.A. KELLEY[1]*, E. COTTRELL[2] AND M.N. BROUNCE[1]

[1]GSO, Univ. of Rhode Island, Narragansett, RI 20882 USA (*correspondence: kelley@gso.uri.edu)
[2]NMNH, Smithsonian Inst., Washington, DC 20560, USA

Calc-alkaline differentiation, a process by which magmas become rapidly depleted in Fe early in their crystallization history, is observed exclusively in magmas in subduction zone settings and is thought to drive magmas towards the bulk composition of continental crust. Basaltic arc magmas have been proposed to achieve calc-alkaline affinity through either high magmatic H_2O, which delays the onset of plagioclase crystallization, or high magmatic fO_2, which enhances the onset of magnetite crystallization, or both. The relative importance of H_2O, fO_2, and magmatic bulk composition in generating calc-alkaline magma series, however, is not yet clearly resolved. Here, we present new measurements of the oxidation state of Fe (expressed as $Fe^{3+}/\sum Fe$ ratio) in olivine-hosted melt inclusions from basaltic arc volcanoes in the Mariana and Aleutian arcs, acquired using X-ray Absorption Near Edge Structure spectroscopy. These volcanoes span a range of calc-alkaline affinity, with THI ranging from 0.7 to 1.2 (THI = Tholeiitic Index, <1 is more calc-alkaline, >1 is more tholeiitic [1]). Measured $Fe^{3+}/\sum Fe$ ratios range on average from 0.23-0.28 in the Marianas, and from 0.20-0.28 in the Aleutians, which are uniformly more oxidized than more tholeiitic basaltic glasses from the Mariana trough back-arc basin (THI=1.4; $Fe^{3+}/\sum Fe$=0.15-0.18) or normal MORB (THI=1.6; $Fe^{3+}/\sum Fe$=0.16±0.01). Our results show a correlation between THI and $Fe^{3+}/\sum Fe$ ratios at these volcanoes, such that more tholeiitic magmas contain a greater proprtion of reduced Fe, and more calc-alkaline magmas a greater proportion of oxidized Fe. At the same time, the maximum dissolved H_2O contents of basaltic melt inclusions from these volcanoes also broadly correlate with THI [1], and with measured $Fe^{3+}/\sum Fe$ ratios, which is consistent with prior work [2], although H_2O is not the direct cause of oxidation. These findings suggest that H_2O and fO_2 may both play key roles in the development of calc-alklaine affinity in arc magmas, but their respective functions in this process may be difficult to separate in natural systems because the subducted slab delivers fluids that generate arc magmas with both elevated H_2O and fO_2.

Characterisation of active forest soil *Bacteria* during mineral weathering

KELLY L.C.*, UROZ S[1] AND TURPAULT M.-P.[2]

[1]UMR1136 Interactions Arbres-Microorganismes, Centre INRA de Nancy, 54280 Champenoux, France.
[2]UR1138 Biogéochimie des Ecosystèmes Forestiers, Centre INRA de Nancy, 54280 Champenoux, France.
(*correspondence: laura.kelly@nancy.inra.fr)

Acidic forest soils, while nutrient-poor, are characterised by a reservoir of inorganic nutrients trapped within the minerals contained therein. Despite the significance of such reservoirs to the long-term functioning of acidic forest ecosystems, surprisingly little is known regarding the contribution of the resident bacterial communities to the weathering of soil minerals. While the influence of mineralogy on the phylogenetic composition of mineralosphere communities in soil and other terrestrial environments [1, 2, 3] has been demonstrated, determining the activities and contributions of individual microbial taxa to weathering processes remains an ongoing challenge. Using DNA immunocapture and high-throughput sequencing, in concert with geochemistry and traditional culture-based techniques, we investigated bacterial communities on a variety of minerals during weathering in laboratory microcosms, seeded with a forest soil-derived inoculum. Our primary objectives were i) the comparison of active and inactive bacterial community fractions and ii) to determine whether mineralogy influences the phylogenetic composition of these fractions. Such analyses brings us a step closer to understanding the composition and activities of mineralosphere bacterial communities in acidic forest soils, and the likely ecological significance of particular taxa.

Temporal trends in the seawater osmium inventory and $^{187}Os/^{188}Os$

B. KENDALL* AND X. LU

Department of Earth and Environmental Sciences, University of Waterloo, Waterloo, Ontario, N2L 3G1, Canada (*correspondance: bkendall@uwaterloo.ca)

Recently, several studies have used compilations of redox-sensitive metal abundances (e.g., Mo, Ni, Zn) from organic-rich sedimentary rocks (ORS) and iron formations to infer first-order temporal trends in oceanic metal inventories. These trends provide critical information about atmosphere and ocean oxygenation and associated changes in biogeochemical cycles and biological evolution. Osmium (Os) is a redox-sensitive metal that can provide information about redox conditions and crustal vs hydrothermal fluxes.

Most of the Os supplied to the modern oceans is derived from rivers (via oxidative weathering of the upper crust), with the remainder coming from cosmic dust dissolution and hydrothermal alteration of oceanic crust and peridotites. Osmium accumulates in modern oxygenated seawater (residence time of 10^4 years) but is sequestered into anoxic, organic-rich sediments. Seawater $^{187}Os/^{188}Os$ (= initial $^{187}Os/^{188}Os$ of ORS at the time of sediment deposition) also constrains the relative importance of radiogenic crustal versus unradiogenic hydrothermal (and extraterrestrial) inputs to seawater. Temporal trends in $^{187}Os/^{188}Os$ have been explored, whereas Os abundances in ORS have received less attention.

Here, we present a compilation of ^{192}Os abundances in ORS (total Os abundances are not used because of ^{187}Os contributions from ^{187}Re decay). We find that ^{192}Os abundances in pre-Ediacaran shales are low, typically <300 ppt, but still elevated above average upper crust (~10-20 ppt). The ^{192}Os enrichments and chondritic initial $^{187}Os/^{188}Os$ from Archean ORS require a oceanic Os inventory dominated by hydrothermally sourced Os. However, there is no clear change in ^{192}Os abundances across the Great Oxidation Event. This observation contrasts with a shift from chondritic seawater $^{187}Os/^{188}Os$ in the Archean to moderately radiogenic seawater $^{187}Os/^{188}Os$ in the Proterozoic, which points to an increase in the riverine flux of radiogenic Os to the oceans. To reconcile these obesrvations, we suggest that continued widespread Proterozoic deep ocean anoxia and declining hydrothermal Os fluxes kept the oceanic Os inventory broadly similar to Archean levels. Higher ^{192}Os abundances (>300 ppt) and instances of highly radiogenic seawater $^{187}Os/^{188}Os$ in the Ediacaran Period and Phanerozoic Eon point to an increase in the riverine Os flux and oceanic Os inventory in response to late Neoproterozoic oxygenation.

Possible PGE nano structures, in magmatic systems

KENNEDY, B.[1]*, TREDOUX, M.[1], BALLHAUS, C.[2], COETSEE, E.[3] AND STEYL, G.[4]

[1]Dept. of Geology, University of the Free State, South Africa, (*correspondence: kennedybia@gmail.com)
[2]Steinmann Institute, University of Bonn, Germany
[3]Dept. of Physics, University of the Free State, South Africa
[4]Dept. of Chemistry, University of the Free State, South Africa

The retention of platinum-group elements (PGE) in the mantle restite is difficult to explain by conventional chalcophile models. PGE nano-structures (clusters of 10-100nm), might be the cause that magma can become enriched in PGE, during the early stages of magmatic differentiation. The study focused on the possible formation of these entitites in a magmatic system. If these entities do form, to what extend might they contribute to ore forming processes in ultra mafic deposits, like the Bushveld complex.

A synthetic sulphide system was used to replicate the sulphide portion of a Cu-Ni-S ± PGE system. Sulphides are of the first ore minerals to crystallize in a magmatic environment and thus the ideal place to look for clusters. Experiments were run, using the dry powder silica charge technique. A base mixture of Cu, S and Fe, was doped with variable concentration of PGE (Pt, Pd and Ru) and As. As was chosen as stabilising chalcogene ligand. The systems were manipulated to form a mono sulphide or pyrrhotite phase (Fe_xS_x) and a melt ($Fe_xCu_xS_x$) phase.

Nano scale PGE-ligand phases, ranging from 10-1000 nm, were measured in the synthetic samples, by high resolution SAM and TOF-SIMS. This observation indicated that the PGE may form phases, on a nano level, without sulphide saturation having been achieved. The clusters form due to the physio-chemical association of the PGE with chalcogene ligands, such as As, Fe and Cu, before formal chemical bonding, to from PGMs. A fraction of the clusters are reabsorbed into the melt, while a fraction may act as nucleation points to form nano-crystals and minerals in the incompatible sulphide, oxide or silicate phases. The clusters form during the early stages of magmatic differentiation.

Chemical behaviour may govern the secondary distribution of PGE-phases, but clustering is potentially the primary (physical) enrichment mechanism. This behaviour cannot be explained by sub-solidus immiscibility properties as has been suggested to account for the frequent presence of PGE in base metal sulphide minerals.

Spectroscopically visualising the availability of goethite-sorbed phosphate to soil microorganisms

JANICE P.L. KENNEY [1]*, REINER GIESLER[2] AND PER PERSSON[1]

[1]Department of Chemistry, Umeå University, Umeå, Sweden, [2]Department of Ecology and Environmental Science, Umeå University, Umeå, Sweden (*correspondence: janice.kenney@chem.umu.se)

Phosphorus (P) is an essential nutrient, limiting biomass production in many soils. The biogeochemical cycling of P is highly influenced by soil minerals, such as goethite, which has the ability to strongly sorb soluble phosphates. However, the mechanisms by which soil microorganism take up sorbed phosphate is still not completely understood.

In this study we investigate whether soil microorganisms can use phosphate pre-adsorbed to goethite. To test this we ran experiments under four sets of experimental conditions; with or without P (+P/-P) and with or without glucose and nitrogen (+CN/-CN). The goethite was deposited as a mineral film on BaF_2 slides, after which the soil (clay-rich oxisol from South Africa), was deposited onto the goethite films. Prior to addition to the goethite layer, half the soil was amended with glucose and ammonium sulphate (2.0 and 0.3 g per g of soil organic matter, respectively).

The experiments were monitored over 13 days using FT-IR microspectroscopy. During this time it was found that there was no significant growth of microorganisms from the soil onto the goethite mineral film in both cases where C and N were not amended to the soil (-CN). However, in both cases where C and N are amended to the soil (+CN) we see microbial growth. When there is no P added to the mineral film (+CN/-P), we see only minimal growth of yeast cells close to the soil deposition site. When there is P added to the mineral film (+CN/+P) we see significant fungal hyphae growing out onto the goethite within 6 days of incubation. The FT-IR microspectroscopy results show distinct differences in the goethite near the fungal hyphae. These results show that goethite-sorbed P is bioavailable and can greatly affect the soil microbial growth.

Submarine meteorite impact craters as potential cradles of life: Mineralogical evidence from the Onaping Formation, Sudbury

G.G. KENNY[1]* AND B.S. KAMBER[1]

[1]Department of Geology, Trinity College Dublin, Dublin 2, Ireland (*correspondence: kennyg2@tcd.ie)

A difference between terrestrial versus lunar and martian impact basins is the possibility of submarine impacts. The thick meltsheet of a very large terrestrial impact acts as an effective heat source below water-filled craters and can potentially sustain prolonged phreatomagmatic activity. The Sudbury impact basin, Ontario, Canada, is the largest accessible and well-preserved example of a submarine impact. Although it is mainly known for its magmatic sulphide Ni-Cu deposits, it also hosts a number of VMS-type base metal deposits in the crater fill. Using observations from the fill, we highlight the potential importance of submarine meteorite impact craters as a location for the development of the life on the heavily bombarded early Earth.

We report the discovery of monocrystalline igneous quartz in the Onaping Fm. of the Sudbury crater fill – a complex unit composed of both the immediate fall-back of brecciated impact material and also later-formed igneous rocks. The crystallisation temperatures of the quartz grains have been calculated by applying the titanium-in-quartz thermometer to titanium contents obtained by LA-ICP-MS.

This finding provides support for continued in-crater igneous activity after the initial impact (e.g. [1]), and thus highlights the potential of submarine impact craters as sites where life might have emerged. Submarine Hadean impacts were likely common (e.g. [2]) as there is evidence for a liquid hydrosphere at this time (e.g. from abundance of halogens; [3]). From an emergence of life point of view, submarine craters are contained, confined bodies of water surrounded by highly friable rock, supporting a very high nutrient load. In addition, the hydrothermal processing of this fluid at volcanic vents was an effective factory for creating complex precursor molecules. Interestingly, the upper half of the Onaping Fm., like the overlying sedimentary Onwatin Fm., is rich in isotopically light [4] reduced carbon of possibly biologic origin (e.g. [5]).

Investigation of fungal decomposition of leaf lignin using synchrotron infrared microspectroscopy

J.L. KERR[1], D.S. BALDWIN[2], M.J. TOBIN[3], L. PUSKAR[3], G. REES[2] AND E. SILVESTER[1]*

[1]La Trobe University, Australia (*correspondence: e.silvester@latrobe.edu.au)
[2]MDFRC, La Trobe University, Australia
[3]The Australian Synchrotron, Australia

Fungi are a major decomposer group in the aquatic carbon cycle, and are one of few groups though to be capable of breaking down woody (lignified) tissue [1]. Here we have used synchrotron Fourier tansform infrared (S-FTIR) microspectroscopy to study the interface between fungal tissue and lignified leaf tissue (xylem) in two eucalypt species (River Red Gum and Snow Gum) during aquatic decomposition.

Aquatically decomposed River Red Gum leaf samples show strong depletion of lignin-bound carbohydrate immediately adjacent to the fungal tissue, spatially correlated with oxidation (de-polymerisation) of the lignin framework [2]. This observation has now been replicated with Snow Gum leaf samples (Figure 1 (a-c)) and investigated at even greater resolution using a synchrotron-coupled Focal Planar Array (FPA)-FTIR spectrometer (Figure 1(d)). S-FPA-FTIR offers sub-micron spatial resolution and can probe more subtle spatial changes in leaf chemistry at the fungal interface.

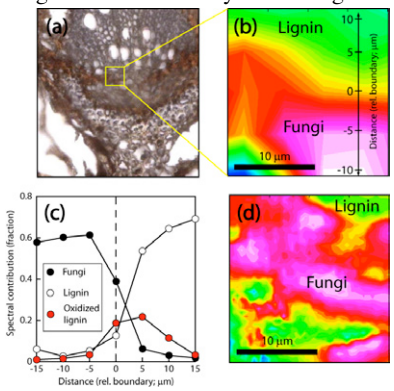

Figure 1.(a) Bright field image of Snow Gum vein; (b) S-FTIR map of fungi-xylem interface; (c) line scan across interface; (d) S-FPA-FTIR map of fungi-xylem interface.

Preliminary evaluation of trace hydrocarbon speciation and abundance as an exploration tool for footwall-style sulfide ore, Sudbury Igneous Complex, Ontario, Canada

MITCHELL J. KERR[1]* AND JACOB J. HANLEY[2]

[1]Saint Mary's University, Halifax, NS. B3H 3C3 (*correspondence: mitchjkerr@gmail.com)
[2]Saint Mary's University (jacob.hanley@smu.ca)

The North Range of the Sudbury Igneous Complex (SIC) hosts footwall-style Cu-Ni-platinum group element (PGE)-rich sulfide deposits of predominantly magmatic origin but that have been influenced by multiple syn- and post-magmatic hydrothermal events. The composition of reduced carbonic phases (unsaturated and saturated hydrocarbons, C1 to C6) in fluid inclusions within the matrix of Sudbury breccia, a rock unit that is permeable to circulating volatiles and that commonly hosts footwall-style Cu-Ni-PGE deposits, has been investigated by in-line rock-crushing gas chromatography. This was done on samples from zones of breccia that are known to contain economic footwall sulfide deposits and zones barren of such deposits. Subtle but strategically significant differences have been found in the composition and abundance of bulk hydrocarbons that are released from mineralized and barren breccias when fluid inclusions are opened. These findings include: (i) statistically higher average abundances of light, saturated hydrocarbons (C1-C4) in mineralized, embayment-associated footwall packages than in breccia from barren environments (maximum difference of approx. half an order of magnitude for propane abundances; mol/g rock), and (ii) no statistically significant differences in average unsaturated hydrocarbon abundances between the two breccia environments, but differences are present when considering the spatial variations of hydrocarbons within the mineralized breccia package itself relative to massive sulfide mineralization.

Additionally, samples of breccia and quartz (from mineralized alteration assemblages) from PGE-rich environments significantly deviate from expected hydrocarbon signatures and are considerably more enriched in unsaturated hydrocarbons. It is suspected that PGE, particularly Pt, play a direct role in the catalytic dehydrogenation of saturated, into unsaturated hydrocarbon species in hydrothermal environments. These findings strongly suggest that fluid hydrocarbon signatures should be taken into consideration when exploring for Cu-Ni-PGE-rich footwall-style ore bodies as a supplemental criterion to traditional visual and geochemical approaches.

Coprecipitation: Mechanisms and quantitative models

M. KERSTEN[1]

[1]Gutenberg-University, Mainz 55099, Germany
(*correspondence: kersten@uni-mainz.de)

Coprecipitation is referred to as the simultaneous removal of a trace with host constituent in the aquatic environment. Solid-solution aqueous-solution (SSAS) equilibrium models have been developed to close the often huge solubility gap in the continuum between surface complexation and single-component precipitation of trace elements [1]. These models were originally development to explain incongruent dissolution and secondary mineral formation in weathering reaction path modeling including carbonates and clay minerals [2,3]. They became of major interest, however, in long-term environmental assessment of radionuclide repositories, in particular for evaluation of near-field geochemical barrier performance. Such barrier concepts include radionuclide co-precipitation with more or less long-term stable minerals like sulfates [4], carbonates [5], and silicate hydrates [6]. More recently, the SSAS modeling concept became also of interest to manage enhanced geogenic radium leaching [7], which may occur during deep geothermal resource exploitation or hydraulic fracking for shale gas recovery. This keynote contribution will give an overview on the most promising applications in geochemical engineering, as well as model concepts spanning from the classical Lippmann equation approach for drawing aqueous solubility diagrams of binary solid solutions [8] to the most advanced non-ideal multi-site sublattice concept [9,10].

Arsenate adsorption by akaganéite

M. KERSTEN[1]* AND N. VLASOVA[2]

[1]Gutenberg-University, Mainz 55099, Germany
(*correspondence: kersten@uni-mainz.de)
[2]NAS Institute of Surface Chemistry, Kiev 03164, Ukraine

The β-type is the last among the FeOOH polymorphs for which there is yet no multi-site surface complexation (MUSIC) model, which requires information about the proton affinity of the various types of surface groups. Enigmatic behavior during acid-base titrations where protons are co-released from tunnel sites renders interpretation a challenge for akaganéite. In batch experiments, our akaganéite sample show a CIP at pH 7.7. However, the apparent surface charge is not equal to zero at this CIP but shows an offset by -0.25 C/m^2, obviously due to the excess tunnel site protons. We propose to monitor the chloride exchange with at least two days batch equilibration time (Fig. 1). The chloride is not significantly re-adsorbed on outer surfaces and may be used to monitor and quantify the excess tunnel HCl release. The thus corrected σ_0 vs. pH curves become sigmoidal and can be fitted to parameterize a reliable surface complexation model based on recently published site densities for singly and triply coordinated hydroxyl surface groups [1]. This provides a sound basis to set up CD-MUSIC adsorption models for arsenate and competing oxyanions. Furtheron, breakthrough curves of akaganéite based GFH fixed-bed adsorber column units can be calculated for different groundwater chemistry using a homogeneous surface diffusion model and Langmuir adsorption isotherms predicted by the surface complexation model.

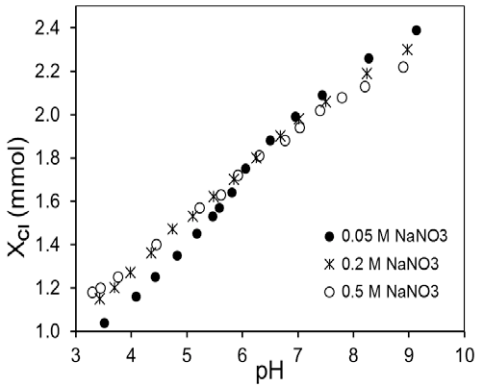

Figure 1: Tunnel chloride ion release vs. pH at different $NaNO_3$ electrolyte concentrations

Measuring the isotope fractionation of denitrification in permeable sediments

A.J. KESSLER[1]*, L.A. BRISTOW[2], M.B. CARDENAS[3], R.N. GLUD[2], B. THAMDRUP[2] AND P.L.M. COOK[1]

[1]Water Studies Centre and School of Chemistry, Monash Univ., Melbourne, Australia (*correspondence: adam.kessler@monash.edu)

[2]Nordic Centre for Earth Evolution and Institute of Biology, Univ. Southern Denmark, Odense, Denmark

[3]Department of Geological Sciences, Univ. Texas at Austin, Austin, Texas

Permeable sediments cover a significant proportion of the continental shelf, yet denitrification and other redox biogeochemistry in these sediments remains poorly understood. This is mostly due to the complex advective transport patterns in such sediments [1].

Despite benthic denitrification accounting for a significant oceanic nitrogen sink, no isotope effect (ε) associated with denitrification in permeable sediment has been published. Rather, most models assume an isotope effect of zero for this process, based on work solely in cohesive sediments [2]. However, permeable sediments could potentially impose substantial fractionation if nitrate is only partly comsumed during advective transport through the sediment.

We performed flow-through column experiments to quantify the organism-scale nitrate N isotope effect (ε_{cell}) during benthic nitrate reduction, the first step of denitrification using sand from Kerteminde, Denmark. The value of ε_{cell} was 18 ± 1‰, consistent with ε_{cell} values reported in cohesive sediments [3].

In order to estimate the apparent isotope effect (ε_{app}) on the overlying water, a computational model was employed to simulate denitrification and associated N isotope fractionation in a rippled permeable sediment under varied conditions. Simulations indicate that ε_{app} varies between 2‰ and 5‰, driven by advection of partially denitrified nitrate out of the sediment.

This work has significant implications for the global marine nitrogen isotope budget, and may help to explain discrepancies between modelled and measured ocean isotope signatures [2].

Geochemical fingerprinting of corundum from Fiskenæsset, Greenland

NYNKE KEULEN[1] AND PER KALVIG[1]

[1]Geological Survey of Denmark and Greenland (GEUS), Øster Voldgade 10, 1350 Copenhagen, Denmark. ntk@geus.dk, pka@geus.dk

Since the late 1960s it has been known that pink and red corundum occurs in the area near Fiskenæsset (Qeqetarsuatsiaat) in southern West-Greenland. Corundum is hosted in the Fiskenæsset complex, which is part of the Archaean basement of the North Atlantic Craton. To date, *c*. 40 corundum localities are known in the area – a few localities yield stones of gem quality. The most promising locality, Aappaluttoq, is likely to be mined in the near future by the Canadian company True North Gems.

This study is a first attempt to find geochemical characteristics that can be used to tie the Greenlandic rubies to their area of origin. Here, we present laser ablation-ICP-MS trace element geochemistry data and oxygen isotope investigations on samples from the Fiskenæsset area and other known localities in Greenland (Storø, Maniitsoq, Kapisilit, and Nattivit).

Trace element investigations of corundum grains separated from 21 handspecimen from ten localities in the Fiskenæsset complex were performed on 24 different elements with LA-SF-ICP-MS at GEUS, however most of them were not detected. Our investigations of the Greenlandic corundum were concentrated on the elements Mg, Si, Ti, V, Cr, Fe, and Ga. Results are compared with data from other localities in Greenland and from internationally, well-known, ruby occurences. Samples from Fiskenæsset show a considerably higher amount of Cr (up to 14000 ppm) than found in measurements on samples from other areas in Greenland and literature data on most international samples. The Fiskenæsset rubies are relatively rich in Fe and Si, but relatively poor in Ti and Ga, while V and Mg do not show very distinctive values compared to samples from other areas.

Oxygen isotope composition measurements were performed on 11 samples from Greenland at the University of Lausanne, Switzerland using an isotope ration mass spectrometer. Samples from the Fiskenæsset region yield $\delta^{18}O$ values between 1.62 and 4.20‰, which is low compared to the other areas in Greenland and world-wide.

The two methods discussed here are efficient in characterising the Fiskenæsset rubies. More independent methods are necessary for a high-confidence fingerprinting.

The study of polymorphs of Wordian Amb Formation, Salt Range of Western Pakistan in relation to Geochemistry

SAJJAD KHAN[1] AND NAGHMA HAIDER[2]

[12] Geoscience advance Research Laboratory, Geological Survey of Pakistan, Islamabad (pkpkgeo@gmail.com)

The Amb Formation of Wordian age (Martmann, 2003) was investigated for geochemistry. Twenty six samples were collected from out crop for geochemistry at Zaluch Nala of Western Salt Range of Pakistan.

The results of the collected samples displayed major oxides of K_2O, P_2O3, Na_2o, MgO, Al_2O3, TiO_2, Fe_2O_3, FeO, P_2O_5, SiO_2 & C (with addition of H_2O).

To find the number of polymorphs of twenty six out crop sample of thirty grams was processed one by one.

The productivity level of each sample was controlled by the comparative amount of CaO, MgO and C (both inorganic and organic).

Fifty six polymorphs species of thirty two were reported. Among these, eleven genera and nineteen species belong to trilete, six genera and nineteen species to monosaccates, twele genera and twenty four species to bisaccates. Pollens Colpates (two species) and acolpate (one species) were also reported from the samples.

The Role of Swamps in Formation of Chemical Composition of River Waters in Western Siberia

J.A. KHARANZHEVSKAYA[1], E.S. IVANOVA[1]*, E.S. VOISTINOVA[1] AND A.A. SINYUTKINA[1]

[1]Siberian Research Institute of Agriculture and Peat, Tomsk, 634050 (*ivanova_e_s@bk.ru, kharan@yandex.ru)

The landscape is characterized by the wide spread occurrence of raised oligotrophic swamps with the dominant role of the ridge-pool and ridge-lacustrine-pool systems in combination with areas of riams–oligotrophic complex piny-suffruticous-sphagnous swamps and narrow bands of transitional swamps along the periphery of watershed areas. Geographical coordinates of the area are N56є03'07" E82є22'42".

Water samples for the analysis were taken within the basin of the Klyuch River in the most typical swampy geobiocoenoses: piny-suffruticous-sphagnous with a 10-15 meter pine (point 2); piny-suffruticous-sphagnous with a scrubby pine (point 3); sedge-sphagnum (point 5).

Index	Max. allowable conc. (MAC) est. Russia	the Klyuch River	Mire		
			Point 2	Point 3	Point 5
pH	6.5–8.5	6.5	4.4	3.8	4.1
mineralization	1000	72.0	30.2	25.1	15.1
NH_4^+	1.9	3.8	6.7	6.0	3.5
COD,mgO/dm^3	15	122.2	262.4	157.7	162.2
humic acid	-	6.7	8.9	9.5	5.5
fulvic acid	-	41.1	66.6	53.1	43.3
Fe_{total}	0.3	2.5	2.9	1.8	1.3

Table: Chemical composition of swamp and river waters for 2006 – 2011 years of research, mg/dm^3

The chemical composition of swamp waters of area under study is an averaged sample of the one-meter peat mire layer and represents biochemical and biological processes occurring in them. The content of water-soluble carbon in the water under study at its maximum values varies from 106.6 mgC/dm^3 in point 2 to 63.4 mgC/dm^3 in point 5. This index for river waters falls by 3-5 times. Due to that fact that the intensity of the peat decomposition processes in a high bog increases from the center to the periphery (from point 5 to point 2), the content of all components of the geochemical runoff increases in this direction. A high content of NH_4^+ (5.4 mg/dm^3) is observed in swamp waters: it almost three times exceeds the maximum allowable concentrations. The content of NH_4^+ in river water is one and a half time lower –3.8 mg/dm^3. It should be also noted that the value of dichromate oxidizability in the swampy area 25 times exceeds MAC, as compared with river waters, where this index is exceeded only by 11 times. Thus, for a number of natural reasons, swamp and river waters contain high concentrations of organic and biogenic substances, the content of which in river waters is several times lower.

Isotopes of oxygen and hydrogen in natural waters from NE of Asia

N.A.KHARITONOVA, G.A.CHELNOKOV AND I.V.BRAGIN

690022, Russia, Primorsky region, Vladivostok, Prospect 100-letya 159, Far East Geological Institute Russian Academy of Science (tchenat@mail.ru)

Isotopes of oxygen and hydrogen are ideal natural tracers for describing phenomena of the water cycle so they are constituents of the water molecule. The $\delta^{18}O$ and $\delta^{2}H$ in waters violently rely on meteoric processes, and so infiltration into specific sediments leads to a characteristic isotopic signature which tags as the origin of groundwater as surface water–groundwater interactions. ^{3}H is the most attractive radioisotope for studying the principles of water circulation in nature so it is a perfect water tracer. The first particular data about the content of stable and radiogenic isotope of oxygen and hydrogen in natural water of region were presented in some studies (Chudaeva *et al*., 1999; Kharitonova *et al*., 2012), however simultaneous measurements $\delta^{2}H$, ^{3}H and $\delta^{18}O$ were never performed for this area.

The aims of this study are to define local meteoric waters line of Russian Far East, to identify the forming conditions of various groundwater types of area using isotopic parameters and estimate residence time of groundwater basing on tritium values.

More than 120 samples of precipitation, seawater, surface water and groundwater were collected across territory of Russian Far East during last 7 years and then analyzed for isotopic composition. Geochemical characteristics of these samples were published earlier (Chelnokov & Kharitonova, 2008).

Our data let us conclude:

1. All studied groundwater is meteoric water and shift from GMWL for some spas is the result of water-rock-gas interaction. Local meteoric water line for the southern part of Russian Far East can be determined by the equilibrium: $\delta D=7.6385\times\delta^{18}O+3.96‰$. Continental and lateral zonal distribution of stable isotopes on this territory is being observed.

2. There is the universal increasing in ^{3}H values in surface water from ocean to inland. Content of tritium is 20 TU in rivers of Amurskiy region, ~13 TU in rivers of Primorsky region and to ~5.5 TU in ones of Kuril Islands. Most of studied groundwater, excluding brackish waters of Rechitza outlet, have short residence time (less 50 years).

Low thermal Northern Dvina iodine water field: History of prospection and perspectives of development

I.L. KHARKHORDIN[1]*, F.G. ATROSCHENKO[1] AND V.V. NAZIMA[1]

[1]Geostroyproekt Ltd., 22-th Line, 3, St. Petersburg, 199106, Russia (*correspondence: kharkhordin@rambler.ru)

[2]Geostroyproekt Ltd., 22-th Line, 3, St. Petersburg, 199106, Russia (fatroschenko@mail.ru)

[3]Geostroyproekt Ltd., 22-th Line, 3, St. Petersburg, 199106, Russia (v.v.nazima@gmail.com)

Iodine water field is located at Northern Dvina River basin, north-west of European part of Russia [1]. Uncommon features of the field are as follows.

1) Depth to iodine water containing aquifer is only 100-120 meters.

2) Iodine water field was formed at low temperature conditions (below 10 ºC).

3) The source of iodine is organic fosils associated with marine clays (Q_{IIImk}) [2]. This clays was consolidated by ice shield, iodine water was espressed into upper part of padun aquifer (V_{pd}).

At present study analysis of hydrodynamic and hydrochemical conditions of iodine water field was performed, the numerical models of groundwater flow and iodine transport were created using MODFLOW-96 [3] and MT3DMS [4] computer codes. The main issues are:

- the present day recharge through mikulinski clays is impotant for iodine water field existence due quarternary time, it partly compensates iodine water discharge into Nothern Dvina River;
- resources of iodine water was estimated;
- limiting factor of iodine water field exploitation is fresh water upconing from low part of padun aquifer;
- strategy for iodine water field exploitation was elaborated.

Provenance tracing of aerosols in the South Atlantic Ocean using Pb and Nd isotopes and select trace and rare earth elements

R. KHONDOKER[1]*, D. WEISS, T. VAN DE FLIERDT[1], M. REHKÄMPER[1], R. CHANCE[2], A. BAKER[2], S. STREKOPYTOV[3], E. WILLIAMS[3] AND J. NAJORKA[3]

[1]Dept. of Earth Sciences, Imperial College London, SW7 2AZ , UK (roulin.khondoker04@imperial.ac.uk)
[2]University of East Anglia, Norwich, NR4 7TJ, UK
[3]Natural History Museum, London, SW7 5BD, UK

The atmosphere is an important pathway of delivering nutrients to ocean surface waters. These nutrients can play a vital role in marine biogeochemical processes and ultimately the global carbon cycle. However, our understanding of the atmospheric inputs and their influences on marine micronutrient cycles is limited, particularly in the South Atlantic, a region where models predict widely variable fluxes of micronutrients to the ocean from the atmosphere.

Moreover, in reent years it has become clear that atmospheric emissions from cities and human activities, such as road traffic and industrial plant emissions, can significantly impact atmospheric inputs and thus alter micronutrient fluxes to the ocean. Although air quality studies have been carried out for some cities bordering the South Atlantic Ocean, including São Paulo and Buenos Aires, the impact of emissions from such cities on marine micronutrient budgets has not been studied in detail.

Here, we present rare earth and selest trace element data as well as results from Pb and Nd isotope analysis of sediments, volcanic ash, road dusts, aerosol filters and lichens from Patagonia, recent Cotopaxi, Chaitan and Puyahue volcanic eruptions, and the cities of São Paulo, Buenos Aires and Johannesburg. All sites are potential atmospheric aerosol sources for the South Atlantic Ocean. The rare earth and trace element concentration data and the isotopic results allow characterisation of the different source sites with adequate resolution to distinguish between South American and Southern African as well as anthropogenic and natural aerosol sources. This provenance information will be applied to interpret the first comprehensive geochemical data set (comprising rare earth, other trace element concentrations, and Pb, Nd isotope compositions) for aerosol filters collected in the South Atlantic Ocean at approximately 40° S during the UK GEOTRACES cruises D357 and JC068.

Mineralogy and origin of uranium deposits from central Jordan

HANI N. KHOURY

Department of Geology The University of Jordan, Amman – Jordan 11942 (khouryhn@ju.edu.jo)

Secondary uranium surficial mineralization is hosted by travertine and calcrete in central Jordan [1]. The paleocirculating water in the combusted bituminous marl has oxidized the dissolved V4+ to V5+ and fixed the uranyl-ion as uranyl vanadate in strelkinite and metatyuyamunite. Carnotite was favored depending on the availability of K in solution. The uranyl vanadate minerals were precipitated from highly alkaline solutions during the dry periods after the precipitation of the thick travertine deposits.

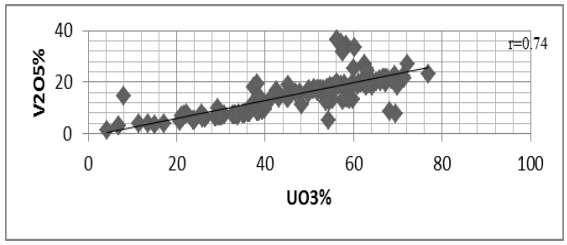

Figure 1: EDS results: UO3 vs V2O5 correlation of the uranium minerals

Discussion of Results

U and V are associated in the same mineral phases as indicated in the figure above. The travertine is an evidence for discharges of hyperalkaline groundwater in the past [1]. Oxidizing alkaline circulating water oxidized dissolved V4+ to V5+, and mobilized uranium as uranyl complexes before the precipitation of uranium vanadate minerals as strelkinite and tyuyamunite and carnotite.

The assessment of the incidence of arsenic (As) and other oxyanions forming trace elements was examined in Bengal delta floodplain groundwaters from Matlab Upazila, Bangladesh and Murshidabad District, India. These field areas cover an area of about ~400km^2 (von Brömssen *et al*. 2008) and ~438km^2 (Datta *et al*. 2011) respectively. The study focuses on the sediment geochemistry and adsorption behavior of oxidised red brown and reduced grey sediments and their respective capacity to attenuate As. Sediment cores were collected at regular intervals within depth of 125m in Matlab and ~40m in Murshidabad. Detailed sequential extractions of sediments indicate relatively low amount of As released from oxidized sediments. The study describes the lithofacies, mineralogy and results of adsorption experiments on the sediments from two sites and establishes a relationship between aqueous and solid phase geochemistry along the various depths of the aquifers. DNA recovered from Matlab core samples averaged 450ng/g from course-grained samples and 800ng/g from fine-grained samples. Sequencing of the DNA is utilised to identify microbial communities and their role in the biogeochemical processes controlling the groundwater As levels. Synchrotron aided μXANES and μXRD studies conducted for solid state As and S speciation in the core samples at different depths indicate the occurrences of hotspots of As differently distributed in red-brown and grey sediments in both these sites. The projected outcome is to incorporate detailed sediment characteristics of the different aquifers including all possible color variations available in exploited depths within Matlab and Murshidabad respectively. Porewater from Matlab abstracted from oxidized reddish sediments, in contrast to reducing greyish sediments contain substantially lower amount of dissolved As and can be a source of safe water. This study has wider implications towards broad scale regional approach for As mitigation that incorporates the enquiry of efficiency of sediment color as a simple and easy tool for identifying safe aquifers in major As prone areas.

Peat and sapropel as the sources of humus for the restoration of degraded lands of the Amur region (Far East, Russia)

VARVARA KICHANOVA AND VALERY KICHANOV

Institute of Geology and Nature Management FEB RAS, Blagoveshchensk, Russia, (barbara@mail.ru)

The natural ability of soil to produce biological products decreases each year. The problem of the land resources has become one of the largest global problems. It is connected with the growth of world population and, consequently, decrease of sown area per capita; increased area of degraded and disturbed soils. In particular, in the Amur region of degraded and disturbed lands is increasing every year. Also because of the lack of organic fertilizers, that has decreased from 63 kg/ha in 1995 to 5 kg/ha in 2011 [1]. The specific weight of fertilized area of organic fertilizers in the total sown area in 1995 was 0.5 %, in 2011 – 0.09%. Only 2% of the soils of the region (660 thousand hectares) are characterized by high soil fertility, where humus horizon reaches 20 - 40 cm sometimes 50 cm. Humus content in the upper part of the soil is from 4 up to 8%. The annual loss of humus soils of the Amur region is 0.45 tons per ha. At the same time with the loss of humus, the destruction of soil structure is mentioned, soil compaction lead to a deterioration of its physical and chemical characteristics [2]. Soil restoration is possible with the introduction of organo-mineral fertilizers produced from peat and sapropel deposits of the Amur region. The region possesses significant reserves of peat and sapropel. The total area of deposits of sapropel, in the border of the industrial depth of the deposits is 1493 ha. The total content of useful (1553 g/t) and harmful (436 g/t) elements in sapropels of Amur region in comparison with other sapropels and soils of Russia has the highest - lowest values [3]. Peat general reserves of the Amur region include 600 deposits. The total projected resources of peat, including reserves of explored fields, are 158.5 million tonnes, with 40% of the conditional humidity. Total area of the deposits is 5663.5 km2 [4]. These reserves are sufficient to restore the fertility of the soils of the region.

Ethanol Variability in Rainwater and its Impact on the Chemistry of the Troposphere

R.J. KIEBER[1], J.D. WILLEY[1], G.B. AVERY[1], R.N. MEAD[1], F.F. GIUBBINA[2] AND M.L. CAMPOS[2]

[1]University of North Carolina Wilmington, Department of Chemistry and Biochemistry, Wilmington, NC USA 28403 (*correspondence: kieberr@uncw.edu)

[2]Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Av Bandeirantes, 3900, 14040-901 Ribeirão Preto, SP, Brazil

We present the first detailed analysis of the occurrence and variability of ethanol in precipitation collected in coastal North Carolina (NC) USA and at the Universidade de São Paulo, Brazil. Concentrations ranged from 23 nM to 908 nM with a volume weighted average (VWA) concentration of 193 nM at the NC collection site (n=52). The VWA concentration of ethanol is more than an order of magnitude higher (2.7 μM) in Brazilian rain (n=40) relative to the NC site with the highest concentrations exceeding 10 μM. There was a great deal of variability in the abundance of ethanol between rain events at both sites driven primarily by temporal and air mass back trajectory influences.

The presence of significant quantities of ethanol in precipitation has important implications for fundamental properties of atmospheric waters including the oxidizing and acid generating capacity of the troposphere, photochemical smog formation, as well as indirect effects on solar radiative transfer and light attenuation. Also, because rainwater is an important mechanism by which CH_3CH_2OH is transported from the atmosphere to surface waters, greater wet deposition of ethanol from increasing biofuel usage could dramatically influence the biogeochemistry of receiving watersheds which typically have concentrations one to two orders of magnitude lower than rainwater.

Factors affecting fractionation of Ni and Cr in ultrabasic soils from southwestern Poland

J. KIERCZAK[1], A. PĘDZIWIATR[1], J. WAROSZEWSKI[2], AND R. TYSZKA[2]

[1]University of Wrocław, Institute of Geological Sciences, Cybulskiego 30, 50-205 Wrocław, Poland; jakub.kierczak@ing.uni.wroc.pl, artur_pedziwiatr@op.pl

[2]Wrocław University of Environmental and Life Sciences, Department of Soil Sciences and Environmental Protection, CK Norwida 25/27, 50-375 Wrocław; jaroslaw.waroszewski@gmail.com, tyszkarafal@gmail.com

Weathering of ultrabasic rocks, naturally enriched in some trace elements (e.g., Ni and Cr) leads to the formation of soils having distinctive properties caused primarily by a specific chemical composition of parent rocks. The parent ultrabasic rocks commonly cause infertility of serpentine soils, which results from the low ratio of calcium to magnesium, and the high content of Ni and Cr in the parent rock and the soil.

We have analysed shallow and well drained soils (Leptosols) developed on a variety of ultrabasic rocks, from hornblende peridotite through partially serpentinized peridotite to proper serpentinite. The Ni and Cr concentrations in soils decrease upwards in analysed pedons and range from 72 to 2350 ppm for Ni and 160 to 3500 ppm for Cr. Studied ultrabasic soils have similar physicochemical charcteristics (e.g., slightly acidic to neutral pH, clay content approximately 10% etc.) however mineralogical composition seems to be strongly influenced by different types of ultrabasic roks. Soils developed on peridotites have more complex mineralogy and contain important proportions of swelling phases (smectite, vermicullite, interstratified chlorite/smectite) whereas only traces of swelling phases were detected in soil derived from serpentinite. Fractionation of Ni and Cr, estimated using the 0.05 M EDTA, aimed to determine the easily mobilizable proportions of these elements. In all studied soils proportions of Ni-EDTA extractable (5-42% of total Ni) are larger than proportions of Cr-EDTA extractable (1-7% of total Cr). The highest proportions of EDTA extractable fractions of both Ni and Cr were noted in topsoil horizons of all studied soils. Soils developed on peridotites have hihger proportions of Ni-EDTA extractable than soils derived from serpentinite.

Our study shows that type of parent rock strongly influence fractionaction of Ni and Cr in ultrabasic soils, however other factors (e.g., organic matter content, local climatic conditions etc.) should also be taken into account.

Residence times of ancient water in Outokumpu (Finland) revealed by noble gases

R. KIETÄVÄINEN[1]*, L. AHONEN[1], I.T. KUKKONEN[12], S. NIEDERMANN[3] AND T. WIERSBERG[3]

[1]Geological Survey of Finland, Espoo, Finland (* correspondence: riikka.kietavainen@gtk.fi)
[2]University of Helsinki, Department of Physics, Helsinki, Finland
[3]Deutsches GeoForschungsZentrum, Potsdam, Germany

Deep saline groundwaters in the Precambrian crystalline bedrock of Outokumpu, eastern Finland, host ecosystems that may be remarkably old. Based on water stable isotopes, these waters have been suggested to be recharged during climatic conditions up to 10°C warmer than at present, which would be indicative of residence times on the order of tens of millions of years [1].

In order to better define residence times, concentrations of radiogenic (^{4}He, ^{40}Ar), nucleogenic (^{21}Ne) and fissiogenic (^{134}Xe, ^{136}Xe) noble gas isotopes were measured in water and gas samples covering a depth range from 500 m to 2450 m in the Outokumpu Deep Drill Hole.

The observed vertical variation of geochemistry and microbiology together with hydrogeological and geophysical measurements indicate negligible fluid flow in the bedrock. Furthermore, more than 99 % of the air-corrected He is crustal in origin with an average ^{3}He/^{4}He ratio of $1.5 \cdot 10^{-8}$, and no concentration gradient indicative of diffusive flux through the crust was observed. Therefore an *in situ* accumulation model [2] using average values for porosity, density and concentrations of radioactive elements (U, Th and K) in the Outokumpu deep drill core [3] was applied to calculate residence times.

Residence times between 12 and 45 Ma are indicated by the ^{4}He accumulation. Similarly, ^{21}Ne and ^{40}Ar ages fall between 5 and 70 Ma whereas ^{134}Xe and ^{136}Xe indicate longer residence times. The results thus confirm the existence of ancient groundwaters in Outokumpu. This should be taken into account when rates of microbial metabolism, adequacy of substrates, and biological cycling of elements within the deep subsurface are considered.

Can radioactive cesium be used as a hydrological tracer for crater lake study?

YOSHIKAZU KIKAWADA[1]*, AYA OKAWA[1], KO NAKAMACHI[2], TERUYUKI HONDA[2], TAKAO OI[1] AND KATSUMI HIROSE[1]

[1]Sophia Univ., Tokyo 102-8554, Japan. (*correspondence: y-kikawa@sophia.ac.jp)
[2]Tokyo City Univ., Tokyo 158-8557, Japan.

The Fukushima Dai-ichi Nuclear Power Plant (FDNPP) accident in March 2011 resulted in serious radiological contamination in areas adjacent to the plant. Meanwhile, radioactive cesium originated from the accident was detected over a wide range of the northeastern half of Honshu, the main island of Japan. In this study, we discuss the possible use of radioactive cesium newly deposited on the ground from the FDNPP accident as a hydrological tracer for crater lake study in Japan, taking crater lakes of the Kusatsu-Shirane volcano, located about 240 km west-southwest from the FDNPP, for example. Water budget of crater lakes, especially on active volcanoes, is very complicated, because most of them are closed ones. The budget and circulation of water in active crater lakes provide very important information connected to the hydrothermal activities and subsurface structures of the volcanoes.

The Kusatsu-Shirane volcano with three crater lakes on its summit area is one of the most famous active volcanoes in Japan. Yugama, the largest and deepest one among the three is well known as an active crater lake filled with water of high salinity and strong acidity. We determined the contents of radioactive isotope of cesium, ^{134}Cs and ^{137}Cs, and the stable isotope, ^{133}Cs, and their content ratios in waters of three crater lakes of the Kusatsu-Shirane volcano collected in 2012. The obtained activity ratio of ^{134}Cs/^{137}Cs revealed that the radioactive cesium released by the accident has reached the summit area of the volcano. However, the concentration of radioactive cesium was not uniform among the three crater lake waters. This ununiformity is most probably ascribable to the difference in the water supply and circulation system among the three. This suggests that the temporal changes in the concentration of radioactive cesium and their concentration ratios against the stable isotope can provide us useful information to clarify the water budget in the summit area of the Kusatsu-Shirane volcano. In this context, we are now investigating the temporal changes in the concentrations of ^{134}Cs, ^{137}Cs and ^{133}Cs in the crater lakes.

High-resolution imaging and quantification of Au in sulphide minerals using NanoSIMS

M.R. KILBURN[1]* AND R. LIU[1]

[1]Centre for Microscopy, Characterisation and Analysis, The University of Western Australia, Crawley, 6009, Australia (*correspondence: matt.kilburn@uwa.edu.au)

With its high lateral resolution and high sensitivity, NanoSIMS is the ideal tool for mapping the distribution of trace elements within sulphide minerals. In Carlin-type deposits, Au is typically present as narrow rims along the edges or within the matrix of the sulphide grains. The low concentrations of Au in solid solution with the sulphide are notoriously difficult to detect by most in situ techniques, such as EPMA, and is thus commonly referred to as 'invisible gold'. As SIMS is very sensitive to Au, and other commonly associated trace elements such as Te and Sb, NanoSIMS provides the ability to image these elements with sub-micron resolution. At such scales it is possible to investigate the intricate relationships between the Au and associated elements to help determine the nature and evolution of the Au-bearing fluids [1]. Furthermore, through the development of ion-implanted standards, it is possible to quantify the concentration of Au directly from the NanoSIMS secondary ion images. Preliminary data also show the potential to obtain S isotope measurements from the same regions of interest.

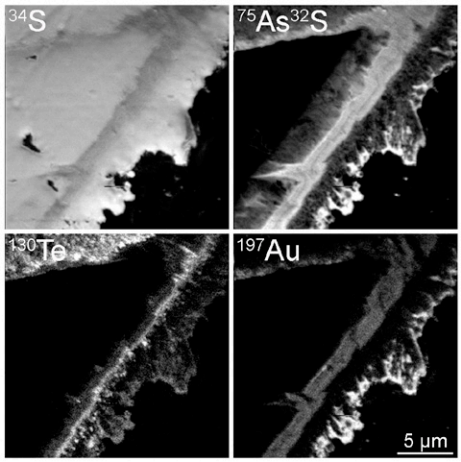

Figure 1: Secondary ion images showing the distribution of S, As, Te and Au in a pyrite grain from a Carlin-type deposit.

Investigating the role of noble gases as tracers for CO_2 storage

R. KILGALLON[1]*, S.M.V. GILFILLAN[1], C.I. MCDERMOTT[1] AND K. EDLMANN[1]

[1]School of GeoSciences, The University of Edinburgh, King's Buildings, Edinburgh, EH9 3JW (*correspondence: Rachel.Kilgallon@ed.ac.uk)

The capture and long term storage of carbon dioxide (CO_2) in the subsurface is one of the most promising ways of mitigating the current level of anthropogenic CO_2 being released to the atmosphere. A major issue surrounding long term storage is the risk of failure of CO_2 containment. Developing a monitoring strategy which would allow early detection of CO_2 leakage would enable measures to be implemented to mitigate and remediate the impact of containment failure. Experiments and modelling results have shown that noble gases have the potential to act as early warning tracers for CO_2 arrival [1]. Previous studies highlight the importance of understanding the transport processes involved for calculating tracer arrival times [2].

This study uses specially constructed equipment for experiments to determine factors affecting the transport of noble gases relative to CO_2. Initial pipeline experiments using argon and CO_2 have determined the parameters required for complete mixing of the gases.

We intend to examine conservative transport processes such as the advection, dispersion and diffusion of noble gases relative to CO_2 in porous media. The existence of any non-conservative transport processes such as sorption and dissolution are also considered. These data are compared to results from core flow experiments in order to determine the relationship between CO_2 and noble gases on rock core samples. The choice of sample used for experiments are low permeability porous sandstones.

Preliminary data will establish how noble gases and CO_2 behave in porous media during migration. Upscaling of the initial results will determine how effective different noble gases could be at acting as early warning tracers in a real world storage site.

Antimony in hydrothermal chimneys of Kolumbo shallow-submarine vent field (Santorini, Greece)

S.P. KILIAS[1]*, A. GODELITSAS[1], P. GAMALETSOS[12], T.J. MERTZIMEKIS[1], P. NOMIKOU[1], J. GÖTTLICHER[2], R. STEININGER[2], A. ARGYRAKI[1], M. GOUSGOUNI[1] AND D. PAPANIKOLAOU[1]

[1]University of Athens, School of Science, 15784 Zographou, Greece (*correspondence: kilias@geol.uoa.gr)

[2]KIT, ANKA Synchrotron Radiation Facility, Hermann-von-Helmholtz-Platz 1, 76344 Eggenstein, Germany

Polymetallic sulfide/sulfate chimneys, collected during the NA014 expedition of the E/V *Nautilus* (2011) from the Kolumbo shallow-submarine hydrothermal field (Santorini, Greece), are exceptionally enriched in antimony (up to 2.2 wt%) [1]. SEM-EDS data show that colloform banded trace-element-rich zoned possibly biogenic Fe-sulfides show oscillatory zoning; zones "bright" in BSE are enriched in Sb (up to 11 wt%), and/or Pb, As and Si. However, preliminary SR μ-XRF elemental maps confirmed that Sb is mostly concentrated in the core relative to rim (Fig. 1).

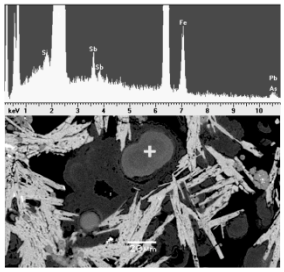

Figure 1. Colloform banded masses of amorphous trace-metal rich Fe-sulfides surrounded by barite blades

Subsequent μ-XAFS spectra, in micro-areas with accumulated Sb, have indicated a possible dominance of the relatively more toxic trivalent species (Sb^{3+}) rather than pentavalent species (Sb^{5+}) forms [2]. It is known that pyrites may accommodate Sb-ions and Sb-sulfosalt nanoparticles [3], but there are no particular studies on the nature of Sb in amorphous Fe-sulfides from recent submarine hydrothermal fields, unless stibnite is formed. Future work will include further evaluation and upgrading of the SR data in combination with microscopic investigation in nanoscale.

Statistical Approach and Heavy Metal Analyses of Konyaalti (Antalya, Turkey) Coast Water

S. KILIC[1], F. YALCIN[2] AND M.G. YALCIN[3]*

[1]Akdeniz University, Ar-Ge Lab, 07058, Antalya, Turkey, (serpilkilic@akdeniz.edu.tr)

[2]Akdeniz University, Department of Mathematics, 07058, Antalya, Turkey, (fusunyalcin@akdeniz.edu.tr)

[3]Akdeniz University, Department of Geological Engineering, 07058, Antalya, Turkey, (gurhanyalcin@akdeniz.edu.tr)

The aim of the study conducted on Konyaalti (Antalya) coast, which is one of the important coasts of Turkey, is to determine the heavy metal (Ni, As, Cr, Pb, Cd, Cu) contents in the seawater along the coastline. In this study samples were taken systematically from 35 different coastal locations. According to the EPA method 3005A(EPA 3005A, 1992), pre-treatment was applied. The fact that the seawater is rich in the elements such as Na,Ca,Cl posed a problem of contamination. Coal gas was used to prevent the contamination (e.g.$^{40}Ar+^{35}Cl—^{75}As$).DRC(Dynamic Reaction Cell) method was applied firstly with %0.1 NaCl solution as being a matrix, then by spiking As so that it is to be 20 ppb into %0.1 NaCl solution. According to the recovery data, measurements were analyzed in the ICP-MS device by using EPA method 6020A(EPA 6020A, 1997). Calibration curve (R^2) chart was drawn with the standards of 2, 5, 10, 15, 25, 50 and 100 ppb from 100 ppm VHG multi-element standard. These values were between 0.9999-0.9993 through the whole study. In the recovery process the minimum and maximum values of the 6 spikes are as follows: As (14.152 - 16.415), Pb(14.540-16.483), Ni(14.719-16.621), Cr (15.498 - 16.937), Cu(14.999-16.138), Cd(14.349-15.844). According to this, the mean percentage values of the recovery were calculated as As(%101), Pb(101), Ni(104), Cr(108), Cu (101), Cd(99). The values were determined as <2 ppb in the locations of 7,8,10,13,19,28 and 31 for As; 3,6-8,10,13, 14, 18,19,21,23-27,29-34 for Pb; 1-3,5,6,8-27,29-35 for Ni; 3, 5-8,10,11,13,18-20,22,24-26,30,31 for Cu;2,7,9-16,18, 19, 21-27, 29-35 for Cd. Maximum values were observed in the stations numbered 35(11.19 ppb) for As;4(75.44 ppb) for Pb; 28(61.3) for Ni;5(114.82 ppb) for Cr;9(65.15 ppb) for Cu; 4 (243.63 ppb) for Cd. It is thought that there is an anthropogenic effect especially in the locations numbered 4,5 and 9.

Petrology and geochemistry of mafic and ultramafic metamagmatic rocks emplaced within the anatectic series of the middle crust of the Variscan Pyrenees: example of the Gavarnie-Heas dome, West Pyrenees

M. A. KILZI[1], M. GREGOIRE[1], M. BENOIT[1], P. DEBAT[1], M. ST. BLANQUAT[1] AND Y. DRIOUCH [2]

[1]Laboratoire de Géosciences Environnement Toulouse, Observatoire Midi Pyrénées, Université Paul-Sabatier, CNRS, IRD, *14*, Avenue Edouard Belin 31400 Toulouse michel.gregoire@get.obs-mip.fr

[2]Département de Géologie, Université de Fès, Maroc

Within the anatectic formations of the middle crust of the Variscan Pyrenees occur in some massifs (Alberes, Aston, Trois Seigneurs, Lesponne…) ultramafic and mafic rocks forming polymetric or plutons mileage enclaves. The most significant example is the Héas Gavarnie Dome in the Western Pyrenees. Within this dome of metasedimentary formations affected by a common anatexis (peak conditions at around 730 °C and 4.3 kb) the mafic and ultramafic series form three massifs: the Troumouse massif in the south, mostly made of diorites; the Aguila massif consisting of diorites which contains some hornblendite enclaves; the Gloriette massif, consisting of diorites and norites associated with ultramafic rocks (orthopyroxenites and hornblendites). All of these rocks are affected by variable degrees of metamorphism resulting in the development of secondary amphibole and biotite and cross cutted by a network of granitic bodies.

Petrological and geochemical studies show that theses rocks mostly correspond to a basic metamagmatic series with a calc-alkaline affinity and characterized by enriched REE (432 ppm) contents, and REE fractionation processes (La/Yb)N =7.5; (La/Sm) = 2.5 and (Gd/Yb) = 1). They have positive Eu anomalies (Eu/Eu* = 3.5) and the following trace element characteristics: (1) enrichments in U; (2) Nb and Sr depletion; and (3) large positive Pb anomalies. 87Sr/86Sr isotopic ratios of mafic and ultramafic rocks range from 0.7045 to 0.7117 and eNd from -5.2 to -10.5. These signatures are typically crustal and show that these rocks have preserved the isotopic fingerprints of lower crustal magmatic processes

Interpretation of hydrochemistry data using Bayesian statistical approaches to delineate groundwater contamination vulnerability

HO-RIM KIM[1], KYOUNG-HO KIM[1], KYUNG-GOO KANG[2], SOO-HYUNG MOON[2] AND SEONG-TAEK YUN[1]*

[1]Korea University, KU-KIST Green School and the Department of Earth and Environmental Sciences, South Korea, styun@korea.ac.kr (* correspondence)

[2]Jeju Special Self-Governing Province Development Corporation, Jeju, South Korea

Well understanding of the source(s) and landuse control of groundwater contamination is highly needed to better manage groundwater quality. In this context, we perfirmed the interpretation of hydrochemical data of groundwater using the Bayesian statistical method in conjunction with a GIS technique to produce a spatial map showing groundwater vulnerability to contamination. In particular, we used the Weight of Evidence (WofE) method (a Bayesian probabilistic model) and relevance vector machine (RVM) regression (a Bayesian machine learning technique) that was recently developed to find out the correlations among factors influencing the occurrence of groundwater contamination. Hydrochemistry data of 46 groundwater samples from the Pyosun watershed of Jeju volcanic island, South Korea were used, because the groundwater system has been considered to be highly susceptible to surface contamination (esp., agricultural pollution) because of the short residence time in permeable basaltic aquifer.

For the combined use of WofE and RVM, hydrochemistry data were evaluated using multivariate analyses to get the initial information whether a sample is contaminated or not. The results of Principal component analysis (PCA) and Hierarchical Cluster Analysis (HCA) showed a good spatial control of hydrochemistry data in relation to the topography within the watershed. In the next step, we estimated the correlation between topography data and the results of a binary classification from multivariate analyses. The results using Bayesian statistical techniques could predict the contamination vulnerability. Thus, the integrated method developed in this study can be successfully used for evaluating the groundwater vulnerability.

Use of risk-based remediaiton strategy and concept of attainable clean-up level in management of groundwater contaminated sites in Korea

HUN-MI KIM[1]*, SEONGSUN LEE[1], DUGIN KAOWN[1] AND KANG-KUN LEE[1]

[1]School of Earth Environmental Science, Seoul National University, Seoul 151-747, Korea (*correspondence : tweety1@snu.ac.kr), soon3311@snu.ac.kr, dugin1@snu.ac.kr, kklee@snu.ac.kr

There are recognized needs to establish a reliable and effective remediation strategy as groundwater and soil protection from DNAPL(dense non-aqueous phase liquid) contamination is one of the critical issues in Korea. Remediation performance results at DNAPL contaminated field sites have shown that achieving groundwater clean-up is very difficult due to the complexity of site characterization and contaminants (DNAPL). Therefore, a new approach is now necessary to determine the reachable clean-up level and control the groundwater contaminated sites with DNAPLs. Our research team initiated a 5-year GAIA(Geo-Advanced Innovative Action) project to intensively monitor the DNAPL contaminated site with a focus on developing clean-up options under support of Korea Ministry of Environment (KMOE). Woosan industrial complex was chosen as our field site and 16 rounds of groundwater sampling at about 90 monitoring wells were performed from 2009 to 2013. The highest concentration of trichloroethylene (TCE) which was the main pollutant in the source area of this site was 15 mg/L. According to field mornitoring data and hydrogeologic condition, Risk Based Corrective Action (RBCA) program and variable remediation technologies such as soil vapor extraction, pump-and-treat, surfactant enhanced in-situ remediation, in-situ bioaugmentation and Monitoring Natural Attenuation (MNA) were performed. As a result of our field site application, we propose the following step by step- remediation strategy. The 1st step is implementation of site-specific characterization and risk-based site assessment and 2nd step is application of the chosen remediation technologies to enhance the attenuation, plume capture and mass reduction in source zone based on the 1st step result. The 3rd step is establishment of an attainable clean-up level considering the reulsts of mass reduction when there is no further contaminant exposures and plume migration and the final step is application of the MNA until the final clean-up level of groundwater remediation is achieved.

Combined use of ED-EPMA and ATR-FTIR imaging for characterization of individual aged Asian Dust particles

HYEKYEONG KIM, HAE-JIN JUNG, HYO-JIN EOM, XUE LI AND CHUL-UN RO

Department of Chemistry, Inha University, 253 Yonghyun-dong, Nam-gu, Incheon, 402-751, KOREA and curo@inha.ac.kr

In our previous works, it was demonstrated that the combined use of quantitative energy-dispersive electron probe X-ray microanalysis (ED-EPMA), which is also known as low-*Z* particle EPMA, and attenuated total reflectance FTIR (ATR-FTIR) imaging has great potential for a detailed characterization of individual aerosol particles. In this study, extensively chemically modified (aged) individual Asian Dust particles collected during an Asian Dust storm event on November 11, 2002 in Korea were characterized by the combined use of low-*Z* particle EPMA and ATR-FTIR imaging. Overall, 109 individual particles were classified into four particle types based on their morphology, elemental concentrations, and molecular species and/or functional groups of individual particles available from the two analytical techniques: Ca-containing (38%); $NaNO_3$-containing (30%); silicate (22%); and miscellaneous particles (10%). Among the 41 Ca-containing particles, 10, 8, and 14 particles contained nitrate, sulfate, and both, respectively, whereas only two particles contained unreacted $CaCO_3$. Airborne amorphous calcium carbonate (ACC) particles were observed in this Asian Dust sample for the first time, where their IR peaks for the insufficient symmetric environment of CO_3^{2-} ions of ACC were clearly differentiated from those of crystalline $CaCO_3$. This paper also reports the first inland field observation of $CaCl_2$ particles probably converted from $CaCO_3$ through the reaction with HCl(g). HCl(g) was likely released from the reaction of sea salt with NO_x/HNO_3, as all 33 particles of marine origin contained $NaNO_3$ (no genuine sea salt particles were encountered). Some silicate particles with minor amounts of calcium were observed to be mixed with nitrate, sulfate, and water. Among 24 silicate particles, 10 particles are mixed with water, the presence of which could facilitate atmospheric heterogeneous reactions of silicate particles including swelling minerals and non-swelling ones. Using the combined use of the two single particle analytical techniques, this work clearly shows that internal mixing states of the aged Asian Dust particles are highly complicated.

Chemical evolution of perched groundwater flowing through weathered bedrock underlying a steep forested hillslope, northern California

HYOJIN KIM[1]*, JAMES K.B. BISHOP[12]
WILLIAM E. DIETRICH[1] AND INEZ FUNG[1]

[1]Univeristy of California, Berkeley Dept. Earth and Planetary Science, 307 McCone Hall, Berkeley CA94709 hyojin820@berkeley.edu

[2]Earth Science Division, Larence Berkeley National Laboratory, 1 Cyclotron Road, MS 90-1116, Berkeley CA 94709, USA

At the ~4000 m^2 Rivendell study site on a 30^O hillslope underlain by argillite along the South Fork Eel River, we have monitored the chemistry of rainfall and of groundwater that seasonally perches on dense, fresh bedrock (5 to 20 m below the surface) and flows through a weathered bedrock zone to an adjacent channel. This is a part of a collaborative study focused on coupling hydrologic, geochemical, ecological, and atmospheric processes. Water samples were collected every 1 to 3 days for five years from three wells: upslope (Well 10), mid-slope (Well 3), and downslope (Well 1).

At the beginning of the rainy season Well 10 groundwater is deep with a constant high concentation of major cations (Ca, Mg, and Na). New water arriving from seasonal storms causes water-table rise (4 to 6 m), and systematic dilution until rising water levels reach a new, significantly diluted constant value. Surprisingly, however, Si shows an opposite response and increases in concentration with rising water level. Well 3 response is generally similar. Well 1 behaves differently: its water-table is highly responsive to rainfall inputs, but its chemistry shows no significant change, except briefly during rainstorms.

Our data suggests that the deeper groundwater flow which is highly concentrated is in thermodynamic equilbrium with the argillite. Seasonal rainwater passes quickly through the soil and weathered bedrock where it rapidly uptakes major cations via cation exchange reactions and Si through amorphous silica dissolution. PCO_2 is highly elevated due to biological activity. Intensive biological activities in this layer increase the rate of mineral dissolution and thus continuously replenish exchangeable cations and the amorphous silica pool.

Ship-plume sulfur chemistry: ITCT 2K2 case study

HYUN S. KIM[1], YONG H. KIM[1] AND CHUL H. SONG[1,*]

[1]School of Environmental Science and Engineering, Gwangju Insititute of Science and Technology, 1 Oryong-dong, Buk-gu, Gwangju 500-712, Republic of Korea

The ship-plume sulfur chemistry was investigated for the ITCT 2K2 (Intercontinental Transport and Chemical Transformation 2002) ship-plume experiment, using the ship-plume photochemical/dynamic model developed in this study. In order to evaluate the performance of the model, the model-predicted mixing ratios of SO_2 and H_2SO_4 were compared with those observed. From these comparisons, it was found that the model-predicted levels were in reasonable agreements with those observed ($0.56 \le R \le 0.71$), when the pH of sea-salt particles (pH_{ss}) was $\le$~6.5. The ship-plume equivalent lifetimes of SO_2 (τ^{eq}_{SO2}) were also estimated/investigated for this particular ship-plume case. The magnitudes of τ^{eq}_{SO2} were found to be controlled by two main factors: (i) the mixing ratios of in-plume hydroxyl radicals (OH) and (ii) pH_{ss}. The former is governed primarily by stability conditions of the marine boundary layer (MBL), when the ship NO_x emission rate is fixed. The latter determines if the heterogeneous oxidation of dissolved SO_2 occurs via reaction with hydrogen peroxide (H_2O_2, when $pH_{ss}<6.5$) or with ozone (O_3, when $pH_{ss}>6.5$). According to the multiple ship-plume photochemical/dynamic model simulations, the estimated τ^{eq}_{SO2} over the entire ship plumes ranged from 10.32 to 14.32 hrs under moderately stable (E) to stable (F) MBL conditions. These values were clearly shorter than the background SO_2 lifetime (τ^{b}_{SO2}) of 15.18- 23.20 hrs. In contrast, τ^{eq}_{SO2} was estimated to be 0.33 hrs when the pH_{ss} remained at ~8.0 (a rather unlikely case). In addition, the SO_2 loss budget was further analyzed to estimate the influences of the two main factors on the ship-plume sulfur chemistry. The changes in the loss budget with pH_{ss} clearly showed a shift in the dominant SO_2 loss processes from heterogeneous SO_2 conversion (when $pH_{ss}>$~6.5) to the gas-phase oxidation of SO_2 by OH (when $pH_{ss}<$ ~6.5).

Mineralogical characterization of tremolite asbestos-containing soils

JUHYUN KIM[1]*, JAEBONG PARK[2], SECKWHAN SONG[3], HOJU LIM[4] AND YUL ROH[5]

[1]Chonnam National University, Gwangju, South Korea, fawkes3@hanmail.net
[2]Chonnam National University, Gwangju, South Korea, 20548pjb@chonnam.ac.kr
[3]Joongbu University, Chungnam, South Korea, shsong@joongbu.ac.kr
[4]National Institute of Environmental Research, Incheon, South Korea, limhoju@gmail.com
[5]Chonnam National University, Gwangju, South Korea, rohy@jnu.ac.kr

Asbestos-containing soils occur mainly at ultramafic rocks and hydrothermally altered carbnate rocks in S. Korea. Remediation of asbestos-containing soils is considered a high priority by the Korean Government because these soils, if left untreated, represent a hazard to the environment and human health. The objective of this study was to show a priori physicochemical and mineralogical characterization of asbestos-contaminated soil can direct the development of remediation strategies.

Two sites (Seosan and Jaecheon, S. Korea) at abandoned asbestos mines were selesected for soil and mineralogical characterization. Parent rock of the two sites is hydrothermally altered carbnate rocks in S. Korea. At each site, samples were taken at soil surface. Soil preparation consisted of sieving air-dried soil through a 2-mm sieve. The sieved soils (< 2-mm) were used for soil characterization and mineralogical analysis. Following particle size fractionations, mineralogical characterization was investigated by TG-DTA, XRD, PLM, SEM and EDS analyses. Point counting was used to quantify asbestos in the whole soil and size fractionated samples.

The soil color of the both sites was dark red (Seosan site) and dark brown (Jaecheon site). The soil texture of the Seosan and Jaecheon sites was loam and sand, respectively. XRD analysis showed mineral assemblages of the Seosan and Jaecheon site were tremolite-talc-vermiculite-quartz-diopside and tremolite-talc-vermiculite-quartz-dolomite, respectively. XRD, PLM, SEM and EDS analyses showed that the needle-shaped tremolite was observed at both soils. Size fraction between 425 ㎛ to 2㎜ of the Seosan and Jaecheon soils contained 1.5 % and 2 % asbestos, respectively. Therefore, the soils of the both sites were designated as asbestos-containing materials (greater than or equal to 1%) according to the criteria of the U.S. EPA. TG-DTA showed that tremolite asbestos at both soils were transformed to diopside with the temperatures about 1,100℃. These results indicated that thermal treatment of asbestos-containing soils was effective for phase transformation of the asbestos in soils.

Mineralogical and geochemical characteristics of the Korean coal ashes from the perspective of the coal and combustion types

KANGJOO KIM[1]*, GI-YOUNG JEONG AND JAE-CHUL LEE[3]

[1]Department of Environmental Engineering, Kunsan National University, Jeonbuk, 573-701, Korea (correspondence: kangjoo@kunsan.ac.kr)
[2]Department of Earth and Environmental Sciences, Andong National University, Kyeongpook, 760-749, Korea
[3]Korea Western Power Co. Ltd., Seoul, 135-984, Korea

Fly ashes produced from 9 coal burning power plants in Korea were investigated to see the changes in mineralogical and geochemical characteristics according to the coal types and combustion methods. Our results indicate that the mineralogical and geochemical features of the fly ashes are more dependent on the combustion methods than the coals used. Five and two out of the nine investigated plants were originally constructed to burn bituminous (or subbituminous) coals and anthracite coals, respectively, by applying pulverized coal firing system. The remaining two plants burn anthracite or bituminous coals together with fine sand-sized limestone grains using the fluidized bed combustion method. According to the SEM and XRD investigation, it was revealed that spheres, mullite, and glasses were absent and sometimes illite, a clay mineral, was present in the fly ashes produced from the plants of the fluidized bed combustion method due to the low combustion temperature (800 - 850 °C). These ashes particularly contains calcite and anhydrite phases due to the co-combustion of limestone grains. The high temperature phases such as mullite and glass were observed in all the ashes of the pulverized coal firing plants. However, their contents were generally higher in the fly ashes of the pulverized anthracite coal burning plants. This is due to their higher combustion temperatures (1200 – 1500 °C) than those of the bituminous or subbituminous coal burning plants (1200 – 1300 °C). The chemical composition of the ashes also reflected the combustion methods.

Estimation of POC and Biogenic silica export fluxes using $^{234}Th/^{238}U$ disequilibrium in the Amundsen sea, Antarctic

MI SEON KIM [1] MAN SIK CHOI [1]* AND SANG HEON LEE[2]

[1]Chungnam National University, Daejeon, Korea
seonkim@cnu.ac.kr (*correspondence : mschoi@cnu.ac.kr)
[2]Pusan National University, Busan, Korea
sanglee@pusan.ac.kr

In order to understand the carbon cycle in the Amundsen Sea, the Antarctic, the export fluxes of organic carbon and biogenic silica from the euphotic zone to depth were estimated using $^{234}Th/^{238}U$ disequilibrium method. Seawaters in 14 water columns were collected during February and March 2012, and analyzed for total and dissolved ^{234}Th, and particulate organic carbon and biogenic silica.

The water column activities of total ^{234}Th showed deficiency and excess relative to those of ^{238}U. Deficiency of total ^{234}Th in the euphotic zone showed mirror images both with chlorophyll-a and fluorescence, and was consistent with the loss of nitrate, which indicated the impact of biological activity. In addition, deficiency of total ^{234}Th from deepwater was associated with the increase of total Fe/Mn concentration. Excess total ^{234}Th activity presented below the euphotic zone might be related to the active remineralization process.

The export flux of ^{234}Th estimated using the steady state model was av. 0.87 (±0.25) $x10^3 dpm/m^2/day$. The export fluxes of organic carbon and biogenic silica, which were estimated by the product of total ^{234}Th flux and ratio of $POC/^{234}Th$ (7.08 ± 4.27μM/dpm) and $BSi/^{234}Th$ (0.80 ± 0.36μM/dpm) in the sinking particles, were av. 5.85 (±2.42) $mmol/m^2/day$ and 0.69 $mmol/m^2/day$, respectively. These fluxes were similar levels to those in the Weddell Sea during February and March 2008. Export ratios (ThE) relative to the primary production in the euphotic zone were in the range of 3~50% (av. 27.8%), which indicated less efficiency in the biological pump than the Ross sea during January and February 1997.

Variation of As-leaching from coal ashes according to extractant pH, reaction time, and shaking methods

SEOK-HWI KIM, BYUNG-HYO KIM, KANGJOO KIM*, BYUNG-GON JEONG AND SEUNG-HYUN CHOI

Department of Environmental Engineering, Kunsan National University, Jeonbuk, 573-701, Korea
(*correspondence: kangjoo@kunsan.ac.kr)

In this study, the leaching characteristics of arsenic (As) from the weathered coal ashes (fly ash + bottom ash mixture), which have been reclaimed in an ash pond of a power plant, and the fresh fly ashes were evaluated using various leaching experiments. The As-leaching experiments were performed considering extractant pH (5, 7, and 9), shaking methods, and extraction time as variables. Especially, the ashes were extracted repeatedly using new extractant to observe the leaching characteristics as a function of time. The As concentration in the fresh fly ash was 16.1 mg/kg. In contrast, the weathered coal ashes showed the lower concentrations 5.77-10.0 mg/kg, reflecting that a part of As already has been leached by the reaction with the pond water. The weathered ashes showed the more As leaching at lower pH, indicating that the contribution from the carbonate-bound fraction becomes greater as the pH becomes acidic. The As leaching decreases drastically as the reaction time increases. Our results also show that the As-leaching is dependent not only on the shaking speeds and stroke distances but also on the bottom areas of the reaction bottles. For example, the As-leaching was greater when the bottles with wider bottom were used even at the same shaking speed and stroke distance.

Characterization of the primary productivity using a year-long high resolution sediment trap experiment in the southwestern part of the East/Japan Sea

S.H. KIM*, G.H. HONG, Y.I. KIM, C.S. CHUNG, K.Y. CHOI AND Y.H. KIM

[1]Korea Institute of Ocean Science & Technology, Ansan, R.Korea 426-744 (*correspondence: shkim@kiost.ac)

The southwestern East/Japan Sea is one of the world's most productive fishing grounds that is readily visible from the space born satellite's day-night band due to bright lights emitted from dense assemblage of fishing fleet. Traps were deployed to collect sinking particles in the depths of 1,020 m and 2,100 m at the inter-plain gap between Ulleung and Dok islands (37°25.77′N, 132°30.27′E, 2300 m) in 1999 with shorter than 10 days sampling interval. The water temperature and current at 350 m depth using RCM 7 at the site adjacent to the sediment trap mooring site were also utilized to aid our data analysis.

This high resolution temporal observations showed many important characteristics related to the productivity of the southwestern East/Japan Sea: 1) Ulleung Warm Eddy enhanced primary productivity as evidenced by a simultaneous variation in water temperature at 100 m and particulate organic carbon fluxes at 1,020 m depth.; 2) Siliceous phytoplankton species dominated spring and autumn blooms. The ratio of biogenic silica flux to particulate organic carbon flux increased during these two seasons; 3) Calcareous productivity was observed during August when surface water temperature was the highest when the ratio of calcium flux to aluminum flux peaked its maximum; 4) Small sized primary producers such as nano- or pico- plankton dominated in summer. Dissolution of sinking particulate organic carbon appeared to be great in the water column between 1,020 m and 2,100 m compare to other seasons; 5) Nitrogen fixer appeared to contribute to comparable high productivity during the apparent N-poor oligotrophic summer and the ratio of particulate organic carbon to particulate nitrogen was relatively high compared with that in other seasons.

Determination of picomolar Zn in seawater of the North and South Pacific with clean sampling methods

T. KIM[1]*, T. GAMO[1] AND H. OBATA[1]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, 5-1-5 Kashiwanoha, Kashiwa-shi, Chiba 277-8564, Japan (*tjkim@aori.u-tokyo.ac.jp)

Zinc (Zn) is an essential micronutrient for bacteria and phytoplankton in the ocean. However, biogeochemical cycles of Zn have not been fully revealed yet in the ocean since determination of Zn in seawater is very difficult because of contamination problems [1]. We have established a precise determination method of picomolar level of Zn in seawater using recent clean technique. Using this method, vertical distributions of Zn were investigated.

Seawater samples were collected in the subtropical North, South Pacific and subarctic North Pacific during the R.V. Hakuho-Maru research cruises. We used Teflon-coated X-Niskin bottles, which were thoroughly cleaned with detergent, acid, and milli-Q water. Zn in seawater was determined by cathodic stripping voltammetry after UV-digestion.

We have compared three different seawater sampling methods. Teflon-coated X-Niskin samplers were 1) deployed on CTD-CMS, 2) attached to Kevlar wire and 3) attached to titanium wire. Because Zn is used as sacrificial anode in the research vessel, especially around main propellers of the Hakuho-Maru, Zn contamination was observed during Kevlar wire hydrocasts that were performed from the stern of the vessel. By minimizing the influence from the propellers, we obtained almost the same Zn concentrations within the analytical error among those three different sampling methods. In the subarctic North Pacific, surface Zn concentrations showed the decrement from west to east, indicating that high eolian dust inputs from the Asian deserts may contribute to relatively high Zn concentration in western North Pacific [2] .

Characterization of the white precipitates found in acid mine drainage

YEONGKYOO KIM*, CHANG-MIN LEE AND HAE-YONG GWAK

Department of Geology, Kyungpook National University, Daegu 702-701, Korea, ygkim@knu.ac.kr

The mobility of heavy metals released from acid mine drainage can be controlled by sorption on the iron and aluminum precipitates. There have been plenty of reports on the iron precipitates found in acid mine drainage. However, the white precipitates, mainly composed of aluminum, have not been throughly investigated. Previous study have reported hydrobasaluminite and gibbsite as possbile phases. Recently Al_{13}-tridecamer was suggested as a possible aluminum phase in precipitates. We used chemical analysis, XRD, SEM, NMR, and sequential extraction method to characterize the white precipitates collected at three different sites.

XRD and SEM data show that most white precipitates are amorphous with small amount of gypsum. ^{27}Al MAS NMR spectra provide more detailed information on the alumiunm species in precipitates, showing that there are 4- and 6-coordinated aluminums in the samples. The aluminum with 4-coordination can be assigned to Al_{13}-tridecamer, which has been known as one of the most toxic aluminum species. The calulations based on chemical and ^{27}Al MAS NMR data, show that the relative amounts of Al_{13}-tridecamer, hydrobasaluminite, gibbsite and gypsum are different for each sample. The results of sequential extraction experiment also show that each sample has different aluminum and heavy metal fractions, indicating that the toxicity caused by aluminum and heavy metals can be different for each sample. Sequential extraction results show that one sample (S-1) has higher water soluble fraction and sorebed and exchangeable fraction of aluminum than other samples. However this sample does not contain Al_{13}-tridecamer based on NMR data, indicating that careful characterization of white precipiates is needed to estimate the toxicity of aluminum of white precipitates found in acid mine drainage.

Sorption Behavior of Mercury (Hg) on Hydroxylapatite

YOUNGJAE KIM[1] AND YOUNG JAE LEE[1]*

[1]Department of Earth and Environmental Sciences, Korea University, Seoul 136-701, Korea (*Correspondence: youngjlee@korea.ac.kr)

Hydroxylapatite (HAP) has been known to be ubiqotous in various environments. Mercury (Hg) is notorious in ecosystems including humans due to its toxicity. Neverthelesss, Hg interactions with HAP has been barely addressed yet. In this study, systematic batch experiments were conducted to investigate Hg sorption on HAP over a wide range of physicochemical conditions such as pH, ionic strenths, and ligands forming complexes.

Hg sorption increases with increasing pH up to pH 6.0 whereas the sorption decreases with pH at pH ≥ 7.0. This result is in good agreement with species modling calculation showing that $Hg(OH)_2^0$ is dominant at neutral and basic pHs. It is found that Hg sorption on HAP increases with increasing Hg concentration. At pH 5.0 and 7.0, Hg uptake by HAP steeply increases up to $[Hg]_{ini.} \leq 10$ μM, and then gently increases at higher concentration. At pH 9.0, however, the Hg sorption on HAP shows linear slope with increasing Hg concentration.

Upon Hg sorption edges and isotherms, it is shown that the sorption is little influenced by variation of ionic strengths. This result indicates that Hg would form inner-sphere surface complexes at the HAP. In kinetics, Hg sorption on HAP reaches ~70 % of total sorbed Hg within the first 3 hr, indicating that adsorption plays a major role in cotrolloing the initial uptake of Hg by HAP. During desorption, ~90 % of the sorbed Hg is retained by HAP suggesting that the sorbed Hg is bounded tightly to the surface and irreversible. It is also found that Hg sorption on HAP is decreased by Cl wheareas Hg desorption is enhanced in the presence of Cl. These results suggest that Hg interactions with HAP are significantly influenced by various physicochemical conditions in ecosystems.

Thermal history energy balance compared with convection modeling

SCOTT D. KING*

Department of Geosciences, Virginia Tech, Blacksburg, VA 24061, USA (*correspondence: sdk@vt.edu)

Thermal history calculations are based on balancing the flux of heat into and out of the mantle with the heat generated internally due to the decay of radiogenic elements [1]. In order to reduce this balance to a tractable equation, a relationship between the surface heat flow and temperature is necessary. Often this is a relationship between the Nusselt number and Rayleigh number and variants of this relationship have been proposed based on both theory and numerical experimentation [1, 2, 3]. The power of thermal history calculations is that they can explore a large parameter space with minimal computational resources; however they provide only an average mantle temperature as a function of time.

3D spherical-shell convection calculations are becoming increasingly prevalent. These solve the conservation of mass, momentum and energy in a 3D spherical geometry; however two important aspects of thermal history modeling are infrequently employed in 3D convection calculations: a cooling core boundary condition and decreasing radiogenic heating with time. In many recent investigations the time-span of interest is such that these do not vary significantly.

This raises an interesting question: *Just how comparable are thermal history calculations and 3D spherical-shell convection calculations?* In this presentation I will compare 3D convection and thermal history calculations with the same properties. These will include temperature and pressure dependent rheology and a 'mobile lid' using the methodology outlined by *van Heck and Tackley* [4], decaying radiogenic heat sources, and a cooling core boundary condition. Even with advances in computing power, it is unlikely that solving the set of conservation equations will replace thermal history models any time soon. The goal is to assess whether given the same parameters these two formulations will produce a similar temperature history. While there are a myriad of parameters and assumptions, many of which are unknown and perhaps even unknowable (e.g., the average mantle temperature at formation), both 3D and thermal history calculations face these challenges. While the observations relevant to Earth's thermal evolution are being assessed, so to should the computational tools used to model it.

Distribution and migration of americium-241 in the East Pacific

NORIKAZU KINOSHITA[1]*, MIKA NAGAOKA[2], TAKAHIRO SUMI[3], KIYOTAKA TAKIMOTO[3], AKIHIKO YOKOYAMA[3] AND TAKASHI NAKANISHI[3]

[1]Shimizu Corporation, Tokyo 135-8530, Japan.
[2]Japan Atomic Energy Agency, Ibaraki 319-1194, Japan.
[3]Kanazawa University, Ishikawa 920-1192, Japan.
(*norikazu.kinoshita@shimz.co.jp)

Anthropogenic radionuclides of plutonium-239, 240 and americium-241, that is, a decay product of ^{241}Pu, are present on the earth as a result of atmospheric nuclear tests carried out during the 1950s and 1960s. It is known that most of the nuclides deposited in ocean and deposition in North Pacific is higher than South Pacific due to location of the test site. Few data on ^{241}Am in marine environment have been reported, so far. Depth profile, residence time, applicability as a tracer of migration of the nuclide have not been well investigated yet. We have investigated on its distribution at the East Pacific by assaying large volume seawater collected in 2003.

The Am atoms were collected as hydroxides together with iron from 250 L of sea water spiked with ^{243}Am yield tracer. The Am atoms were isolated through a solvent extraction and anion exchange procedure, followed by an assay in α-spectroemtry. The concentration of ^{241}Am was found low in surface water and the depths below 2000 m as well, and enhanced at the depths around 800 m. The depth profile shows a pattern similar to that of $^{239+240}$Pu [1]. Although concentration and depth of the subsurface maximum were different depends on the location, the subsurface maximum was observed in a isopycnic surface; the distribution is affected by water mass structure.

Comparing the present data on ^{241}Am with previous data on $^{239+240}$Pu [1], ^{241}Am/$^{239+240}$Pu activity ratio showed constant value. Substantial differences between different locations and depths have not been observed in the profiles of ^{241}Am/$^{239+240}$Pu ratio. The Am atoms appear to have the same residence time as those of Pu in the East Pacific.

Besides, The ^{241}Am inflow from North Pacific to South Pacific across the equator is observed in a depth of 500 – 1500 m along longitude of 95° W. Similar flows were observed for the Pu isotopes and the nutrients in the same area as well [1]. Our result supports a model simulation of migration in the East Pacific reported by Nakano *et al*. [2].

Inverse modeling in a CO_2 natural analogue – long term processes in carbon dioxide storage

KIRÁLY, CS.[1], SENDULA, E.[1], SZAMOSFALVI, Á.[2], FALUS, GY.[2], SZABÓ, CS.[1], SZŐCS, T.[2] AND FORRAY, V.[1]

[1]Litosphere Fluid Research Lab, Eötvös University, Hungary
[2]Geological and Geophysical Institute of Hungary

To guarantee the long term safety of the geologically stored CO_2, long timescale behavior of the CO_2-rock-porewater system must be well understood. The most suitable way to describe a future CCS system is study of long-term natural CO_2 accumulations and their footprint on the mineralogical and fluid compositions. One of these natural CO_2 occurrences is in the western part of Hungary, in the Little Hungarian Plane, where the studied system is composed by 38 reservoirs (26 CO_2, 10 hydrocarbon, and 2 mixed gas). The carbon dioxide is produced since 1948 for industrial purposes. The CO_2 is contained by the (late Miocene) Pannonian sedimentary sequence of a prograding delta system (mainly sandstone, siltstone and clay), in a depth of about 1400 m.

Based on the mineralogical composition of the available core samples and water chemistry data from the studied area, and using mineralogical composition of a CO_2-free brine containing sandstone from the same formation, a geochemical modeling was applied with the PHREEQC program to reproduce the observed effects and determine the major fluid-rock interactions which could have taken place in the reservoir. These interactions are believed to have a major impact on long term safety of carbon dioxide geological storage as they may strongly affect the petrophysical parameters of storage and sealing lithologies.

The work was carried out in collaboration between Eötvös University and Geological and Geophysical Institute of Hungary.

Geochemical and petrographical investigation of chromite occurences in Burdur-Salda, Turkey

DEMET KIRAN YILDIRIM[1], SERENA UZASCI SULTANYAN[1], SALIH BURAK KARABEL[1], ALEV KAN BOSTANCI[1] AND MUSTAFA KUMRAL[1],

[1]Istanbul Technical University, Department of Geological Engineering, 34469, Istanbul, TURKEY

Lithological units in research area from oldest to youngest are Cretaceous aged ophiolites, intrusive gabbros in ophiolites, sedimantary units mostly composed of limestones and Quaternary aged alluvials.

There are four types of chromite ocurrences in the area. These are massive, nodular, disseminated and banded ores. Chromite ores which include Cr_2O_3 from 18% to 50% were bedded in podiform type. Slope directions of masses are different in northern and southern parts. It is estimated that this diffrences of slope depend on faulting in the region. Chromite deposits are can be seen in the outcrop, have continuities in the strike and dip directions and in the form of extensions of each other. Chromite deposits in the middle and edge parts of the ophiolitic series are small and individual appearances.

Samples from the research area were analized for determining the petrographical and geochemical characteristics. Samples were taken from the research region are examined according to major oxide contents to determine geochemical content ratio of this units.

The percentage of SiO_2 is between 10% an 31% and Al_2O_3 content is approximately %3-3,6. N39, which is one of five samples tested to establish Fe_2O_3 content, have the highest Fe_2O_3 content is 15,972%. It is seen that the sample is rich on account of Cr_2O_3 with the percentage of is 50,181. Moreover, the content of CaO was determined between 0,02% and 0,5% for all samples.

The Olympic Dam giant ore deposit – a fossil nuclear reactor?

MARIA KIRCHENBAUR[1,2], KATHY EHRIG[3], ROLAND MAAS[4], VADIM KAMENETSKY[5], CHRIS BALLHAUS[2] AND CARSTEN MÜNKER[1]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, Germany; [2] Steinmann-Institut, Universität Bonn, Germany; Kirchenbaur@uni-bonn.de

[4]School of Earth Sciences, University of Melbourne, Australia
[5]CODES, University of Tasmania, Hobart, Australia

The Olympic Dam (OD) supergiant Cu-U-Au-Ag deposit in the Gawler Craton of South Australia occurs within tectonic-hydrothermal breccia hosted by 1.59 Ga granite of the Gawler silicic large igneous province. With probable reserves of ~200000 t of U, OD is one of the world's largest U deposits. The high uranium content and a possible Proterozoic age of mineralization raises the possibility of Oklo-style fossil nuclear reactor activity, although a much smaller degree of burn-up, similar to that documented in many other Proterozoic and Phanerozoic U deposits, is more likely, given the low average U concentration (450 ppm) at OD. We explore this possibility using U-Sm-Nd isotope data.

High-precision U isotope data for 43 samples with U concentrations up to 10.5% were obtained by MC-ICPMS at Cologne/Bonn, employing both double spiking and standard-sample bracketing to correct for instrumental mass bias. $\delta^{238}U$ (relative to a $^{238}U/^{235}U$ of 137.856 for REIMEP 18a) ranges from -0.5‰ to +0.2‰ (average $\delta^{238}U$ = -0.2‰). Only four samples yield the positive $\delta^{238}U$ expected from consumption of ^{235}U in sustained nuclear fission, well below $\delta^{238}U$ found at Oklo (up to 560‰), but consistent with the minute isotopic effects reported for other old U deposits. Depletion of ^{149}Sm by slow neutron capture, observed in many U deposits, reaches 1.5 ε-units and only occurs in the few samples with positive $\delta^{238}U$. Isotope ratios of Nd are indistinguishable from normal. We conclude that OD contains U with a near-natural abundance of ^{235}U, but some U-rich domains appear to have experienced a small degree of induced ^{235}U fission with associated neutron capture effects in other elements.

The vast majority of our samples (10-8000 ppm U) exhibit slightly negative $\delta^{238}U$. Consistently negative $\delta^{238}U$ (-0.3 to -0.7‰) was previously found for 'magmatic' U deposits, defined to include hydrothermal (200-400ºC) deposits [1]. ^{238}U depletion in such deposits is thought to reflect natural isotope fractionation during U deposition.

Calibration of the Δ_{47} (clumped isotope) thermometer for biogenic and inorganic carbonate using the MIRA IRMS.

R. KIRK[1]*, P. F. DENNIS[1], J. FARKAS[2] AND A. MARCA[1]

[1]University of East Anglia, Norwich, NR4 7TJ, UK (*correspondence: r.kirk@uea.ac.uk)
[2]Czech Geological Survey, 152 00 Prague 5, Czech Republic

Using a suite of brachiopod samples collected from natural marine environments (5-22°C) and inorganic hydrothermal calcites collected from springs precipitated at up to 56°C we have determined a new calibration for the Δ_{47} isotope thermometer. This is the first reported calibration using the MIRA IRMS. All other previous determinations have been made using the Thermo-Finnegan 253 IRMS.

For all samples, 10mg of homogenised powder were reacted with ca. 2mL of 102% orthophospheric acid for 12 hours at 25°C. CO_2 was collected by cryo-distillation after passing through sequential cold traps at -100 and -120°C to ensure complete removal of water vapour. Yields were determined barometrically before transferring the CO_2, via a short packed column to remove any hydrocarbons, into gas tubes for mass spectrometric analysis. The MIRA mass spectrometer was operated at 8kV energy with an ionising electron current of 750μA and m/z = 44 signal strengths of $4x10^{-8}$A. Reported measurements are the average of 9 runs of 20 samples-reference cycles, with a 10 second integration per cycle. The measurement precision for δ^{47} approaches the shot-noise limit of ca. 0.01‰. All results are presented on the absolute reference frame outlined by Dennis *et al*. [1].

Between 5 and 56°C the Δ_{47} Vs. T relationship for both biogenic and inorganic calcite can be described by a single equation:

$$\Delta_{47} = 0.0368\ (\pm 0.0037) \times 10^6 . T^{-2} + 0.2345\ (\pm 0.042)$$
$$(r^2 = 0.92)$$

The gradient of the response, within measurement error, is the same as recently reported studies [1, 2] and similar to the theoretical response [3]. There are, however, significant differences in the intercept that may result from different sample reaction conditions and procedures.

An experimental study of the geochemical impact of CO_2 leakage in siliclastic aquifers

KIRSCH, K.[1], NAVARRE-SITCHLER, A.,[2] WUNSCH, A.,[3 A] AND MCCRAY, J.E.[3]

[1]Department of Geology and Geological Engineering, Colorado School of Mines, kkirsch@mines.edu
[2]Department of Geology and Geological Engineering, Colorado School of Mines, asitchle@mines.edu
[3]Department of Civil and Environmental Engineering, Colorado School of Mines

Leakage of CO_2 from deep storage formations into an overlying potable aquifer may mobilize trace metals leading to undesireable water quality degradation. Understanding CO_2-water-rock interactions under leakage conditions is therefore an important step toward the safe implementation of geologic carbon sequestration. In this study we investigated the geochemical response of three sandstone samples from the Mesaverde Group in northwestern Colorado. Two batch dissolution experiments were conducted in which samples were reacted with water and CO_2 at partial pressures of 0.01 and 1 bar, representing natural background levels and levels expected in an aquifer impacted by a small leak of CO_2, respectively. The pH dropped sharply after CO_2 was introduced into the system, and then rebounded slightly as the minerals in the rocks dissolved. Concentrations of major (e.g., Ca, Mg, Fe) and trace (e.g., As, Ba, Cd, Pb, Sr, U) elements in the fluids increased over the 4 week duration of the expeirments. These concentrations increased more in the 1 bar CO_2 experiments compared to the 0.01 bar CO_2 experiments. Throughout the experiments the concentrations of potentially toxic constituents remained below regulatory limits. Sequential extraction results suggest that carbonate minerals, although volumetrically insignificant in sandstones, are the dominant source of metals. A simple geochemical model was developed that simulates observed changes in fluid composition and supports the interpretation that carbonate minerals are an important source of metals in silicalstic aquifers impacted by CO_2 leakage.

Reaction path geochemical modelling of CO_2-SO_2-water-rock experiments

D. KIRSTE[1,2], J. PEARCE[1,3], S. GOLDING[1,3] AND A. FRANK[1,2]

[1]Cooperative Research Centre for Greenhouse Gas Technologies,
[2]Dept. of Earth Sciences, Simon Fraser University, Burnaby, BC V5A 1S6, Canada; dkirste@sfu.ca, anjaf@sfu.ca
[3]School of Earth Sciences, University of Queensland, Brisbane, QLD 4072, Australia; j.pearce2@uq.edu.au, s.golding1@uq.edu.au

The CO_2CRC has conducted an in depth study of the geochemical impacts of CO_2 storage with co-contaminant SO_2. In this study, laboratory experiments were conducted in static reaction vessels to investigate the chemical evolution of the CO_2-SO_2-water-rock system of core samples from 3 different geologic formations in the Surat Basin of southern Queensland, Australia. Numerical modelling of the experiments was undertaken to evaluate modelling capabilities as well as to determine which factors contribute significantly to the chemical behaviour of the system. This work reports on the geochemical modelling component of the study.

The experiments were conducted at 60°C and 120 bar with $scCO_2$ and $scCO_2$ + SO_2 in a low salinity water and 3 different rock types (see Pearce *et al*., Goldschmidt 2013). Changes in the gas and water chemistry as well as mineralogy were determined. Static reaction path geochemical modelling using Geochemist's Workbench was conducted to simulate the experimental conditions and output of the experiments. The simulations generated provided a reasonable history match to the experiments. It was noted that the experiments and even more so the numerical models were very sensitive to redox state. In the case of the experiments it appeared that the most important contribution to redox related to aqueous phase species, particular O_2 and Fe. In the geochemical modelling, the presence of ferric iron (usually initially in the form of hematite) played a significant role in determining model outcomes. The presence of oxidised iron drove SO_2 oxidation to H_2SO_4 to take place as well as the disproportionation reaction to H_2SO_4 and H_2S leading to increased mineral dissolution and pyrite precipitation in the simulations. However, without oxidised iron the disproportionation reaction dominated leading to elemental sulphur and pyrite precipitation. The experiments and modelling clearly indicate that understanding the redox state in terms of minerals and aqueous phase of any potential sites will be critical to the geochemical behaviour.

Impacts of arc collision on small orogens: New insights from the Coastal Range detrital record of Taiwan

LINDA A. KIRSTEIN[1], ANDREW CARTER[2] AND YUE-GAU CHEN[3]

[1]School of Geosciences, University of Edinburgh, Edinburgh, EH9 3JW, UK (linda.kirstein@ed.ac.uk)
[2]Dept. of Earth & Planetary Sciences, Birkbeck College, London, WC1E 7HX, UK
[3]Dept. of Geosciences, National Taiwan University, Taipei, Taiwan, ROC

Taiwan is seen as the archetypical orogen in the development of critical wedge models of mountain building however, despite intense study the issue of how arc collision progressed along the Taiwan margin remains poorly understood. It has been suggested that punctuated collision took place (e.g. Byrne *et al*., 2011) and therefore the classic wedge model may not be applicable. To resolve this, the detrital archive of orogenesis preserved in Coastal Range rocks of eastern Taiwan was used to reconstruct the erosional response of arc collision.

There is a distinct geographic division to the thermochronology data linked to the location of volcanic arc centres of Chimei and Chengkuangao. Detrital zircon fission-track results record grains that were exhumed from depths of 6-8 km ~6 Ma in the region between Chimei and Chengkuangao. These grains were transported and deposited into adjacent retro-foredeep basin(s) bounded by the discrete volcanic centers starting at 1.9 Myr.

South of Chengkuangao rapidly exhumed zircons are detected in sediments deposited < 1.3 Myr hence both exhumation and deposition must be fast. The pattern of exhumation and location of exhumation ages is consistent with southwards progression of arc-continent collision in a punctuated rather than sequential manner and deposition was confined to small foredeep basins.

Decreased export productivity at onset of Eocene hyperthermal events

SANDRA KIRTLAND TURNER[1]*

[1]Scripps Institution of Oceanography, La Jolla CA, 92093, USA *skirtlan@ucsd.edu

Hyperthermals, or abrupt global warming events, occurred frequently throughout the warm early Eocene (~56 to 47 Ma). Two lines of evidence widely used in their identification include a negative $\delta^{13}C$ excursion recorded in marine and terrestrial sources of inorganic and organic carbon and a drop in deep sea sedimentary carbonate content (wt% $CaCO_3$), indicative of the release of large quanities of isotopically depleted carbon to the atmosphere and oceans and subsequent dissolution of deep sea carbonates due to a shoaling carbonate compensation depth. For a number of the smaller hyperthermal events, including H2 [1], C22rH2, C22nH2, C22nH3, and C21rH1 [2], records from multiple deep sea sites show a notable offset in the timing of the $\delta^{13}C$ excursion and the wt% carbonate minimum, though carbonate content never drops below 10%, indicating deposition above the CCD throughout each event. The minima in wt% carbonate have an apparent lead of ~1 to 20 kyr compared to the minima in carbonate $\delta^{13}C$. For each event, the temporal offsets occur at multiple deep sea sites, though the magnitude of the lead varies between sites.

Experiments using the intermediate complexity Earth System model cGENIE (Grid-ENabled Integrated Earth system model) designed to reproduce these hyperthermal events show the same pattern in modeled sediment 'cores.' Hyperthermals are simulated by forcing the addition and removal of isotopically depleted carbon to the atmosphere in order to match the observed $\delta^{13}C$ excursion, with the results recorded in sediment model tracers of carbonate content and isotopes. In the model, the timing of the minimum in sedimentary wt% $CaCO_2$ is a function of decreased $CaCO_3$ export from the surface ocean occurring coincident with the addition of excess carbon to the atmosphere and oceans. In contrast, the carbonate $\delta^{13}C$ minimum records a whole ocean change in the $\delta^{13}C$ of dissolved inorganic carbon and is therefore delayed relative to the carbon addition. Both model results and observational data thus indicate an early reduction in export productivity as a consequence of small hyperthermal events.

Geochemistry of fluids from the Eastern Carpathians and Transylvanian Basin boundary (Romania)-constraints on the origin of mineral waters and dissolved gases

BOGLÁRKA-MERCEDESZ KIS*[1] FRANCESCO ITALIANO[2] CĂLIN BACIU[1] ANDREA RIZZO[2] AND KRISZTINA KÁRMÁN[3]

[1]Babeş-Bolyai University, Fântânele street 30, Cluj-Napoca, Romania (*correspondence: kisboglarka85@gmail.com)
[2]Istituto Nazionale di Geofisica e Vulcanologia, Via Ugo La Malfa 153, Palermo, Italy (f.italiano@pa.ingv.it)
[3]HAS, Institute for Geological and Geochemical Research, Budaörsi street 45, Budapest, Hungary

The Eastern Carpathians, along the Rodna-Bârgăului subvolcanic area and Călimani-Gurghiu-Harghita volcanic chain, with the Transylvanian Basin boundary, host important resources of Romanian CO_2-rich mineral waters. Results of a comprehensive study on the volatiles dissolved in artesian thermal waters discharged over a 200 km-long transect show large contents of CO_2-dominated gases.

The circulation of fluids on the study area is enhanced by tectonic fragmentations which are considered to be the main upraising path for CO_2 and mineral waters. The geochemical features of the gas phase extracted by water samples reveal amounts of CO_2 up to about 2000 cm^3 STP/L_{H2O}, and helium up to 0.02 cm^3 STP/L_{H2O}. Our investigations show that the wide range of chemical and isotopic composition can be explained in terms of contemporary occurrence of Gas-Water Interactions (GWI) affecting the circulating waters after their infiltration. Carbon ($\delta^{13}C_{TDC}$ Total Dissolved Carbon, ranging from -17 to +10‰ vs PDB) and He systematics (He isotopes in the range of 0.38-0.9Ra, Ra = air-normalized $^3He/^4He$ ratio), coherently indicate the presence of fluids from sources located at different depths in the crust (e.g. sediments, oil reservoirs) besides minor but detectable contributions of mantle/magmatic-derived fluids.

The present work was financially supported by the RNRC, Project PN-II-ID-PCE-2011-3-0537 and by the European Social Fund and the Romanian Government through the POSDRU project "DOCTORAL STUDIES FOR EUROPEAN PERFORMANCES IN RESEARCH and INOVATION - CUANTUMDOC" ID79407

Chalcophile element partitioning between silicate and sulphide liquids

EKATERINA S. KISEEVA[1] AND BERNARD J. WOOD[1]

[1]University of Oxford (*correspondence: Kate.Kiseeva@earth.ox.co.uk, berniew@earth.ox.ac.uk)

We report the partitioning of the elements Cu, In, Tl, Pb, Ag, Zn, Cr, Co, Ni, Sb, Mn and Cd between FeS-rich sulphide liquids and anhydrous basaltic melts at high P and T. There are simple relationships between the FeO contents of the silicate melts and the sulphide-silicate partition coefficients for the individual trace elements. These relationships can be generally represented as follows:

$$\log D_M^{sulph/sil} \approx A + \frac{n}{2}\log[FeO]$$

where A is a constant related to the free energy of Fe-M exchange, n is a constant related to the valence of the element and [FeO] is the FeO content of the silicate melt in mole fraction or weight %. At 1.5 GPa and 1400oC, with [FeO] in weight %, we report the following values of n and A:

At 1.5 GPa and 1400ºC we found, with [FeO] in weight %, the following values of A and n/2: Cu (3.33; -0.82); In (2.24; -1.12); Tl (1.86; -0.76); Pb (2.64; -1.09); Ag (3.47; -0.82); Zn (1.15; -0.79); Cr (1.23; -0.87); Co (2.76; -1.09); Ni (3.65; -0.84); Sb (2.56; -1.23); Cd (2.69; -0.93); Mn (0.46; -0.59).

We calculated the composition of the putative Hadean sulphide matte extracted from primitive mantle during the final stages of accretion and possibly responsible for the current "spiky" abundance pattern of chalcophile elements in silicate Earth. Starting with the current primitive mantle abundances of these elements and calculating matte composition, however, we find that it is not possible to generate an initial abundance pattern which approximates chondritic. The simple "Hadean matte" model is inadequate.

We calculated Ce/Pb and Nd/Pb ratios of basalts generated by mantle melting. Calculated Nd/Pb is essentially constant over wide ranges of partial melting and fractional crystallization with a value of ~18.6 if we assume that depleted mantle contains 65 ppb Pb. Calculated Ce/Pb varies slightly during batch partial melting from 21-29 with the canonical value of 25 being achieved at ~10% partial melting. These trends are in excellent agreement with measurements of oceanic basalt glasses. Our partitioning relationships enable calculation of the concentrations of a number of incompatible chalcophile trace elements in depleted mantle. These are as follows: 30ppm Cu, 65 ppb Pb, 7.6 ppb Ag, 12ppb In, 23 ppb Cd, 1.6 ppb Sb and 1.3 ppb Tl.

Chemical weathering and regolith development over Rajmahal basalt and Chotanagpur gneiss: A comparative study

PREMCHAND KISKU[1], JITENDRA K. PATTANAIK[1]*, TARUN K. DALAI[1] AND S. BALAKRISHNAN[2]

[1]Department of Earth Sciences, Indian Institute of Science Education and Research-Kolkata, Mohanpur 741252, INDIA (*correspondence: jitendra.bapi@iiserkol.ac.in)
[2]Department of Earth Sciences, Pondicherry University, Puducherry 605014, INDIA

Mineralogical, geochemical and field investigations were carried out on weathering profiles developed over Rajamahal basalt and Chotanagpur gneiss in eastern India to study and understand chemical weathering, elemental mobilization and development of regolith. Samples (n=38) were collected from three different locations, including fresh rock, variably weathered saprolite and soil. Variable thickness of soil cover and saprolith was observed in the study area. Fresh Rajamahal basalt consists of plagioclase phenocrysts enclosed by clinopyroxene and plagioclase groundmass, glass and opaque minerals. Chotanagpur gneiss is mainly composed of K-feldspar, plagioclase, quartz, mica and bands of mafic minerals. Weathered basalt shows red coloration along the fractures indicating precipitation of iron oxy-hydroxides.

The Chemical Index of Alteration (CIA) in the weathering profile developed over the basalt and gneiss varies from 40 to 95 and 46 to 85, respectively. High CIA values of pedoliths indicate extensive chemical weathering in the study area. Data of fresh and slightly weathered rocks plot close to the feldspar line in the A-CN-K diagram, indicating that feldspars are the most abundant minerals. Weathered samples show loss of $CaO+Na_2O+K_2O$, indicating extensive destruction of feldspar and clinopyroxene. XRD analysis shows progressive upward increase of clay mineral abundance in the soil profile. With respect to fresh rocks, Fe, Mn, Ti, Ni, Cr, Zr and Al are enriched, and Ca, Mg, Na, Sr and Si are depleted in the weathered basalt, whereas, in the weathered gneiss Si is enriched and Fe and Mn are depleted. For different elements, zones of leaching and accumulation vary within a profile.

Results of this study bring out the differences in the alteration and weathering of minerals in profiles developed on basaltic and gneissic rock types.

A low blank technique for the measurement of iron isotopes in seawater and results from the tropical Atlantic Ocean

J. K. KLAR[1]*, R. H. JAMES[1], I. J. PARKINSON[2], E. P. ACHTERBERG[1] AND C. SCHLOSSER[1]

[1]National Oceanography Centre, University of Southampton Waterfront Campus, European Way, Southampton, SO14 3ZH, UK, (*correspondance: J.klar@noc.soton.sc.uk, r.h.james@noc.ac.uk, eric@noc.soton.ac.uk, cs2u09@noc.soton.ac.uk)
[2]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Wills Memorial Building, BS8 1RJ, UK, (Ian.Parkinson@bristol.ac.uk)

Iron (Fe) is essential for marine photosynthesis, respiration and nitrogen uptake, but low Fe supply and low solubility under oxic conditions results in Fe-limitation of microbial communities in large parts of the world's ocean. For this reason the oceanic Fe cycle is linked to global carbon cycle. Recent studies [1, 2] have shown that analysis of the Fe isotopic composition can provide unique information about its sources, and Fe cycling within the oceans. Here we present a protocol for the accurate and precise measurement of Fe isotopes in seawater using a low blank, double-spike technique. To this end, Fe is pre-concentrated from seawater using a NTA resin, and then separated from the sample matrix by anion exchange chromatography (AG1-X8 resin). Isotope ratios are analysed by multi-collector inductively coupled plasma mass spectrometry (ThermoFisher Neptune) coupled to a sample desolvator (Aridus II or Apex-Q), and corrected for mass bias effects using a double-spike technique. Our model simulations show that the optimal spike composition is 47% ^{57}Fe, 53% ^{58}Fe, with a small amount (<0.5%) of ^{54}Fe, which allows precise measurements of a wide range of sample to spike mixing ratios, the optimum being ~1:1. The precision of the MC-ICPMS measurements is δ^{56}Fe ~0.05 ‰ (2 SD), based on replicate analyses of haematite standards.

We also present results of the preliminary analysis of Fe isotopes in seawater samples (0.2 µm filtered) collected from within the Oxygen Minimum Zone (OMZ) of the tropical Atlantic Ocean along ~12° N (GEOTRACES cruise GA06, 7 depth profiles sampled at 4 to 9 depths, ranging from surface waters to 5600 m depth). Fe concentrations ranged from 1.04 to 3.77 nM within the OMZ (located between 200 and 1000 m depth). The Fe isotope data will be used to (i) identify the sources of Fe to this region, and (ii) to identify processes of Fe cycling in oxygen minimum zones.

Availability of light and chemical energy determines the structure of natural sulfide oxidizing biofilms

JUDITH KLATT[1]*, STEFFI MEYER, DIRK DE BEER[1] AND LUBOS POLERECKY[1]

[1]Max-Planck-Institute for Marine Microbiology, Bremen, Germany (*correspondence: jklatt@mpi-bremen.de)

In the Frasassi cave system, Italy, sulfidic streams and pools are colonized by aerobic chemolithoautotrophic biofilms. Upon emergence of this water from the caves, light becomes available and gives rise to biofilms that are additionally inhabited by highly abundant phototrophic microorganisms. The structure of these biofilms varies between two end-members, one characterized by a cyanobacterial layer on top of a distinct *Beggiatoa* layer (C/B biofilms) and the other one by an inverted structure (B/C biofilms). We used microsensors to study how this structure depends on the availability of light and chemical energy.

C/B biofilms form where the availability of oxygen, and thus of chemical energy, from the water-column is limited (<5 μM). Aerobic chemolithotrophic activity in the *Beggiatoa* layer depends entirely on the supply of oxygen from the cyanobacteria, which occurs at high incident light intensities. Therefore, light is the energy source that drives the community and the main factor that regulates the spatial organization of its dominant functional groups. In B/C biofilms, which occur at locations where oxygen in the water column is comparatively abundant (>45 μM) and continuously present, *Beggiatoa* are independent of the photosynthetic production of oxygen and outcompete the cyanobacteria in the uppermost layer of the biofilm (i.e., closest to one of the energy sources). The proliferation of cyanobacteria in these biofilms seems to be disadvantaged by the extensive interval of darkness during night and by high back scattering of light in the *Beggiatoa* layer during the day. Therefore, although the daily flux of light energy to the biofilm is much greater than the daily flux of chemical energy derived from the oxidation of sulfide with oxygen, light is only peripherally utilized. Instead, the continuity of the input of chemical energy appears to be a more important factor determining the community structure and its dominant functional traits. Our study thereby introduces a scenario, where apparent uncoupling of phototrophic and aerobic chemolithotrophic activity leads to outcompetition of photosynthetic microbes even in the presence of light showing that both microbial interactions and available thermodynamic energy must be considered to understand the biogeochemical cycling.

Spational and temporal variation in provenance of Eastern Mediterranean sediment: Implications for Aegean volcanism

M. KLAVER*, T.T. DJULY AND P.Z. VROON

VU University Amsterdam, De Boelelaan 1085, 1081HV Amsterdam, The Netherlands (*correspondence: martijn.klaver@vu.nl)

Subducted sediment is one of the principal geochemical components of island arc magmas. Along-arc variation in subducting sediment composition is reflected in geochemical trends in the arc volcanics [e.g. 1]. The predominantly Quaternary Aegean volcanic arc is the result of northward subduction of the African plate underneath the Aegean microplate. East-west geochemical variation in Aegean arc volcanics has often been related to differences in subducted sediment composition in the Eastern Mediterranean Sea (EMS) resulting from contrasting source regions.

Recent studies [2,3,4] investigating the provenance of EMS sediment suggest mixing between Sahara dust (old, felsic) and Nile sediment (young, mafic). These studies however, lack a spational and temporal framework as they focus exclusively on Quaternary deposits while the subducted sediment underneath the Aegean arc is Pliocene to Mesozoic in age. We present an extensive new geochemical dataset of EMS sediment samples obtained from DSDP and ODP drill cores along the Aegean arc from Quaternary to middle Miocene age.

The new dataset, in conjunction with previously published results, allows us to accurately trace the along-arc temporal variation of EMS sediment provenance. In line with previous results, we conclude that Quaternary EMS is a mix of Nile sediment, Sahara dust and autogenic carbonate or evaporite components. A clear along-arc trend in principal component can be observed, and the geochemical composition of subducting sediment is highly variable. However, in the Plio- to Miocene, the Nile component appears to be dominant in the entire EMS, leading to much less pronounced geochemical variation of subducted sediment along the Aegean arc. Hence, the assumption that east-west geochemical trends in Aegean arc volcanics are due to differences in subducted EMS sediment composition, may be unjustified.

Chondritic Sm/Nd in the Earth, Moon and Mars

T. KLEINE[1], C. BURKHARDT[2] AND P. SPRUNG[1]

[1]Institut für Planetologie, University of Münster, 48149 Münster, Germany (thorsten.kleine@wwu.de)
[2]Origins Laboratory, Department of Geophysical Sciences, The University of Chicago, IL 60637, USA

One of the most fundamental assumptions in geochemistry is that refractory lithophile elements occur in chondritic relative abundances in the bulk Earth. However, the accessible silicate Earth exhibits a ~20 ppm higher $^{142}Nd/^{144}Nd$ than most chondrites [1], and this may reflect a higher-than-chondritic Sm/Nd of the bulk Earth [2-4]. Caro *et al*. [2] argued that because the ^{146}Sm-^{142}Nd isochrons of the lunar and martian mantles intersect at a higher-than-chondritic $^{147}Sm/^{144}Nd$ *and* at the $^{142}Nd/^{144}Nd$ of the modern terrestrial mantle, the Earth, Moon and Mars all are characterized by a common, superchondritic bulk composition (termed 'SCHEM' [3]). Such non-chondritic compositions may result from collisional erosion of early-formed crust or may reflect assembly of the terrestrial planets from non-chondritic materials [4].

Here we re-examine the lunar and martian ^{146}Sm-^{142}Nd systematics and show that the lunar and shergottite isochrons intersect almost exactly at the chondritic $^{147}Sm/^{144}Nd$, whereas SCHEM plots off both isochrons. This as well as evidence from the Hf-Nd isotope systematics of lunar samples [5] indicates chondritic Sm/Nd in the Earth, Moon and Mars. The $^{142}Nd/^{144}Nd$ of the lunar and shergottite isochrons at a chondritic Sm/Nd are slightly lower than albeit not clearly resolved from that of the modern terrestrial mantle, but are distinctly higher than the mean $^{142}Nd/^{144}Nd$ of ordinary and carbonaceous chondrites. We interpret these $^{142}Nd/^{144}Nd$ variations to be nucleosynthetic in origin and show them to be consistent with a heterogeneous distribution of *s*- and *p*-process Nd. Of note, the resulting nucleosynthetic anomalies in Sm and non-radiogenic Nd isotopes are small and consistent with currently available data for chondrites [*e.g*., 6].

A nucleosynthetic origin of the ^{142}Nd difference between the Earth and chondrites provides further evidence that the *isotopic* composition of the Earth is distinctly non-chondritic [7]. However, the *chemical* composition of the Earth, at least for refractory lithophile elements, appears to be chondritic.

Investigation of boron, carbon, and oxygen isotope systematics in the aragonite-CO_2-H_2O system

C.D. KLEIN GEBBINCK[1], S.-T. KIM[1]*, M. HENEHAN[2] AND G.L. FOSTER[2]

[1]School of Geography and Earth Sciences, McMaster University, Hamilton, Canada (*correspondence: sangtae@mcmaster.ca)
[2]Ocean and Earth Sciences, University of Southampton, Southampton, UK

Calcium carbonate has been ubiquitous on the surface of the Earth. Therefore, marine and continental carbonates, such as forams and speleothems, play a critical role in paleoceanography and paleoclimatology as a key climate archive. Hence, a proper understanding of stable isotope systematics in carbonates with respect to their formational environment is important for the reconstruction of Earth's climate history.

Stable isotope systematics of boron, carbon, and oxygen in the aragonite-carbon dioxide-water system were simultaneously investigated using synthetic aragonite as a function of solution chemistry at 25 °C. A refined version of the constant addition method [1] was used to synthesize a polymorph of $CaCO_3$, aragonite, in aqueous solutions of various, but constant pH values and ionic strengths. The mineralogy of the carbonate was confirmed by XRD analysis and their isotopic compositions were determined by either IRMS or MC-ICPMS.

Results of our study suggest that the effect of ionic strength (~0.7 mol/kg) on the stable isotope fractionation between aragonite and water (for oxygen) as well as between aragonite and DIC (for carbon) in the aragonite-CO_2-H_2O system is negligible. In addition, boron isotope analysis of synthetic aragonite prepared from aqueous solutions of seawater-like ionic strength indicates that borate ions are preferentially incorporated into the aragonite crystal.

Tracing old SCLM in Pan-African granitoids from Dronning Maud Land (East Antarctica) with Sr-Nd isotope signatures

I.C. KLEINHANNS[1]*, J.JACOBS[2], A. K.ENGVIK[3], B.BINGEN[3], N.W.ROLAND[4], A. LÄUFER[4] AND R.SCHOENBERG[1]

[1]Universität Tübingen, Wilhelmstrasse 56, D-72074 Tuebingen; *kleinhanns@ifg.uni-tuebingen.de

[4]BGR, Stilleweg 2, D-30655 Hannover

Dronning Maud Land (DML) represents the southern end of the East African Antarctic orogen that was created during the final amalgamation of Gondwana in the Neoproterozoic. The suture between parts of East and West Gondwana spans over more than 8000km from present Egypt-Arabia to present Mozambique-Antarctica. The part north of the Lurio belt (LB) is characterised by accretionary tectonics visible in the Arabian-Nubian Shield contrary to the part south that shows evidence for continent-continent collision. Within southern Mozambique and DML numerous late-tectonic granitoids are observed, which are characterised as ferroan A-type granitoids that evolved under high-T conditions. The geodynamic regime is explained by extensional tectonics within a collapsing orogen accompanied by astenospheric upwelling through delamination of the orogenic root [1]. In this project we studied an E-W-profile along the 72°S-latitude starting from the Mühlig-Hofmann mountains (MH) (4°-7°E) via central Dronning Maud Land (cDML) (8°-14°E) and finally samples from Sør Rondane (SR) (23°-25°E). TDM (Nd) for MH and cDML samples are of Meso- to Paleoproterozoic age although the oldest (yet detected) crust in that region is of Grenville-age. We take this as evidence for the existence of an old subcontinental lithospheric mantle underneath this part of East Antarctica and its contribution to the granitoids. SR granitoids are different as they show grenville-aged TDM (Nd) and could thus have been developed by simple crustal melting. Initial Sr isotope signatures for both regions are similar and indicate homogenisation during time of emplacement. Finally, samples from the LB show large similarities with MH and cDML, but are different to SR granitoids. This allows to place certain paleogeographical constraints on Gondwana configuration.

Experimental study of trace element partitioning between spinel and silicate melts: Effects of oxygen fugacity and spinel composition

S KLEMME[1], CH WIJBRANS[1,*], C VOLLMER[1], M MENNEKEN[1] AND J BERNDT[1]

[1]Institut für Mineralogie, Universität Münster, Germany, *ineke.wijbrans@uni-muenster.de

Spinel is a common accessory mineral that occurs in a variety of rocks such as evolved basaltic magmas or chromitites in ultramafic rocks. Spinels often contain large amounts of transition metals or other redox sensitive elements, but the partitioning of these elements in these rocks is not well constrained, probably because it depends on several parameters which are difficult to disentangle: temperature, pressure, oxygen fugacity and composition of the crystals and melt.

Experiments are performed in 1 atm. gas mixing furnaces at temperatures between 1200 and 1430ºC and oxygen fugacities ranging from log -12 to log -0.7. Starting materials consist of glasses in the system (Cr_2O_3-FeO)-CaO-MgO-Al_2O_3-TiO_2-SiO_2 doped with a large number of trace elements.

The experimental run products were characterized with electron microprobe for major elements and 193nm Laser Ablation ICPMS for trace elements. The experiments all contained spinels and glass, some experiments contained additional phases (olivine or plagioclase).

The Fe^{2+}/Mg^{2+} ratio in spinel has little effect on trace element partitioning, but the concentration of trivalent cations such as Al, Fe and Cr appears to have an (large) effect on the partitioning of Ti, Sc and the HFSE; D values for these elements are lowest in Al rich spinels, are slightly elevated in spinels that contain chromium, and are about an order of magnitude higher in spinel high in Fe^{3+}.

Our results show that partition coefficients for some elements are redox sensitive; D_{Ni}, D_{Co}, and D_{Mo} decrease slightly with increasing fO_2 and D_V decreases over four orders of magnitude. In contrast, D_{Pt} and D_{Rh} increase strongly with increasing oxygen fugacity. To investigate peculiar high Pt and Rh concentration in the some of the experimental spinels, a TEM study was performed to investigate the presence of platinum group element nuggets as inclusions in the spinel. However, preliminary TEM results show no inclusions in these spinels suggesting that the measured high D's are correct.

[2]Institute of Chemical Kinetics and Combustion SB RAS, Novosibirsk, Russia;
[3]Institute of Cosmophysical Research and Aeronomy SB RAS, Yakutsk, Russia

Clouds in the atmosphere have a significant influence on weather conditions, and play a prominent part in the processes of energy exchange between the Sun, the surface of the Earth and the atmosphere. That is why it is important to research the mechanisms of clouds formation and the processes developing at different stages of formation. It is essential to estimate the influence of cosmic radiation, as well as other natural and anthropogenic factors on these processes.

Nucleation of droplets in the cooled water vapor requires the presence of condensation centers [1-3]. In order to observe the dynamics of droplets nucleation, the Institute of Atmospheric Optics SB RAS developed a unit on basis of the two-chambered cell with capacity exceeding 40 m^3 [4] which allows creating supersaturated H_2O vapor. At that, the unit offers the possibility of controlling thermodynamic parameters under varied pressure, test gas mixture composition and influence of ionizing radiation.

The study was focused on nucleation of nanoparticles and droplets. The nucleation developed under the gradual decrease in pressure of the test gas mixture when the unit conditions were made similar to Wilson chamber, type-II. The gas mixture was also exposed to the charged particle beam under gradual pressure decrease and supersaturated H_2O vapor. To this effect the unit was equipped with the electron gun [5]. Air, binary mixtures of H_2O-CO_2 and H_2O-N_2, as well as the air with high concentration of CO_2 and N_2 were used as test mixtures.

Exploring synergies of aerosol and climate mitigation strategies

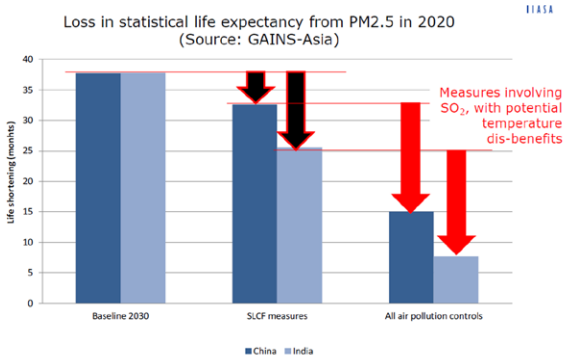
Z. KLIMONT[1]*, M. AMANN[1], S. RAO[1] AND F. DENTENER[2]

[1]IIASA, Schlosspltatz 1, 2361 Laxenburg, Austria (*correspondence: klimont@iiasa.ac.at)
[2]JRC/IES, 21027 Ispra, Italy

Recent work has highlighted the scope for reductions of short-lived climates pollutants (SLCP) that yield significant benefits to human health and agricultural crops at the local scale while limiting temperature increase in the near-term [1, 2]. Identified measures would achieve large cuts in emissions of CH_4 and BC, but minimize further emission reductions of cooling aerosols, such as SO_2, beyond what is already implied in current legislation. Climate policies, cutting emissions of several pollutants, would also bring important health benefits [3].

While implementation of measures addressing SLCP or specific climate polices would result, beyond climate benefits, in significant air quality and ecosystem improvements, they will not be sufficient to remediate all current air quality problems and achieve sustainable air quality around the world. Additional air quality measures will need to involve further reductions of cooling aerosols, such as SO_2 emissions, which however will result in a clear climate dis-benefit, at least in the near term (Figure 1).

The presentation will review available emissions scenarios



for measures or policies that could compensate climate dis-benefits of SO_2 mitigation by co-controls of long-lived greenhouse gases.

Geochemistry of organic matter from Triassic U-bearing sandstones of Peribaltic Syneclise (N Poland)

KLIMUSZKO E., WOLKOWICZ S.* AND MIECZNIK J.B.

PGI-NRI, 4 Rakowiecka, 00-975 Warsaw, Poland (stanisław.wolkowicz@pgi.gov.pl)

In central parts of the Peribaltic Syneclize, Triassic rocks display sandstone type uranium mineralization. Mineralization is related to gray sandstones poor in TOC.

5 samples were covered by geochemical studies, including TOC, bitumen fractions, saturated hydrocarbons and aromatic hydrocarbons.

Small TOC values (below 0,1%) indicate poor hydrocarbon generation potential. Amounts of bitumens are small, from 70 to 170 ppm. The share of hydrocarbons in these bitumens ranges from 26,7% to 52,3%, being lower than that of the asphaltene and resin fraction. Migration coefficient of hydrocarbons is raised, ranging from 0,03 to 0,09, which suggests epigenetic origin of labile components. N-alkanes with 21 – 24 carbons in chain are most common, suggesting that the organic matter is of the sapropel type. Analyses of compounds of the terpane group showed predominance of pentacyclic compounds over the tricyclic, indicating high share of bacteria in original organic matter as well as low level of maturation. The composition changes in lower part of the studied series. In that part, tricyclic compounds predominate over the pentacyclic which indicates a higher level of maturation. Moreover, difference between contents of 17α (H)-trisnorhopane (Tm) and 18α (H)-trisnorhopane II (Ts) compounds which further supports higher level of maturation of the studied organic matter. C27 (cholestane) appears fairly common in the group of identified steranes but content of sterane C29 sterane (stigmastane) is higher which suggests some contribution of terrigenous material in organic matter. Significant share of C28 compound (ergostane) was found in lower part of the studied series which evidences presence of material of the lacustrine origin.

The Triassic rocks are poor in TOC and their hydrocarbon generation potential is very low. At the same time they yield small amounts of labile components which would be epigenetic origin. The organic matter was generally of the marine origin. In lower part of the rock series, the parent organic matter comprises material of the lacustrine type, and in the upper – organic matter of the marine type is enriched with supposedly allochtoneous terrigenous material.

A microscopic and ToF-SIMS study on the Ra uptake by barite

KLINKENBERG, M[1]*., BRANDT, F.[1], BREUER, U.[2] AND BOSBACH, D.[1]

[1]Institute of Energy and Climate Research (IEK-6) Forschungszentrum Jülich, Germany; m.klinkenberg@fz-juelich.de(*presenting author), f.brandt@fz-juelich.de, d.bosbach@fz-juelich.de

[2]ZEA-3 Analytics, Forschungszentrum Jülich, Germany; uwe.breuer@fz-juelich.de

Long-term safety assessment studies of nuclear waste repositories for spent nuclear fuel commonly consider a scenario, in which radium released from the fuel comes into contact with an aqueous solution saturated with barium [1]. An open question is whether a Ra containing solution will equilibrate with solid $BaSO_4$ under repository relevant conditions due to complete recrystallization. Previous studies have indicated that uptake of Ra is not limited by pure adsorption at close to equilibrium conditions but involves a significant fraction of the bulk solid [2,3]. So far, only macroscopic data indicate that barite may fully recrystallize to radiobarite. For this microscopic (SEM) and ToF-SIMS study, samples of two different barites were prepared in batch sorption experiments to investigate the recrystallization of barite in the presence of Ra. Based on gamma spectrometry, it was observed that one barite incorporates Ra faster than the other barite.

A broad grain size distribution was determined via SEM observation for the fine grained barite. During recrystallization of the crystals, an additional effect on the grain size evolution due to the presence of Ra was detected compared to the coarsening of a blank sample due to Ostwald ripening. In contrast, the narrow grain size distribution of the coarse grained barite didn't show significant changes with time and no influence of the presence of Ra. Here, morpholgical changes were observed instead.

The results of ToF-SIMS indicate a homogeneous uptake of Ra into the crystals. After 443 days the integrated Ra concentration corresponds with the size of the barite particles. The Ba/Ra ratio was calculated from several ToF-SIMS measurements. The Ra/Ba intensity distribution has its maximum between 2 and $4 \cdot 10^{-3}$, corresponding well with the macroscopic results from bulk solution chemistry.

Hybrid Multispectral Analysis (HMA): Innovative technology for continuously monitoring the biogeochemistry of urban waterways

GARY P. KLINKHAMMER[1] AND CHRIS J. RUSSO[2]

[1]CEOAS, Ocean Admin. Bldg. 104, Oregon State University, Corvallis OR, USA 97331
[2]ZAPS Technologies Inc., 4314 Research Way, Corvallis OR, USA 97333

Hybrid Multispectral Analysis (HMA) uses a fiber optic spectrometer to analyze source and waste waters for multiple parameters. Hybrid refers to the HMA capability of measuring fluorescence and absorption as well as scattering to produce a rich array of optical data. No chemicals are required in HMA analysis. The optical information is then used to correct for artifacts such as turbidity and signal overlap before calculating concentrations based on laboratory calibrations performed in a clean water matrix. HMA data quality is maintained over time with automated cleaning and correction protocols. The HMA menu for source water includes TOC, nitrate, chlorophylls, turbidity, biochemical oxygen demand (BOD), total suspended solids (TSS), color, *E. coli* bacteria, fluorescent dissolved organic matter (FDOM) and other water quality parameters. Each value is displayed on a graphical web-user interface once every 2-3 minutes depending on the number of measurements in the menu. In this paper HMA data will be compared for several urban-impacted waterways including a small creek in Corvallis Oregon (Oak Creek) and a river-estuary in Sydney Australia (Parramatta River). The biogeochemistry of these urban streams will be compared to the relatively pristine, mountain-fed Santiam River in coastal Oregon. The high-resolution data from HMA allows details of important inter-parameter relationships to be examined in detail for the first time.

Abiotic reactions of nitrite during microbial Fe(II) oxidation and their influence on cell-encrustation of nitrate-reducers

NICOLE KLUEGLEIN, FABIAN ZEITVOGEL, MARTIN OBST AND ANDREAS KAPPLER*

University of Tuebingen, Centre for Applied Geoscience, Sigwartstrasse 10, 72076 Tuebingen, Germany
(nicole.klueglein@uni-tuebingen.de)
(fabian.zeitvogel@student.uni-tuebingen.de)
(martin.obst@uni-tuebingen.de)
(*correspondence: andreas.kappler@uni-tuebingen.de)

Anoxic, nitrate-reducing bacteria are widespread in soils and sediments. They use nitrate (NO_3^-) and the following intermediates (NO_2^-, NO and N_2O) as electron acceptors. In addition to heterotrophic denitrifiers, nitrate-reducers have been isolated which were suggested to couple nitrate reduction to the oxidation of Fe(II). Recently, however, it has been questioned whether the observed Fe(II) oxidation is completly enzymatic or whether it is at least partly due to an abiotic reaction between Fe(II) and the reactive N-species formed during mixotrophic growth [1,2,3]. Here we present data that demonstrates that NO_2^- is able to oxidize Fe(II) under pH-neutral and particularly under acidic conditions at high rates. Fe(II) analysis using sulfamic acid instead of HCl prevents the abiotic reaction of NO_2^- and Fe(II) during acidic extraction and yields correct Fe(II)/Fe(III) values. To evaluate the role of bacterially produced nitrite in Fe(II) oxidation, we compared two strains that were isolated as nitrate-dependent Fe(II)-oxidizers [1,2] with two heterotrophic nitrate-reducers (*Paracoccus denitrificans* ATCC 19367 & 1222) in their ability to oxidize ferrous iron and the formation of Fe(III) mineral crusts around the cells. All four tested strains oxidized Fe(II) and using SEM/TEM we observed heavy encrustation of all strains. However, the shape, crystallinity and localization of minerals inside and outside the cell varied distinctly between the strains. Applying fluorescent lectins in the CLSM, we also observed a significant production of exopolymeric substances, maybe as a protection mechanism against high Fe(II) concentrations. Our observations suggest that cell encrustation is a side effect caused by abiotic Fe(II) oxidation by nitrite during heterotrophic denitrification.

Fluid migration along a dense, intersecting array of faults on the outer-shelf of Southern Costa Rica: Insights from 3D seismic attributes and multibeam data

JARED W KLUESNER[1], ELI SILVER[1], STEPHANIE NALE[1], NATHAN L BANGS[2] AND KIRK D MCINTOSH[2]

[1]Earth and Planetary Sci Dept, Univ California Santa Cruz, Santa Cruz, CA, USA, (jwkluesn@ucsc.edu)
[2]Institute for Geophysics, Univ. of Texas, Austin, TX, USA

We use 3D seismic reflection attributes and multibeam data to map and analyze fluid-flow along a dense network of intersecting normal faults imaged on the outer shelf offshore Southern Costa Rica. Faults were imaged on the seafloor using (i) high-resolvability EM122 multibeam data, and (ii) in 3D below the seafloor using seismic reflection data, both collected during the 2011 CRISP seismic survey. Multibeam bathymetry reveals a series of high-backscatter ridges on the seafloor cut by numerous faults with roughly N-S and E-W trends. Vertical profiles within the 3D seismic volume reveal that faults have normal displacements and extend deep into the sedimentary section, some of which cut through top of the margin. Numerous indicators of fluid-migration and fluid-rich sediments, such as bright spots, dim spots, and acoustic turbidity zones, are present along fault traces imaged on vertical inlines and crosslines. Within the seismic volume we use seismic discontinuity attributes (e.g., coherency and similarity) of a dip-steered seismic volume to reveal and map fault traces in horizontal time slices. We then use a neural network of multiple seismic attributes to create a 'fault cube' and a 'chimney cube' to detect high probability zones fluid leakage along faults. Indicators of seafloor seepage, such as high-backscatter pockmarks and mounds, are imaged on the seafloor along fault traces and above seismic indicators of fluid migration. Use of seismic discontinuity attributes massively improves 3D interpretability of a very complex set of intersecting faults, and provides insight into understanding the pathways of fluids and gas within the margin of Costa Rica.

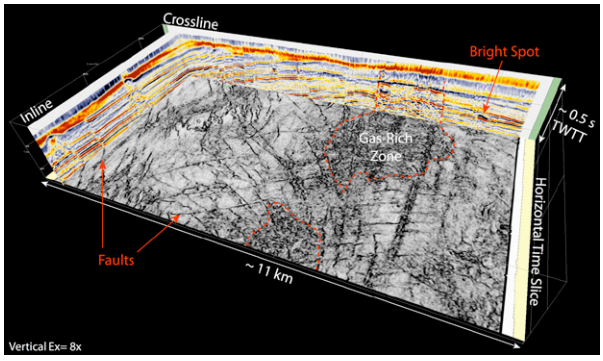

Figure 1. 3D perspective view of subset of 3D seismic data below the outer shelf of southern Costa Rica.

Constraints for the clumped isotope application in diagnetic environments involving high salt concentrations

TOBIAS KLUGE*, CÉDRIC M. JOHN AND SIMON DAVIS

Department of Earth Science and Engineering and Qatar Carbonate and Carbon Storage Research Centre, Imperial College London, SW7 2BP, United Kingdom; *correspondence: t.kluge@imperial.ac.uk

Carbonate clumped isotopes is a promising proxy for the reconstruction of mineral formation temperature and their parent fluid composition. Clumped isotopes has a wide range of potential applications, such as the reconstruction of the diagenetic history of sedimentary basins that involve fluids with a high salt concentration and elevated temperatures. As salt ion effects are known to impact bulk oxygen isotopes, here we assessed the influence of salinity on clumped isotopes in the temperature range from 20-90°C.

Samples were precipitated from a super-saturated $CaCO_3$ solution via N_2 bubbling. Prior to starting the carbonate precipitation the solution was equilibrated at the respective experiment temperature. Different salt ions (Na^+, Ca^{2+}, Mg^{2+}) were added to the solution and compared to samples without added NaCl, MgCl or $CaCl_2$ to evaluate ionic effects on ^{13}C-^{18}O clumping. No effects were observed for NaCl at temperatures between 23 and 90°C and salt concentrations up to 6 molal. Preliminary results indicate that moderate concentrations of $MgCl_2$ (0-0.4 molal) and $CaCl_2$ (0-0.5 molal) have no observable influence on ^{13}C-^{18}O clumping. Furthermore, polymorphism of $CaCO_3$ produced no observable effect. In summary, our results indicate that carbonate clumped isotopes can be applied to carbonates precipitated from saline parent fluids without the need to correct for salt ion effects in common NaCl brines or fluids containing moderate levels of $CaCl_2$ and $MgCl_2$.

We gratefully acknowledge funding from Qatar Petroleum, Shell and the Qatar Science and Technology Park.

Petrological constraints on magma plumbing dynamics of the 2011 El Hierro eruption (Canary Islands)

A. KLÜGEL*[1], M.-A. LONGPRÉ[2] AND J. STIX[2]

[1]University of Bremen, Geosciences Department, Bremen, Germany [akluegel@uni-bremen.de]
[2]Earth and Planetary Sciences, McGill University, Montréal, Québec, Canada [m-a.longpre@mcgill.ca]
(*correspondence: akluegel@uni-bremen.de)

A submarine eruption took place off the south coast of El Hierro, Canary Islands, from October 2011 to March 2012. The well-monitored eruption was preceded and accompanied by numerous earthquakes and ground deformation. Eruptive products sporadically rose to the ocean surface and were sampled at different stages of the eruption. We carried out a detailed geochemical and petrological study to constrain magma plumbing dynamics associated with the eruption.

All bulk lava samples are basanites with essentially identical matrix glass compositions, implying very little change in magmatic liquid composition through time. The MgO content of the bulk lava increased at the late eruptive phase due to increasing contents of ferromagnesian crystals. Final phenocryst crystallization took place at 500-710 MPa (17-24 km depth, within the upper mantle), as was determined by 73 clinopyroxene-melt pairs. This depth range for an inferred magma reservoir coincides perfectly with the depths of syn-eruptive seismicity. In contrast, the analysis of 260 CO_2-rich fluid inclusions in phenocrysts yields two pressure ranges, one at 280-440 MPa (10-16 km depth, lower crust to upper mantle) and one at 450-580 MPa (16-19 km). The shallower range corresponds well with the depths of pre-eruptive seismicity, and reflects lateral movement of magma within the lower crust over a distance of ca. 15 km before ascending to the eruptive site.

Detailed analysis of zoning patterns in olivine and clinopyroxene phenocrysts and compositions of melt inclusions reveal that at least two distinct magmas were involved in the eruption. Both magma batches were initially stored in the upper mantle, one probably at 19-25 km depth and one at 15-18 km. Diffusion modelling indicates that mixing of these magmas likely began about three months before eruption, resulting in intrusions to the lower crust and associated seismic crisis and surface deformation. Strikingly, mixing must have continued for many weeks after the onset of the eruption. The abundance of complexly zoned phenocrysts in the late eruptive products is interpreted to reflect mobilization of crystal mush and cumulates as a consequence of magma withdrawal and reservoir collapse.

Established and advanced solid-state NMR spectroscopy for a better understanding of the structure and function of natural organic matter in soils, water and sediments

In geobiogeochemistry, 1-dimensional solid-state NMR spectroscopy has been proven as a powerful tool for the characterization of natural organic matter (NOM) in soils, sediments and waters. However, compared to solution NMR spectroscopy, this technique suffers from broad resonance lines and low resolution, which could be overcome by the use of *2-dimenstional solid-state* NMR pulse sequences. Until recently, this approach has been unfeasible as a routine tool in geochemistry, mainly because of the low NMR sensitivity of the respective samples. Alternative to the use of higher magnetic fields, considerable signal enhancements can be achieved with the new developments in the field of dynamic nuclear polarization (DNP) solid-state NMR spectroscopy. Here, the improvement is achieved by a microwave-driven transfer of polarization from a paramagnetic centre to nuclear spins. Application of DNP to magic angle spinning (MAS) spectra of biological systems (frozen solutions) showed enhancements by factors of 40 to 50 (Hall *et al*., 1997). Applying this technique for the first time on NOM, lower but still promising enhancement factors were obtained which allowed the successful acquisition of 2D solid-state NMR spectra of such samples. In the present contribution, the possibilities and limitation of established solid-state NMR techniques in NOM research are discussed and first results obtained with solid-state DNP NMR are presented. Those first data demonstrate the great potential of the latter and that this approach opens new doors for a better understanding of biochemical processes in soils, sediments and water.

Coupling of nitrogen inputs and losses during the Permian-Triassic biotic crisis

J. KNIES*[1], S.E. GRASBY[2,3], B. BEAUCHAMP[3] AND C.J. SCHUBERT[4]

[1]Geological Survey of Norway, 7491 Trondheim, Norway (*correspondence: jochen.knies@ngu.no)
[2]Geological Survey of Canada, Calgary, Alberta T2L 2A7, Canada
[3]University of Calgary, Calgary, Alberta T2N 1N4, Canada
[4]Swiss Federal Insitute of Aquatic Science and Technology, EAWAG, 6407 Kastanienbaum, Switzerland

We report coupling of dinitrogen (N_2) fixation and denitrification in oxygen deficient waters in the Sverdrup Basin, Arctic Canada, during the Permian-Triassic biotic crises. Sediments deposited prior to the latest Permian extinction (LPE) event are characterized by positive $\delta^{15}N$ values of ~9 ‰ associated with the presence of lycopane implying upwelling of denitrified waters from an expanded oxygen minimum zone (OMZ). The data show anoxic bottom water conditions were not developed in northeastern Panthalassa during the Late Permian. Promoted by dispersing coal ash from Siberian Traps volcanic, as marked by abrupt rise in C/N ratios (>20) prior to the LPE event, euxinic conditions first developed at the LPE. Nutrient-induced anoxia was likely prevalent during the Early Triassic in the aftermath of the LPE, however, the nutrient N pool was predominantly fuelled by N_2-fixing cyanobacteria.

Tellus: Regional-scale baseline geochemical mapping of soil, stream sediment and stream water for the island of Ireland

KNIGHTS, K.V[1]. AND SCANLON, R.[2]

[12]Geological Survey of Ireland, Beggar's Bush, Haddington Road, Dublin 4, Ireland (kate.knights@gsi.ie, ray.scanlon@gsi.ie)

Systematic geochemical surveying of the northern region of the island of Ireland, comprising Northern Ireland (NI) and the northernmost counties of the Republic of Ireland (RoI), is now complete. The Geological Survey of Ireland recently conducted regional-scale surveying of soils, stream sediments and stream waters geochemistry across the northern region of Ireland under the Tellus Border project. A survey of neighbouring Northern Ireland was completed in 2007 under the Tellus project by the Geological Survey of Northern Ireland. Multi-element analytical data for the entire region are currently being integrated to provide seamless cross-border mapped datasets. These surveys also took place alongside mutiparameter low-level airborne geophysical surveys collecting magnetic field, electromangnetic and radiometric data; resulting in a high-quality and comprehensive geo-environmental database.

There are challenges in merging these data; with two ground survey designs conducted at differing densities. However the same general field collection, sample preparation and anaytical methodologies have been utilised. Topsoils (c.5–20 cm) have undergone *aqua regia* ICP analyses, stream sediments (<150 μm wet-sieved fraction) by XRFS and stream waters analysed by IC, ICP-MS and for DOC.

Legacy and new data have been combined and are being assessed using multivariate statistical techniques (*e.g.* factor analyses) to characterise and map factors which help to define geochemical signatures; to understand sources and processes at play. They reveal broad geogenic controls and influence of agricultural practices that overprint the rural geochemical baseline.

The region now has a rich geochemical dataset with improved detail across this geologically diverse region. Elements of interest to agricultural applications are compared to results from prior national soil surveys and the European-wide GEMAS study.

The effect of marine biological activity on aerosol generation and cold cloud formation

D. A. KNOPF[1]*, P. A. ALPERT[1], W. KILTHAU[1], J. RADWAY[1] AND J. Y. ALLER[1]

[1]School of Marine and Atmospheric Sciences, Stony Brook Univ., Stony Brook, NY, 11794-5000, USA (*correspondence to daniel.knopf@stonybrook.edu)

Sea salt particles are a major contributor to atmospheric aerosol. Recent observations have indicated that these and other marine derived particles can be enriched in organic material (OM), particularly during periods of high primary production. This OM can impact atmospheric particulate matter loading and the ability of particles to act as cloud condensation and ice nuclei, with subsequent consequences for the global radiative budget.

Here we report the effects of marine biological activity on aerosol generation and cloud formation potential. Aerosols were produced by plunging jets and glass frits from 1000L mesocosms containing three phytoplankton species cultured in artificial seawater, exudates derived from phytoplankton, a bacterial culture, and a natural seawater microbial community. The 14-day experiments simulated bloom development as evidenced by changes in cell numbers. At each sampling time, aerosolized particles were size discriminated under dry and 80% humidified conditions, collected, and characterized. Bubble-size spectra were determined. To interpret relationships between biological activity and aerosol size distributions, we characterized concentrations of dissolved and particulate organic matter, transparent exopolymer particles, and microgels; numbers of phytoplankton and virus-like particles; and the proportion of live:dead bacteria. Aerosols were collected on substrates for single particle chemical analyses using electron and X-ray micro-spectroscopy. Water uptake and ice nucleation capabilities for temperatures as low as 200 K were determined.

As phytoplankton growth reached stationary phase, the number of particles smaller than 100 nm increased threefold. Ice active particles in a population characterized by a sea salt core with OM coating are 1.0-5.0 μm in diameter. Water uptake is observed until 220 K and 60% RH. Immersion freezing occurs between 80% and 100% RH. Deposition ice nucleation occurs below 215 K and around 70% RH. Our experiments show that biological activity can affect marine derived aerosol, with implications for cloud formation and the radiative budget.

Impact of long term wetting on hydrology and biogeochemistry of a peat bog in Ontario, Canada

KLAUS-HOLGER KNORR[1], CHRISTIAN BLODAU[1], SVEN FREI[2], KLAUS KASPARBAUER[2]AND JONAS SCHAPER[2]

[1]Institute for Landscape Ecology, Hydrology Group, WWU Münster, Heisenbergstr. 2, 48149 Münster, Germany; kh.knorr@uni-muenster.de

[2]Department of Hydrology, University of Bayreuth, Universitätsstr. 30, 95447 Bayreuth, Germany

Peatlands of the northern hemisphere store vast amounts of carbon but also contribute to global methane emissions. As large areas in the boreal and temperate zones are predicted to undergo significant changes in climate and concomitant changes in hydrology, it is crucial to understand the response of peatlands to altered climatic and hydrological boundary conditions. In this study we investigated the response of peatlands to long term wetting, as especially in winter for large areas wetter conditions have been predicted. We hypothesized that long term wetting will result in changes in vegetation, concomittant changes in peat decomposability and also nutrient input from the adjacent water body.

To this end, we chose the Luther Marsh site in Ontario, Canada, that has been partly flooded since the 1950s due to the construction of a reservoir. Water management in the reservoir flooded a large part of the peatland, but also causes seasonal flooding and draining, shifting hydrological flow patterns and vegetation gradients. Hydrology was monitored by means of piezometers and pressure transducers over one growing season over a transect of 7 sites from the reservoir to the inner, pristine part of the bog. At the same sites, we obtained pore water chemistry data and dissolved gases.

Partial flooding resulted in obvious changes in vegetation, increased nutrient availability, and thus increased decomposition activiy in the wet part. This was reflected more narrow CH_4 to CO_2 ratios in the pore water and higher concentrations and calculated turnover rates. Advective transport removed decomposition end products and introduced nutrient enriched reservoir water, as indicated by elevated pH amd increased concentrations in Ca and Mg. DOC quality as assessed by fluorescence spectroscopy also gradually approached quality indices observed in the reservoir.

This study demonstrated that partial flooding of a peatland significantly changes vegetation and the nutritional status, resulting in a shift towards more CH4 production and higher turnover rates.

Molecular Dynamics Study of Cement-Aqueous Solution Interfacial System: Cesium Ion Fixation

K. KOBAYASHI[1], Y. LIANG[1], I.C. BOURG[2] AND T. MATSUOKA[1]

[1]Environment and Resource System Engineering Lab., Kyoto Univ., Kyoto 615-8540, Japan (kobayashi.kazuya.44n@st.kyoto-u.ac.jp, liang.yunfeng.5x@kyoto-u.ac.jp, matsuoka.toshifumi.7x@kyoto-u.ac.jp)
[2]Earth Science Division, Lawrence Berkeley National Lab., Berkeley, CA 94720, USA (icbourg@lbl.gov)

Cs^+ ion is one of radioactive species generated by nuclear electric power. It is one of the most problematic ions because of its long half-life and high mobility. Cement material is considered as a candidate for the solid fixation of Cs^+ ions, and the engineered barrier for the geological disposal of such radioactive species. The structures of the cement is complicated, and considered as nano-crystalline aggregation phase with two distinct local structures, tobermorite and jennite, by the difference of Ca/Si ratio and the silica-chain length. The goal of this research is to detect which structural or compositional feature is essential to ionic adsorption into cement matrix.

By using molecular dynamics simulations, we have studied the aqueous solution-mineral (cement) interfacial systems for two different cement local structures (tobermorite and jennite) and two different solutions (NaCl and CsCl). It was found that Na^+ ion could form both inner-sphere complex and outer-sphere complex, without full hydration shell and with full hydration shell at the time of adsorption, respectively. In contrast, Cs^+ ion could only form inner-sphere complex for both mineral cases. This finding is in good correspondence with previous NMR studies[1]. Furhtermore, we found that the inner-sphere complex Na^+ is tightly binded with the depronated oxygen. More importantly, it was found that tobermorite presents better binding property than that of jennite. The fact that differences in cement structure and ion spiecies may cause these differences in adsorption state and binding property will enhance our understanding on cement materials in the case of the solid fixation and the geological disposal.

Halogen and noble gas compositions are complementary tracers of H_2O (or aqueous fluids) in the mantle. Via subduction of sedimentary pore-fluids, halogens and noble gases are carried into the mantle [1, 2]. Here, we present the halogen and noble gas compositions of mantle peridotites from subduction zones (the Avacha volcano in Kamchatka, the Pinatubo volcano in Philippines, and the Horoman massif in Japan) to investigate how far the influence of subducted pore fluids extends in the mantle wedge. H_2O-rich fluid inclusions are present in the studied peridotites as previously described [3–5]. To determine noble gas and halogen compositions of the fluid inclusions and bulk peridotites, we converted halogens (Cl, Br and I) to Ar, Kr and Xe isotopes by neutron irradiation, and extracted the noble gases by *in vacuo* crushing or heating.

The Br/Cl and I/Cl values of the fluid inclusions obtained by crushing show a sedimentary pore-fluid signature with some variation between localities. The halogen ratios obtained by heating are slightly lower than crushing suggesting the presence of additional Cl in minerals such as amphibole and/or silicate glass [3] in the peridotites. Slab-derived, seawater-like noble gases are also dominant in fluid inclusions as previously reported [6, 7].

The composition of subducted halogens and noble gases in the mantle peridotites demonstrates that sedimentary pore-fluid signatures are carried beneath the island arcs through subduction and survive in the mantle wedge. Deeper subduction of pore-fluid like noble gases into the deep mantle accounts for the same signature of the convecting mantle [2].

Zinc isotopes as a tool to study zinc uptake by marine phytoplankton

M. KÖBBERICH[1]*, A. D. COX[2], AND D. VANCE[1]

[1]Institute of Geochemistry and Petrology, ETH Zurich, Switzerland
[2]School of Earth and Space Exploration, Arizona State University, USA

The availability of metals to marine phytoplankton has been suggested to control oceanic carbon uptake from the atmosphere and its sequestration to the deep sea. Metal variability across glacial/interglacial periods could have driven changes in the composition of atmospheric greenhouse gases [1]. Many transition metals, including zinc, are often extremely scarce in the euphotic zone and are coupled with deep enrichments, consistent with biological uptake at the surface and regeneration at depth. However, abiotic processes, such as scavenging, can also contribute to this depth cycling [2]. If the surface to depth cycling is associated with zinc isotopic fractionation, then isotopic studies should be able to elucidate the key contolling processes, both now and in the past.

Here we seek to evaluate zinc isotopes as a potential tool to track metal cycling in the oceans. Recently obtained depth profiles of dissolved zinc isotopes from the NE Pacific reveal anomalously light compositions in the shallow sub-surface immediately below the isotopically heavier euphotic zone. This dataset suggests shallow zinc recycling in the upper ocean, possibly caused by the release of biologically bound light zinc [3,4]. To our knowledge, the diatom *Thalassiosira oceanica* is thus far the only planktonic organism that has been shown to fractionate zinc isotopes during uptake [5]. We have cultured this organism, and a variety of other marine phytoplankton strains, in order to explore systematic and species-dependent changes in their isotopic fractionation. Thermodynamic reaction modelling of our experiments and natural systems elucidates zinc isotopes as a potentially powerful tool to reconstruct biological metal cycling in both modern and past oceans.

Noble gas signature of Tertiary alkaline basalts and xenoliths from central Europe

YU. KOCHERGINA[1,2], S. NIEDERMANN[3], V. RAPPRICH[1] AND T. MAGNA[1]

[1]Czech Geological Survey, Klarov 3, CZ-11821 Prague, Czech Republic; julia.kocergina@geology.cz
[2]Faculty of Science, Charles University, Albertov 6, CZ-12843 Prague, Czech Republic
[3]GFZ Potsdam, Telegrafenberg, D-14473 Potsdam, Germany

We present preliminary He and Ar isotope data for two suites of pristine alkaline basaltic rocks associated with the Eger Rift, Bohemian Massif, in order to deconvolve the noble gas signature of the sub-continental lithospheric mantle beneath central Europe. In addition, He and Ar data were collected from xenoliths enclosed in these alkaline basalts in order to compare the noble gas isotope signature of the mantle source of the xenoliths, thought to be located at shallower depths than that inferred for alkaline volcanic rocks.

Most xenolithic and phenocrystic olivines have $^{3}He/^{4}He$ ratios between 4.7 and 6.6R_A, clearly more radiogenic than MORB, and rather constant despite ^{4}He concentrations varying by nearly two orders of magnitude ($0.1–8.9\times10^{-8}$ cm^3 STP/g), although the highest ^{4}He concentration is associated with an elevated $^{3}He/^{4}He$ of 7.2R_A. The latter may suggest sampling of a convective mantle similar to MORB. Homogeneous $^{3}He/^{4}He$ ratios (5.5–5.7R_A; n=3) are found for olivines from the Doupovske hory volcanic complex, whereas clinopyroxene shows a slightly more radiogenic signature (4.1R_A). Collectively, He isotope data shows a remarkable homogeneity across two chemically distinct volcanic centres associated with the major Eger rift lineament, attesting to their temporally and spatially invariant lithospheric mantle source, and confirms further the observations of a homogeneous He isotope signature of the sub-continental mantle beneath central Europe [1]. $^{40}Ar/^{36}Ar$ ratios for the same samples are between 306 and 3690. Atmospheric Ar could be admixed by infiltration of air from basaltic melts; such a process of metasomatism of mantle xenoliths by basaltic melts has been reported from other localities of the Eger rift [2]. Further He and Ar isotope analyses of alkaline basaltic and basanitic rocks and xenoliths of distinct mantle layers from between 32 and 70 km in depth are in progress.

Trace metals in plants of Chadak gold ore field, Uzbekistan

O.KODIROV[1]* , F. MARTIN[2] AND N. SHUKUROV [1]

[1]Institute of Geology and Geophysics, Academy of Sciences of Uzbeksitan, 49-Olimlar, 100041, Tashkent, Uzbekistan (*correspondance: o.kodirov@gmail.com)

[2]University of Granada, University Campus Fuentenueva s/n 18071- Granada, Spain (fjmartin@ugr.es)

Among the set of conditions that determine the status of the biota and the environment in general, geochemical factors related to the geologic history of the area and its constituent chemical composition of rocks and soils play a major role. It is known that the chemical composition of plant communities are closely related to the concentration of some elements in soil. From this perspective, the study of the relationship between the components of geochemical environment is the main objective of our investigation.

The study area is characterized by a relatively developed mining industry, here since 1970 operates the Chadak mine and the gold-extracting factory.

Plant samples (*Artemísia absínthium* and *Phrágmites austrális*) were collected in the vicinity of Chadak mining area and in tailing dumps which were formed as a results of mining activity. Dry ashing was conducted in a muffle furnace at temperatures of 450 to 500^0C for 3-4 hours. After the ashing the ashe dissolved in dilute HNO_3+3HCl. The final solution was analized for Cu, Zn, Pb, Mn and As with ICP-MS.

Results show that trace elements were to exceed normal concentration in plant leaves [1] and reaching (mg/kg): Cu – 37-639, Zn – 174-1798, Pb – 5-282, Mn – 361-2969, and As – 2-341, respectively.

As can be seen from the results trace elements are found in excessive or toxic concentration despite the fact, that some of these elements are essential for plants. Not always observed relationship with the soil composition as the concentration of trace metals are much higher than in soil samples. Perhaps this is due to selective ability of some plant species or such high content of trace metals related to ore deposit.

Many studies have shown that there is a correlation of trace metals in plants on the content of their mobile forms in soil solution. With this respect, future investigations on the mobile forms of trace metals are required in our studied area.

Platelet degradation in diamonds. Insights from infrared microscopy and implications for the thermal evolution of cratonic mantle.

S.C. KOHN*, E. WIBBERLEY, C.B. SMITH, G.P. BULANOVA AND M.J. WALTER

School of Earth Sciences, University of Bristol, Queens Rd., Bristol, BS8 1RJ, UK (*simon.kohn@bristol.ac.uk)

Crystallographic defects in diamonds provide a wealth of information that can, in principle, be used to constrain the thermal evolution of diamond source regions. The simplest method consists of using the average N concentration and aggregation of whole diamonds of known age to obtain an estimate of residence temperature in the mantle. Detailed studies of the spatial dependence of N abundance and aggregation provide an improvement in temperature estimation and can provide constraints on multistage diamond growth events (Kohn *et al*., in prep). However, temperature estimates can only be obtained if the diamond has been dated by an independent method and the temperature obtained is neither the maximum nor mean temperature experienced during residence in the mantle, because of the exponential temperature dependence in the kinetic equation.

In the present study we are exploring the potential of platelet degradation rate as an additional constraint on thermal histories of diamonds and their cratonic mantle hosts. The approach is to measure nitrogen abundance and aggregation in core-to-rim profiles across diamonds from Argyle (Australia) to determine apparent temperature profiles. These profiles are then compared with the degree of platelet degradation at each point. If platelet degradation occurs at a fixed rate for a given temperature, then for diamonds with a single mantle residence time there should be a clear correlation between the degree of platelet degradation and temperature. Our data show that for a single diamond such a correlation usually exists, but that for the whole data set there are wide variations in the apparent degradation rate. The diamonds with the slowest apparent rates were found to have eclogitic (E) inclusions while those with the fastest rates are peridotitic (P). For Argyle the mantle residence times are around 0.4 and 1.4 Ga for E and P respectively [1], suggesting that the degradation rate could be constant at a given T, and that the different degrees of degradation reflect the different residence times of the two parageneses.

The potential role of plastic deformation and other complicating factors in modifying the calculated temperatures and degree of platelet degradation will also be discussed.

OH incorporation in quartz as a tracer of formation conditions

MARZENA A. KOHUT[1] ROLAND STALDER[1] AND JÜRGEN KONZETT[1]

[1]Institute of Mineralogy and Petrography, University of Innsbruck, Austria, Marzena.Kohut@uibk.ac.at, Roland.Stalder@uibk.ac.at, Juergen.Konzett@uibk.ac.at

Quartz as a common nominally anhydrous mineral of the Earth's crust contains traces of hydrogen as a molecular water in fluid inclusions, or as structurally incorporated hydroxyl ions. The structurally bound hydrogen commonly acts as a charge compensator, associated with point defects, such as substitution of Si^{4+} by Al^{3+} and/or B^{3+} with charge balance maintained by monovalent cations substitutions (H^+, Li^+ and Na^+). The occurence of hydrogen affects thermodynamic properties of minerals and influences their kinetic behavior during diffusion and phase transformations. Even small amounts of OH defects can dramatically change physical properties of minerals that are a key to understand rock-formation mechanisms within the crustal conditions.

The geochemical behavior of OH incorporation in quartz in the systems granite-tourmaline-water and granite-spodumene-water was studied in order to explain the effect of pressure and temperature on structural defect generation. Piston-cylinder experiments were carried at pressures between 5 and 25 kbar and temperatures between 800 and 1050°C. Oriented and polished quartz crystals from each run were characterized with FT-IR spectroscopy and water contents were calculated using mineral-specific and general wavelength-specific calibrations.

The OH absorption features were assigned to Al^{3+}-substitution (Al-H defect, band-triplet at 3320, 3383 and 3434 cm^{-1}), B^{3+} -substitution (sharp absorption band at 3597 cm^{-1}), Li^+ -substitution (weak absorption band at 3475 cm^{-1}) and hydrogarnet $(4H)_{Si}$ defect (absorption at 3585 cm^{-1}).

In this study point defects cause various OH contents in quartz, depending on different pressures, temperatures and chemical environments. Synthesized crystals showed a negative correlation of calculated water content vs. pressure. Under lower pressures quartz incorporates more hydrogen (5 kbar: 450-750 ppm H_2O) than at higher pressures (25 kbar: 72-106 ppm H_2O). Therefore, our results imply that IR spectra of quartzes have a potential to be used as a geobaromether to indicate petrological formation conditions. Moreover, the B- and Li-specific OH absorption bands may be used to quantify the charge balancing B^{3+}- and Li^+- content that could be used as a novel and indirect analytical tool to detect traces of B and Li in quartz crystals.

Ion microprobe U-Pb dating of individual phosphate grains in Martian meteorite

M. KOIKE[1]*, Y. OTA[1] , N. TAKAHATA[1] , Y. SANO[1] AND N. SUGIURA[2]

[1]AORI, Univ. of Tokyo, Chiba, Japan, mizuho_k@aori.u-tokyo.ac.jp (*presenting auther)

[2]School of Science, Univ. of Tokyo, Tokyo, Japan

A Martian meteorite ALH 84001 shows extremely old age of over 4 Ga and is expected as a key to the ancient history of Mars. Its crystallization age is still controversial due to the complicated impact history. While volumetrically minor, phosphates are important carriers of trace elements. Previous SIMS U-Pb dating of several merrillite and apatite grains in ALH 84001 showed ~4 Ga [1]. However, intra-grain systematics was not observed because of limited spatial resolution. In-situ analysis of a single grain will provide further information regarding cooling and reheating process. Here we measured single grain U-Pb ages using a laterally high-resolution secondary ion mass spectrometer (NanoSIMS) at Atmosphere and Ocean Research Institute, University of Tokyo.

Two polished thick sections of ALH 84001 were firstly observed by SEM-EDS. Two merrilite grains with ~100 μm in diameter were found. The sections were polished again, gold-coated and baked overnight, and then analyzed by a NanoSIMS. A 2-10 nA O- primary beam was used with spot size of ~10-20 μm. An apatite from Prairie Lake circular complex, PRAP, with a known age of 1155 ± 20 Ma [2] was used as a standard of UO/UO_2-Pb/UO calibration.

For both analyzed grains, the obtained ^{238}U-^{206}Pb and ^{206}Pb-^{207}Pb ages show good agreement with ~4 Ga, suggesting the intra-grain U-Pb system is concordant. There is also chemical zoning of U abundance. Since diffusion rate of U in apatite is slower than Pb by ~4 orders of magnitude [3], the observed zoning was possibly made during crystal growth and preserved since then. Meanwhile, Pb may have been homogenized within a grain at crystallization (and/or later impacts), which makes single grain U-Pb dating possible. The interpretation of the ages (igneous or impact-reset) is related to the processes of crystallization and impacts. Further studies including micro scale analyses of other elements are required. This is the first report of single grain U-Pb dating of phosphates using a NanoSIMS.

The effect of carbon dioxide on metal transport by geological fluids

MARIA A. KOKH[1]*, GLEB S. POKROVSKI[1], DAMIEN GUILLAUME[1] AND STEFANO SALVI[1]

[1]GET, CNRS, University of Toulouse, France (*maria.kokh@get.obs-mip.fr)

Carbon dioxide is the second major component (after water) of most crustal fluids responsible for metal ore deposit formation. Its contents amount up to 10-20 wt% in porphyry Cu-Au-Mo fluids [1] and more than 50 wt% in metamorphic, skarn, orogenic gold, and PGE deposits [2]. In contrast to H_2O-dominated fluids, models of metal transport and deposition by high-temperature and pressure (T-P) CO_2-rich fluids are subjects to debate.

In this contribution, we combined thermodynamic modeling, based on few data available from the literature, with new solubility experiments in H_2O-CO_2-salt-sulfur systems to assess, in a systematic way, the role of CO_2 on the behavior of metals at hydrothermal conditions. Our analysis shows that the presence of CO_2 may have the following impacts on metals transport: a) the presence of CO_2 expands the field of vapor-liquid immiscibility, which causes both changes in metal solubility in the liquid phase (mostly owing to changes in pH), and a redistribution of metals between vapor and liquid; b) CO_2 decreases both water activity and the dialectric constant of the solvent, which in turn affects ion pairing and the activity coefficients of charged species; c) the formation of complexes with C-bearing ligands (CO_3^{2-}, HCO_3^-, CO, COS) may be important for some metals (e.g., Rare Earth Elements, U, Sn, Fe, Ni); and d) at high concentrations (>~50 wt%), CO_2 may also specifically solvate some non-polar complexes (e.g., AuHS(H_2S) [3]) and thus enhance their solubility.

To evaluate the contribution of these factors, we are currently investigating experimentally the solubility of major ore minerals (FeS_2, $CuFeS_2$, MoS_2, SnO_2, PtS, and Au) in H_2O-KCl-CO_2-H_2S supercritical fluids in the presence of acidity and redox mineral buffers, and as function of CO_2 content. Data obtained in H_2O-dominated experiments allow a revision of the available speciation models for metals in high T-P aqueous fluids. These results will provide the necessary basis for interpreting experimental runs in CO_2-rich fluids, which are in progress.

Using model mineral-organic matter-water interfaces as a step towards determining the fate of pollutants in the environment

P.E. KOLIC[1], B. SUBRAMANIAN[1], D.A. SPIVAK[1] AND R.L. COOK[1]*

[1]Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803, USA (*correspondence: rlcook@lsu.edu)

Mineral-organic matter-water interfaces play a valuable role in our ecosystem and are a major role player in determining the bioavailability as well as the fate and transport of anthropogenic contaminants (ACs) in the environment. Anthropogenic contaminants include a vast amount of compounds that are harmful to the environment and its inhabitants. The mineral-organic matter component of the mineral-organic matter-water interface has been found to play a major role in the sorption of ACs in soils and sediments, thus decreasing their presence in other environmental compartments, such as groundwater. This mineral-organic matter component is highly complex, especially in terms of the organic matter constituent, leading to a lack of detailed chemical insight into AC sorption. In order to address this void and gain valuable information that a real soil and sediment samples cannot provide, a simpler more homogeneous mineral-organic matter model system is needed to serve as a model system. To better understand the chemical mechanism of pollutant sorption to the mineral-organic matter component, this project uses a combination of highly adjustable model synthetic mineral-organic matter sorbent systems. The model system consists of silica, a model mineral surface, functionalized with alkyl, aromatic, and O-alkyl groups to echo the natural structure of organic matter. Solid state Nuclear Magnetic Resonance (NMR) as well as a range of other techniques are used for characterization of the model synthetic mineral. Sorption and desorption batch experiment studies are performed using commonly used pesticides as model organic pollutants as an initial step towards understanding the geochemical mechanisms that occur at mineral-water interfaces.

Geochemistry of uranium in lakes of West Mongolia

KOLPAKOVA M. N.[12]*

[1]Tomsk Department of the Trofimuk Institute of Petroleum-Gas Geology and Geophysics, Siberian Branch of the Russian Academy of Sciences, Academichesky ave. 4, Tomsk, 634055, Russia, marina.kolpakova@gmail.com

[2]National Research Tomsk Polytechnic University, Lenin ave. 30, Tomsk 634050, Russia

Natural lakes with high concentrations of uranium are widespread, for example, Van in Turkey (110 μgL^{-1}) [1],), Mono in the USA, California (300 μgL^{-1}), Shar Burdiin in Eastern Mongolia (15000 μgL^{-1}) [2]. In Western Mongolia, we have also discovered lakes with concentrations of uranium as high as 3000 μgL^{-1}. In the arid climate of western Mongolia, where evaporation is by 2-3 times higher than the amount of precipitation, evaporation concentration processes contribute to the growth of salinity and content of the U. However, our investigation indicated a significant role in uranium accumulation in the waters of the upper hydrodynamic zone is provided by aquiferous rock catchment lakes. Geologically, granite massifs are widespread on the studied territory, which are known to be possessed of natural radioactivity. But the type of rock is not the main factor. The time of water–rocks interaction which determines the degree of accumulation of U in the lakes is more important. Precisely, the equilibrium-nonequilibrium state of the system water-rock determines the possibility of U concentration in the water during the whole time of its interaction with rocks: the longer interaction time, the more uranium will be concentrated in the water, of course, the other things being equal. Analysis of the lake waters equilibrium with uranium minerals shows that only a few can precipitate out of solution and only three lakes with total salinity more than 300 gL^{-1} equilibrium with the investigated minerals. Water store U by getting into the rocks of any composition and dissolving them. Uranium, in turn, forms complexes with carbonate-ions and migrate to the lakes, and precipitates in lake sediments by influence of evaporation and water-rock interaction time. In this case, the more uranium will be accumulated in the water for the entire migration path to the lake, the greater amount will be precipitated. Consequently, the lakes are a unique geochemical barrier for the migration of uranium which forms oxides, hydroxides, carbonates, phosphates, fluorides and other minerals in lakes sediment.

Evaluating the efficiency of a synthetic amorphous manganese oxide for chemical stabilization of Cu in a contaminated soil

M. KOMÁREK*, L. TRAKAL, Z. MICHÁLKOVÁ AND L. DELLA PUPPA

Czech University of Life Sciences Prague, Department of Environmental Geosciences, Kamýcká 129, 165 21, Prague 6, Czech Republic
(*correspondence: komarek@fzp.czu.cz)

Chemical stabilization techniques aim at rendering less available the metal(loid) fractions that can pose significant environmental and toxicological risks and protecting the functionality of the soil environment [1]. Recently, a synthetic amorphous manganese oxide (AMO) has been proposed as an efficient metal sorbent and stabilizing agent for contaminated soils [2]. This work aims to evaluate AMO (up to 2 wt.%) stabilization efficiency in a soil contaminated predominantly with Cu (400 mg/kg; pH 3.6) using (i) batch experiments with soil solution samplers (rhizons), (ii) small-scale columns and (iii) a novel set-up of a large-scale column experiment together with direct sampling of the soil solution and chemical extraction methods (0.01 M $CaCl_2$, 0.05 M EDTA, BCR sequential extraction procedure).

The results suggest that the application of the AMO increased the soil pH and its high reactivity resulted in increased DOC concentrations originating from dissolved soil organic matter (SOM). The AMO was efficient in stabilizing Cu proved by significant decreases in Cu in soil solution, in the exchangeable fraction and $CaCl_2$/EDTA extracts. When further metals (Cd, Cu, Pb, Zn) were added to the soil columns, the AMO was able to stabilize them in the subsurface layers. However, due to SOM dissolution, metals (especially Cu) bound to the organic soil phase can be released to the soil solution. This preliminary study assess the efficiency of the AMO for metal stabilization in a Cu-contaminated soil and proposes a combination of experimental set-ups evaluating the efficiency of stabilizing amendments in general.

Simultaneous determination of carbon and hydrogen isotope enrichment factors of methane during microbial oxidation in a natural water environment

D. D. KOMATSU[1], U. TSUNOGAI[1], S. SATO[2], F. NAKAGAWA[2] AND A. TANAKA[3]

[1]Graduate school of Environmental Studies, Nagoya University, Nagoya, 464-8601, Japan (*correspondence: ddkomatsu@nagoya-u.jp)
[2]Graduate school of Science, Hokkaido University, Sapporo 060-0810, Japan
[3]NIES, Tsukuba, 305-8506 Japan

The stable carbon and hydrogen isotope compositions ($\delta^{13}C$ and $\delta^{2}H$) of methane (CH_4) were analyzed using a newly developed CF–IRMS method in a hydrothermal plume in the water column of Lake Towada, Japan. The CH_4 concentration, $\delta^{13}C$-CH_4, and $\delta^{2}H$-CH_4 in the lake water column varied widely, ranging from 0.6 to 246.5 nM, –54.9 to +54.2‰ (vs VPDB), and –258 to +762‰ (vs VSMOW), respectively, reflecting rapid CH_4 oxidation in the water column. Rapid CH_4 oxidation was further confirmed through bottle incubation experiments of the lake water sampled below 150 m, which found an extreme increase in the values of both $\delta^{13}C$-CH_4 and $\delta^{2}H$-CH_4 corresponding to a decreasing CH_4 concentration, after the incubations of more than 48 hours. The isotope enrichment factors for carbon and hydrogen were determined through incubation experiments to be –26.2 ± 0.9‰ and –233 ± 12‰, respectively, and the rapid rate constants ranged from 0.05 to 0.67 day^{-1}. These enrichment factors were the highest values ever reported in natural environments. In addition, we found that a greater isotope fractionation occurred at larger rate constants, i.e., higher populations of CH_4 oxidizing microbes. However, we also found that the ratios between the isotope enrichment factors of hydrogen and carbon (Λ values) were always constant around 11.3 ± 0.9, which coincides well with previous laboratory and field observations under elevated CH_4 concentration. The coincidence in the Λ value of approximately 10 between this study and previous studies indicates that the Λ value can be a robust tracer for distinguishing microbial CH_4 oxidation from the other processes such as mixing, even in environmental samples of nanomolar per liter quantities of CH_4.

LIME Olivine and Pyroxene: Multi-Stage Thermal Histories of AOAs

M. KOMATSU[1]*, T. FAGAN[2] AND T. MIKOUCHI[3]

[1]Waseda Institute for Advanced Study, Waseda University. Tokyo 169-8050, Japan (*komatsu@aoni.waseda.jp)
[2]Dep. of Earth Sciences, Waseda University.
[3]Dep. of Earth and Planetary Science, University of Tokyo.

Low-iron, Mn-enriched (LIME) silicates are interpreted as indicators of nebular condensation conditions [1-4]. They have been identified in IDPs [1], in rare chondrules and matrices of primitive chondrites [2, 3], and in Wild 2 cometary grains [4]. LIME olivine has also been observed in amoeboid olivine aggregates (AOAs) in primitive chondrites [6, 7]. In this study, we compare the roles of nebular and asteroidal thermal processing on formation and alteration of LIME silicates in AOAs.

Most AOAs in Y-81020 (CO3.0) are compact, with closely intergrown minerals. The compact AOAs have concentric textures of anorthite ±spinel cores, Al-diopside-rich mantles and closely-packed forsterite rims. Some AOAs appear to be more loosely-bound (fluffy). The fluffy AOAs have more irregular shapes, contain less Al-diopside and lack the well-defined concentric textures of the compact AOAs.

LIME olivines are commonly observed in AOAs in Y-81020. They typically occur (i) in the rims of compact AOAs, and (ii) as uniformly distributed grains in fluffy AOAs (see [7]). Most olivines in both types of AOAs are nearly pure forsterite ($Fo_{99\text{-}100}$). LIME low-Ca pyroxenes are also observed in rims of some AOAs. Their MnO concentrations are similar to those of coexisting LIME olivines.

LIME olivine and pyroxene both occur in the rims of compact AOAs in Y-81020, consistent with a model calculation that predicts Mn-enrichment with decreasing condensation temperature in the nebula [5]. AOAs in metamorphosed type 3 carbonaceous chondrites apparently lack LIME silicates [8]. We suggest that LIME silicates were originally present as primary phases in many AOAs, and then were lost during asteroidal thermal processing.

Ocean sections and stoichiometry of dissolved bioactive trace metals in the North Pacific Ocean

WATARU KONAGAYA[1], LINJIE ZHENG, TOMOHARU MINAMI AND YOSHIKI SOHRIN

Institute for chemical research, Kyoto University, Uji, Japan, (wkonagaya@inter3.kuicr.kyoto-u.ac.jp)

Bioactive trace metals have strong influence on production and community structure of phytoplankton. In turn, such biological processes affect the distribution of bioactive trace metals. So it is clear that bioactive trace metals have interactive influence with biological processes in the ocean.

The Subarctic North Pacific Ocean is an important area sensitive to the effects from the Asian continent, where the Subpolar Gyre, consisting of the Kamchatka Current and North Pacific Current, makes the southern boundary.

We report the distribution of dissolved bioactive trace metals from the subtropic to subarctic region in the North Pacific Ocean. In this study, we used of a new automated preconcentration system and determined the concentration of nine elements.

Sea water samples were collected using clean technique in accordance with the GEOTRACES protocol. The bioactive trace metals were preconcentrated by solid extraction using NOBIAS CHELATE-PA1 chelating resin (Sohrin *et al*., 2008) in an automated preconcentration system and determined by HR-ICP-MS.

The blank value of a procedure with the automated preconcentration system was low enough. In recovery tests, target metals were quantitatively recovered at 90-110% from seawater. The measured values of them in seawater reference material NASS-5 agreed with the certified values. We are going to report the results on ocean sections along 47°N and 165°E.

Heavy metal attenuation and mobility in the Wood Creek Sand Channel aquifer: Correlation of experimental and field study

MACOURA KONÉ[1,3]*, K. ULRICH MAYER[2] AND ANIA C. ULRICH[3]

[1]Suncor Energy Inc., mkone@suncor.com (*presenting author),

[2] University of British Columbia, Earth and Ocean Sciences, umayer@eos.ubc.ca

[3]University of Alberta, Department of Civil & Environmental Engineering, aulrich@ualberta.ca

The storage of process affected (PA) water in tailings ponds over glacial till formations in the oil sands region in Alberta (Canada) has the potential to cause contamination of groundwater and surface water with trace metals and dissolved major ions. To predict the fate of contaminants in the aquifers underlying and adjacent to tailings impoundments, a detailed understanding of the processes controlling metal release and attenuation is required. In this study, column experiments were performed under anaerobic conditions to simulate interactions between aquifer soils and PA water. Experimental results were compared with and correlated to field observations obtained from monitoring of groundwater wells located in an oil sands facility over a time period of 6 years.

Results from the column experiments indicated that Fe, Mn, Ba, and Si were released from the sediments while other trace metals present in PA water (Zn, Cr, Ni, U, Mo, As, B, etc.) were either weakly attenuated or completely retained by the soils. A DNA extraction performed on the columns sediments identified iron and sulphate reducers suggesting that microbial reductive dissolution of Mn(IV) and Fe(III) is likely the geochemical process by which the metals were released and mobilized into the effluent solution. The groundwater monitoring results are in agreement with those from the columns. However, observed metal concentrations are much higher in the field than in the columns. Variation in the released amounts may be attributed to different materials characteristics, but are most likely due to longer residence times, and longer flow paths. Results also demonstrate that microbial reduction of Mn(IV) and Fe(III) may have important environmental implications on water quality. Potential metals of concerns include Fe, Mn, Zn, Cr and B. Concentrations of these elements measured in both the column effluent and the groundwater were above environmental standards.

These results have important applications in the prediction, protection and potential evaluation of remedial technologies for the immobilization of metals.

Evidence for mantle heterogeneity from Selenium-Tellurium systematics in peridotites

STEPHAN KÖNIG*[1], AMBRE LUGUET[1], JEAN-PIERRE-LORAND[2], D. GRAHAM PEARSON[3] AND ALESSANDRO BRAGAGNI[1]

[1]Universität Bonn, Steinmann Institut für Mineralogie, Germany, stephan.koenig@uni-bonn.de (* presenting author),

[2] Laboratoire de Planétologie et Géodynamique de Nantes, University of Nantes, France,

[3] University of Alberta, Department of Earth and Atmospheric Sciences, Edmonton, Canada

Selenium and Tellurium belong to the group of highly siderophile elements (HSE), which may constitute key tracers for planetary processes such as formation of the Earth's core and the Late Veneer composition. Constraints on HSE systematics on the planetary scale require a solid understanding regarding the behaviour of these elements during petrogenetic processes and their abundances in the Earth's mantle. However, the upper mantle has been shown to bear significant long-term geochemical and lithological heterogeneities as a result of repeated melt depletion and re-enrichment processes. In addition to petrographic and mineralogical investigations and geochemical and isotopic studies on platinum group element systematics, these mantle heterogeneities can now be further constrained with new results obtained from Se and Te geochemistry.

Recent studies have shown systematic differences in Se/Te between fertile lherzolites and depleted harzburgites from both oceanic and continental settings. In contrast to fertile lherzolites which scatter around broadly chondritic values of ca. 9 [1,2], depleted peridotites are generally highly fractionated with up to suprachondritic Se/Te (up to 35). The increase of Se/Te correlates with decreasing Te concentrations [3]. Similar fractionations are also observed at the scale of single samples and likely result from the heterogeneous distribution of micrometer sized Te-bearing host phases in highly depleted harzburgites. The marked differences in Se-Te systematics observed between fertile lherzolites and depleted harzburgites as well as the μm-scale heterogeneity can be explained by the combined effect of i) different abundances and proportions of residual and metasomatic base metal sulfides and ii) discrete micrometric to nanometric platinum-group minerals. Together with platinum group elements, the Se-Te systematics in ophiolitic peridotites, mantle-derived peridotite xenoliths (both alkali-basalt and kimberlite-hosted) and orogenic massifs therefore provide further evidence for the mineralogical control on the heterogeneity of highly siderophile elements as well as osmium isotope signatures in the Earth's mantle.

Depressurization-induced gas production from methane hydrate sediment formed in a giant cell

YOSHIHIRO KONNO*, YUSUKE JIN, AND JIRO NAGAO

ProTech, MHRC, National Institute of Advanced Industrial Science and Technology (AIST), Sapporo 062-8517, Japan (*correspondence: yoshihiro-konno@aist.go.jp)

We have conducted a gas production test from methane-hydrate-bearing sediment artificially formed in a giant pressure-cell to evaluate feasibility of depressurization method. Unique apparatus named High-pressure Giant Unit for Methane-hydrate Analyses (HiGUMA), which is consist of a pressure-cell with an internal volume of 1710 liter, a vertical well system, and a separator for gas and water, was used for the test.

Methane hydrate with saturation of over 60% was formed in artificial sediment made of Toyoura standard sand within the pressure-cell. Production test was performed by decreasing the pressure of vertical well from 10 MPa to 5.0 MPa. Gas production rate showed the increasing tendency during pressure reduction of the well. The gas water ratio of production fluid increased to about 150 with time. Gas from methane hydrate was successfully produced by this method.

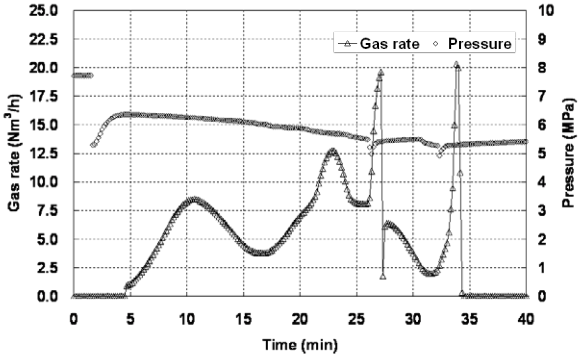

Figure 1: Time-dependent variations of gas production rate and well pressure.

Acknowledgment

This study was financially supported by the Research Consortium for Methane Hydrate Resources in Japan (MH21 Research Consortium) that carries out Japan's Methane Hydrate R&D Program conducted by the Ministry of Economy, Trade and Industry (METI).

Timing and sources of pre-collisional Neoproterozoic sedimentation along the SW margin of the Congo Craton (Kaoko Belt, NW Namibia)

J. KONOPÁSEK[12]*, J. KOŠLER[12], J. SLÁMA[13] AND V. JANOUŠEK[2]

[1]Department of Earth Science and Centre for Geobiology, University of Bergen, Allégaten 41, N-5007, Bergen, Norway (*correspondence: jiri.konopasek@geo.uib.no, jan.kosler@geo.uib.no, jiri.slama@geo.uib.no)
[2]Czech Geological Survey, Klárov 3, 118 21, Praha 1, Czech Republic (vojtech.janousek@geology.cz)
[3]Institute of Geology AS CR, v.v.i., Rozvojová 269, 165 00, Praha 6, Czech Republic

Isotopic dating of detrital zircons from metasediments and of magmatic zircons from intercalated metavolcanics in the medium- to high-grade part of the Kaoko Belt in Namibia provides first robust constraints on the age of Neoproterozoic sedimentation along the southwestern margin of the Congo Craton. Zircons from metasediments directly overlying the cratonic basement suggest maximum sedimentary protolith ages of c. 1.00 and c. 1.45 Ga, and age populations comparable with protolith ages from the gneisses of the Congo/Kalahari cratons. Dating of zircons from associated metavolcanics constrains the age of the earliest preserved sediments at c. 740–730 Ma and at c. 710 Ma.

Detrital zircons from the samples collected from upper parts of the succession contain only small proportion of grains with ages similar to those from the Congo Craton. Samples show dominance of c. 1.00 Ga, c. 750 Ma and c. 650 Ma old zircon grains that can only be derived from the Punta del Este – Coastal Terrane (Dom Feliciano and Kaoko belts) that acted as an (back)arc domain at c. 650–630 Ma. Neodymium model ages for the studied metasediments provide another argument that the youngest sediments could not have been derived from the Congo Craton.

Recognition of the Punta del Este – Coastal Terrane crust as a source region for the youngest pre-collisional sediments of Kaoko Belt suggests that the c. 650–630 Ma (back)arc Punta del Este – Coastal Terrane has developed directly on top of, or very close to, the attenuated Congo Craton passive margin.

Geochemical zoning of the spodumene vein series of the mineral deposit Tastig Tuva, Central Asia

S. I. KONOVALENKO

Tomsk State University, Tomsk, Russia (*konov@ggf.tsu.ru)

Spatial zoning is an essential characteristic of all ore-magmatic systems. It is quite definite, if there is a logical (naturally determined) change in falling, rising, spreading trends, or in a trend from an axial deposit zone to borders of productive mineral parageneses. However, zoning is not so obvious, if scalar parameters composing a single paragenetic complex are being changed consistently along these trends. In such a case, forecast valuation of an object is often challenged. The latter refers entirely to vein series of rare metal spodumene-albite pegmatites, which are still the main industrial type of endogenous lithium deposits.

The author of the work has studied steep-grade vein series (with a pitch angle/angle of fall of 70-80°) of spodumene pegmatites from the deposit Tastig in the republic Tuva in order to define elements of such a spatial zoning. It is outcropts within the absolute altitude range (2600-2200 m), but oriented in a way, where the veins of the lying side of the series are at the maximum heights (2600-2500 m), whereas the veins of the hanging side are revealing within the height interval from 2200 to 2350 m. It was ascertained by sampling of rock-forming pegmatite feldspars, that the indicator of Rb/Ba ratio, which shows degree of a system differentiation, changes logically in accordance with the following pattern. It increases sharply from the lying side of the vein series (where it is equal 15) to its axial zone (61-73), and then decreases slightly (34) in a vein microcline of the hanging side.

The discovered pattern shows that there is rather a hidden transversal zoning within the mineral deposit, which is much more contrast in the modern erosive cut, than a poorly revealed vertical zoning. Insignificance of the last one in the type chemical features of the rock-forming potassium feldspar is probably connected with poor studying of the deep parts of the object, and that a real vertical spread of mineralization exceeds noticeably the natural cut observed (400 m).

This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.0686, 14.B37.21.1257).

The composition of the spodumene of Asian pegmatite fields

S.I. KONOVALENKO

Tomsk State University, Tomsk, Russia (konov@ggf.tsu.ru)

The composition of the rock forming spodumene from rare metal pegmatite of the Enisei ridge, the Sangilen Plateau, the Southern Tian-Shan, the Pamir, and the Gindukush was studied using a X-ray microprobe analysis. The age of them ranges from Pre-Cambrian to Palaeogene inclusively. The spodumene demonstrates two types of bodies: classic albite-spodumene veins with profile lithium specific, and spodumene-microcline-albite complex ones (Li, Rb, Cs, Ta, Nb, Be) from zoning pegmatite fields. It is found that the main components defining a mineral composition, except of kind-forming (Li, Al, and Si), are Fe, Mn, Na, K, Ti, and partly Ca and Mg. In addition, the spodumenes of linear separate lithium vein series of albite-spodumene type are always significantly more enriched in Fe, Mn, Ti, Ca, Mg despite their age, whereas the complex-type spodumenes of spodumene-microcline-albite veins from zoning fields are constantly enriched in Na and K. The same tendency was found while sampling the spodumenes with different generations of all vein types. An early spodumene is always more contaminant than a later one, especially with Fe, Mn, and Ti. Generally, late spodumenes are less contaminant, but have more Na and K. The discovered tendency correlates with changing the color of a mineral from greenish-grey to white and pinkish-white, and with growth of excretion size (from sm to dm). Ca and Mg as contaminants are not very typical for a spodumene and always seen in minerals of lithium pegmatites from the Sangilen (Central Asia). That is probably related to localization of province veins in the carbonate suite, which is responsible for modification of initial melts that enriches these veins in Ca and Mg. Sampling demonstrates direct correlation between Al and Si. At the same time, significant Al-abundance is often seen while calculating the crystal chemical formulas. This all indicates that the isomorphic replacement of silicon by the element takes place in tetrahedrons of mineral structure.

This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.0686, 14.B37.21.1257).

Combined accessory mineral micro-analysis: The strength of a multi-phase approach

ELLEN KOOIJMAN[12], BRADLEY HACKER[2], ANDREW KYLANDER-CLARK[2], LOTHAR RATSCHBACHER[3] AND VLAD MINAEV[4]

[1]Swedish Museum of Natural History, Stockholm, Sweden, Ellen.Kooijman@nrm.se.
[2]Department of Earth Sciences, UC Santa Barbara, USA.
[3]Institut für Geologie, TU Freiberg. Germany.
[4]Tajik Academy of Sciences, Dushanbe, Tajikistan.

Accessory mineral micro-analysis provides a diverse and versatile toolbox for deciphering the timing and conditions of petrological processes. We explore the use of multi-mineral U-(Th-)Pb geochronology and trace-element analysis using LA-'split-stream'-ICP-MS in a study of rare near-UHP crustal xenoliths in the Pamir (peak conditions 2.5-2.8 GPa, 1000-1100 °C, eruption ~11 Ma [1]). These direct samples of the deep crust recovered from under an active collisional orogen provide a unique opportunity to assess how orogenic roots form and evolve.

We analyzed zircon, monazite, and rutile from a variety of rocks (eclogites to grt-ky-qtz granulites) in thin section using an excimer laser couped to a Nu Plasma HR and a Nu AttoM. This set-up provides REE-HFSE concentrations and U-Th-Pb isotope ratios—hence, petrogenetic, thermometric and age data—for small amounts of ablated analyte. Our analysis yielded 1) U-Pb ages, Ti concentrations and REE in zircon, 2) U-Pb and Th-Pb ages and REE in monazite, and 3) U-Pb ages and HFSE concentrations (incl. Zr) in rutile.

Zircon and monazite defined 6 age populations between 55-11 Ma, each typically having uncertainties of 1 Ma or better. The Ti-in-zircon and zircon U-Pb ages imply a three-stage P-T-t history, involving Barrovian metamorphism (55-20 Ma), deep burial leading to near-UHP conditions at ~12 Ma, and rapid magmatic heating shortly before the 11-Ma eruption. Monazite data complement this history. Rutile yielded ~11-Ma U-Pb dates exclusively, demonstrating the reliability of this thermochronometer.

The data show that different accessory mineral techniques are largely complementary and that their combined use is very powerful in refining and redefining geodynamic models. In addition, we demonstrate that, through ongoing development in LASS-ICP-MS technology, we are able to identify and resolve a wide range of petrological processes on a Myr time scale for Cenozoic rocks.

Using DMT and AF4-HR-ICP-MS to characterize trace metal speciation in soil water extracts

GERWIN F. KOOPMANS, INGE C. REGELINK AND ROB N.J. COMANS

[1]Dep. of Soil Quality, Wageningen University, Wageningen, The Netherlands (*correspondence: Gerwin.Koopmans@wur.nl)

Diffuse contamination of soils with trace metals like Cu and Zn is an ubiquitous problem all over the world. Trace metals in 0.45 μm-filtered soil solution samples can be present in the free form or they can be associated with inorganic ligands, DOM, and inorganic colloids. Inorganic colloids like clay and Fe-(hydr)oxide nanoparticles can pass the 0.45 μm-filter, but their concentration, composition, and effect on trace metal speciation is largely unknown. For ecological risk assessment of contaminated soils, total trace metal concentrations in soil solution are often measured. However, uptake of trace metals by plants and soil organisms is not necessarily related to their total dissolved concentrations, but generally correlates best with their free concentrations. Hence, the speciation of trace metals in soil solution needs to be known to understand their bioavailability in soils. During the presentation, we will focus on the Donnan Membrane Technique (DMT) and Asymmetric Flow Field-Flow Fractionation (AF4), which can be used to measure the trace metal speciation in soil solution. The DMT allows for the measurement of free trace metal concentrations in solution [1]. Using a chemical equilibrium model in combination with the NICA-Donnan model, the complexation of trace metals with inorganic ligands and DOM can be predicted [2]. However, the role of inorganic colloids in soil solution in the binding of trace metals remains poorly understood when using this approach. An emerging analytical technique with a high potential to analyse the colloidal trace metal fraction in 0.45 soil μm-filtered solution samples is AF4. AF4 is a chromatographic-like technique for size fractionation of colloids, and allows for online multi-element detection in combination with HR-ICP-MS. We will briefly describe the analytical developments in the DMT and present examples of the application of both DMT and AF4-HR-ICP-MS to measure specific trace metal forms in soil solution extracts to demonstrate (i) the complementary character of both analytical techniques and (ii) their potential to obtain a full speciation of total dissolved trace metals.

Use of 10^{12} and 10^{13} Ohm resistors in TIMS analysis of Sr and Nd isotopes in sub-nanogram geological and environmental samples

J.M. KOORNNEEF[1], C. BOUMAN[2], J.B. SCHWIETERS[2] AND G.R. DAVIES[1]

[1]Faculty of Earth and Life Sciences, Vrije Universiteit Amsterdam, the Netherlands, j.m.koornneef@vu.nl
[2]Thermo Fisher Scientific, Bremen, Germany

Analysis of isotope ratios in small geological and environmental samples such as inclusions in diamonds or individual human hairs is ultimately limited by the detection system of the mass spectrometer. We report a technique using a TRITON Thermal Ionisation Mass-Spectrometer (TIMS) to measure sample sizes up to 10 times smaller than currently feasible. Use of current amplifiers with 10^{12} Ohm and 10^{13} Ohm resistors instead of the standard 10^{11} Ohm resistors promises a 2-3 fold and 4-5 fold improvement in signal to noise ratios, respectively. This improvement results in higher precision on analyses of small ion beams.

Internal precision and external reproducibility are both better for Sr and Nd isotope ratios collected on small samples using 10^{12} Ohm and 10^{13} compared to the standard 10^{11} Ohm resistors. At a ^{87}Sr intensity of 3 mV the internal precision (2SE) of ^{87}Sr/^{86}Sr is twice better for 10^{12} Ohm and 5 times better for 10^{13} Ohm resistors compared to 10^{11} Ohm resistors. The external reproducibilities (2SD) at this beam intensity are 4 and 9 times better, respectively.

We additionaly tested the precision of ^{143}Nd/^{144}Nd measured by 10^{13} Ohm resistors in the beam intensity range usually covered by ion counting (< 3 mV or 2×10^5 cps). For a ^{143}Nd intensity of 6.25×10^4 cps (1 mV) the precision is 480 ppm (2SE) and at 2×10^3 cps (32 µV) it is 1%. At intensities higher than 2×10^4 cps the precision using the 10^{13} Ohm resistors is better than 0.2%, which is the lower limit for ion counting owing to the instability and non-linearity of ion counters. This observation indicates that the high gain amplifiers can be used instead of multi ion counting or Faraday cups equipped with the standard 10^{11} Ohm resistors in the range between 2×10^4 cps and 20 mV.

The reproducibility of ^{143}Nd/^{144}Nd and ^{87}Sr/^{86}Sr ratios for 100 pg standards using 10^{12} Ohm resistors is 176 ppm for Nd (2RSD, n=28) and 92 ppm for Sr (2RSD, n=20). Using 10^{13} Ohm resistors the reproducibility is twice better. Thus, variability in Nd and Sr isotope ratios in the 4th decimal place, e.g. ^{143}Nd/^{144}Nd 0.5110 – 0.5119 or ^{87}Sr/^{86}Sr 0.7100-0.7109, can be resolved in such small samples provided that the procedural blanks and chemical separation are optimal.

Using stable isotope tracers to elucidate the *in situ* metabolic activity of microbial populations in the cystic fibrosis lung

S. KOPF[1,4]*, R. HUNTER[2], A. LARIVIERE[2,3], Y. HU[2], M. DIETERLE[2], A. SESSIONS[1], V. ORPHAN[1] AND D. NEWMAN[1,2,4]

[3]Children's Hospital, Los Angeles, CA 90027, USA
[4]Howard Hughes Medical Institute, Pasadena, CA 91125, USA
(*correspondence: skopf@caltech.edu)

Background

Cystic fibrosis is a genetic disorder that causes the accumulation of mucus in a variety of organs. The genetic defect allows for the colonization and chronic infection of the pulmonary system by opportunistic pathogens and ranks as the most common lethal genetic disorder in Caucasian populations. The formation of complex microbial communities and their physiological heterogeneity within the cystic fibrosis lung are suspected to contribute to rapid disease progression and antibiotic resistance. However, because of the inherent challenges of working *in situ* with human patients, very few studies of the *in situ* metabolic programs of infectious agents exist and the development of effective antimicrobial therapies is often hindered by our limited knowledge of the physiological state of microbial populations within the human host. It is currently unknown how even basic metabolic indicators, such as microbial growth rates, may correlate with disease progression.

Discussion

Here, we present a novel approach based on techniques developed in the (bio)geochemical sciences to tackle this knowledge gap. Using ^{2}H and ^{15}N isotope tracers, combined with GC-IRMS and nanoSIMS analytical techniques, we characterize the growth rate, community structure and metabolic state of microbes within the lungs of cystic fibrosis patients. Contrary to the traditional model of a rapidly multiplying infectious population, our results from compound specific lipid analysis of biosynthetic ^{2}H incorporation suggest microbial activity consistent with slow growth (a physiological adaptation known to confer antibiotic resistance in the laboratory). At the same time, analyses of spatial variation in microbial activity using fluorescent *in situ* hybridization and nanoSIMS highlight metabolic heterogeneity within the microbial community. This approach provides a first glimpse at the *in situ* biosynthetic activity of pathogens involved in chronic infection of the cystic fibrosis airways and contributes to building a basis for physiologically informed laboratory experiments.

Highly dynamic cellular-level response of symbiotic coral to sudden increase in environmental nitrogen

Metabolic interactions with endosymbiotic photosynthetic dinoflagellates *Symbiodinium* sp. are fundamental to reef-building corals (Scleractinia) thriving in nutrient-poor tropical seas. Yet detailed understanding at the single cell-level of nutrient assimilation, translocation, and utilization within this fundamental symbiosis is lacking. Using pulse-chase ^{15}N-labeling and quantitative ion-microprobe isotopic imaging (NanoSIMS) we visualized these dynamic processes in tissues of the symbiotic coral *Pocillopora damicornis* at the sub-cellular level. Assimilation of ammonium, nitrate, and aspartic acid resulted in rapid incorporation of nitrogen into uric acid crystals (after ~45 minutes), forming temporary N-storage sites within the dinoflagellate endosymbionts. Subsequent intracellular remobilization of this metabolite was accompanied by translocation of nitrogenous compounds to the coral host, starting at ~6 hours. Within the coral tissue, nitrogen is utilized in specific cellular compartments in all four epithelia, including mucus chambers, Golgi bodies, and vesicles in calicoblastic cells. Our study shows how nitrogen-limited symbiotic corals take advantage of sudden changes in nitrogen availability and opens new perspectives for functional studies of nutrient storage and remobilization in microbial symbioses in the changing reef environment.

Primary alkali kimberlite melt: The myth dispelled

M.G. KOPYLOVA[1], S.I. KOSTROVITSKY[2] AND K.N. EGOROV[3]

[1]University of British Columbia, Vancouver, BC V6T 1Z4, Canada (*correspondence: mkopylov@eos.ubc.ca)
[2] Institute of Geochemistry SB RAS, 1a Favorskogo St., Irkutsk, Russian Federation, 664033
[3] Institute of the Earth's Crust SB RAS, 128 Lermontova St. Irkutsk, Russian Federation, 664033

After decades of studies, the composition of the primary kimberlite melt is still poorly constrained. One of the models for the kimberlite origin suggests the melt is low in H_2O and high in alkalies, as observed in the "uniquely fresh" Udachnaya East kimberlite. Papers that proposed the alkali-rich affinity for the melt focused on geochemical evidence and did not report petrography or geology of the rocks, which are critically important for the geochemical interpretation. We present geological, petrographic and geochemical evidence that the alkali-rich affinity of the Udachnaya kimberlite and other kimberlites in Southern Yakutia relates to crustal contamination. Alkali carbonates, sodalite, gypsum, anhydrite, halite and sylvite are present in the groundmass and matrix of the Udachnaya, Mir and International'naya pipes (southern Yakutia). The kimberlites were emplaced through 2 km-thick evaporite-bearing carbonate sediments saturated with brines. In the global context, southern Yakutian kimberlites are unprecedented in the amount of the crustal carbonate and evaporite material included in the pipes. The secondary, crustal origin of Na, K, Cl and S-rich minerals is supported by the following: 1. A regional correlation between the geology and hydrogeology of the local country rocks and the kimberlite mineralogy, in particular the difference between southern and northern Yakutian kimberlites; 2. A restriction of halite or gypsum mineralization in the Mir and International'naya pipes to depths where pipes intersect country rock strata with the similar mineralogy; 3. The localization of the highest abundances of Na-K-Cl-S-bearing minerals in the Udachnaya East kimberlite at a depth interval that correlates across three magmatic phases of kimberlites and coincides with the roof of the halite-bearing country rock and an aquifer carrying anomalously Na-rich brines; 4. The presence of evaporite xenoliths and veins of halite, gypsum and carbonate cutting through the kimberlite and xenoliths; 5. The geochemical and Sr, C, O, Cl and S isotopic evidence for crustal contamination. Addition of crustal salts to kimberlite melt began prior to the volcanic fragmentation as a result of preferential melting and assimilation of evaporite xenoliths and may have continued in-situ after the pipe emplacement via reactions with external saline fluids. The hybrid, alkali-, S- and Cl-rich compositions of residual melts and fluids were trapped in secondary inclusions in olivine. Alkali-rich compositions of fluids trapped in fibrous diamonds shortly febore the kimberlite emplacement cannot support the model of the alkali-rich primary kimberlite melt, as the latter is significantly more Ca-, Na-, B-, and S-rich than the K- and Ba-rich fluid inclusions.

Composition of hydrocarbon source rocks of the Hayrettin Formation (Denizli/Western Turkey): Provenance, source weathering and tectonic setting

DEMET BANU KORALAY[1]

[1]Pamukkale University Engineering Faculty, Department of Geological Engineering, 20070 Denizli/TURKEY dbkoralay@pau.edu.tr

The geochemical composition of the Oligocene hydrocarbon source rocks of the Hayrettin Formation of Denizli (Western Turkey) province were analyzed for major and selected trace elements to infer their provenance, intensity of palaeoweathering of the source rocks and tectonic setting. Total organic carbon (Corg, %) contents of organic matter rich rocks are between 0.21 % and 39.61 %. Plots of organic matter rich rocks on Al_2O_3 wt.% versus TiO_2 wt.% diagram and discriminant functions diagram indicate that the samples plot between the granodiorite and gabbro field, and quartzose sedimentary and mafic igneous rocks constitute the source rocks in the provenance. To constrain the climatic condition during sedimentation of organic matter rich rocks on SiO_2 wt.% versus (Al_2O_3+K_2O+Na_2O) wt.% diagram the samples plot in the field of semiarid climate. Plots of samples on bivariate discriminant function diagram reveal an active continental margin setting for the provenance. The chemical index of alteration (CIA) monitors the progressive alteration of plagioclase and potassium feldspars to clay minerals. CIA values for the Oligocene Hayrettin Formation organic matter rich samples vary from 26 to 81 with an average 70 indicating significant weathering at the source areas.

Origin of High-K Ignimbrite in the Miocene Volcanism Surrounding Uşak Region (Western Turkey): Rb-Sr, Sm-Nd Isotopic Evidence

T. KORALAY[1], Y. K. KADIOGLU[2-3], S.Y. JIANG[4], K. DENIZ[3] AND B. GÜLLÜ[5]

[1]Pamukkale Univ., Geol.Eng. Dept., 20017 Denizli TURKEY **tkoralay@pau.edu.tr; tkoralay@gmail.com**
[2]Ankara Univ. Earth Sci. Application&Res. Center-TURKEY
[3]Ankara Univ., Geol. Eng. Dept., 06100, Ankara-TURKEY
[4]Nanjing Univ., Dept. of Earth Sci., 210093, P.R.China
[5]Aksaray Univ. Dept. of Geological Eng., Aksaray

The Western Turkey is an active region formed in a complex crustal extensional regime, generating large volume of subduction and post-collisional-related magmas took place during the Middle Miocene-Quaternary time. The ignimbrite is mainly composed of plagioclase (oligoclase, andesine) + biotite + Fe-Ti oxides (magnetite, hematite) ± amphibole (brown hornblende) and has eutaxitic texture. Whole rock geochemical data reveal that ignimbrite, characterized by their trachy-andesite composition, high-K in character, show fractional crystallization primarily controlled by plagioclase, biotite, Fe-Ti oxide. The ignimbrite samples have Th/Nb (1.00-1.20), Nb/Ta (3.57-14.67), Ba/Nb (37.32-64.43), Hf/Th (0.18-0.44), K/P (16.99-34.76), Ce/P (0.06-0.10) and Th/U (1.60-4.03) incompatible element ratios and show Volcanic Arc Basalts (VAB) in character. According to spider diagrams; ignimbrite exhibits a clear enrichment in LILE and HFSE. Although it is close to Continental Crust value, there are generally slight decreases in the content of Sr, Ba, Nb, P and Ti ratios reflecting subduction related magma (Wilson, 1989). In REE diagram, it displays marked enrichment in light rare earth elements (LREE) ($(La/Sm)_N$ = 5.03-5.97) relative to heavy rare earth elements (HREE) ($(Sm/Yb)_N$ = 4.36-5.15). Furthermore, all samples have negative Eu anomalies ($(Eu/Eu^*)_N$ = 0.77-0.90), indicating the significant role of plagioclase in the fractional crystallization. The ignimbrite display limited range in $^{87}Sr/^{86}Sr$ (0.708048 to 0.708782) and $^{143}Nd/^{144}Nd$ (0.512420 to 0.512436) isotopic ratios and similar to Continental Margin Volcanics. Petrographic, geochemical and Sr-Nd isotope datas indicate that the ignimbrite evolved through fractional crystallization and crustal contamination of the parent magma were formed during the partial melting of the lower crust and mixing with the upper crust material.

Metal mobilization by iron- and sulfur-oxidizing bacteria in a multiple extreme mine tailings in the Atacama Desert, Chile [2]

H. KOREHI[1], M.BLÖTHE[1], M.A. SITNIKOVA[1], B. DOLD[2], AND A. SCHIPPERS[1]*

[1]Federal Institute for Geosciences and Natural Resources (BGR), Stilleweg 2, D-30655 Hannover, Germany (hananeh_k@hotmail.com; marco.bloethe@bgr.de; maria.alexandrovna.sitnikova@bgr.de; axel.schippers@bgr.de)
[2]FCFM- Universidad de Chile, Departamento de Geología, Departamento de Geología, Plaza Ercilla 803, Santiago de Chile, Chile (bernhard.dold@gmail.com)

The marine shore sulfidic mine tailings dump at the Chañaral Bay in the Atacama Desert, northern Chile, is characterized by extreme acidity, high salinity and high heavy metals concentrations. Due to pyrite oxidation, metals (especially copper) are mobilized under acidic conditions and transported towards the tailings surface and precipitate as secondary minerals [1]. Depth profiles of total cell counts in this almost organic-carbon free multiple extreme environment showed variable numbers with up to 10^8 cells g^{-1} dry weight for 50 samples at four sites. Real-time PCR quantification and bacterial 16S rRNA gene diversity analysis via clone libraries revealed a dominance of *Bacteria* over *Archaea* and the frequent occurrence of the acidophilic iron(II)- and sulfur-oxidizing and iron(III)-reducing genera *Acidithiobacillus*, *Alicyclobacillus* and *Sulfobacillus*. Acidophilic chemolithoautotrophic iron(II)-oxidizing bacteria were also frequently found via most-probable-number (MPN) cultivation. Halotolerant iron(II)-oxidizers in enrichment cultures were active at NaCl concentrations up to 1 M. Maximal microcalorimetrically determined pyrite oxidation rates coincided with maxima of the pyrite content, total cell counts and MPN of iron(II)-oxidizers. These findings indicate that microbial pyrite oxidation and metal mobilization preferentially occur in distinct tailings layers at high salinity. Microorganisms for biomining with seawater salt concentrations obviously exist in nature [2].

The biogeochemical system of chemical elements distribution in the hydrosphere

V.D. KORZH

Shirshov Institute of Oceanology, Nakhimovsky pr. 36, Moscow 117997, Russia (E-mail: okean41@mail.ru)

The chemical elements composition of the oceanic water is a result of substance migration and transformation on river-sea and ocean-atmosphere boundaries. Stability of these processes is the main condition of the hydrosphere ecosystems stability. Detailed studies revealed three types of chemical element distribution in the ocean: 1) Conservative: concentration normalized to salinity is constant in space and time; 2) Nutrient-type: element concentration in the surface waters decreases due to the bio-consumption; and 3) Litho-generative: complex character of distribution of elements, which enter the ocean with the river runoff and interred almost entirely in sediments. The correlation between the chemical elemental compositions of the lithosphere and ocean is relatively weak (r = 0.68) while for river and oceanic water it is high (r = 0.94).

In our presentation, we shall show intensities of global migration and average concentrations in the ocean in the coordinates lg C_{ocean} – lg τ_{ocean} , where C_{ocean} is an average element concentration and τ_{ocean} is its residence time in the ocean. In this plot elements form groups reflecting the similarity of their properties. The System indicates an existence of the relationship between three main geochemical parameters of the dissolved forms of chemical elements in the hydrosphere: 1) average concentration in the ocean, 2) average concentration in the river runoff and 3) the type of distribution in oceanic water. This allows using knowledge of two of these parameters to gain theoretical knowledge of the third. Finally, the mean concentrations of elements and patterns of their distribution in the ocean can be used to determine pre-techno-generative concentrations of elements in the river runoff [1, 2, 3].

Accumulation mechanisms and bonding of high-tech metals in marine ferromanganese crusts

A. KOSCHINSKY[1]*, J. HEIN[2], D. MOHWINKEL[1], A. FOSTER[3] AND J. BARGAR[4]

[1]Jacobs University Bremen, D-28759 Bremen, Germany (*correspondence: a.koschinsky@jacobs-university.de)
[2]U.S. Geological Survey, Santa Cruz, CA 95060
[3]U.S. Geological Survey, Menlo Park, CA 94025
[4]SLAC National Accelerator, Menlo Park, CA 94025

Marine ferromanganese crusts (Fe-Mn crusts) are abundant throughout the global ocean and provide a potential economic resource for a wide range of rare metals for high technology applications. Understanding the geochemical processes that govern the interactions of these rare metals with natural Fe-Mn oxides has far reaching implications that span the range from global-ocean geochemical balances to the development of new techniques for extractive metallurgy. In our project we used synchrotron-based XANES spectroscopy to assess oxidation states in natural samples and samples in which metals were sorbed onto synthetic and natural Fe and Mn oxides. EXAFS spectroscopy was used to resolve the local structure around the metals in these same samples. We focussed on the metals Te, Pt, Mo, Zr, and Pb.

Our results confirm that Te is largely Te(VI) in Fe-Mn crusts and predominantly bound to FeOOH by inner-sphere complexation. For most model compounds, most Te(IV) transformed into Te(VI) during sorption. These data confirm that oxidative surface adsorption is the process responsible for the extremely high enrichment of Te in crusts (up to about 200 ppm) as compared to seawater. Since Pt concentrations are too low in natural Fe-Mn crusts, we investigated Pt only on sorption samples. As for Te, the results suggest that during uptake of Pt(II) from seawater a surface oxidation to Pt(IV) on the crusts takes place, explaining the high enrichment of Pt in crusts (up to 1-3 ppm). Of the model compounds, especially Mn oxide was very effective in oxidizing Pt(II). Molybdenum (as Mo(VI)) shows a strong association with the Mn oxide phase of crusts, while in sorption and sequential leaching experiments it also strongly binds on FeOOH. Lead displays a complex distribution, especially in phosphatized crusts, where it seems to form unsoluble phosphate compounds. Zirconium was found to be bound as Zr(IV) to both FeOOH and MnO_2 phases, in contrast to the expected predominant binding to FeOOH. A more detailed evalution of the spectra is presently carried out to resolve open questions.

Petrology and geochemistry of mafic rocks in the Acasta Gneiss Complex

KEIKO KOSHIDA[1]*, AKIRA ISHIKAWA[1], HIKARU IWAMORI[2] AND TSUYOSHI KOMIYA[1]

[1]Earth Science and Astronomy, The University of Tokyo, Tokyo 153-8902, Japan, koshida@ea.c.u-tokyo.ac.jp
[2]Earth & Planetary Sciences, Tokyo Institute of Technology, Tokyo 152-8550, Japan

Eoarchean crustal records are rare, so that the details of early Earth are not revealed yet. Acasta Gneiss Complex (AGC), located in the western part of the Slave Province, Canada, is one of the Early Archean terranes, and contains the oldest rocks in the world [1]. It is dominated by ca. 3.6-4.0 Ga felsic and layered gneiss suites, but minor mafic to intermediate gneiss occur as rounded to elliptical enclaves and inclusions [2]. The Acasta mafic rocks are composed of variable amounts of hornblende ± plagioclase ± quartz ± chlorite ± epidote ± biotite ± apatite ± sphene ± garnet ± clinopyroxene ± opaque ± cummingtonite, and are classified into hornblendite, garnet-bearing and garnet-free amphibolites. The garnet-free amphibolites can be further subdivided into fine- and coarse-grained amphibolites. Petrological examination and mineral composition demonstrate that all rocks underwent up to upper amphibolite facies metamorphism.

The composition of our studied samples ranges from basalt to basaltic andesite (SiO_2 = 43-57 wt%, MgO=4.1-19.1 wt%). Some systematic differences can be seen among each group in terms of major elements and chondrite-normalized REE patterns. The hornblendites have high MgO contents and show strong negative Eu anomaly, reflecting the effect of anatexis. The garnet amphibolites have high FeO contents and slightly fractionated REE patterns (La_N/Sm_N=1.2-1.8, Gd_N/Yb_N=2.0-2.2). The coarse-grained amphibolites are enriched in Al_2O_3 and LREE contents (La_N/Sm_N=1.3-5.4) with moderately fractionated MREE to HREE patterns (Gd_N/Yb_N=1.2-2.0), whereas the fine-grained amphibolites display flat REE patterns (La_N/Sm_N=0.8-1.4, Gd_N/Yb_N=1.0-1.2). MORB-normalized trace element patterns show depletion in Nb and Zr relative to Th and LREE for all studied samples. Although variable incompatible trace element patterns were possibly due to alteration during regional metamophism, depletion in Nb and Zr contents suggest subduction zone magmatism for the mafic rock inclusions in the AGC.

[1]Bowring & Williams (1999) *Contrib. Mineral. Petrol.*, **134**, 3-16. [2]Iizuka *et al.* (2007) *Precamb. Res.* **153**, 179–208.

The heavy metals in Halocynthia aurantium tissues of the Japan Sea

KOSJANENKO A.A.* AND KOSJANENKO D.V.

V. I. Il'ichev Pacific Oceanological Institute, 43, Baltiyskaya Street, Vladivostok, 690041, Russia.
(E-mail: KosyanPOI@inbox.ru)*

The problem of concentration of elements of living organisms of the marine environment is of great importance. This problem was first posed VI Vernadsky [1]. Intermediate stage in the cycle of TM in the estuaries of the seas is a planktonic organisms that accumulate TM and send them to the bottom [2]. Ascidians (A), as bottom marine animals, are the final link in the cycle TM of the oceans and seas.

The aim was to determine the selectivity of HM accumulation various tissues ascidian H. aurantium. In addition, ascidians tissue use in medical applications: in recent years, mining H. aurantium is to produce raw materials for the production of biologically active food supplement "Haurantin" (POI FEB RAS) Overseas pharmacists from the body squirts identified cancer drugs ezteinastsidin-743 and ascidin [3]. Individuals of H. aurantium were collected in the Kievka Bay (Sea of Japan) in 2011. For the analysis of seized samples of the following tissues: stomach, digestive gland, gonads, muscle and tunic. Analyses of the composition of animal tissues were determined by atomic absorption spectroscopy.

Tissue	Fe	Zn	Cu	Mn	Ni	Cd	Pb	Co
t	140,6	13,9	2,7	30,8	1	0,1	1	0,3
m	48,6	65,3	1,4	4,9	0,1	0	22,2	0,1
dg	898,3	29,5	7,1	24	1,3	0,2	1,4	0,8
g	41,4	202	4,3	12	0,7	0	34,1	0,4
s	344	188,4	4,2	21,1	0,9	0	344	0

Table: The concentration of heavy metalls in *H. aurantium* tissues (t – tunic, m – muscle, dg – digestive glands, g – gonads, s – stomach, mcg/g.)

Thus, we can judge the selective accumulation of certain tissues purple ascidian TM in large enough quantities that can be explained by their peculiarities of life, the structure of tissues themselves and also, to a large extent, the state of their environment.

Fractionation of elements during laser ablation (LA) is a significant source of error in quantitative and isotope ratio analysis by ICP-MS. It has been demonstrated that phase separation and formation of particles of variable size and composition are the primary cause of laser-induced elemental fractionation [1], and that the element decoupling can be further enhanced by variable aerosol transport and processes in the ICP [2]. Interaction of laser radiation with zircon ($ZrSiO_4$) typically results in its thermal breakdown to ZrO_2 and SiO_2 and formation of aerosol particles with different composition, size and transport properties [3]. As a result of the preferential partitioning of U+Th and Pb into ZrO_2 and SiO_2 phases, respectively, the decomposition of zircon by transfer of laser heat can efficiently fractionate these geochronologically important trace elements, resulting in erroneous U-Th-Pb ages obtained by LA-ICP-MS dating.

Previous studies have related the laser-induced decoupling of U+Th from Pb in zircon to different element volatilisation temperatures [2], chemical composition of the zircon matrix [4] and radiation damage accumulated since the last closure for annealing in zircon [5]. Recently obtained laser ablation ICP-MS data for a suite of well characterized zircon samples with range of composition and accumulated radiation damage suggest that these factors alone cannot explain the observed variations in the rate of laser-induced elemental fractionation; they may, however, affect the kinetics of the phase separation during the thermal breakdown of zircon. Additional parameters that will be evaluated for effects on laser-induced fractionation include the composition of ambient gas during the ablation and transport properties of aerosol particles formed by laser ablation of zircon.

Metagenomic insights into the response of indigenous microbial communities in beach sands to the Deepwater Horizon oil spill

J.E. KOSTKA[1], L.M. RODRIGUEZ-R.[1], W.A. OVERHOLT[1], X. LIN[1], K. MARKS[1], K. KONSTANTINIDIS AND M. HUETTEL[2]

[1]Georgia Institute of Technology, Atlanta, GA, USA
[2]Florida State University, Tallahassee, FL, USA

Biodegradation mediated by indigenous microbial communities is the ultimate fate of the majority of hydrocarbons that enter the marine environment. A large amount of oil from the Deepwater Horizon oil spill was transported to and subsequently buried in Gulf of Mexico beaches. The objective of this research is to characterize the *in situ* response of microbial communities in parallel with the fate and chemical changes in oil hydrocarbons. Our time series database encompasses >500 sediment and water samples collected from Pensacola Beach, FL, USA, from 2010 to 2012. Illumina MiSeq and HiSeq platforms were used to obtain an average of 10000 SSU rRNA gene amplicon sequences and 35 million (100bp) paired-end reads on a subset of these samples. A bloom of bacteria was observed in parallel with oxygen consumption rates and the depletion of the majority of highly degradable oil hydrocarbons during the first 4 months after oil came ashore. SSU rRNA gene amplicon and metagenome analysis revealed an initial sharp drop in community diversity after oiling. Moreover, evidence of succession was detected across the time-series, featuring a marked increase in relative abundance of Alcanivorax spp. during the first two months (up to 40% of the community) followed by enrichment in other members of the Gammaproteobacteria (*Parvularcula, Hyphomonas, Xanthomonadales*) in subsequent months. By July 2011, community diversity had sharply rebounded, and sequences of taxa associated with oligotrophic conditions, such as the Thaumarchaeota (*Nitrosopumilus*) were detectable, whereas phylotypes associated with the oiling event were undetectable. Finally, we observed that genes for central-metabolism functions were enriched in clean samples, while genes related to peripheral metabolism (e.g. aromatics degradation, nitrogen fixation, phosphorus uptake) were enriched in oiled samples, reflecting the community response to a oil-derived carbon source and nutrient depletion. Overall, multiple lines of independent evidence from a time series describe the microbial response to hydrocarbon discharge as a succession dynamics model driven by nutrient availability and hydrocarbon chemistry.

Provenance and metamorphic conditions of very low-grade metasedimentary rocks of the Variscan accretionary prism of the Kaczawa Mts (SW Poland): Geochemical and mineralogical evidence

JOANNA KOSTYLEW[1], RYSZARD KRYZA[1] AND JAN ZALASIEWICZ[2]

[1]Institute of Geological Sciences, University of Wrocław, ul. Cybulskiego 30, 50-205 Wrocław, Poland, e-mail: joanna.kostylew@ing.uni.wroc.pl

[2] Department of Geology, University of Leicester, University Road, Leicester LE1 7RH, UK

The Kaczawa Complex in the West Sudetes (SW Poland) is interpreted as a fragment of a Variscan accretionary prism. Together with neighbouring basement units, it forms a structural mosaic of the Sudetes at the NE edge of the Bohemian Massif.

Some previous studies of the Kaczawa Complex aimed at determination of the provenance and metamorphic conditions of metasedimentary rocks of the complex. These questions have become particularly important since the 1970's when some of the rocks were classified as mélange, rather than fragments of coherent stratigraphic successions as previously thought. Their depositional age remains controversial, though scarce conodonts suggest a Devonian - Early Carboniferous age.

We present new results of mineralogical (microprobe, XRD) and bulk-rock chemical investigations of various metasedimentary rocks from different structural units of the Kaczawa Complex.

The provenance of metasedimetnary rocks of the Kaczawa Complex is assessed based on the Chemical Index of Alteration (CIA) and discrimination function analysis, using major-element and selected trace-element data (i.e. Eu/Eu*, Zr/Sc, Th/Sc Th/U and Gd_N/Yb_N). The results point to an old continental crust as the likely main source for the sediments, with minor recycled sedimentary and trench-derived components.

Based on the white mica and chlorite chemistry, as well as on illite 'crystallinity' index, we provide further evidence that the mélange and some other metamudstones in the Kaczawa Complex were metamorposed under very low-grade conditions (T < 250°C) which is in line with the accretionary prism model.

Is there an extreme pressure dependence of sulphur solubility in hydrous silicate melts?

A.V. KOSTYUK* AND N.S. GORBACHEV

Institute of Experimental Mineralogy RAS, Academica Osipyana 4, Chernogolovka, Russia (correspondence*: nastya@iem.ac.ru, gor@iem.ac.ru)

The question of the dependence of the solubility of sulphur in hydrous silicate melts on the pressure still remains one of the most discussed and relevant. There are a lot of experimental works studying the SCSS in silicate melts, but there is no clear answer on the effect of pressure on it. We have proposed an alternative hypothesis about existence of extreme pressure dependence of sulphur solubility with a maximum at 1.5-2.0 GPa [1]. Since, the available literature data are quite extensive at P from 0.5 to 3 GPa [2-4], we decided to study experimentally peridotite-basalt-sulphide-H_2O system at P=0.1-0.5 GPa and T=1200-1300°C.

Experiments were carried out in an internal-heated pressure vessels by a quenching technique. We used Pt-peridotite ampoules filled with powder of tholeiitic basalt and FeS as starting compositions in the ratio of 3:1. The total volatile (H_2O) in system were 5 wt.%. Fugacity of sulphur and oxygen buffered by Pt-PtS and WM buffers respectively. Duration of experiments was 24 hours. Products of experiments were studied by microprobe.

There was a positive dependence of the solubility of sulphur on the pressure after experiment. The concentration of sulphur in the water-containing silicate melt at T=1200°C was 0.2±0.12wt.% at P=0.1GPa; 0.35±0.03wt.% at P=0.3GPa; 0.42±0.19wt.% at P=0.5 GPa. The sulphur concentration at T=1300°C was 0.2± 0.12wt.% at P=0.1GPa; 0.27±0.06wt.% at P=0.3GPa; 0.46±0.12wt.% at P=0.5GPa. These data confirm our previous assumption about extreme pressure dependence of sulphur solubility in hydrous sulphide-bearing silicate melts. Confirmation of this theory can be very useful for a better understanding of transport of sulphide sulphur and ore elements from the deep magmatic centres to the upper levels of the Earth crust where most of known sulphide ore deposits were discovered.

[4]"Topaz" geological exploration company LTD, Oskemen, 070001, Republic of Kazakhstan

Kalba-Narym granitoid batholith located on the territory of East Kazakhstan. Batholith has a polychronic structure and is composed of rocks of five intrusive complexes, which differ in composition and formation time [1].

Results of U-Pb and Ar-Ar granitoids complexes isotopic dating are:1) kunush plagiogranite complex (U-Pb, Zrc - 306±9, 299±2 Ma); 2) kalguta association of Bt-Grt-granodiorites and Hbl-granite (Ar-Ar, Hbl (2 dates) - 286±3 Ma, Bt - 272±1 Ma); 3) Kalba granodiorite-granite complex (Ar-Ar, Bt - 5 dates from 291 to 273 Ma); 4) monastyr leucogranite complex (U-Pb, Zrc - 284±4 Ma, Ar-Ar, Bt - 6 dates from 285 to 269 Ma); 5) kainda granite complex (Ar-Ar, Bt - 5 dates from 290 to 267 Ma).

Obtained results allow us to determine the maximum duration of formation of Kalba-Narym batholith at ~ 30 million years. The formation of the main volume of granitoids occurred during a short interval - no more than 10 million years (290-280 Ma), which corresponds to most of the Ar-Ar dates. Younger Ar-Ar dates from 280 to 270 Ma can be interpreted as the result of later disbalance in K-Ar isotopic system because the north-eastern part of the batholith is adjacent to a major fault - Irtysh shear zone, within which the fixed stages of tectonic activity are 280-275 Ma and 270-265 Ma[2].

Geochemistry of sediments from the Khai River – Nha Trang Bay estuarine system, South China Sea

S.E KOUKINA*, N.V. LOBUS, V.I. PERESYPKIN, G.N. BATURIN AND N.A. SHULGA

PP Shirshov Institute of Oceanology of RAS, 117997 Nakhimovsky pr. 36, Moscow, Russia (*correspondence: skoukina@gmail.com)

The Khai River and the Nha Trang Bay form one of the major estuarine systems in the South China Sea that is inhabited by unique biota. This area now experiences a significant anthropogenic load from the local people activities and, especially, from the quickly growing tourist industry.

Trace (Cr, Ni, Cd, V, Zn, Cu, Pb, Sb, Bi, Sn, Ag, Li, Co, As, Zr, Mo, Hg), minor (Mn) and major (Al, Fe, Ti, Mg, Ca, Na, K) along with nutrients (TOC, TS, TP) and TIC were first determined in surface sediment samples from the Khai River and Nha Trang Bay along the salinity gradient.

According to the sediment quality guidelines and reference background values data on the shale, pelagic clays, average river bed sediments and rural and industrial Vietnamese soils most of the element contents that were studied were below the threshold levels, while the content of Cu, Pb, Ni and, especially Ag exceeded significantly the hazardous levels in the most of the samples from the Nha Trang Bay.

Aluminum normalization and Spearman correlation analysis revealed some specific features in distribution of elements along the salinity gradient. Thus, Ca, Ba and Sr are largely dependent on the carbonates content in sediments. Sedimentary P, Al, Fe, Mn, Ti, Na, K, Li, Co, Cs, Zn and V are most likely controlled by the accumulation of their fine grained aluminosilicate host minerals and therefore tend to increase seaward. The contents of S, As, Sn, Bi, U, Cd and Mo are slightly elevated in sediments of estuarine part of the river – sea transect. These elements may be scavenged by and/or co-precipitated with the dissolved and particulate materials of the river discharge and further deposited on the geochemical barrier within the river – sea water mixing zone.

The distribution of Ni, Cr, Zr, Cu, Pb, Sb, Hg and, especially, Ag was characterized by anomalous high concentrations in the urban area of river-sea transect. This might be due to the point anthropogenic pollution from local human activities, i.e., fishing, shipping, fueling, and waste and sewage sludge outflow. The anthropogenic and/or environmental sources of Ag in the region need special study.

Integrated geological and geophysical probing of lithospheric dynamics in a young extensional basin (Carpathian-Pannonian Region)

ISTVÁN KOVÁCS[1], GYÖRGY FALUS[1], CSABA SZABÓ[2], JÁNOS KISS[1], TAMÁS FANCSIK[1], ENDRE HEGEDŰS[1], ZSANETT PINTÉR[2], NÓRA LIPTAI[2] AND LEVENTE PATKÓ[2]

[1]Geological and Geophysical Institute of Hungary, H-1143, Srefánia út 14, Budapest, Hungary
[2]Lithosphere Fluid Research Lab, Institute of Geography and Earth Sciences, Eötvös University, Budapest, Hungary, H-1117, Pázmány Péter sétány 1/c

Detailed analysis of numerous of mantle xenoliths from the Carpathian-Pannonian region revealed that the present lithosphere may be divided into two major sub-horizontal domains.

The shallower “layer” is characterized mostly by fine grained, equigranular to porphyroclastic xenoliths, generally displays an ’axial [010]’ deformation pattern. Mineral constituents show high Mg#, low H_2O content in nominally anhydrous minerals (NAMs) and depleted in basaltic major elements implying that this layer may have undergone considerable depletion.

The xenoliths from the deeper “layer” show mainly coarse grained, protogranular texture with ’A-type’ deformation pattern. Minerals usually have lower Mg# and richer in basaltic major elements. The NAMs from this “layer” show higher H_2O content than those in the shallow layer. This layering may also be seen as seismic reflections in the present lithospheric mantle 10-15 km below the MOHO, accompanied by a considerable increase in seismic velocities. Anomalous seismic anisotropy pattern showing E-W direction in contrast to the general NNW-SSE trend may be due to the fossil directions frozen in the juvenile deeper lithosphere which may be the result of an asthenospheric flow related to the Alpine collision.

Influence of long-term diagenesis on the REE content in marine reptile remains from the Middle Triassic bonebed (S Poland)

MONIKA KOWAL-LINKA [1]*, KLAUS PETER JOCHUM[2] AND DAWID SURMIK[3]

[1]A. Mickiewicz University in Poznań, Institute of Geology, Poland, (*correspondence: mokowal@amu.edu.pl)
[2]Max-Planck-Institut für Chemie, Mainz, Germany, (k.jochum@mpic.de)
[3]University of Silesia, Faculty of Earth Science, Sosnowiec, Poland (dawid@surmik.pl)

The geochemical signals recorded in fossil bones are commonly used to reconstruct conditions of sedimentary and diagenetic environments, but recent data suggest insufficient recognition of particularly the long-term impact of diagenesis on vertebrate remians. We have examined with LA-ICPMS 29 bones of marine reptiles collected from the ~247-245 Ma old (Middle Triassic) bonebed, outcropped in Żyglin (S Poland). This bonebed (a crinoidal limestone) comprises reworked vertebrate remains deposited originally in various coastal and marine settings and at different times. The two main objectives of the present study are: (1) to check whether concentrations and ratios of REE and other trace elements are useful to distinguish between relatively younger and relatively older bones in the marine bonebed, and (2) whether the early diagenetic element contents and ratios characteristic for the various depositional settings can still be deciphered.

The REE concentrations in the profiles (average ∑REE in individual profile is ~2900-3500 ppm) tend to be more or less constant. All samples are enriched in REE with regard to the PAAS. The samples/PAAS diagrams reveal “bell shaped” patterns with two peaks for Sm and Gd, a small low for Eu, and with HREE values far below the LREE values. The bones form a small cluster in the $(La/Sm)_N$ vs. $(La/Yb)_N$ diagram, although some samples are located distinctly outside the cluster margin. In the Ce/Ce* vs. Pr/Pr* diagram the bones reveal a slightly negative Ce_N anomaly or lack of it, and smoothly positive and negative La_N anomaly. Most of the samples display similar REE concentrations and distribution patterns, probably due to long-term diagenesis which obliterated the early diagenetic geochemical signals. Only several samples show different features.

Fractionation of Si isotopes during core formation from first principles calculations

PIOTR M. KOWALSKI*[1] AND SANDRO JAHN[2]

[1]Forschungszentrum Jülich GmbH, Institute of Energy and Climate Research - IEK-6: Nuclear Waste Management, D-52425 Jülich, Germany (*correspondence: p.kowalski@fz-juelich.de);
[2]GFZ German Research Centre for Geosciences, Telegrafenberg, D-14473 Potsdam, Germany.

Recently, we have developed an efficient ab initio based computational approach to predict equilibrium isotope fractionation factors between chemically and structurally complex crystalline solids, fluids and melts at high T and P [1,2]. Our method has been successfully applied to "non-traditional" stable isotopes of light elements such as B and Li, which are important geochemical tracers widely used in petrology. We have shown that we are able to correctly reproduce the experimentally observed fractionation sequences: fluid-tourmaline-mica for B and staurolite-fluid-mica-spodumene for Li isotopes with a computational uncertainty comparable to the experimental error. Moreover, with the calculations we explained the discrepancy between the results of in-situ experiments and measurements on natural samples [2].

With this well tested methodology we investigate here the Si isotope fractionation between silicate melt and liquid metal under the extreme P-T conditions of Earth's core formation (P~25 GPa, T~3000 K) that are not yet accessible to experiment [3]. The equilibrium Si isotope fractionation factors between these materials are of great interest as they are needed to understand the origin of the difference in the isotopic signatures observed between the Bulk Silicate Earth (BSE) and Chondrite meteorites [3]. It has been proposed that the observed difference reflects the fractionation of Si isotopes between silicate melt and iron-rich metal during the formation of Earth's core [4]. We will present a comparison of our predictions with the available experimental data and discuss the effect of the pressure-induced changes in the melt structure on the fractionation of Si isotopes. Our results shed new light on the origin of the excess of the heavy Si isotopes in BSE and may also help to further constrain the silicon content of the Earth's core.

Characteristics of metal bearing phases in MSWI residues from Poland

P. KOWALSKI[1]*AND M. MICHALIK[1]

[1]Institute of Geological Sciences, Jagiellonian University ul.Oleandry 2a, 30-063 Krakow (*correspondence: p.kowalski@uj.edu.pl)

Mineralogical characteristic of MSWI (municipal solid waste incineration) residues is important, especially in time of ongoing changes in municipal waste management system in Poland. These changes leads to significant reduction of the amount of landfilled raw wastes. A way to achieve this goal is construction of nine incineration power plants with assumed slags production around two hundred thousand tons per year. The increasing slag production makes that it is essential to take a closer look into this material in terms of possible environmental pollution.

The aim of this study is mineralogical and chemical characteristics of the metal-bearing phases of the MSWI residues. Slags were collected from two the biggest incineration power plants in Poland. One of them is oriented to incineration of non-hazardous municipal waste and the other on industrial and hazardous municipal wastes.

Slags from incineration of wastes are non-consolidated, grainy materials, containing large amount of amorphous phase, mostly composed of Si-rich glass.

Metals in slags are present in several forms:

1. As large fragments which are mixed with slags grains and pa of uncombusted materials (rock fragments, glass and ceramics),
2. In form of metallic inclusions in glass or minerals,
3. As a component of mineral and amorphous phases.

Metals in form of metallic inclusions are monometallic (mainly Fe, Al, Pb, Zn, Cu) or in form of alloys (Fe-Ti, Fe-Ni, Fe-Cu, Cu-Sn+Pb and Cr-Fe). Metals in minerals are concentrated mostly in form of oxides (mainly Fe and Al oxides) and in silicates, aluminosilicates and sulfates (e.g. Cu). The content of metals in glass varies in wide range. High concentration of them is connected with presence of metallic inclusions inside the glass. Content of metals in slags varies within broad range – e.g. Cu from 330 to 4900 ppm, Zn from 1500 to 4700 ppm, Pb from 50 to 6300 ppm and Cr from 300 to 600 ppm in municipal slags and from 2000 to 2500 ppm in industrial slags. These concentrations could be potentially hazardous and further studies about leaching potential and mobility of these metals are needed.

Electrolyte ion binding at iron oxyhydroxide surfaces

PHILIPP A. KOZIN*, ANDREI SHCHUKAREV AND JEAN-FRANÇOIS BOILY

*correspondence philipp.kozin@chem.umu.se

Electrolyte ion loadings at the surfaces of synthetic goethite (α-FeOOH) and lepidocrocite (γ-FeOOH) nano-sized particles that were pre-equilibrated in aqueous solutions of 10 mM NaCl and $NaClO_4$ were investigated by means of cryogenic X-ray photoelectron spectroscopy (XPS) [1]. Atomic concentrations of Cl^- and ClO_4^- in acidic pH regions and of Na^+ cations [2] in alkaline pH regions were correlated to potential determining ion (*p.d.i*; H^+, OH^-) adsorption obtained by potentiometric titrations. (Fig. 1)

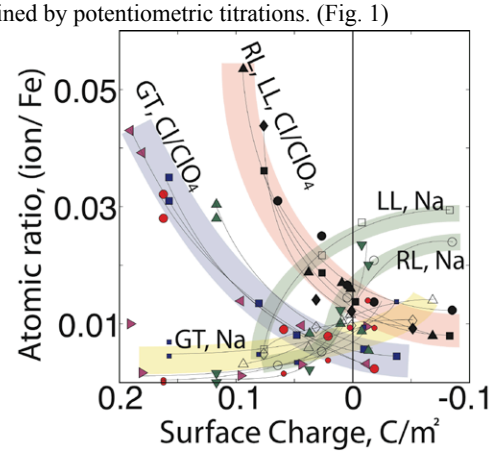

Figure1. Ionic surface loadings as a function of surface charge developed on rod- (RL) and lath-shaped (LL) lepidocrocite, as well as in two different goethite with specific surface area of 69 (GT69) and 122 (GT122) m^2/g.

The data revealed a strong dependency of *p.d.i.* and electrolyte ion adsorption on mineral particle morphology, as seen by comparison of rod- (RL) and lath-shaped (LL) lepidocrocite particles, as well as on surface roughness, as in case of samples with different surface porosity (Fig. 1). LL particles with a predominantly proton-inactive (010) surface acquired greater sodium but lower anion loadings. GT122 particles contained greater surface roughness and thereby acquired greater *p.d.i.* and anion loadings than GT69.

Petrogenesis of mafic-ultramafic rocks from the Berit metaophiolite massif: implications for REE, PGE, base metal and Al-rich chromitite composition

[1]H. KOZLU[2A] AND V. RUDASHEVSKY

[1]General Directorate of Mineral Research & Exploration, Mineralogy-Petrography, 06800 TR Çankaya/Ankara Turkey, E-mail:haticekozlu@mta.gov.tr

[2]CNT Labs, 1 Roentgena Str.197101, St.Petersburg, Russia

Mantle heterogeneity in terms of corundum bearing mafic rocks, as including eclogite and/or pyroxenite within peridotite is observed in Berit massif. The bulk chemical analytical results of the patterns from mafic and ultramafic rocks indicate that they relatively enriched in the REE-PGE and base metals. The refertilized and inhomogeneous mantle is capable of yielding more voluminous and compositionally diverse magma than normal. The REE and PGE distribution of high-Al chromitite patterns and mafic layers in Berit peridotite are, therefore, very important geochemical tool for determining the upper mantle heterogeneity. REE values of mafic rocks are between (La/Ce: 0.40-0.69, Ce/Yb: 1.05-16.29, La/Yb: 0.44-7.62, La/Sm: 0.88-6, La/Lu: 2.8-55) 12-165 ppm. The LREE-enrichment in peridotites are explained by interaction of the peridotites with LREE-enriched melts. The REE and PGE are generally considered to be relatively immobile during low-temperature alteration. However some elements, such as Eu, can be modified some what by hydrothermal processes. It has been determined the positive Eu anomalies in the normalised diagram for some chromitites and ultramafic mafic rock samples (dunite-pyroxenite-gabbro-diabase) from Berit metaophiolite. A relative enrichment in siderophile elements (as ppm) in the both of mafic and ultramafic rocks and in the high-Al chromitites for base metals (Ag: 0.3-0.9, Bi: 0.03-0.11, Cu: 13-2626, Ni: 134-7172, and Te: 0.1-3 ppm) is also determined. It is noteworthy that especially Pt (2.5 ppm) and Pd (4 ppm) enrichments are encountered in the high-Al chromitites.

Two chromite generations are determined in Berit:1) primary spinel component-rich (Al2O3-and MgO-rich compositions); 2) developed on the boundary of grains of chromite I – chromite and II enriched by chromite and magnetite minerals (in Fe, Cr and Ti). The association of base metals (Cu, Ni, Bi, Se, Te, Au, Ag) and Ti as well as Pd and Pt itself in composition of accessory minerals has been suggested that they may be brought into chromitites by fluids in basic composition.

Migration of hydrocarbons recorded in calcite-hosted inclusions, Dead Sea area: trace elements and isotopic evidence

O.A. KOZMENKO*, E.V. SOKOL AND V.N. REUTSKY

V.S.Sobolev Institute of Geology and Mineralogy, prosp. Koptyuga 3, Novosibirsk, 630090, Russia (*olg@igm.nsc.ru)

The mechanisms of hydrocarbon (HC) migration with water fluids, as well as the ability of container minerals such as vein calcite to preserve HC geochemical tracers, have received much recent interest [1]. Calcitic veins enclosing HC and soot carbon have been discovered in the western side of the Dead Sea rift, where basin opening induced venting of water-methane fluids [2]. All veins share similar REE spectra defined by the calcite rare earths patterns. Calcite crystallized from solutions with seawater chemistry signatures [3]. The reconstructed water generation temperatures of 55-90°C fit the regional "oil window" located at the depths 2.5-4 km. Significant negative Ce/Ce* anomaly indicates calcite growth at high oxygen fugacity. The organic matter hosted by calcite has C:N:S ratios from 30:2:15 to 15:0.1:2 (in mole fraction) and contains abundant asphaltenes with trace amounts of alkanes and carbonyl groups. Measured values $\delta^{13}C_{org}$ (–26.9 to –27.2 ‰ PDB) and $\delta^{34}S$ (+5.5 ‰ CDT) are similar to those of the Dead Sea asphaltenes [4]. As the obtained data imply, the calcite veins with inclusions of both oxidized and biodegraded HC and soot carbon precipitated from Ca-Na-HCO_3-Cl sediment waters that entrained crude oil drops.

Gramaccioliite-(Y) – rare yttrium carrier in metamorphic rocks (Subpolar Urals, Russia)

KOZYREVA I.V[1]., AND SHVETSOVA I.V.

Institute of Geology Komi SC UB RAS, Syktyvkar 167982, Russia ([1]kozyreva@geo.komisc.ru)

Gramaccioliite-(Y) is related to crichtonite group which includes the series of complex titanium and iron oxides with general formula $ABC_{18}T_2O_{38}$, where A = Sr, Pb, Ca, Na, R, REE, Ba, U; B = Mn, Y, REE, U, Zr; C = Ti, Fe^{3+}, Cr и T = Fe^{3+}, Mg. For the first time it was found in biotite gneisses of Piedmont province (Italy) and named in honor of Professor of Milan University Carlo Maria Gramaccioli [1]. We found gramaccioliite-(Y) on Maldynyrd Ridge (Subpolar Urals) in hematite-sericite shales. This is the first find in Russia. The mineral was found as well composed tabular crystals with trigonal habit with rhombohedral side planes, with black coloring and metal shine. In association with it we found leucoxene, rutile, anatase, apatite, cyanite, epidote, garnet, tourmaline, monazite and fuchsite, gold in important quantities. Gramaccioliite-(Y) was studied with scanning electron microscope JSM-6400 with energy spectrometer Link. The calculated empirical formulas of gramaccioliite-(Y) are as follows:

$(Pb_{0.61}Sr_{0.27}Ba_{0.02}U_{0.02})_{0.93}(Y_{0.49}Mn_{0.37}Ce_{0.08}Ca_{0.04}Nd_{0.02}La_{0.02})_{1.01} \times (Ti_{13.53}Fe_{5.49}Zn_{0.22}V_{0.04}Nb_{0.04})_{19.33}O_{38}$ [1].

$(Pb_{0.60}Sr_{0.39})_{0.99}(Y_{0.55}Mn_{0.42})_{0.97}(Ti_{13.32}Fe_{6.01}Zn_{0.53}V_{0.18})_{20.04}O_{38}$ – our data.

It is noticeable that the mineral, discovered by us, differs from the one, discovered in Italy, by considerably lower quantity of impurities, and its formula is practically identical to approved one (IMA 2001–034): $(Pb,Sr)(Y,Mn)(Ti,Fe)_{18}Fe_2O_{38}$ [1]. The formation of gramaccioliite-(Y) is conditioned by geochemical and mineralogical features of metamorphized rocks, formed on Precambrian substrate of contrasting content and modified by hypergenic processes. On the one hand the high titanium content of basites, presence of lead and zinc as galenite and sphalerite inclusions, on the other hand – rare earth and manganese anomaly, which is characteristic for rhyolites of this region – all these were favorable formation factors for complex titanium and iron oxide - gramaccioliite-(Y).

The work is completed with financial support from the Program of Basic Researches of UB RAS #12-C-5-1020 "General and local criteria of difference between high-disperse exogenous and low-temperature hydrothermal ore-forming systems".

Benthic nutrient fluxes and iron-phosphorus cycling in sulfidic estuarine muds

PETER KRAAL[12], EDWARD D. BURTON[1], RICHARD T. BUSH[1], ANDREW L. ROSE[1], MICHAEL D. CHEETHAM[1] AND LEIGH A. SULLIVAN[1]

[1]Southern Cross GeoScience, Southern Cross University, PO Box 157, Lismore, New South Wales, Australia

[2]As per June 1, 2013: Department of Geochemistry, Utrecht University, Budapestlaan 4, 3584 CD Utrecht, The Netherlands

Estuaries are crucial geochemical filters at the land-ocean interface that have been widely impacted by human activities. We investigated sediment biogeochemistry and benthic nutrient fluxes in the shallow, eutrophic Peel-Harvey Estuary in Western Australia. Our results reveal localized deposition of organic-rich, fine-grained surface sediments characterized by high sulfate reduction rates and abundant accumulation of metastable iron (Fe) monosulfides. Core incubations showed high rates of nitrogen and phosphate release from these sulfidic surface sediments, even though they are reworked and overlain by a well-mixed, oxygenated water column. This suggests decoupling between bottom water oxygenation and sedimentary phosphorus (P) retention. Phosphate sorption experiments emphasized the stark contrast in phosphate binding capacity between the 'normal' estuarine sediments and the strongly reducing muds.

In addition, we observed rapid and extensive sulfidization of reactive Fe within centimeters of the sediment surface below the oxygenated water column, indicating that Fe speciation may not necessarily reflect bottom water oxygenation, at least under the investigated environmental conditions. These findings may be of importance to the use of Fe-based paleoredox-proxies.

Despite strongly reducing conditions, our results suggested that Fe-associated P may be an important P sink in the investigated muds. Using a combination of sequential chemical Fe and P extractions, Fe Extended X-ray Absorption Fine Structure (Fe EXAFS) and micron-scale multi-energy X-ray element mapping, we examine the nature of this Fe-P association.

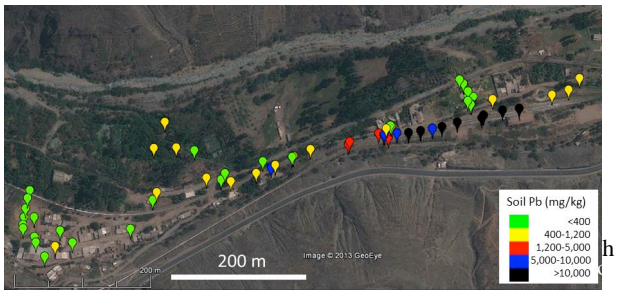
Overall, our detailed geochemical results and benthic flux measurements challenge some of the existing paradigms regarding the links between bottom water oxygenation and the cycling of essential elements such as Fe and P.

Mapping lead contamination of soil due to mining in Peru

S.X. KRAGIE[1] AND A. VAN GEEN[1]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY10964, USA

An estimated 1.6 million people live within 5 km of an active mine, ore processing plant, smelter, or former mining site in Peru [1]. In a country with such a long mining history, towns have often been built on top of former mine tailings contaminated with Pb. The health consequences of allowing children to play in soil contamined with Pb have been well documented. What is less widely know is that the distribution of Pb in soil contaminated by mining activities can be spatially highly heterogeneous. One such example along the railroad track that links the capital Lima to the main mining centers in the Andes is illustrated below.



The data show concentrations exceeding 10,000 mg/kg Pb along a 200 m section of the railroad while other sites along the rail road generally are well within the current US EPA standard of 1,200 mg/kg for residential soil where children do not play. The particularly contaminated area is a turning point for railroad cars containing ore concentrate and this has been associated with contamination of an area commonly used as a walkway. Additional examples of Pb hot-spots will be included in the poster, typically from older mining sites. Results of soil surveys around modern mining operations showing little Pb contamination will also be shown.

Handheld XRF analysers are relatively expensive and their deployment requires training. We have therefore also been testing the soils collected in Peru with a simple Pb extraction and detection protocol relying on citric acid and rhodizonate. The poster will include results from this alternative approach.

U phase evolution in the bedrock around Forsmark, eastern Sweden

L. KRALL[1]*, B. SANDSTRÖM[2] AND E-L. TULLBORG[3]

[1]SKB, Stockholm University, Sweden *Lindsay.Krall@skb.se
[2]WSP Group, Gothenburg, Sweden
[3]Terralogica AB, Gråbo, Sweden

Elevated gamma emisisons from some pegmatites, cataclasites, and vein fillings were found in drillcores from Forsmark, Sweden. A proposed host for nuclear waste repositories, these findings prompted interest in the geochemistry of U in the local bedrock. Coupled with existing knowledge of the site, characterization of solid-phase U has implications for the deposition, evolution, and behavior of U in this environment. A model of the low- to moderate-temperature evolution of the area was established during preceding fracture mineral studies. Four generations of fracture minerals record the relative timings and types of fluid migration and have been traced to regional events, such as orogeny and glaciation, by means of stable isotope, fluid inclusion, radiometric dating, and fracture orientation analysis [1]. This model has contributed to a working hypothesis on the stages of U alteration: 1) Palaeoproterozoic, U was introduced, likely as uraninite, by pegmatitic intrusion, 2) formation of cataclasite, U was mobilized and uraninite was altered to pitchblende then partially coffinitized, 3) Palaeozoic, U was remobilized and U-phospate precipitated on fracture surfaces and 4) Palaeozoic or later, amorphous U-silicate formed in fractures.

Thin sections from zones of elevated gamma radiation have been analyzed using SEM-EDS. A primary (U,Pb)-oxide mineral (250 μm) confined by a rim of (Fe, Mn)-chlorite has been found in a small pegmatite. Most U phases found in pegmatites are low-Pb, probably secondary U-silicates (10-30 μm) of mutually different habit and composition (e.g. Ca, Fe, Ti, Mn, Al, and/or Ba) and are associated with minerals like chlorite, hematite, quartz, K-feldspar, and calcite. In the cataclasite, both primary (Th, U, REE)-silicates (150 μm) within pegmatite clasts and secondary U(Ca, A1)-silicates were along calcite and quartz grain boundaries. In vein fillings, disseminated grains of secondary U-silicate were found associated with laumontite, a marker within the fracture mineral generation of 1.10 – 1.03 Ga. Additionally, U-phosphates were found with pyrite, mixed layer clays, and Palaeozoic asphaltite. These findings complement the hypothesisized stages of evolution and offer new U phases for integration.

Drainage water chemistry reflects monolithologic Critical Zones

P. KRÁM*, J. ČUŘÍK, F. VESELOVSKÝ, O. MYŠKA, V. ŠTĚDRÁ, V. BLÁHA AND J. HRUŠKA

Czech Geological Survey, Klárov 3, 118 21 Prague 1, Czech Republic (*correspondence: pavel.kram@geology.cz)

Three small (27-55 ha) catchments covered by spruce, each underlain by geochemically contrasting rocks (LYS: granite, NAZ: amphibolite, PLB: serpentinite) were studied in the Slavkov Forest, Czech Rep [1]. Hydrochemical patterns were ascertained by concurrent stream water sampling (2001-2013) and soil water sampling by lysimeters placed at five depths in 2012-2013 (Fig. 1). Three boreholes drilled to 26-30 m probed deep critical zones. Strongly acidified LYS exhibited incomplete neutralization of acidic deposition and had chronically low drainage water pH and elevated levels of toxic Al [2]. PLB exhibited the most efficient neutralization by chemical weathering. LYS was Mg deficient with respect of spruce and ectomycorrhizal fungi, PLB was P and K deficient and NAZ was not deficient in any nutrients [1,3].

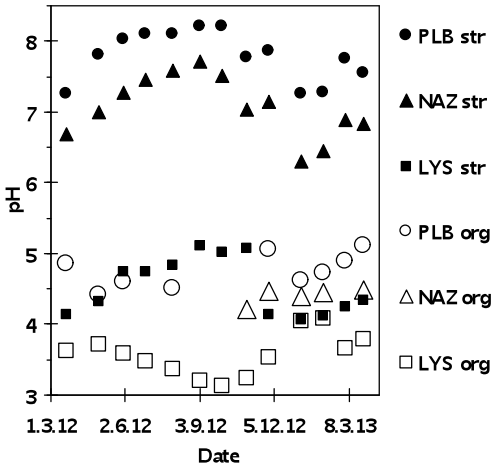

Figure 1: Temporal patterns of stream water (str) and organic horizon soil water (org) at Lysina (LYS), Na Zeleném (NAZ) and Pluhův Bor (PLB) in March 2012 - March 2013.

This study was supported by the EC (FP7 SoilTrEC 244118).

Indirect evidence for the presence of secondary phosphorus in continental fine aerosol

K. KRASSOVÁN[1]*, Z. KERTÉSZ[2], K. IMRE[3] AND A. GELENCSÉR[1,3]

[1]Institute of Environmental Sciences, University of Pannonia, Veszprém 8200, Hungary (*correspondence: krassovank@uni-pannon.hu)

[3]Air Chemistry Group of the Hungarian Academy of Sciences, Veszprém 8200, Hungary (kornelia@almos.uni-pannon.hu)

The role of the atmosphere in the biogeochemical cycle of phosphorus is generally associated with the emission of soil dust, sea-salt particles, bioaerosols and industrial aerosols. Quite independently, a reduced gaseous phosphorus compound (phosphine, PH_3) was measured over various sources such as marshes and sewage plants [1] and also in the global troposphere. Given that phosphine is a reactive gas that rapidly yields low-volatility phosphoric acid in the atmosphere [2], secondary aerosol formation can be an important sink that has never been considered in the global phosphorus cycle. In our study we present mass size-distribution measurements of phosphorus in aerosol samples collected at two locations in Hungary. The bimodal size distribution of phosphorus indicated two distinct formation mechanisms in the fine and coarse modes. As expected, the mass concentration of phosphorus was dominated by the coarse particles (aerodynamic diameter >1 μm), the contribution of fine mode phosphorus was in the range of 10–27 % (median 19 %) of the total. The contribution of biomass burning to the fine mode phosphorus was inferred from measured K concentrations and P/K ratios reported for biomass smoke [3]. It was found that biomass burning accounted for only a small fraction of fine mode phosphorus, the rest of which likely formed as secondary aerosol component from gaseous phosphine. Secondary aerosol phosphorus can be even more important in providing this essential nutrient for remote ecosystems since it is associated with fine aerosol particles which have longer residence time and thus are more prone to long-range atmospheric transport than coarse primary particles.

Aquatic microbial aerobic methane oxidation (MOx) causes the production of carbon dioxide, leading to decrease of liquid phase pH. Therefore, MOx activity impacts the carbonate system, potentially favouring dissolution of calcium carbonates. In addition, carbonate dissolution has recently also been attributed to microbially produced organic polymers. To date, the impact of metabolic products from MOx on carbonates has been poorly constrained. To discriminate between different mechanisms acting on carbonate stability, calcite dissolution experiments were conducted with (1) prospering cells (2) starving cells, and (3) dead cells of the methanotrophic bacterium *Methylosinus trichosporium,* as well as abiotic controls, under brackish conditions (salinity 10) near calcite saturation (saturation state (Ω) 2.22 to 1.76). Abiotic controls showed no calcite dissolution during the experiment. In contrast, dissolved calcium and total alkalinity markedly increased in experiments containing *M. trichosporium* cells, indicative for calcite dissolution. After initial system equilibration, calcite dissolution, ranging from 29.6 to 14.9 μmol l^{-1} d^{-1} between treatments, was observed. While concentrations of transparent exopolymer particles concentrations declined considerably over time in the presence of prospering and starving cells, concentrations increased in experiments with dead cells. Scanning electron microscopy of calcite crystals revealed surface corrosion after exposure to prospering, starving, and dead *M. trichosporium* cells. The results of this study demonstrate a strong potential impact of MOx bacteria on calcite stability, clearly facilitating calcite dissolution. In addition to CO_2 production by methanotrophically active cells and starving cells, we suggest that the release of acidic and/or calcium-chelating organic carbon compounds also facilitated enhanced calcite dissolution.

Glass ceramics and mineral materials for the immobilization of lead and cadmium from Municipal Solid Waste Incinerator ashes

KATERINA KRAUSOVA[1]*, LAURENT GAUTRON[1], GILLES CATILLON[1] AND STEPHAN BORENSZTAJN[2]

[1]Laboratory of Earth Materials and Environment, University Paris East – Marne la Vallée, 77454, France, (*krausovak@seznam.cz, gautron@univ-mlv.fr, gilles.catillon@univ-mlv.fr)

[2]Laboratory of Interfaces and Electrochemical Systems,University Pierre and Marie Curie, France (stephan.borensztajn@upmc.fr)

Waste management is one of the major global issues. Incineration is an efficient treatment since it offers both a reduction of mass and volume and a possibility of energy recovery. One of the problems of incineration is the production of bottom and fly ashes which are considered as hazardous waste with obligation of final disposal into a specific landfill.

The objective of the present study is to investigate glass ceramics and sintered ceramics as new mineral materials for a sustainable immobilization and possible recycling of these incineration wastes. Toxic elements can be incorporated into embedded crystals in a glass matrix which has a function of the second barrier, or in highly resistant crystalline structure. Based upon cations size considerations, this study is focused on Ca-rich or Ba-bearing minerals as possible hosts of lead and cadmium.

Promising results have been obtained for $CaMgSi_2O_6$ diopside-bearing glass ceramics and sintered $Ba_{1.5}Mg_{1.5}Ti_{6.5}0_{16}$ hollandite, both in terms of toxic elements incorporation and of chemical and mechanical resistance.

Stable isotope composition of anthropogenic thallium deposition

K. KREISSIG[1], M. REHKÄMPER[1]* AND M. KERSTEN[2]

[1]ESE, Imperial College, London SW7 2AZ, UK (*correspondence: markrehk@imperial.ac.uk)

[2]Gutenberg-University, Mainz 55099, Germany

Thallium compounds are volatile at high temperature and not efficiently retained by emission control facilities of combustion sources. This study represents the first use of stable isotope ratios to apportion near-source Tl deposition to the emitter. In 1979, dust containing Tl was emitted by a cement plant near Lengerich, NW Germany. The emission event was caused by a ferric oxide additive to the powdered lime (used for the production of special cements), which contained a Tl-bearing residue of pyrite roasting. Following the emission event, sheep died and rabbits and horses were reported to loose fur and hair in the vicinity of the cement plant [1]. The cement plant owners denied responsibility for the bulk of the emissions. We determined the Tl isotope compositions (ε^{205}Tl) of the cement dust (open symbol) and soil cores down to 100 cm depth (black symbols), and the data are in accord with a two-source mixing line (Fig. 1). Our novel isotope analysis ultimately helped the plaintiffs to settle the case by showing the causation of the pollution event, even though the emissions happened more than 30 years ago.

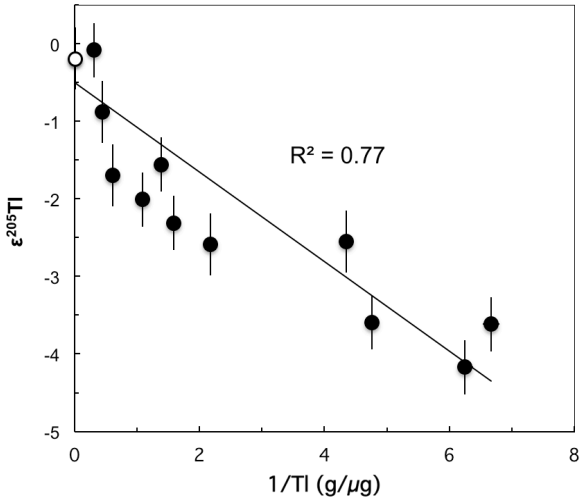

Figure 1: Tl stable isotope data vs. inverse Tl concentrations for soil samples of increasing depth from left to right.

Fractionation of Cd isotopes during evaporation and re-condensation

V. KREMSER[1], F. WOMBACHER[1], W. ERTEL-INGRISCH[2], D. B. DINGWELL[2] AND C. MÜNKER[1]

[1]Universität zu Köln, Institut für Geologie und Mineralogie, Köln, Germany (v.kremser@uni-koeln.de)
[2]Ludwig-Maximilians-Universität, Department für Geo- und Umweltwissenschaften, München, Germany

Stable isotope studies of volatile elements can provide constraints on possible scenarios of volatile element loss and redistribution [e.g, 1, 2]. Here, Cd stable isotope and volatile element fractionation during evaporation from silicate melt at about 1300 °C and during re-condensation onto Al_2O_3 condensation plates is studied experimentally, at atmospheric pressure in air and in CO-CO_2. The experiments can serve to address questions that are important for the interpretation of volatile element stable isotope data in cosmochemistry, e.g.: How much do atmospheres with variable fO_2 suppress (Cd) isotope fractionation? Are there conditions where volatile metal loss by evaporation can occur without measurable stable isotope fractionation? Will (kinetic) condensation result in significant stable isotope fractionation?

Our experiments show that evaporation at atmospheric pressure only yields strongly suppressed Cd isotope fractionation, with a vapor-melt fractionation factor α for $^{114}Cd/^{110}Cd$ that corresponds to -1.6 ‰ (air) and -0.3 ‰ (CO-CO_2). This compares to about -10 ‰ observed for evaporation into vacuum [3] and the theoretical prediction of -17.7 ‰ as calculated from Graham's law.

In addition, Cd also displays isotope fractionation along the temperature gradient of the Al_2O_3 condensation plates with light Cd isotopes being enriched in the condensates closest to the melt.

The observed suppressed isotope fractionation during evaporation may result from back reaction into the melt phase and more efficient Cd^0 vapor formation at reduced conditions.

A method to constrain the size of the Protosolar Nebula

KRETKE, K. A.[1]*, LEVISON, H. F.[1], BUIE, M. W.[1] AND MORBIDELLI, A.[2]

[1]Southwest Research Institute, Department of Space Studies, 1050 Walnut Street, Suite 400, Boulder, CO 80302, USA *correspondence: kretke@boulder.swri.edu
[2]Observatoire de la Côte d'Azur, BP 4229, 06304 Nice Cedex 4, France

Observations indicate that the gaseous circumstellar disks around young stars vary significantly in size, ranging from tens to thousands of AU. Models of planet formation depend critically upon the properties of these primordial disks, yet in general it is impossible to connect an existing planetary system with an observed disk. We present a method by which we can constrain the size of our own protosolar nebula using the properties of the small body reservoirs in the solar system. In standard planet formation theory, after Jupiter and Saturn formed they scattered a significant number of remnant planetesimals into highly eccentric orbits. In this paper, we show that if there had been a massive, extended protoplanetary disk at that time, then the disk would have excited Kozai oscillations in some of the scattered objects, driving them into high-inclination ($i >\sim 50°$), low-eccentricity orbits ($q >\sim 30$ AU). The dissipation of the gaseous disk would strand a subset of objects in these high-inclination orbits; orbits that are stable on Gyr timescales. To date, surveys have not detected any Kuiper-belt objects with orbits consistent with this dynamical mechanism. Using these non-detections by the Deep Ecliptic Survey and the Palomar Distant Solar System Survey we are able to rule out an extended gaseous protoplanetary disk ($R_D >\sim 80$ AU) in our solar system at the time of Jupiter's formation. Future deep all sky surveys such as the Large Synoptic Survey Telescope will allow us to further constrain the size of the protoplanetary disk.

Speciation and mobility of trace elements in wetland soils

RUBEN KRETZSCHMAR

Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (kretzschmar@env.ethz.ch)

Wetlands including peatlands, riparian floodplains, and paddy soils play key roles in the biogeochemical cycling of carbon, sulfur, phosphorus, and many essential or potentially toxic trace elements (e.g., As, Se, Hg, Zn, Cu, Cd). Understanding the solid-phase speciation, micro-scale distribution, and mobility of trace elements in such soils is an important challenge in soil biogeochemistry. Prof. Willem van Riemsdijk and his coworkers were among the leaders in developing our current understanding of competitive sorption of cations, anions, and NOM to soil mineral surfaces. Competitive sorption of arsenate or arsenite with other anions such as phosphate or carbonate, for example, are now rather well understood and can be modelled quantitatively using the CD-MUSIC approach [1]. However, sorption and speciation changes of trace elements during reduction/oxidation cycles in soils, often coupled to iron mineral transformations and sulfur redox reactions in the presence of NOM, are still poorly understood. We therefore explored the influence of soil flooding on trace element speciation and mobility and found formation of metallic Cu(0) and metal sulfide nano-particles by suspended bacteria to be an important mechanism controlling pore water concentrations of Cu, Hg, Zn, and Pb [2]. More recently, we explored the speciation of As in different wetlands and found As(III) bound to reduced sulfur groups of NOM to be the dominant species in anoxic peat layers [3]. Subsequent model studies confirmed this newly discovered binding mechanism of As to NOM [4], which may of great importance in other NOM-rich, reducing environments. In contrast, in a mining-affected river floodplain, As was mainly present as As(V) coprecipitated with Fe(III) in poorly-crystalline mineral phases, exhibiting similarity to amorphous ferric arsenates, partly forming rims around weathering pyrite and arsenopyrite grains. The solid-phase speciation greatly influences the kinetics of microbial Fe and As reduction and release, and is therefore important for understanding As release under reducing conditions in soils [5].

Juvenile crustal growth during the Palaeoproterozoic: U-Pb-O-Hf isotopes of detrital zircon from Ghana

BÁRA D. KRISTINSDÓTTIR[1], ANDERS SCHERSTÉN[1], ANTHONY I.S. KEMP[23] AND ANDREAS PETERSSON[1]

[1]Department of Geology, Lund University, Sölvegatan 12, SE-223 62 Lund, Sweden. anders.schersten@geol.lu.se; barakristins@gmail.com

[2]School of Earth and Environmental Sciences, James Cook University, Townsville, Queensland 4811, Australia. tony.kemp@uwa.edu.au

[3]School of Earth and Environment, the University of Western Australia, Crawley, Western Australia 6009, Australia.

The Palaeoproterozoic domains of the West African Craton (WAC) (~2.15 Ga) have been described as a fast growing segment of juvenile crust based on geochronological data and Nd-model ages. Detrital zircon from four rivers in Ghana, southeastern WAC, were analysed for U-Pb, O and Lu-Hf isotopes and a zircon population from a fifth river was analysed for U-Pb and Lu-Hf isotopes. U-Pb crystallisation ages mainly cluster between 2.24 and 2.09 Ga with a peak at ~2.14 Ga, reflecting peak magmatic activity. The zircon population from the Birim river, representing the Kibi-Winneba belt, in southeast Ghana have zircon with U-Pb ages >2.2 Ga, which is nearly absent in other rivers.

The entire zircon population has ε_{Hf} values ranging from 0.9 to 7.1, except four grains from the Birim river population that have negative ε_{Hf}. Although there are contrasts between the zircon populations from the different rivers, the data imply relatively juvenile crust without any significant reworking of ancient crustal components. ~2.2 Ga zircon from the Birim river have depleted ε_{Hf}, while a younger (2.15 Ga) subset of zircon requires a reworked Archaean component. Zircon from Sihili and Black Volta rivers form a losely defined trend that suggest the reworking of mafic crust, while the others do not.

Contribution of reworked supracrustal rocks were minor during the initial growth stages as indicated by the absence of zircon with $\delta^{18}O>6.5‰$ prior to 2.174 Ga. The proportion of grains with elevated $\delta^{18}O$ gradually increases after 2.174 Ga, suggesting increasing amounts of reworked supracurstal sedimentary components. However, these zircon grains with high $\delta^{18}O$ have depleted ε_{Hf}, which suggests fast reworking of young supracrustal rocks, perhaps in a maturing arc system.

Are mafic microgranular enclaves in durbachites plutonic equivalents of common minettes?

LUKÁŠ KRMÍČEK[1]* AND ROLF L. ROMER[2]

[1]Brno University of Technology, Faculty of Civil Engineering, Veveří 95, CZ-602 00 Brno, Czech Rep. (*correspondence: l.krmicek@gmail.com)

[2]Deutsches GeoForschungsZentrum (GFZ), Telegrafenberg, D-14473 Potsdam, Germany

Durbachites are K-feldspar-phyric biotite-bearing MgO-rich rocks of syenitic composition whose formation involves the mixing of mafic high-potassium partial melts from an enriched mantle with granitic melts. Due to this process, durbachites encompass a broad compositional range and contain variable amounts of mafic microgranular enclaves (MME). The mafic members are considered to be the plutonic equivalent of common mica lamprophyres, i.e., minettes [1]. Large volumes of durbachites (e.g., the Třebíč Massif) have been emplaced in the Moldanubian Zone of the Bohemian Massif. Regionally contrasting geochemical fingerprints of mantle metasomatism and the role of mantle contribution in durbachtite magmatism may be the key control on the distribution of durbachites in the Bohemian Massif. MME from the Třebíč Massif have been investigated petrologically and geochemically (including Sr-Nd-Pb isotopes) and compared with Variscan mafic dikes of the Bohemian Massif. The geochemical composition of the MME does not correspond to the composition of typical minettes from which they are noticeably shifted toward higher $^{87}Sr/^{86}Sr(i)$ values and more negative εNd(i) values. Moreover, the composition of MME also differs from newly recognised peralkaline lamproitic rocks cropping out around the Třebíč Massif [2]. Instead, the MME compositionally overlap with micaceous mafic dykes that could be best described as cocites [2]. Both cocites and MME show high Mg-values and are characterized – in comparison with minettes and lamproites – by a remarkable negative Eu anomaly, an extremely high positive Pb anomaly, and an unusually high Sm/La ratio. It is the particular geochemical and isotopic signature of mantle metasomatic component that is common for the durbachites and the cocite dykes and that distinguishes them from Variscan minettes of other parts of the Bohemian Massif.

Volcanic activity represents a major natural source of sulfur dioxide (SO_2) to the Earth's atmosphere, and thus is an important component of the global sulfur cycle. In addition, the very high concentrations of SO_2 and particulate matter in the areas immediately surrounding volcanoes can have serious effects on human and ecological health. In order to better understand the atmospheric fate of volcanogenic emissions in the near field (in the first few hours after emission), we have carried out *in situ* studies of key sulfur species on the Big Island of Hawai'i. Measurements were made as part of MIT's Traveling Research Environmental eXperiences (TREX) program, aimed at introducing undergraduate students to environmental fieldwork. A suite of instruments for characterizing oxidized sulfur in both the gas and particle phase, including an SO_2 monitor and an Aerosol Chemical Speciation Monitor (ACSM), were deployed on a mobile ground-based platform, with sampling carried out at a range of locations on the island. To our knowledge these measurements represent the first real-time measurement of the chemical composition of volcanic aerosol. The high time resolution of the instruments, combined with the high spatial coverage of the mobile measurements, enables the characterization of the volcanic plume at different times/distances downwind of the point of emission. From these measurements we are able to track the initial lifecycle of volcagenic sulfur, including emission, oxidation to particulate sulfuric acid, and neutralization by ammonia. Results are compared with continuous measurements taken by air quality monitoring sites on the island.

Origin of water on the chondrite asteroids: Evidence from oxygen-isotope compositions of aqueously-formed minerals

A. N. KROT[1,2]*, P. M. DOYLE[1,2], K. NAGASHIMA[1], K. JOGO[3], S. WAKITA[3], F. J. CIESLA[4] AND I. HUTCHEON[5]

Fayalite and magnetite in CV3.1 and CO3.1 carbonaceous chondrites (CCs) resulted from water-rock interaction on their parent asteroids at water/rock volume ratio of ~0.2 and temperatures of ~100–200°C [1,2]. The inferred $^{53}Mn/^{55}Mn$ ratios in fayalite in Asuka 881317 (CV) and MacAlpine Hills 88107 (CO-like) are $(2.77\pm0.48)\times10^{-6}$ and $(2.45\pm0.33)\times10^{-6}$ [3] The ^{53}Mn-^{53}Cr ages of the CV and CO fayalite formation anchored to D'Orbigny angrite [4,5] are 3.7 (+1.1/–0.9) and 4.4 (+0.9/–0.7) Ma after CV CAIs [3] having an absolute age of 4567.3±0.16 Ma [6]. These ages are indistinguishable from the ^{53}Mn-^{53}Cr ages of calcite in CMs [7] and dolomite in CMs and CIs [7,8]. The high peak metamorphic temperatures experienced by CVs and COs of petrologic type $\geq$ 3.6 ($\geq$600°C) and the old formation ages of fayalite imply a rapid accretion of their parent asteroids after chondrule formation (~2–2.5 Ma after CV CAIs) followed by a short onset of aqueous alteration. The accretion of CVs and COs predated by ~ 1Ma accretion of the more extensively aqueously-altered, but less metamorphosed CMs and CIs [7,8]. Near terrestrial oxygen-isotope compositions of the CV and CO fayalite and magnetite ($\Delta^{17}O \sim -1‰$), and CM and CI carbonates and magnetite ($\Delta^{17}O \sim +2‰$ to $-3‰$) may indicate water in the CC parent asteroids had preferentially a local, inner Solar System origin, consistent with the inferred hydrogen-isotope composition of the CC asteroidal water [9]. The low influx of isotopically heavy (i.e., enriched in ^{17}O, ^{18}O, and D/H) water ices from the outer Solar System at the time of accretion of CC asteroids may be due to an early growth of Jupiter that could have prevented significant radial transport of dust and gas from outside its orbit.

Nucleosynthetic W isotope anomalies in CAI: Implications for Hf-W chronology

T.S. KRUIJER[1,2,*], T. KLEINE[1], C. BURKHARDT[3] AND R. WIELER[2]

[1]Institute for Planetology, University of Münster, Germany
[2] Institute of Geochemistry and Petrology, ETH Zürich
(*correspondence: thomas.kruijer@erdw.ethz.ch)
[3]Origins Laboratory, Department of the Geophysical Sciences, The University of Chicago

The application of the short-lived ^{182}Hf-^{182}W decay system to investigate the timing of early solar system processes requires knowledge of the initial Hf and W isotope compositions at the beginning of the solar system [1,2]. These can most directly be determined from Ca-Al-rich inclusions (CAI), which are the oldest yet dated objects that formed within the solar system [*e.g*., 3,4]. However, the interpretation of W isotope data in CAI is complicated by the presence of nucleosynthetic W isotope anomalies [1], which may significantly bias the inferred initial $^{182}W/^{184}W$ of CAI [2]. The aim of this study is to explore the range of nucleosynthetic W isotope variations in CAI to better quantify the initial Hf and W isotope compositions of the solar system.

Here we report W isotope compositions for six bulk CAI (one type B, five type A) from the Allende CV3 chondrite. Tungsten isotope compositions of the CAI were measured on a Neptune *Plus* MC-ICPMS at the University of Münster and are reported as $\varepsilon^{i}W$ (*i.e*., 0.01 % deviations from terrestrial values). The investigated CAI display large variations in $\varepsilon^{183}W$, extending to much larger anomalies than previously observed [1,2] and indicating variable abundances of *s*- and *r*-process W isotopes in CAI. The CAI define a precise empirical correlation between $\varepsilon^{183}W$ and initial $\varepsilon^{182}W$, which allows correction of measured $\varepsilon^{182}W$ for nucleosynthetic heterogeneity. The corrected $\varepsilon^{182}W$ *vs*. $^{180}Hf/^{184}W$ define a bulk CAI isochron (MWSD=1.5) with a precise initial $^{182}Hf/^{180}Hf$ of $\approx1.0\times10^{-4}$, which when anchored to the angrite D'Orbigny [5] corresponds to an absolute age of CAI that is in good agreement with their Pb-Pb ages [3,4]. The bulk CAI isochron confirms the recently revised CAI initial of $\varepsilon^{182}W \approx -3.5$ [2]. Relative to this value, magmatic iron meteorites have more radiogenic neutron capture-corrected $\varepsilon^{182}W$ [6], corresponding to core formation timescales of ≈1-3 Ma after CAI formation and indicating a time gap of ≈ 0.5-1 Ma between the formation of the first solids and accretion of the oldest planetesimals.

Re–Os Age and Gold Source for Mayskoe Quartz-Vein Deposit (Northern Karelia, Baltic Shield)

R.KRYMSKY[1], B.BELYATSKY[2], N.GOLTSIN[1], S.SERGEEV[1] AND S.BUSHMIN[2]

[1]CIR VSEGEI, St.Petersburg, Russia, robert_krysmsky@yahoo.com
[2]IPGG RAS, St.petersburg, Russia, bbelyatsky@mail.ru

Mayskoe deposit located in Northern Karelia within the Svecofennian orogen near the boundary with the Belomorian–Lapland orogen is the only known gold deposit of the quartz–vein type in the Karelian–Kola region. The host Paleoproterozoic volcanogenic–sedimentary rocks metamorphosed from greenschist to amphibolite facies within the Svecofennian time. Metamorphic rocks are strongly scheared and metasomatized, where early quartz and late gold-bearing quartz veins are located. Ore association in quartz veins is represented by native gold, chalcopyrite, pyrrhotite, galena, pyrite, and sphalerite, as well as Se and Te minerals.

We investigated the Re–Os isotope system of native gold and syngenetic chalcopyrite from the eastern lode-gold quartz vein. Gold grains and chalcopyrite were manually collected from two gold-bearing milky–white quartz samples. Re and Os contents in the analyzed gold range from 1.8 to 13.8 and from 0.2 to 2.3 ppb, which is comparable with the concentrations measured in syngenetic chalcopyrite: 0.5–2.1 ppb Re and 0.1–1.0 ppb Os. According to the Os concentration, the studied samples differ significantly from hydrothermal sulfide gold deposits and are comparable with those associated with conglomerates [1]. The correlation between Re/Os and Os isotope composition for the studied samples corresponds to the age of 397 ± 15 Ma and $(^{187}Os/^{188}Os)i = 0.1469 \pm 0.0051$ ($\gamma Os = +18$).

The measured Os composition of gold and chalcopyrite ($^{187}Os/^{188}Os$ = 0.2160–0.4376) differs significantly from typical crustal (> 1.0) and mantle values (0.1296), and may be obtained either by mixing of Os from these sources or as a result of in situ Re decay. The age character of obtained trend is provided by the model Re–Os age of the samples: from 430 to 515 Ma, similar to the isochron one. Thus, the ore-forming fluid may have been formed in the Early Paleozoic by mixing of 75% upper mantle material and 25% Proterozoic crust and have come to quartz veins 400 m.y. ago. The primitive upper mantle (Os = 2.5 ppb and $^{187}Os/^{188}Os$ = 0.1239), in this case, was the main source of gold. Alternatively, formation of gold-bearing mineralization was plausible realised under the influence of the Caledonian mantle plume due to remobilization of basic–ultrabasic matter (or mantle restites) of Paleoproterozoic rocks (2.0–2.2 Ga) of the Karelian–Kola region characterized by high concentrations of gold and PGEs.

Experimental and computational spectra and thermodynamics of biogeochemical interfaces

JAMES D. KUBICKI[1] AND NADINE KABENGI[2]

[1]Dept. of Geosciences, The Pennsylvania State University, University Park, PA 16802 USA (*correspondence: jdk7@psu.edu)
[2]Dept. of Geosciences and Chemistry, Georgia State University, Atlanta GA 30303

The molecular-level chemistry of biogeochemical interfaces influences dissolution of minerals, transport of bacteria and degradation of contaminants. Detailing these interactions is problematic, however, because surfaces are difficult to characterize and biological compounds can be complex. Significant advances have been made by collecting spectra (e.g., ATR-FTIR, NMR, etc.) of samples representing key biogeochemical reactions and interpreting the spectra with quantum mechanical calculations. Generally, these experimental studies are performed on simplified binary systems with one substrate and one adsorbent. Predictions of biogeochemistry in the field may be erroneous because competing reactions are not considered in the laboratory-based studies.

A missing component of these types of studies is the thermodynamics of the adsorption reactions. One can model surface complexes and the spectroscopic properties observed, but without knowledge of the thermodynamic favorability of the surface complexes, one cannot estimate their prevalence or dominance in natural systems.

This talk will focus on progress in developing methods to calculate spectroscopic properties and thermodynamics of adsorption in biogeochemical systems. The incorporation of thermodynamic data from flow-adsorption calorimetry into modeling of these adsorption reactions will also be discussed. Examples of test systems such as goethite-phosphate will be used as the basis for more complex reactions with biological compounds.

[4]Illinois State Water Survey, University of Illinois, Champaign, IL 61820 USA
[5]Department of Earth and Space Sciences, University of California, Los Angeles CA USA
[6]Center for NanoMaterials Science,Oak Ridge National Laboratory, Oak Ridge, TN USA

Although TiO_2 is not a major rock-forming mineral, it is an important technological material, and it has been used extensively as a model for oxide-water studies. Because the surfaces of the common TiO_2 phases, rutile and anatase, have been characterized experimentally and modeled with density functional theory (DFT), they serve as good model systems for understanding the size and shape effects of nanoparticles on the oxide-water interface.

In this talk, we will present results of DFT calculations on rutile and anatase surfaces and nanoparticles interactions with H_2O. The relationship of surface site defects (i.e., corner and edge sites) to H_2O adsorption energy is investigated. DFT calculations on anatase surfaces with adsorbed ions are also presented.

These DFT calculations were then used in developing a reactive classical force field, ReaxFF, for the Ti-O-H system. The ReaxFF was used to perform molecular dynamics simulations of rutile and anatase particles in water and aqueous salt solutions. Differences in the electrical double layer around finite nanoparticles as compared with flat, infinite surfaces will be discussed.

Hybrid Pressure Coring System of D/V *Chikyu*

YUSUKE KUBO[1], YASUHIKO MIZUGUCHI[2] AND FUMIO INAGAKI[3]

[1]CDEX, JAMSTEC, 3173-25 Showa-machi, Kanazawa-ku, Yokohama, Japan 236-0001. kuboy@jamstec.go.jp
[2]CDEX, JAMSTEC, 3173-25 Showa-machi, Kanazawa-ku, Yokohama, Japan 236-0001
Submarine Resources Research Project and Kochi Institute for Core Sample Research, JAMSTEC, Monobe B200, Nankoku, Kochi 783-8502, Japan

Pressure coring is a technique to keep *in-situ* conditions in recovering subseafloor sediment samples, which are potentially rich in soluble or hydrated gas. Gas fractions are easily lost in regular core sampling through the pressure and temperature change during core recovery, and subsequently change the chemical components of the sample: e.g., degassing may cause critical changes and/or damages of original structures. To study original characteristics of gaseous subseafloor sediment, a New Hybrid Pressure Coring System (Hybrid PCS) was developed for the D/V *Chikyu* operation by adapting some of the existing pressure sampling technologies. Hybrid PCS is composed of three main parts: top section for the wireline tool, middle section for the accumulator and pressure controlling system, and the bottom section for the autoclave chamber. The design concept is based on that of Pressure Core Sampler used in Ocean Drilling Program, and of Pressure Temperature Core Sampler (PTCS) and Non-cooled PTCS of Japan Oil, Gas and Metals National Coporation (JOGMEC). Modifications were made on the ball valve, which operates to close the autoclave after coring. The core samples are 51 mm in diameter and up to 3.5 m in length. The system is combined with the Extented Shoe Coring System on the *Chikyu* and best suited for coring of semi-consolidated formation up to about 3400 m from the sea level. Sample autoclave is compatible with Pressure Core Analysis and Transfer System of Geotek Ltd for sub-sampling and analysis under *in-situ* pressure. The analysis includes X-ray CT scan and core logging with P-wave velocity and gamma density. Depressurization provides accurate volume of gas and its sub-sampling.

Hybrid PCS was first tested during the *Chikyu* Exp. 906 at a submarine mud-volcano in the Nankai Trough. A 0.9 m of hydrate rich material was recovered from the summit (water depth: 2000 m) and the intact hydrate structure was observed by X-ray CT scan. Hybrid PCS was also used in the following JOGMEC methane hydrate cruise, resulting in the good recovery of methane hydrate-bearing cores (approx. 69%).

Trace elements in ectomycorrhizae determined by neutron activation analysis

JAROSLAVA KUBROVÁ[12] AND JAN BOROVIČKA[2]*

[1]Institute of Geochemistry, Mineralogy and Mineral Resources, Faculty of Science, Charles University, Albertov 6, CZ-128 43 Prague 2

[2]Nuclear Physic Institute, v.v.i., Academy of Sciences of the Czech Republic, Řež 130, CZ-250 68 Řež near Prague (*correspondence: borovicka@ujf.cas.cz)

In recent years, interest in the biochemical roles of macrofungi in the environment has increased rapidly. Macrofungi play important roles in biogeochemical cycling of chemical elements in the critical zone and many species are known as effective accumulators of toxic metals.

Ectomycorrhizal fungi live in symbiosis with vascular plants. In this reciprocally profitable relationship, the exchange of nutrients occurs in a mutual organ called ectomycorrhiza (pl. *ectomycorrhizae*). Ectomycorrhizae are formed on fine roots of host plants, distributed throughout the soil profile in both organic and mineral horizons, and are composed of plant biomass and fungal hyphae.

As has been repeatedly demonstrated, metal-adapted mycorrhizal fungi play as an effective biological barrier against metal toxicity in trees. Only few data have been published on concentrations of heavy metals in ectomycorrhizae: a relatively high degree of accumulation of Cd, Cu, Pb and Zn was observed from polluted sites in Norway and Poland.

In this study, we have focused on natural concentrations of trace elements in ectomycorrhizae and fine roots of *Picea abies* from pristine sites above gneissic and granitic bedrocks. Trace elements were analyzed using short-term thermal and long-term epithermal neutron activation analysis. The individual fungal species in analyzed ectomycorrhizal tips were determined by DNA sequencing (rDNA ITS molecular marker, semi-nested PCR).

According to our preliminary results, the most striking accumulation was noted in Cd. Its concentrations, however, varied in a wide range (with the highest content of 50 $mg \cdot kg^{-1}$ dry weight). On the other hand, very low concentrations (mostly below 20 $mg \cdot kg^{-1}$ dry weight) were found for Cu.

This research was supported by the projects 535112 (Grant Agency of Charles University in Prague) and P504/11/0484 (Czech Science Foundation).

Depth-dependent links between surface and subsurface as reflected by microbial community structures in limestone aquifers

KIRSTEN KUESEL*, MARTINA HERRMANN, ANNA RUSZNYAK, DENISE AKOB, UTE RISSE-BUHL, SEBASTIAN OPITZ AND KAI-UWE TOTSCHE

Friedrich Schiller University Jena, Jena, Germany
*correspondence: kirsten.kuesel@uni-jena.de

One quarter of the drinking water supply for the world´s population is derived from limestone aquifers, yet they are to date poorly represented in studies focussing on surface-subsurface interactions. Lithoautotrophy might be an important metabolic strategy in these oligotrophic habitats for coupling carbon cycling to the cycling of other elements, e.g. nitrogen, metals or sulphur accumulated from rock weathering. Within the framework of the AquaDiva project we started to explore the influence of surface conditions on the subsurface biosphere. We compared the diversity of microbial communities, some of their key functions, and potential links within food webs in the groundwater of a shallow, suboxic, and a deep, oxygen-rich limestone aquifer located in the Hainich region (Thuringia, Germany) below sites subjected to different land management.

Pyrosequencing of 16S ribosomal RNA revealed a clear separation of the shallow and the deep aquifer based on the structure of the active microbial communities. Results of quantitative PCR targeting *cbbL* and *cbbM* genes encoding RubisCO type I and II suggested that approximately 0.3 to 14 % of the groundwater bacterial population had the genetic potential to fix CO_2 via the Calvin Cycle. Analysis of *cbbM* and *cbbL* transcripts showed that the active CO_2-fixing bacterial communities were dominated by organisms related to *Sulfuricella denitrificans*, *Sideroxydans lithotrophicus*, *Acidithiobacillus sp.*, and *Nitrosomonas ureae* with the latter being more abundant in the deep, oxygen-rich aquifer.

Our data provide strong evidence that chemolitho-autotrophy linked to metabolisms involving sulphur, iron, and nitrogen contributes to the carbon flow in a limestone aquifer. Moreover, analyses of the eukaryotic microbial communities in the groundwater revealed a diverse protist community consisting mainly of bacterial feeders such as ciliates, flagellates and amoeba but also representatives of higher trophic levels such as heliozoa and nematodes, suggesting complex food web interactions. In the light of surface-subsurface interactions, the observed geochemical and microbial patterns point to a depth-dependent impact of surface activities on the aquifer system with the shallow aquifer being more strongly affected by agricultural practices.

Origin of refractory organics in chondrites: An experimental study

M. KUGA[1]*, B. MARTY[1] AND Y. MARROCCHI[1]

[1]CRPG-CNRS, Université de Lorraine, Nancy, France (*mkuga@crpg.cnrs-nancy.fr)

Most organic matter found in chondrites occurs as insoluble organic matter (IOM). This refractory organic material has been studied through a wide range of techniques, which has provided insights in its molecular structure [1-2]. Despite these efforts, the origin, nature of precursors and synthesis of this IOM is still debated [1-3].

This study describes a Miller-Urey inspired experiment [4], designed to produce organics by condensation and polymerisation from gas molecules representative of the protosolar nebula. The experiment consists of a gas mixture ($CO:N_2$:noble gases = 5:0.5:0.5 + traces of H_2O) flowing at ~ 1 mbar in a quartz reactor through an electric discharge. Electrons from the plasma (average energy ~ 2 eV) initiated gas-phase chemistry by dissociating and ionizing gas molecules. At the end of the experiment, dark solids deposited on the reactor wall were recovered for ex-situ analysis by SEM, TEM, py-GC-MS, Raman and FTIR techniques. Noble gases and C, H, N content and isotopes were also measured.

TEM imaging indicates that these solids are mainly composed of amorphous carbon with small domains showing stacks of a few graphene layers. The poorly organized carbon structure was confirmed by Raman spectroscopy. Py-GC-MS, FTIR and elemental analyses indicate an aromatic material composed of small units (1-3 rings). O (carbonyl, phenol) and N (nitrile, heterocycles) functional groups were also identified. Elemental and isotopic fractionation of noble gases, similar to that observed for Q relative to Solar [4] were measured. This preliminary characterization of these synthetic organic material shares similarities with features of IOM.

Both characterization of experimental organics and the trapped noble gases suggest that ionization and dissociation of CO and N_2 in the disk, either by electrons or far-UV photons, could be a possible mechanism for formation of precursors of organics recovered in chondrites. Subsequent reaction and processing of these organic precursors during evolution of the protoplanetary disk could form the complex organic macromolecule we call IOM.

Don't forget the salty soup: Calculations for bulk marine geochemistry and radionuclide geochronology

GERHARD KUHN[1]

[1]Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Am Alten Hafen 26, 27568 Bremerhaven, Germany (gerhard.kuhn@awi.de)

In reference to marine sediments I would like to add to the theme of this session: "Your data are only as good as your standards and methods!" if you remember to correct your analytical data for pore water salt.

Performing sophisticated analytics in marine geochemistry constantly aims at improving the detection limits as well as minimizing the margin of error regarding the precision and accuracy of the method. However, this holds true only if you are genuinely aware of what are you actually analyzing. The normal procedure of sample preparation for marine sediments consists of drying and grinding. Thereafter, these samples are analyzed with regards to their elementary or mineral concentrations. In the best case scenario, sampled water content data are available for calculations of physical properties, such as porosity and dry bulk density, which are both absolutely necessary for the calculation of elementary flux or geochemical budgets. In addition, based on the water content (w, in % of the wet weight) and a normal salinity of 3.5% (or 35 PSU), the amount of salt (s in mass%) in the dry sample can be determined by:

1. Calculating the mass percentage of the salty pore water (w') as: $w'=w\bullet100/96.5$
2. Calculate the salt as: $s=100\bullet(w'-w)/(100-w)$.

This is especially important for samples with water contents above 50% (s=3.6%; w=80% s=14.5%), which are very common in the biogenic opal-rich, diatomaceous sediments of the Southern Ocean around Antarctica. These calculations could be improved by using known salinities, obtained through chlorine determinations, of samples or pore water directly.

Although these calculations are simple, they are often ignored, giving rise to two potential errors, sometimes greater than 14% (relative concentration). The first, greatest and often neglected mistake is a "wrong" net weight - the input is not the pure sediment but sediment + salt. For most ratios of elements, the salt content is irrelevant, but every calculation of concentrations must be corrected accordingly, also radiogenic activity calculations (e.g. ^{210}Pb, ^{230}Th). Geochemists try to avoid the second error by using a salt correction when subtracting the salt related element concentrations directly from the composition analyzed.

Visualization of dynamic changes and the effects of coatings on silver nanoparticles by Surface Enhanced Raman Spectroscopy

M. KÜHN*, N.P. IVLEVA, R. NIESSNER AND T. BAUMANN

Institute of Hydrochemistry, Technische Universität München, 81377 Munich, Germany (*correspondence: melanie.kuehn@tum.de)

A wide variety of applications for engineered nanoparticles leads to increasing emissions into the environment. After entering the aquatic or terrestrial compartment, nanoparticles likely undergo changes caused by weathering or interactions with dissolved substances forming coatings on the particles. Hence, the surface properties will no longer be characterized by the nanoparticle itself, but rather by the properties of the coating material. Stability and transport properties particles will be altered significantly by different coating materials.

Knowledge of the development and stability of coatings is therefore crucial to predict the fate of nanoparticles in the environment. Surface enhanced Raman Spectroscopy (SERS) is a spectroscopic technique, which makes use of the signal enhancement caused by surface plasmon resonance and chemical enhancement typically found at silver nanoparticles and other nanostructured metals (e.g. Au, Cu). Thus the signal of the molecules adsorbed to the nanoparticles will be enhanced significantly and dynamic changes of the materials adsorbed to the particles can be studied. SERS is rather insensitive to dissolved molecules since the electromagnetic SERS enhancement strongly decreases with growing distance ($\sim d^{-12}$). The technique works with little sample preparation and sample volumes suitable for microfluidic experiments and environmental samples.

Citrate reduced and stabilized as well as hydroxylammoniumchloride reduced silver nanoparticles were coated with humic acid, seeweed extract, and polygalacturonic acid. After adding the coating materials, the suspensions were centrifuged to remove excess coating materials. Changes of the pH-value of the solution and an exchange of the coating material were done to study the stability of the coating. Here, Raman spectroscopy gives direct access to the protonation of humic acid on the surface which immediately effects the spectrum.

The characterized nanoparticles were then brought into contact with physically and chemically heterogeneous surfaces to investigate the attachment coefficients and potential blocking. Chemical mapping using Raman microspectroscopy and SERS not only gives access to the spatial distribution of the nanoparticles but also to the chemical environment around the nanoparticles.

Water $H_2{}^{18}O$ isotope studies in the AIDA cloud simulation chamber

B. KUEHNREICH[1], J. LANDSBERG[2], J. HABIG[4], S. WAGNER[1], E. MOYER[3], H. SAATHOFF[4], V. EBERT[1] AND E. KERSTEL[2]

[2]University of Grenoble, France (erik.kerstel@ujf-grenoble.fr)
[3]University of Chicago, USA (moyer@uchicago.edu)
[4]Karlsruhe Institue of Technology, Germany (harald.saathoff@kit.edu)

Isotopic studies can provide additional information on cloud physics, which have a significant impact on global climate. The conventional isotope-selective measurement technique, Isotope Ratio Mass Spectrometry (IRMS) is however not adapted to study dynamic processes such as cloud formation. Laser based measurement techniques offer both high precision and a fast response to follow the cloud formation process in real time. In the recent ISOCLOUD campaign at the AIDA cloud and aerosol chamber, different laser-based instruments were used to jointly obtain information about isotope ratio changes in both the water vapor and ice phases during simulated cloud formation processes. Here we report on two instruments used to quantify the $H_2{}^{18}O/H_2{}^{16}O$ ratio. One of the instruments, ISO-APicT (PTB/KIT), an open path spectrometer based on tunable diode laser absorption spectroscopy (TDLAS) measures the isotopic ratio of the vapor phase. Open-path TDLAS has been successfully applied to in-cloud studies on $H_2{}^{16}O$ [2]. The second instrument based on Optical Feedback Cavity Enhanced Absorption Spectroscopy (OF-CEAS, Grenoble/KIT) extractively samples either total water or, if connected behind a pumped counterflow virtual impactor, the ice phase only. The OF-CEAS technique has already been used in different water isotope studies, including airborne studies [3]. We show a characterization of both instruments, including their time response to sudden isotope ratio changes, as well as preliminary results obtained during ice cloud formation.

Dissolved organic matter composition across a coastal-open ocean gradient in the eastern Pacific Ocean

ELIZABETH B. KUJAWINSKI*[1], WINIFRED JOHNSON[2] AND KRISTA LONGNECKER[1]

[1]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution (WHOI), Woods Hole MA 02543 [*correspondence: ekujawinski@whoi.edu, klongnecker@whoi.edu]

[2]MIT/WHOI Joint Program in Oceanography and Applied Ocean Sciences, Woods Hole, MA 02543 [wjohnson@whoi.edu]

Dissolved organic matter (DOM) in marine systems is an important component of the global carbon cycle whose molecular-level composition is determined by a combination of abiotic and biotic factors related to sources, sinks and transformations. Molecular-level characterization of this heterogeneous mixture has become practical only recently with the advent of ultrahigh resolution mass spectrometry (ESI FT-ICR MS). To date, systematic surveys of DOM composition in the surface and deep oceans are rare, but those conducted to date have highlighted the potential of this tool to identify new marker compounds for different biological processes. Here we examine the DOM composition along Line P in the eastern Pacific Ocean, collected during the interdisciplinary GEOMICS cruise in May 2012. We explore the shifts in DOM composition from the coast to the open ocean as well as down the depth profile at selected locations. We further explore the source of surface DOM through comparison with culture-based investigations of metabolites exuded by phytoplankton and heterotrophic bacteria. Using multivariate statistical tools, we observe significant changes in compound distributions along the primary spatial gradients of Line P, notably an increase in N:C and S:C ratios with depth. We hypothesize that microbial activity is responsible for these changes and leads to the sequestration of N and S in increasingly recalcitrant molecules. These data will provide important chemical contexts for other omics-based analyses undertaken by GEOMICS colleagues and are an integral component of an emerging systems-biology view of the ocean.

New experimental data on TiO_2 solubility in hydrous rhyolite melts: Implications for titanium-in-quartz thermobarometry

K. KULARATNE[1] AND A. AUDÉTAT[1]*

[1]Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany (*correspondence: andreas.audetat@uni-bayreuth.de)

Application of the titanium-in-quartz (TitaniQ) thermobarometer to natural magmas requires estimation of the activity of TiO_2 because most natural magmas are not TiO_2-saturated. However, currently available methods to calculate TiO_2 activities in silicate melts return highly inconsistent results that commonly differ by a factor of up to two, which introduces large uncertainties in the calculated TitaniQ temperatures or pressures. In order to further constrain TiO_2 solubility in silicic melts we conducted experiments at 800-900 °C and 2 kbar in H_2O-saturated haplogranite melts with molar Al/(Na+K)-ratios ranging from 0.81 to 1.2.

Due to the slow diffusivity of Ti in silicate melts at these conditions we developed a new method to determine TiO_2 solubility. In a first step, anhydrous glasses with smooth TiO_2 concentration gradients over several millimeters were produced in an 1 atm high-temperature furnace. Pieces of these glasses were then hydrated for 3 days at 750 °C and 2 kbar at H_2O-saturated conditions in cold-seal pressure vessels, which caused crystallization of rutile in the TiO_2-rich parts of the samples. Finally, the recovered pieces were welded together with untreated ones (plus H_2O) into new Au capsules and were equilibrated at 800-900 °C and 2 kbar for 7 days, after which time the samples were rapidly quenched. In this way, forward and reverse runs could be conducted within single experiments. TiO_2 concentrations measured at the contact between rutile-bearing and rutile-free glass agree well between forward and reverse runs, suggesting that equilibrium was obtained.

An empirical best-fit model to our data predicts TiO_2 solubilities that are similar to those measured by [1], thus validating the TitaniQ model and corresponding tests on natural samples published in [2].

GEMS: Gibbs energy minimization software for geochemical modeling

D. A. KULIK[1]*, S.V. DMYTRIEVA[2], T. WAGNER[3], T. THOENEN[1] AND U. BERNER[1]

[1]Laboratory for Waste Management, Paul Scherrer Institut, 5232 Villigen, Switzerland (*dmitrii.kulik@psi.ch)
[2]Institute of Environmental Geochemistry, Kyiv, Ukraine
[3]Department of Geosciences and Geography, University of Helsinki, Finland

Geochemical modeling is relevant in ore geochemistry, CO_2/radioactive/toxic waste disposal, cosmochemistry, petrology, and hydrogeochemistry. GEMS is an advanced software tool for modeling complex systems that involve non-ideal solid solutions, fluids and aqueous solutions, mineral phases metastability, adsorption, and ion exchange. GEMS (http://gems.web.psi.ch) comprises the GEM-Selektor code; default thermodynamic databases; the GEMS3K kernel code [1,2] included into the GEMSFIT code [3] and available open-source for coupling into reactive transport codes.

The GEM-Selektor v.3 is the main tool for interactive geochemical thermodynamic modeling. It integrates a multi-document graphical user interface with a built-in script interpreter, a database management system, and a context-driven help browser. These features support forward- or inverse modeling tasks, plotting or exporting results, and creating GEMS3K input files. The usage is focused around a *modeling project* database that accumulates all input data and results for a given application. Any project can be shared with others, which greatly facilitates the data exchange in teams. GEMS databases equally support thermochemical and reaction-based formats of standard-state thermodynamic data. Creation of new projects is facilitated by the supplied thermodynamic databases, derived from the PSI/Nagra 12/07 [4] and the SUPCRT92 [5] datasets. Third-party databases for specific application fields are also available in GEMS format.

Current development is focused on adding the kinetics of mineral-aqueous reactions and trace element uptake; implementing sorption models using a concept of linked phase metastability; improving GEM numerical algorithms; moving to industrial NoSQL database format in connection with the general parameter-fitting code GEMSFIT. Our goal is to make GEMS the software of choice for all kinds of geochemical modelling applications.

Southward transport of the Fukushima-derived radiocesium due to the subtropical mode water

Y. KUMAMOTO[1]*, A. MURATA[1], T. KAWANO[1] AND M. AOYAMA[2,]

[1]Japan Agency for Marine-Earth Science and Technology, 2-15 Natsushima-cho, Yokosuka 237-0061, Japan (*correspondence: kumamoto@jamstec.go.jp, murataa@jamstec.go.jp, kawanot@jamstec.go.jp)
[2]Meteorological Research Institute, 1-1 Nagamine, Tsukuba 305-0052, Japan (maoyama@mri-jma.go.jp)

Fukushima-derived Radiocesium

The massive Tohoku earthquake and consequent giant tsunami of March 11, 2011 resulted in releases of radiocesium from the Fukushima Dai-ichi nuclear power plants. The total amount of the radiocesium derived from the direct discharge into the North Pacific Ocean was estimated to be about 4 PBq for Cs-137 [1, 2]. However, that from the atmospheric deposition contains large uncertainty mostly due to the restriction of available data in the open ocean.

Sample Collection and Radiocesium Analysis

We measured the radiocesium in seawaters from surface to 800-m depth at stations along approx.149°E line more than hundreds km away from the plants in the western North Pacific Ocean in January and February 2012. Radiocesium in the seawater was concentrated onto ammonium molybdophosphate and then measured using a gamma-spectrometry with Ge detectors.

Results and Discussion

Cs-134 was found in surface waters at all the stations from 20°N to 42°N. Activity of Cs-134 in the surface mixed layer was highest (~ 20 Bq m^{-3}) in the transition area between the subarctic and subtropical regions, which was due to the direct discharge into the transition area. Below the surface mixed layer Cs-134 activity decreased sharply and was not detected in deeper layers than 400-m depth in the subarctic region and transition area. However, in the subtropical region we observed Cs-134 maxima just below the mixing layer that corresponds to about 25.3 sigma-theta, implying that the Cs-134-rich waters in the transition area have been transported southwardly to the subtropical region due to formation of the subtropical mode water.

Isotopic characterization of winter time aeolian dust over Cape Verde

A. KUMAR[1]*, W. ABOUCHAMI[1,2], S.J.G. GALER[1], K.W. FOMBA[3] AND M.O. ANDREAE[1]

[1]Biogeochemistry Department, Max Planck Institute for Chemistry, Mainz, Germany (*ashwini.kumar@mpic.de)
[2]Westfälische Wilhelms Universität, Institut für Mineralogie, 48149 Münster, Germany
[3]Department of Chemistry, Leibniz Institute for Tropospheric Research, Leipzig, Germany.

Radiogenic isotope tracers are robust tools for tracking dust provenance and atmospheric transport pathways. Recent studies of African sources have shown spatial isotopic heterogeneity locally and on short time scales. High-temporal-resolution isotopic time series are thus essential for resolving seasonal changes in dust provenance. Here, we report Sr, Nd and Pb isotopic compositions of aeolian dust collected during a campaign in late winter (1-20 February 2012) on the island of São Vicente at the Cape Verde Atmospheric Observatory (16.9°N, 24.9°W).

Total suspended particulate (TSP) and PM10 (particulate matter less than 10 μm aerodynamic diameter) were collected on acid-cleaned cellulose filters on a daily basis (~24 hrs). During the dust storm event, from 6-8 February 2012, samples were collected at shorter time intervals (every 5-8 hrs). About 1-20 cm^2 of filter was leached with ultrapure MilliQ water to remove sea-salt Sr and subsequently leached with 0.5 N HBr to extract the anthropogenic Pb and soluble particulate fraction. The remaining silicate fraction was fully dissolved using HF-HNO_3 acids. Isotopic measurements were obtained on all fractions by TIMS; Pb isotope ratios were corrected for instrumental mass bias using a triple spike.

The silicate fractions show consistently more radiogenic Pb and Sr compared to those of the leachates, while Nd isotopic compositions are nearly uniform in both fractions. A shift towards higher Pb isotope ratios is observed during the dust event, followed by a continual decrease. By comparison, Sr and Nd isotopes record small changes, with a noticeable excursion to low values after the dust event. Lead and Nd isotopic compositions of TSP and PM10 are similar during dusty days, in contrast to less-dusty days, suggesting that grain-size fractionation depends on dust loading. The radiogenic isotope time-series of winter dust at Cape Verde pinpoints Northwest Africa as a persistent source of dust, while an additional emission source, with more radiogenic Pb, was active during the dust storm event. These inferences are entirely consistent with analysis of air-mass back-trajectories.

The ocean's biological pump in deep time

LEE R. KUMP

Dept. of Geosciences, Penn State, University Park, PA 16802 USA lkump@psu.edu

The importance of biotic processes in the functioning of the Earth system is perhaps nowhere better demonstrated than by the vertical chemical stratification of the ocean. In the face of physical forces of homogenization, life transforms the ocean into a chemically heterogeneous environment, depleted of nutrients, and through fractionation, ^{12}C in surface waters and enriched at depth. This biological pumping of nutrients to depth occurs with the sinking of organic matter and its remineralization in the deep ocean. The "health" of the ocean's biota has been inferred from reconstructed gradients in $\delta^{13}C$, with strong gradients implying a strong biological pump and loss of the gradient, e.g., during the Cretaceous-Paleogene extinction event implying collapse. However, today, the magnitude of the surface-to-deep gradient is inversely related to the rate of export of organic matter to the deep on a regional basis. Rather, it is the efficiency of the biological pump, the ability of organisms to extract nutrients from upwelling waters before those waters mix physically with waters at depth, that is reflected in the gradients, and the most efficient removal occurs in the oligotrophic gyres. The biological pump appears as a robust feature of ocean ecosystems over geologic time, as evidenced through detailed investigations of the carbon isotope gradients inferred from carbonate rocks deposited during the Paleoproterozoic, end Permian, and throughout the Cenozoic.

Heinrich Holland's big event: The Great Oxidation

LEE R. KUMP[1]

[1]Dept. of Geosciences, Penn State, University Park, PA 16802 USA lkump@psu.edu

Although his research delved into many problems in the geochemistry of Earth, for much of his career H.D. Holland was most passionate about what he termed "the Great Oxidation Event," i.e., the establishment of an oxygen-rich atmosphere in the early Paleoproterozoic. From the early 1960's until his passing in 2012, Holland developed and refined a deep understanding of the geological and theoretical constraints on the chemical composition and evolution of the atmosphere and ocean. This understanding, and the way that only Holland could provide simple yet deep quantification to the problem, is perhaps most elegantly displayed in his 1984 book *The Chemical Evolution of the Atmosphere and Oceans*, the manuscript of which served as my introduction to Holland's work when I was a graduate student studying under lifelong friend and scientific foil to Holland, Robert Garrels. Holland sought to answer the questions of "when did the GOE occur?", "why did it occur?", and "how high oxygen levels rose during the event and subsequently?". For Holland, the answer to "when" has been fairly well constrained by the mass-independent sulfur isotope record of the Paleoproterozoic. The answer to "how high" is rather poorly constrained by geological proxies but approximately 10% of today's level just following the GOE. But the answer of "why" continued to perplex him to the end. A diverse group of researchers has been entrained by Holland's passion for the GOE and will carry the torch forward as the timing, pathway, and mechanisms of the GOE become fully illuminated.

Organic genesis of the sulphur occurences and their relationship with black shales in the Isparta Region, SW, Turkey

MUSTAFA KUMRAL[1] AND MURAT BUDAKOGLU[1]

[1]Istanbul Technical University, Department of Geological Engineering, 34469, Istanbul, TURKEY

The study area is located in the triple conjunction area of the "Isparta Angle" in the Western Taurus region of SW Turkey. Due to Neotectonic evolution of Eastern Mediterranean Region, the study area is a geologically very complicated region. The rock units are divided into two groups as either allocthonous or autochtonous. Tectono-stratigraphically, the allocthonous units are Paleozoic quartzite, black shale, limestone, arkozic sandstone, interlaminated radiolarite and autochtonuous units are Triassic and Jurassic limestones, and Upper Cretaceous ophiolite. Trachyte, trachyandesite, feldspathoidal trachyandesite porphyry, tuff and pumice were formed by volcanism during the Plio-Quaternary. Recent alluvium and slope detritus cover all the rock units.

Sulphur outcrops are exposed in the Keciborlu native sulphur, Uyuzpınar volcanic gases, Darıdere altered volcanic rocks , Darıdere pyrite in volcanic rocks, Yakaören altered volcanic rocks, Kasımlar blackshales , Kesme road native sulphur in blackshales , İbişler village in native sulphur, Afyon volcanics, Kınık Kızıltepe altered volcanic rocks, Gölbaşı realgar, Gölbaşı gypsum and Şarkikaraagac barite occurrences. The most important sulphur deposits are found in volcanic tuff and siltstone - marl - shale interbedded unit which contains an organic matter.

Sulphur may accumulate around recent fumeroles existing and also as massive mineralization. Field studies and sulphur isotope data show that the sulphur originated from the uppercrust and probably comes from organic matter- rich Paleozoic and Triassic sedimentary rocks. The sulphur did not migrate between the Triassic and Pliocene periods. However, Plio-Quaternary volcanism was the cause of mobility of the sulphur and was followed by formation of the secondary sulphur mineralization due to post tectonic geothermal activities. $\delta^{34}S$ values of the samples coincide with other samples from different shallow marine environments. Since the isotope values of the sulphur samples are quite similar to those of organic materials, it can be concluded that the sulphur might have occurred in the same anoxic environment together with petroleum source rocks.

Seismic evidence for the α-β quartz transition beneath Taiwan from Vp/Vs tomography

H. KUO-CHEN[123], F. T. WU[13], D. M. JENKINS[1], J. MECHIE[4], S. W. ROECKER[5], C.-Y. WANG[2] AND B.-S. HUANG[6]

[1]Department of Geological and Environmental Sciences, State University of New York at Binghamton, NY, USA.
[2]Institute of Geophysics, National Central University, Jhongli, Taiwan.
[3]Department of Earth Sciences, University of Southern California, Los Angeles, California, USA.
[4]Deutsches GeoForschungsZentrum – GFZ, Section "Geophysical Deep Sounding", Telegrafenberg, 14473 Potsdam, Germany.
[5]Department of Earth and Environmental Sciences, Rensselaer Polytechnic Institute, New York, USA.
[6]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan.

Knowledge of the rock types and pressure-temperature conditions at crustal depths in an active orogeny is key to understanding the mechanism of mountain building and its associated modern deformation, erosion and earthquakes. Seismic-wave velocities by themselves generally do not have the sensitivity to discriminate one rock type from another or to decipher the P-T conditions at which they exist. But laboratory-measured ratios of velocities of P to S waves (Vp/Vs) have been shown to be effective. Results of 3-D Vp and Vp/Vs tomographic imaging based on dense seismic arrays in the highly seismic environment of Taiwan provides the first detailed Vp/Vs structures of the orogen. The sharp reduction in the observed Vp/Vs ratio in the felsic core of the mountain belts implies that the α-β quartz transition temperature is reached at a mean depth of 24 ± 3 km. The transition temperature is estimated to be 750 ± 25 °C at this depth, yielding an average thermal gradient of 30 ± 3°C/km.

In a young orogen such as Taiwan where an extensive root system is extant and rapid deformation and uplifting are well-documented, the knowledge of the present P/T conditions and materials in the core of the orogen could help in the understanding of the dynamics of mountain building. The presence of abundant quartz in the continental crust is important in localizing deformation; while hydration weakening as one of the conditions in the feedback processes the α-β quartz transition in Taiwan may play the role. In any case, Taiwan is an excellent site where patterns of strain focusing and crustal weakening during the early stages of tectonic deformation can be explored in detail.

Isotopic and Geochemical Constraints on the Origin of Post-Collisional Mafic Tholeiites from Erkilet, Central Anatolia

BİLTAN KÜRKCÜOGLU[1]*, TANYA FURMAN[2], MEGAN PİCKARD[2], ERDAL ŞEN[1], BARRY HANAN[3], PINAR ŞEN[4], KAAN SAYIT[3] AND TEKİN YÜRÜR[1]

[1] Hacettepe University , Dept. of Geological Engineering, 06800 Beytepe-Ankara, Turkey, biltan@hacettepe.edu.tr
[2]Pennsylvania State University, Dept.of Geosciences, University Park, PA,16802,USA furman@psu.edu
[3]San Diego State University, Dept. of Geological Sciences, San Diego, CA, USA, bhanan@mail.sdsu.edu
[4]General Directorate of Mineral Research and Exploration (MTA) Balgat-Ankara, Turkey, pinar.alicisen@gmail.com

Central Anatolia is one of the most interesting region displaying extensive volcanic activity related to post-collisional extension. Besides stratovolcanoes, most monogenetic vents and smaller volcanoes (e.g., Karapınar, Develidağ, Sivas, Erkilet) are characterized by basaltic lavas that may be alkaline or tholeiitic or both. The field and geographical occurrance of Erkilet mafic lavas are generally similar to those observed in the Sivas area some 100 km to the northeast (1). These two volcanic provinces are located along an ancient suture separating the Anatolide-Tauride blocks. Erkilet basalts have incompatible trace element abundances that are enriched overall relative to primitive mantle values, but they lack the unusually high contents of large ion lithophile and light rare earth elements that typify Sivas basalts, Erciyes tholeiites, and products of the regional mantle lithosphere (2). The Erkilet basalts have low Nb-Ta contents (but not Ti, Zr, Hf) that are typical of arc lavas and suggest a contribution from a source area with rutile that remains stable during shallow melting. Their high Ba/Nb (25-36) and La/Nb (~2) values reflect these low Nb contents, and require a source region distinct from that for MORB or Sivas basalts. Low Rb/Sr (~0.01) and moderate Ba/Rb (33-36) values suggest a source with modal amphibole but not phlogopite, consistent with low Tb/Ybn values that indicate melting within the shallow mantle, i.e., above the garnet stability field. The Sr-Nd isotopic signatures of Erkilet mafic lavas are depleted relative to those of Sivas and Erciyes basalts (~0.7037, 0.5128), consistent with their smooth and OIB-like incompatible trace element abundance patterns. Their Pb isotopic values, however, plot within the range of Sivas and Erciyes basalts that are interpreted as including contributions from a mantle lithosphere affected by enrichment in fluid-mobile trace elements during an ancient subduction event (3). These isotopic signatures are consistent with trace element evidence supporting existence of an arc environment during the evolution of the source region for Erkilet basalts. Further work will explore the nature and degree of interaction between identifiable lithospheric and asthenospheric sources during extension-related melting along this ancient suture zone. Single-crystal elastic properties of $Fe_{0.04}Mg_{0.96}SiO_3$ – perovskite at high pressure

A. KURNOSOV *[1], D. M. TROTS [1], T. BOFFA BALLARAN[1], AND D.J. FROST [1]

[1]Bayerisches Geoinstitut, Universität Bayreuth, 95447 Bayreuth, Germany.

Perovskite structured $MgSiO_3$ is widely accepted to be the dominant phase in the Earth's lower mantle where it coexists with ferropericlase. An understanding of the plausible chemical variation of $MgSiO_3$-perovskite (enrichment with Fe/Al) in addition to the consequent effects on density and elastic properties is important in order to understand the origin of seismic velocity anomalies in the lower mantle reported in a number of studies [1-3].

In this study two differently oriented single-crystals of magnesium silicate perovskite containing 4 mol% of the $Fe^{2+}SiO_3$ component [(Mg,Fe)SiO_3] have been studied by means of Brillouin spectroscopy and X-ray diffraction in-situ in diamond anvil cells. Helium was used as the pressure transmitting medium and experiments were performed in the pressure range from 2 to 31 GPa. Ruby pressure markers were used to obtain similar pressure conditions in both diamond anvil cells. The Brillouin spectra were measured in symmetric platelet geometry for each crystal at different orientations in the plane of the platelet. The data at each pressure were fitted for both crystals simultaneously in order to reduce correlations of Cij constants. Using the data from two crystals with different non-specific orientations we were able to obtain all 9 independent Cij elastic constants for orthorhombic symmetry at 8 different pressure points. The orientation matrix and cell parameters for each crystal at every pressure point were refined using in-situ x-ray diffraction measurements. From sample densities obtained from x-ray diffraction data and simultaneous measurements of the adiabatic bulk modulus obtained from Brillouin measurements, it was possible to calculate the absolute pressure for all our experimental points. This approach allowed the elastic properties of (Mg,Fe)SiO_3-perovskite to be determined as a function of primary pressure, i.e. without resort to a secondary pressure standard. This consequently provides a more reliable data set to be compared with seismic data for the lower mantle.

Sedimentary osmium isotopic records of Mediterranean basins

JUNICHIRO KURODA[1]*, FRANCISCO J. JIMENEZ-ESPEJO[12], TATSUO NOZAKI[1] AND KATSUHIKO SUZUKI[1]

[1]Japan Agency for Marine-Earth Science and Technology (JAMSETC), Yokosuka 237-0061, Japan (*correspondance: kurodaj@jamstec.go.jp)
[2]Nagoya University, Nagoya 464-8602, Japan

Mediterranean Sea has experienced an extreme event called Messinian Salinity Crisis (MSC) that represents a formation of gigantic evaporite deposits in deep basins (e.g., Ryan *et al*., 2009). In this study we report sedimentary Os isotopic record of marine sediment cores from four Deep-Sea Drilling Project (DSDP) sites in the Mediterranean Sea (Hsü & Montadert, 1978); DSDP Site 372 in the western Mediterranean (Balearic Basin), DSDP Site 374 in the central Mediterranean (Ionian Basin), and DSDP Sites 375 and 376 in the eastern Mediterranean (Florence Rise). Osmium isotopic ratios of the pre-MSC sediments of Miocene (Burdigalian to Serravallian) in the western Mediterranean are identical to that of the coeval ocean water. In contrast, the pre-MSC sediments (Langhian to early Messinian) in the eastern Mediterranean have significantly low $^{187}Os/^{188}Os$ values than those of the Middle to Late Miocene ocean water. This suggests that Os in the eastern Mediterranean was not fully mixed with that of other seas such as western Mediterranean and North Atlantic, and that the basin isolation has already started before the MSC, probably as early as Middle Miocene. The unradiogenic Os would have been supplied to the eastern Mediterranean by selective weathering of ultramafic rocks in the surrounding ophiolite bodies, which contains high amount of non-radiogenic Os. The isotopic compositions of Os in gypsum samples from all sites are significantly lower than the end-Miocene ocean water values, suggesting isolation of all Messinian basins. Sediments from Pliocene show Os isotopic ratios more radiogenic, and close to the seawater values of Pliocene but slightly less radiogenic, indicating that Os started mixing with global seawater again. We will further discuss possible scenarios about Mediterranean hydrology during the MSC, based on the sedimentary Os isotopic records.

Helium isotopic and concentration variations in a clinopyroxenite vein: Implications for mantle evolution

M.D. KURZ[1], V. LEROUX[1], J.M. WARREN[2], J. CURTICE[1], AND S. NIELSEN[1]

[1]Quissett Campus, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, USA

[2]Geological and Environmental Sciences, Stanford University, 450 Serra Mall, Stanford CA 94305-2115,USA

In an effort to constrain the behavior of noble gases during melting and melt migration in the mantle, we have measured helium concentrations and isotopic compositions in a 10 centimeter transect through a clinopyroxenite vein in the Josephine Ophiolite (Oregon, USA). The 4 cm thick clinopyroxenite is hosted by harzburgite and was sampled with 1-2 millimeter resolution. The vein has ^{4}He concentrations up to 10 times higher than the host harzburgite (5.0 to 9.0 x 10^{-7}, as compared to 3.4 x 10^{-8} to 1.7 x 10^{-7} cc STP/gram). Because the veins are thought to form through mantle melt percolation, the enrichment confirms that helium behaves as an extremely incompatible element. There is a sharp helium concentration contrast at the vein/host interface, suggesting that the concentration variations were produced during vein emplacement, and that clinopyroxene has higher helium storage capacity. Total ^{3}He/^{4}He in the host harzburgite ranges from 6.5 to 7.1 times atmosphere (Ra), in agreement with previous measurements of the area, suggesting that mantle helium isotopic compositions are dominant (Recanati *et al*., 2012). The bulk ^{3}He/^{4}He in the vein varies between 4.5 and 5.3Ra, significantly lower than the harzburgite, reflecting radiogenic production since vein emplacement or slab related fluxes. These data demonstrate that isotopic and concentration variations have been preserved since emplacment at ~ 157 Ma, and that mantle helium isotopic compositions are retained. The isotopic variations suggest that it may be possible to determine Th-U-He vein emplacement ages. The short length scale variations place time limits for diffusion and post-emplacement cooling below the closure temperature. This study may not be representative of the mantle, as the Josephine veins are thought to derive from a sub-arc or back-arc basin setting, and are preserved only by rapid cooling. However, these preliminary data do suggest that preferential melting of this vein type will yield lower ^{3}He/^{4}He than the host mantle, and that vein melting models therefore may not explain elevated values (unradiogenic helium) found in some oceanic basalts.

The Mo-isotopic composition of late Archean Iron Formations

F. KURZWEIL[1]*, M. WILLE[1], R. SCHOENBERG[1] AND M. VAN KRANENDONK[2]

[1]Department of Geoscience, University of Tuebingen, Wilhelmstr. 56, 72074 Tuebingen, Germany, (*correspondence: flokurzweil@hotmail.de)

[2]School of Biological, Earth and Environmental Sciences, University of New South Wales, Kensington, NSW 2052, Australia

The timing of the first appearance of free oxygen in Earth's atmosphere remains highly debated in the literature. The general view places the Great Oxidation Event (GOE) between 2.4 and 2.32 billion years ago (Ga), when oxygen concentrations rose for the first time from 10^{-5} to 10^{-2} of the present atmospheric level. However, some redox-sensitve elements seem to indicate a pre-GOE increase in atmospheric oxygen concentrations at extremely low levels. Mo isotopes and concentrations in late Archean sediments (carbonates and black shales), for example, show δ^{98}Mo values higher than the continental crust average some 100 million years before the GOE. These positive δ^{98}Mo values are attributed to oxidation-reduction processes that per se require oxygenated oceans, in which light Mo is preferentially adsorbed onto Mn- and Fe-(oxyhydr)oxides. The subsequent increase in seawater δ^{98}Mo is thought to be preserved in black shales and carbonates. The occurrence of heavy Mo-isotope signatures in late Archean shales and carbonates infers the presence of a light Mo-reservoir in the sedimentary record. Fe-(oxyhydr)oxides are a possible candidate for such a light Mo reservoir. During early diagenesis they would form Fe-carbonates, -oxides, or -silicates and eventually iron formations (IF's). Consequently, IF's may represent the missing late Archean reservoir for isotopically light Mo.

Here, we tested this hypothesis by measuring Mo isotopes in 2.63 to 2.45 Ga old black shales and IF's of the Pilbara Craton, Australia. Both, black shales and IF's show a similar increase in δ^{98}Mo as time-equivalent shales and carbonates from the Kapvaal craton, South Africa. The youngest IF shows a highly positive δ^{98}Mo value of 1.5‰. Thus, the proposal that IF's represent the reservoir for light Mo is not confirmed by our measurements. The similarity in magnitude and trend of δ^{98}Mo through time suggests a similar removal mechanism of molybdenum from seawater by carbonates, shales and IF's. Furthermore, this observation requires the build-up of a sizeable seawater Mo-reservoir that was linked to more oxidizing conditions before the GOE.

Cathodoluminescence characterization of Norsethite $BaMg(CO_3)_2$

N. KUSANO[1], H. NISHIDO[1], M.MAKIO[2] AND K. NINAGAWA[3]

[1]Department of Biosphere-Geosphere Science, Okayama University of Science, 1-1 Ridai-cho, Okayama 700-0005, Japan (correspondence: nishido@rins.ous.ac.jp)
[2]Graduate School of Social and Cultural studies, Kyushu University, 744 Motooka, Nishi-ku, Fukuoka, 819-0395 Japan
[3]Department of Applied Physics, Okayama University of Science

Anhydrous double salts of $MgCO_3$ and $BaCO_3$ such as norsethite $BaMg(CO_3)_2$ have not been investigated up to date with respect to CL properties, whereas CL of dolomite structurally similar to norsethite has been extensively used to geoscience application. In this study, we have measured CL spectra of norsethite and characterize its CL emission centers.

Norsethite sample from Kremikovtsy, Bulgaria was selected for CL spectral measurements. SEM-CL analysis was conducted using an SEM combined with a grating monochromator to measure CL spectra ranging from 300 to 800 nm in 1 nm steps with a temperature controlled stage from -190 to 250 ºC. All CL spectra were corrected for the total instrumental response.

Norsethit exhibits a red broad band emission in red region between 570 and 770 nm at room temperature. This emission can be assigned to Mn^{2+} as an activator by comparing with the emissions of other carbonates, but with too low concentration of Fe^{2+} as a quencher. A Gaussian curve fitting of the spectra was carried out to clarify emission components in energy units. One emission component at around 1.93 eV (641 nm) was found without the others related to defect centers. Dolomite has two emission components at 1.84 eV (673 nm) for Mn^{2+} activator in Mg site and another component at 2.15 eV (576 nm) for same activator in Ca site. This fact implies that Ba ions with large ionic size might alternate crystal field strength around Mg site in norsethite structure.

An apatite-halogen based probe for fluid-rock interaction events

CHRISTOF KUSEBAUCH[1], TIMM JOHN[1], MARTIN WHITEHOUSE[2] AND ANE ENGVIK[3]

[1]Institute for Mineralogy, Uni Muenster, Germany; c.kusebauch@uni-muenster.de
[2]Swedish Museum of Natural History, Stockholm, Sweden
[3]Norwegian Geological Survey, Trondheim, Norway

Apatite is a typical accessory mineral in many geological settings and is stable over a wide range of pressure and temperature. Natural apatite usually occurs as a solid solution of three end members, i.e. fluor-, hydroxy- and chlorapatite and therefore reflects the F-Cl-OH activity conditions of its formation. Apatite crystallized during fluid-rock interaction can be used as a fluid probe for halogens as it reflects not only F and Cl, but Br and I concentration in the fluid. Also apatite is rather sensitive to changes in fluid composition, undergoing dissolution-precipitation reactions leading to formation of an apatite with a changed composition. This facilitates constraints on the number of fluid events and the characteristics of their potential sources.

Here, we present a halogen concentration and $\delta^{37}Cl$ study of apatite from an alteration sequence from a regional-scale metasomatic event (Bamble Sector, SE Norway). The alteration sequence comprises a complete profile from unreacted to fully altered gabbro, close to a shear zone from which a high salinity fluid pervasively altered the gabbro.

Halogens in apatite, measured in-situ by ion microprobe, show marked diversity. Whereas Br concentrations constantly decrease from the least altered (100-500 ppm) to most altered samples (10-20 ppm), F shows the opposite trend, with a constantly increasing concentration from 40-100 ppm to 2000-12000 ppm. Apatite from the most pristine samples shows low F/Cl ratios and high Br/Cl, while apatite from strongly altered samples is characterized by high F/Cl and low Br/Cl ratios. I/Cl ratios show no correlation with alteration.

Apatite from the pristine gabbro has $\delta^{37}Cl$ values <+0.4‰. With increasing alteration $\delta^{37}Cl$ values increase to as high as +3.5‰. Furthermore, there is a strong correlation between $\delta^{37}Cl$ values and F concentrations within individual apatite crystals.

The observed halogen concentrations and $\delta^{37}Cl$ values of apatite formed during the metasomatic event can be explained by a single fluid event. Characteristics of the fluid are best represented by apatite from highly altered samples (high $\delta^{37}Cl$, high F concentrations). Due to interaction with the gabbro this fluid constantly evolves to lower F concentrations and lower $\delta^{37}Cl$ values.

Ancient mobilisation of radiogenic Pb and Ti during high-grade metamorphism

M.A.KUSIAK[123]* , M.J.WHITEHOUSE[1], S.A.WILDE[2], D.J.DUNKLEY[2], A.A.NEMCHIN[2], R.WIRTH[4] AND K.MARQUARDT[4]

[4]Deutsches GeoForschungsZentrum, GFZ, Potsdam, Germany

Many zircons from early Archaean gneisses in the Napier Complex of East Antarctica, are reversely discordant. High spatial resolution ion microprobe imaging reveals Y and U zonation, characteristic of magmatic zircons, together with a micro-scale patchy distribution of ^{206}Pb and ^{207}Pb that does not correspond to either growth zonation or crystal imperfections. Some of these patches yield ^{207}Pb/^{206}Pb ages >4 Ga, whereas others yield ages younger than the magmatic crystallization age. Zircons from Dallwitz Nunatak record detrital ages between 3.5 Ga and 2.5, whereas those from Gage Ridge define multiple age groups, with concordant data between 3.6 Ga and 3.3 Ga and reversely discordant data that form a distinctive ca. 3.8 Ga population. These oldest zircons are interpreted as xenocrysts, with the age of the protolith being ca. 3.3 Ga or younger. The patchy distribution of Pb is the result of mobilisation of ancient radiogenic Pb, which can lead to reverse discordance [1]; this is independent of the degree of metamictisation, oxygen isotope and REE content of the zircons. Zircons from Mount Sones which show this effect underwent high-grade metamorphism at both ~2.8 Ga and 2.5 Ga, the latter reaching temperatures of >1000°C. It is likely that one or both of these events caused re-mobilisation of Pb. However, the precise mechanism is unclear and further work is in progress in an attempt to constrain this. Importantly, Ti also exhibits a random, patchy distribution in some zircon grains. This has the potential to affect Ti-in-zircon thermometry, with implications for the accurate determination of zircon crystallization temperatures.

Quantitative 18S rDNA analysis using 3rd generation sequencing methods to determine the effects of Modified Circumpolar Deep Water, iron and siderophores on phytoplankton assemblage composition in the Ross Sea

ADAM B. KUSTKA, ASHLEY M. NEW AND BETHAN M. JONES [1]

[1]Rutgers University, Newark, NJ
kustka@andromeda.rutgers.edu

We participated in the SEAFARERS cruise (along with other investigators Hatta, Kohut, Lam, Measures, Milligan and White) in the Ross Sea to test hypotheses regarding the influence of Fe supplied from Modified Circumpolar Deep Water (MCDW) and from putatively accessible and somewhat refractory forms ($FeCl_3$ and Fe-enterobactin) on primary production. Incubation experiments revealed widespread and chronic Fe limitation that was more pronounced in surface waters above Joides Trough than on Pennell Bank. Addition of MCDW did not stimulate growth at any station. Iron supplied as the Fe- catecholate complex enterobactin stimulated bulk chlorophyll production in a station dependent manner, which might be explained by clade-specific differences in Fe-catecholate bioavailability. We developed a quantitative approach to characterize community composition - based on amplification of the v7-v9 regions of 18S rDNA (>500 bp) and single-molecule real-time (SMRT) sequencing - which increased phylogenetic resolution compared to some previous methods. The inclusion of various xenobiotic standards immediately prior to DNA extraction and to PCR amplification allow us to evaluate absolute changes in community composition, facilitating the calculation of clade-specific growth rates under various treatments. To our knowledge, this is the first quantitative application of third generation sequencing methods in marine environments.

Impact of increasing MoO_3 loading on incorporation properties of multi-component borosilicate glass

A. KUTZER[1]*, T. VITOVA[1], K. KVASHNINA[2], T. PRÜßMANN[1], J. ROTHE[1], E. SOBALLA[1], C. ADAM[1], P. KADEN[1], M. A. DENECKE[1], S. WEISENBURGER[1], G. ROTH[1] AND H. GECKEIS[1]

[1]Institute for Nuclear Waste Disposal (INE), KIT, 76021, Karlsruhe, Germany (*correspondence: andrea.kutzer@kit.edu)

[2]European Synchrotron Radiation Facility (ESRF), 38043, Grenoble, France (kristina.kvashnina@esrf.fr)

Mo(VI)-rich residual material remaining after vitrification of high level liquid waste (HLLW) at the 'Karlsruhe Reprocessing Plant' (WAK) site can potentially be immobilized in borosilicate glass for ultimate disposal. Due to its low solubility in borosilicate glass melts, Mo(VI) tends to form molybdate-rich phases during the vitrification process. [1] These phases may crystallize during melt cooling and are able to incorporate radionuclides within their crystal structure. If water soluble alkali molybdates are formed, the release of radioactivity into the environment will be facilitated in case of water intrusion into a deep geological repository. The chemical composition of the formed phases is strongly dependent on the borosilicate glass composition used. Understanding factors favoring the formation of stable crystalline Mo(VI) phases in borosilicate glasses allows development of glass compositions capable of incorporating high Mo loadings, yet avoiding formation of soluble phases.

In this work nuclear waste simulate with varying MoO_3 concentrations vitrified in a multi-component borosilicate glass ([2]) was characterized. Powder X-ray diffraction and Raman spectroscopy studies confirm formation of crystalline $CaMoO_4$ and $BaMoO_4$ phases for MoO_3 concentrations above 4.5 wt%. Observed Mo K-edge high resolution X-ray absorption near edge structure (HR-XANES) spectral changes are correlated to different molybdate environments in the glass depending on the MoO_3 concentration. Fit analyses show that Na^+ cations preferably compensate molybdate charge over Ba^{2+} and Ca^{2+} at low concentrations. ^{29}Si nuclear magnetic resonance (MAS NMR) spectroscopic investigations show a strong impact of the different MoO_3 loadings on the degree of silicon network polymerization of the glass. No evidence for the formation of water soluble crystalline molybdates is found, indicating that the chemical composition of the glass used is favorable for immobilization of Mo-rich nuclear waste with this specific chemical composition.

Correlative imaging of microbial transformations in Nature

M. M. M. KUYPERS

MPI for Marine Microbiology, Bremen, Germany (mkuypers@mpi-bremen.de)

Correlative imaging is widely applied to obtain comprehensive information on the identity, activity and physiology of cells in eukaryotic cell biology. However, in the field of environmental microbiology this method is still little used despite its obvious potential. During the past years substantial progress was made at the MPI for Marine Microbiology (MPI-MM) to establish this method for our field. A particularly powerful approach used in our institute is the use of nano-scale Secondary Ion Mass Spectrometry (nanoSIMS) coupled to stable and radio-isotope labelling experiments to determine single-cell activity in the environment. By combining this approach with Fluorescence in situ Hybridization (FISH) we are able to link the identity of microbial cells in a complex microbial community to their in situ nutrient incorporation, which allows us to calculate cellular uptake rates and directly determine nutrient fluxes. The recent acquisitions of an Environmental Scanning Electron Microscope combined with an EDX system (ESEM/EDX) and a confocal laser Raman microscope coupled with an atomic force microscope provides further elemental, chemical-bond and structural information at a single cell level. I will present results of our correlative imaging studies of complex microbial communities in various marine environments.

[5]Tomsk State University, Tomsk, Russia

Zaisan structural zone refers to traditional auriferous region of East Kazakhstan [1]. This zone includes paleozoic ofiolites and volcanic-sedimentary sequences, those were formed as the result of oblique collision of Kazakhstan and Siberian paleocontinents [2]. Terrigen-carbonate sedimentary sequences are characterized by high contents of gold, but the ore deposits are associated with the introduction of granodiorite-plagiogranite collision magma (Kunush complex, 310-300 Ma). In result of acid magmas and carbonates interaction were formed Carlin-type gold-sulfide jasperoids [3]. This type includes the Suzdal deposit, and a number of promising gold objects (Baibura, Jhaima, etc.)[2]. In the article it is given the characteristic of Baibura ore field. Native gold from this ore field jasperoids is uniform in morphology and geochemical features. The most part of gold granes is of medium and fine dimension, preferably <0.25 mm. Gold granes are not rounded, of yellow color and interstiton, rarely crystal, morphology. Grade of gold indicates the unity of its source and the one-step process of its formation, lying in a narrow range of values 923-959‰. It was indicated the impurity of mercury in amounts up to 0.7%. Presence of mercury confirms ore field belonging to the Carlin-type gold mineralization.

Rare elements of diamond-forming melt chambers formed in the mantle peridotite (estimation with use of experimental K_D at 7.0-8.5 GPa)

KUZYURA A.V.* AND LITVIN YU.A.

Institute of Experimental Mineralogy Russian Academy of Sciences, ul. Ak. Osip'yana, 4 , Chernogolovka, Moscow region, (*correspondence: shushkanova@iem.ac.ru)

Based on the experimental data at 7.0-8.5 GPa [1] rare elements (RE) in the diamond-forming mantle peridotite-carbonatite and eclogite-carbonatite systems are characterized by similar partitioning coefficients (K_D^{RE}) mineral-melt. These values are also closely comparable with those for the silicate and carbonatite melts in equilibrium with mantle silicate minerals [2].

It can be assumed that a chamber of diamond-forming melts was formed witin the host garnet lherzolite mantle when it was affected by a reactive "metasomatic agent» [2, 3]. It is of interest to identify those RE that came to diamond-forming melts with the mantle components, as well as those RE that were infused by the "metasomatic agent".

The contents of RE in diamond-forming carbonatite melt chambers were calculated based on the real content of RE in minerals of peridotite and eclogite parageneses in diamonds and diamond xenoliths of several kimberlite pipes [4-6] and experimental K_D^{RE}. The main contribution of RE in them is made by the mantle component. Parental melt of diamonds and inclusions in them are depleted by medium (Sm, Eu, Gd) and heavy RE (Tb, Dy, Ho, Er, Yb, Lu, Hf), in contrast to primitive peridotite [7]. They are enriched in light (Sc, Rb, Sr, Ba, La, Ce, Pr, Nd) RE and Nb, but their content by 1-2 orders of magnitude lower than in the primitive mantle peridotite. High Sr can be associated with "the metasomatic agent". Mechanisms of replacement reactions of single cerussite $PbCO_3$ crystals by pyromorphite, mimetite and vanadinite

MONIKA KWAŚNIAK-KOMINEK[1] AND MACIEJ MANECKI[1]

[1]AGH – University of Science and Technology, Krakow, Poland (kwasniak@geol.agh.edu.pl)

Formation of thermodynamically stable phases like pyromorphite $Pb_5(PO_4)_3Cl$, mimetite $Pb_5(AsO_4)_3Cl$ and vanadinite $Pb_5(VO_4)_3Cl$ are common in the environment. It is hypothesised here that lead carbonate $PbCO_3$, cerussite, can be readily replaced by polycrystalline lead apatites. This process is analogous to the calcium carbonate – calcium hydroxylapatite system, where such transformation is observed. However, the mechanisms of formation of pyromorphite, mimetite and vanadinite in the presence of cerussite are unknown.

The aim of this study was to experimentally determine the mechanism of the transformation of cerussite to pyromorphite, mimetite and vanadinite and the conditions under with these phases can form. The parameters of the experiments include pH (alkalic or acidic), the presence or absence of chloride ion, and temperature (140 or 5 °C). Experiments were carried out in order to produce partially reacted crystals to provide information about structural and textural relationships between parent and product phases. Cerussite crystals were put into 2M $(NH_4)H_2PO_4$, 2M $(NH_4)H_2VO_4$ or 2M $(NH_4)H_2AsO_4$ to form pyromorphite, vanadinite and mimetite, respectively.

X-Ray powder diffraction was used to identify and characterize the reaction products. Microstructural relationship between parent and product phases were determined by scanning electron microscopy (SEM-EDS) and electron microprobe analysis.

In every case single cerussite crystal were replaced by pollycrystaline pyromorphite, mimetite and vanadinite through dissolution of $PbCO_3$ followed by precipitation of lead apatite. In acidic conditions formation of shultenite $PbHAsO_4$ or phospho-shultenite $PbHPO_4$ were also observed. Products of the reaction in every case are porous, allowing fluid transport to the reaction interface. At all temperatures the product phase and its morphology are the same. Interface coupled dissolution-precipitation mechanisms are confirmed by the textural relationships.

This project is supported by Polish NCN grant No 2011/01/M/ST10/06999.

Vertical lithofacies changes of the Jeonchong tuff cone in the Miocene Eoil Basin, SE Korea: Implication of a series of eruptive and depositional processes

C.W. KWON

Geological Research Division, Korea Institute of Geosciences and Mineral Resource, SE Korea (cwkwon@kigam.re.kr)

The Miocene Eoil Basin, SE Korea, contains abundant volcanic and volcaniclastic deposits because of active volcanism during basin formation. The Jeonchon tuff cone refers to an about 25 m-thick sequence of basaltic lapilli tuff in the central part of the basin. The tuff cone is underlain by pahoehoe lavas (the Lower Eoil Basalt), lacustrine mudstone, and mouth-bar sandstone in ascending order, indicating hydrovolcanic eruption in a shallow lake. It is composed of seven sedimentary facies: massive tuff breccia (TBm), crudely stratified lapilli tuff (LTb), inverse-to-normally graded lapilli tuff (LTin), normally graded lapilli tuff (LTn), massive coarse tuff ($_C$Tm) and massive medium to fine tuff ($_M$Tm & $_F$Tm). It can be divided into five depositional units (unit I to V in ascending order) based on facies characteristics and componentry. Unit I, about 4 m thick, consists of quartz-bearing massive tuffs ($_M$Tm & $_F$Tm), suggesting contact-surface steam explosivity within mouth-bar sand. Unit II, about 1.5 m thick, consists of graded lapilli tuffs (LTin & LTn) with abundant accidental basalt clasts, suggesting bulk-interaction steam explosivity within the Lower Eoil Basalt and deposition from pyroclastic surges and ballistic fallouts of basalt clasts. Unit III consists of tuff breccia (TBm; about 3.5 m thick) and overlying stratified lapilli tuff (LTb; about 0.5 m thick), which are interpreted to have resulted from debris flows and Surtseyan fallouts associated with vent-widening explosions. Unit IV, 0.8 m-thick and composed of massive coarse tuff ($_C$Tm), suggests remobilization of pyroclasts by debris flows during volcanic quiescence. Crudely stratified lapilli tuff (LTb) of Unit V, about 15 m thick, is interpreted to have formed by sustained Surtseyan finger jets without further excavation of the substrate. The vertical lithofacies changes suggest that the Jeonchon tuff cone experienced a series of eruptive and depositional processes during growth because of the changes in depositional environments, types of the substrate (sand vs. lava), and vent geometry.

Geochemical characteristics and microbial community composition of toxic metal-rich sediments contaminated from mine tailings

MAN JAE KWON[1], BAKNOON HAM[1], YUNHO HWANG[1], JAEYOUNG CHOI[1], MAXIM BOYANOV[2], KEN KEMNER[2], EDWARD O'LOUGHLIN[2] AND JUNG-SEOK YANG[1]

[1]Korea Institute of Science and Technology (KIST) – Gangneung Institute, Gangneung 210-340 S. Korea, mkwon@kist.re.kr

[2]Biosciences Division, Argonne National Laboratory, Lemont, IL 60439 USA

The effects of extreme geochemical conditions on microbial community composition were investigated using two distinct sets of sediment samples collected near weathered mine tailings from the Songcheon Au-Ag mine, Korea. One set (SCH) was gray-colored and showed extraordinary geochemical characteristics: As (6.7-11.5%), Pb (1.5-2.1%), Zn (0.1-0.2%), and pH (3.1-3.5). The other set (SCL) was brown-colored and had As (0.3-1.2%), Pb (0.02-0.22%), and Zn (0.01-0.02%) at pH of 2.5-3.1. Terminal Restriction Fragment Length Polymorphism revealed that the bacteiral communities in SCL were more diverse than those in SCH. The clones identified in SCL were closely related to acidophilic bacteria within the genus of *Acidobacterium* (18%), *Acidomicrobineae* (14%), and *Leptospirillum* (10%). Most clones in SCH were closely related to *Methylobacterium* (79%) and *Ralstonia* (19%), both of which are well-known metal-resistant bacteria. The archaeal community in SCL was relatively simple: *Thermogymnomonas* (32%) and unclassified Euryachaeota (48%). No archaeal community was detected in SCH sediments. Although total As was extremely high, over 95% of it was in the form of scorodite ($FeAsO_4{\cdot}2H_2O$), as confirmed by XAFS analysis. Water-soluble As was only ~208 and ~0.06 ppm in SCH and SCL, respectively, which is not known to be toxic to bacteria; As(V) as much as 1000-1300 ppm did not influence bacterial growth. Because As was present in an oxidized and stable form it is likely that other metals released from the sediment were responsible for the differences in microbial community structure (e.g., water soluble Zn was ~234 and ~6.8 ppm in SCH ad SCL, repectively).

Titanite Geochronology by LA-ICPMS: Advantages and Future Objectives

ANDREW R.C. KYLANDER-CLARK, BRADLEY R. HACKER, PAUL R. RENNE AND MICHAEL A. STEARNS[123]

[1]University of California, Santa Barbara, 93106-9630

[2]Berkeley Geochron Center, Berkeley, CA 94709

*correspondence: kylander@geol.ucsb.edu

Titanite has been dated by U/Pb TIMS for many years, but the application of this technique has been tempered by the recognition that titanite in single samples can yield a range of dates, and moreover, titanite dating by TIMS relies on either time/cost-intensive analysis of multiple titanite fractions, or on Pb measurement of an assumed-coeval low-U/Pb phase, such as feldspar, to establish an isochron. One of the great strengths of LA-ICPMS dating is rapid throughput; by analyzing many spots with differing concentrations of common Pb, isochrons can be established from titanite analyses alone, in a fraction of the time it takes for a single TIMS analysis. Furthermore, measuring composition at the same time—in this case laser ablation split-stream ICP petrochronology (LASS)—allows one to discriminate among titanite populations.

Here, we present two examples of the strength of the LASS technique on titanite: 1) grains from the Western Gneiss Region in Norway that (re)crystallized during exhumation, and 2) those from volcanic tuffs at/near the Cretaceous–Tertiary boundary. Both cases yield dates equivalent to those produced by conventional techniques. For the Norwegian samples, younger grains contain elevated Al, Ce/Ce*, and Eu/Eu* and depleted Fe,Ta,Zr,Hf, and LREE compared to the inherited portions of the grain, exemplifying the opportunities this techinique offers with respect to understanding petrologic/geochemical systematics of metamorphic/igneous processes.

Although natural standards exist with little variability in age, the incorporation of variable amounts of common Pb results in variable $^{23X}U/^{20X}Pb$ ratios, thus negating the use of that material as a primary reference material. New standards (natural or synthetic) and/or data processing methods are required to enhance the effectiveness of this technique in the future.

Novel applications of geochemistry to mineral exploration and remediation

KURT KYSER

Department of Geological Science and Geological Engineering, Queen's University, Canada (kyser@geol.queensu.ca)

Mineral deposits are in fact geochemical anomalies, and as such their detection and assessment of their impact on the environment should be facilitated using geochemical techniques. Although geochemistry has been used directly in the discovery of mineral deposits and more indirectly in shaping deposit models, much of the novel application of geochemistry is in formulating effective exploration and remediation strategies. Areas where recent research, application and policy intersect in the extraction of metals from the geosphere include: (1) the use of element mobility in the near surface environment to detect deposits at depth, (2) revealing element distributions in and around deposits to adequately assess the total chemical environment associated with the deposit and to refine effective and relatively beneign extraction and waste disposal techniques, (3) understand the effects of both macro- and micro-environments on element mobility across the geosphere-biosphere interface to define appropriate remediation techniques associated with the extraction of diverse commodities. Research, both pure and applied, play a fundamental role in providing the techniques for these areas, but this is driven largely by what industry requires, which is driven largely by policies formulated in government agencies. Research in applied geochemistry can add value to exploration and remediation stratigies provided the results are adequately conveyed to the appropriate individuals in both industry and government and there is a perceived need to develop new and novel techniques by all concerned. For example, the application of isotope tracing to elucidate the processes by which various elements move through the geosphere and into the biosphere is a novel area of research with boundless potential for exploration and remediation. This area, which is largely driven by those in research, is an evolving one wherein the historically high costs, slow turnover and general mystic are being overcome by a concerted need by all involved to better understand the processes mining has on the total environment.

Non-chondritic sulfur isotope composition of the Earth's mantle: Implications on planetary differentiation

LABIDI J.[1], CARTIGNY P.[1] AND MOREIRA M.[2]

[1]Stable isotope Laboratory, IPGP, Paris, France. (*labidi@ipgp.fr)
[2]Geochemistry and Cosmochemistry Laboratory, IPGP, Paris, France

Sulfur (S) is a siderophile and moderately volatile element. Its abundance and isotope composition in accessible parts of the terrestrial mantle can therefore provide constraints on both accretion and planetary differentiation. We have investigated the $^{34}S/^{32}S$ ratio of 23 glasses dredged on the south-Atlantic ridge between 40° and 55°S. Several of the typical mantle end-members feed the source mantle of the two plumes and analyzed samples have been chosen to reflect this geochemical variability, hence offering a unique opportunity to address $^{34}S/^{32}S$ variations with respect to various mantle heterogeneities.

We show that south-Atlantic MORB display $^{34}S/^{32}S$ ratios directly correlated to $^{87}Sr/^{86}Sr$ and $^{143}Nd/^{144}Nd$. These isotope trends are compatible with a binary mixing between two extreme components : The depleted mantle, having a $\delta^{34}S$ of -1.28±0.33‰, and a S-rich component with a $\delta^{34}S > 1.05 \pm 0.10$‰, that we infer to be subducted sediments (i.e. neither sub-continental lithospheric mantle nor lower continental crust) variably distributed in the sources of two local plumes. Our dataset imply that substantial amount of S survives slab devolatilization and thereby support efficient recycling of S via sediment subduction.

As the chondritic average $\delta^{34}S$ is constrained at +0.04 ± 0.31‰[1,2], the negative value of depleted end-member consistently illustrates a non-chondritic feature. Furthermore, the amount and isotope composition of surficial S cannot balance out the depleted mantle to a chondritic value. Such distinctly non-chondritic $^{34}S/^{32}S$ ratio for the depleted mantle can only be reconciled with a core-mantle differentiation record, implying that most of the sulfur and elements of comparable volatilities have been delivered to the Earth before such planetary differentiation event.

(*correspondence: jlabonte@bigelow.org, rstepanauskas@bigelow.org)

Recent discoveries suggest that subsurface microorganisms constitute a significant fraction of the living biomass on our planet, but little is known so far about their life histories and interactions. Here, we employed single cell genomics to obtain cultivation-independent information about *in situ* bacteria-phage interactions in 0.6 to 3.8 km deep fractures in the 2.9 byr old Witwaterstrand Basin, South Africa.

Genomic sequencing of 17 single amplified genomes (SAGs) revealed viral sequences in nine SAGs, suggesting that viral infections are prevalent in these isolated communities. We recovered partial genomes of Mu-like transposable phages, retrons, and lambda-like prophages from SAGs of Firmicutes *Desulforudis* and *Thermincola*, which are known to be indigenous to deep subsurface environments. The discovered phages, while sharing some conserved genes, are highly divergent from known viruses.

Our results suggest prevalence of lysogenic host-phage systems in the studied subsurface fractures, which may be more sustainable in these extremely isolated and simple microbial communities, as compared to lytic infections. The types and genome content of the discovered phages also suggest involvement in host DNA shuffling, which may be an important mechanism for deep subsurface microbial evolution.

Core cooling and lower mantle crystallisation in the thermal evolution of the Earth

S. LABROSSE[1], J. W. HERNLUND[2], N. COLTICE[1]

[1]Lab. Géologie Lyon, ENS de Lyon, Univ. Lyon-1, CNRS, France (stephane.labrosse@ens-lyon.fr)
[2]Department of Earth and Planetary Science, University of California, Berkeley, California 94720, USA

Models for the thermal evolution of the Earth have traditionnally assumed that the core cools at the same pace as the mantle or more slowly. The latter assumption comes from the idea that the heat flow across the core mantle boundary (CMB) is low, of order 3TW, and given by the buoyancy flux sustaining hotspot swells. The present heat imbalance of the Earth, quantified by the Urey number being lower than 0.5, and the positive feedback between mantle temperature and heat flow through temperature-dependence of the viscosity, typically lead to a thermal catastrophe less than 2 Byr ago in standard parameterised models of thermal evolution. This has pushed many authors to propose non-classical scalings of heat transfer by mantle convection.

The thermal conductivity of core material has been recently revised to values larger than 90W/m/K at the CMB and increasing with depth in the core [1]. With such values, the low CMB heat flow assumed previously would not sustain a geodynamo, even taking into account compositionnal buoyancy released upon inner core growth. A CMB heat flow larger than 10 TW is required, which can effectively solve the thermal evolution for the Earth. Indeed, when considering the CMB heat flow as a source for the mantle, its effective Urey number is in excess of 0.65, a value much easier to accommodate with standard scalings.

For the low amount of potasium usually considered as possible in the core, a large CMB heat flow implies a large cooling rate, more than 750 K in 4.5 Gyr. Dense partially molten regions at the bottom of the mantle provide the best explanations to the seismic observations of ultra low velocity zones. The large cooling of the core implies a thicker molten lowermost mantle in the past [2]. The slow fractionnal crystallisation of this basal magma ocean brings in latent heat, helping to solve the thermal evolution problem. In addition, assuming that heat producing elements partition in the melt at the pressure of the lowermost mantle, a significant fraction of the Earth budget can be stored there.

Modes of formation of the basal magma ocean

S. LABROSSE[1], J. W. HERNLUND[2] AND N. COLTICE[1]

[1]Lab. Géologie Lyon, ENS de Lyon, Univ. Lyon-1, CNRS, France (stephane.labrosse@ens-lyon.fr)
[2]Department of Earth and Planetary Science, University of California, Berkeley, California 94720, USA

The classical view of magma ocean crystallization is based on the assumption that the liquidus gradient is steeper than the isentropic temperature gradient, leading to crystallisation from the bottom upward. In addition, it was usually assumed that the solid thereby formed is denser than the liquid. Recent results on the phase diagram of deep mantle minerals prompt a reconsideration of these assumptions.

Some recent studies propose that crystallization of the magma ocean could start from mid-mantle and produce neutrally buoyant crystals at the same depth. This would naturally lead to a surface magma ocean and a basal magma ocean. On the other hand, some recent results [1] suggest that crystallisation should start at the bottom of the mantle and make dense solids. However, the gradual enrichment of the solid in Fe by fractional crystallization causes an unstable density increase with height and eventually overturn following a Rayleigh-Taylor instability. This would bring down highly fusible Fe-rich solid and the gravitational energy released by viscous friction would remelt it. The Fe-rich formed liquid would then be dense enough to remain at the bottom of the mantle as a basal magma ocean.

Alternatively, the formation of the core could result in a largely superheated core that would melt the mantle from below. The liquid produced could be less dense than the solid despite being enriched in iron. Its rise and subsequent freezing would be a means of rapidly transporting core superheat to the mantle as well as producing an unstably stratified solid mantle whose overturn would also create a basal magma ocean.

We explored quantitatively the outcome of these different scenarios in terms of the thickness of the basal magma ocean produced and the implied geochemical signatures, in particular regarding rare gases [2].

A new database for Nd isotopes in marine environments

F. LACAN[1], K.TACHIKAWA[2] AND NEOSYMPA MEMBERS

[1] LEGOS (CNES/CNRS/IRD/University of Toulouse), 14 av. Edouard Belin, 31400, Toulouse, France, francois.lacan@legos.obs-mip.fr

[2] CEREGE, UM 34 Aix-Marseille Université-CNRS (UMR 7330), Europole de l'Arbois, BP80 13545 Aix-en-Provece, France, kazuyo@cerege.fr

Neodymium isotopic ratios in seawater have been used as a tracer of ocean circulation, continental weathering and exchange processes between dissolved and particulate phases. Over the recent years, the interest in this tracer has been growing with improvement of our knowledge on its behaviour in the modern ocean, thanks to GEOTRACES programme, and identification of archives that can preserve seawater Nd isotopic signatures. In the framework of the French INSU-LEFE project NEOSYMPA (Workshop NEOdymium isotopes in marine environments: SYnergy between Modern, Modelling and PAleo communities), we have updated a database for the available Nd isotopic data in the ocean, and compiled ε_{Nd} values for sedimentary oxyhydroxide coatings, foraminiferal tests, deep-sea corals and fish teeth/debris from the Holocene period (<10 ka). The objective of the study was to update the database of seawater-Nd isotopic ratios, to assess relationships with other more conventional water mass tracers, and to evaluate how well the marine archives could record seawater isotopic ε_{Nd} signatures. Based on the observed relationships between seawater Nd isotopic compositions, salinity and dissolved silica concentrations, we demonstrate that the bottom water Nd isotopic signatures in the Arctic and Nordic Seas and the Bay of Bengal are decoupled from the general trend defined between the North Atlantic and the Pacific, which suggests the importance of local dissolved-particulate interaction. Although seawater and archive samples were not systematically collected at the same sites, the general relationship observed between bottom/deepwater (> 2500 m) Nd isotopic ratios and dissolved silica concentrations allows us to evaluate the reliability of the ε_{Nd} values extracted from the archives. The marine archives generally show Nd isotopic ratios that agree well with estimated seawater values. We will discuss a few cases when they do not.

[2]Geological Survey of Norway, P.O. Box 6315 Sluppen, N-7491 Trondheim, Norway

[3]Geological Survey of Finland, P.O. Box 96, FI-02151 Espoo, Finland

The GEMAS Project (Geochemical Mapping of Agricultural and Grazing Land Soil in Europe) resulted in a large coherent data set displaying baseline levels of elements in agricultural and grazing land soil, on both a European and a regional scale. The geochemical mapping of agricultural and grazing land soil in Norway, Sweden and Finland provides an exceptional opportunity to demonstrate regional geochemical trends in arable soil. When looking at the European data set as a whole, Norway, Sweden and Finland stand out as geochemically distinct, mainly due to the old bedrock and the extent of the last glaciation, and they were thus considered valuable for a study as a separate entity.

The interpretation of the elemental maps and statistics identified several groups of factors influencing the observed trends in the geochemical patterns of Norway, Sweden and Finland, with the most important factors being bedrock geology, the presence of ore deposits, the soil type and its properties, and climate. Anthropogenic impact on soils appears to have a minor influence on the soil geochemistry of both agricultural and grazing land. In mining regions, with the natural signal from the mineralisation, it is often difficult to discriminate between the original anomaly and any anthropogenic contamination.

The results of this survey are available for a public and can be used by both local authorities and research groups.

Nucleation and growth of chrysotile nanotubes: complementary insight from macroscopic to nanoscopic measurements

R. LAFAY[1], G. MONTES-HERNANDEZ[1] AND E. JANOTS[1]

[1]ISTERRE,University of Grenoble I and CNRS, BP 53, 38041 Grenoble Cedex 9, France (romain.lafay@ujf-grenoble.fr)

Chrysotile is one of the most studied asbestos mineral but rare studies have focussed on the nucleation and growth processes of chrysotile because batch (or discontinuous) reactors are generally used. However, various questions still remain unanswered concerning their formation in natural systems as well as their production at laboratory and industrial scales

In the present study [1], we report new insights on the nucleation and growth processes of chrysotile nanotubes [1] by using semi-continuous experiments (i.e. sampling of reacting suspension with time). From macroscopic (N_2 sorption/desorption isotherms, X-ray diffraction, infrared spectroscopy, Thermogravimetric analyses) to microscopic (FESEM, TEM) characterization, three main reaction steps were identified for chrysotile nucleation and growth at 300°C: (1) proto-serpentine precursor formation in the first 2 hours of reaction, accompanied by brucite and residual silica gel, (2) spontaneous nucleation and growth of chrysotile between about 3 and 8h of reaction via a progressive dissolution of proto-serpentine, brucite and residual silica gel and, (3) Ostwald ripening growth of chrysotile from 8 to 30h of reaction as attested by specific surface area measurements and FESEM and TEM observations. Complementary results from batch experiments have confirmed a significant influence of temperature on kinetics of chrysotile formation. Moreover, Si/Mg ratio and molality have been experienced to better characterize the stability field of chrysotile.

Subsurface mineral weathering in transient layers of permafrost in the Canadian High Arctic

M.J. LAFRENIÈRE[1], S. MONTROSS[1], J. HOLLOWAY[1] AND S.F. LAMOUREUX [1]

[1]Department of Geography, Queen's University, Kingston ON Canada, melissa.lafreniere@queensu.ca

Chemical weathering in high latitude regions has largely been dismissed as insignificant, as frozen soils limit weathering reaction rates for more than 8 months a year, and also the movement of weathered products within the soil profile. We present evidence that subsurface mineral weathering in the transient layers of permafrost soils results in the formation and subsequent ejection of authigenic clay, onto the surface.

Hundreds of active and dormant mud ejection features were witnessed and mapped during the summers of 2011 and 2012, on Melville Island, Nunavut, in the Canadian High Arctic. We measured the chemical composition of aqueous and mineral solid phases in material ejected from active features in order to determine the source of material and processess responsible for their formation.

Fluids from these mud ejections are enriched in nutrients (dissolved nitrogen and organic carbon) and trace metals. Stable isotope ratios of water extracted from the mud indicates that water is not from precipitation or surface runoff and is likely from thawed permafrost, or water stored in the transient layer over several melt seasons. Bulk mineralogy, and trace metal and major ion ratios of fluids and mineral solids indicate subsurface chemical weathering reactions are occuring at near freezing temperatures in the permafrost transient layer.

The results show that the material and solutions delivered to the ground surface are the products of extensive subsurface weathering of siliciclastic minerals to authigenic clays. These mud ejection features represent a mechanism that delivers fine grained material rich in dissolved metals and nutrients to the surface, where they are subject to mobilization and delivery to terrestrial and aquatic ecosystems.

New geochronological constraints on the Ruili Metamorphic Belt in western Yunnan, China

C.K. LAI[1*], KHIN ZAW[1] AND S. MEFFRE[1]

[1] ARC Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Tasmania, Australia (*correspondance: chunkitl@utas.edu.au)

The Ruili Metamorphic Belt is located in westernmost Yunnan near the Chinese–Myanmar border. The belt trends NE–SW and comprises mainly augen gneiss, two-mica schist, and plagioclase amphibolite, with various generations of (meta)-granitoids. The Ruili Metamorphic Belt is located close to the Sibumasu-West Burma suture and may extend into the Mogok Metamorphic Belt in NE Myanmar, which hosts rich orogenic sediment-hosted gold and gemstone (e.g., ruby, sapphire) natural resources [1,2]. However, no regional geological correlation between these two belts has been attempted. The new U-Pb zircon age data reported here suggest a complex tectonic history for the belt, with at least four major magmatic/metamorphic phases, as follows:

1. Early Cretaceous (ca. 125-116 Ma);
2. Late Cretaceous (ca. 70-68 Ma);
3. Late Palaeocene (ca. 58 Ma);
4. Eocene (ca. 35-49 Ma).

When compared to the Mogok Metamorphic Belt in Myanmar [1-4], the Jurassic (ca. 170 Ma) and Late Oligocene-Miocene (ca. 20-25 Ma) magmatic/ metamorphic events there have not yet been found in the Ruili Metamorphic Belt, whereas Late Cretaceous metamorphism has not yet been documented in the Mogok Metamorphic Belt. Much more data will be required to clarify their heating and exhumation history and regional tectonic relations between these two belts.

(*correspondence: yi-chen.lai@erdw.ethz.ch)

As one of the most abundant constituent elements, magnesium may have the potential of providing information on the initial composition of primordial building blocks of planetary bodies, especially the processes that fractionate isotope compositions during planetary accretion and differentiation can be studied by comparing the Mg isotope composition of the Earth and meteorites. The dominant reservoir of Mg for the bulk silicate Earth is the mantle (> 99%). This makes it possible to attain a representative samples of the bulk Earth by selecting samples that best representing the Earth's mantle. Here, we present high precision Mg isotope data (<0.03 ‰ on δ^{26}Mg based on long-term analyses of geological reference peridotite, JP-1, n=17) of tectonically emplaced peridotite massifs to avoid diffusive perturbation observed on small mantle xenoliths, which we compare with bulk chondrites, chondrules and CAIs from CV chondrites. More than 10 repeat measurements of the Mg isotope ratios on small amount of samples were obtained to reduce standard error of the determinations and gain a statistically meaningful comparison between bulk chondrites, peridotites, chondrules and CAIs. The Mg isotope data of peridotites fall within a narrow range of δ^{26}Mg values and give mean values of -0.23 ± 0.04‰. However, there is a relatively large range of δ^{26}Mg values in analysed chondrules and CAIs. The Mg isotope data of carbonaceous chondrites are slightly lighter than the terrestrial peridotites. The inconsistent Mg stable isotopic composition between the Earth and carbonaceous chondrites, and hence the possibility that the Earth consists of non-carbonaceous-chondritic Mg, has important implications for Earth's bulk composition and primordial building material of the Earth.

Role of polysaccharides in calcite (re)crystallisation

L.Z. LAKSHTANOV[1,2] AND S.L.S. STIPP[1]

[1]Nano-Science, Department of Chemistry, University of Copenhagen, Copenhagen Ø, Denmark (ll@nano.ku.dk)
[2]Institute of Experimental Mineralogy RAS, Chernogolovka, Russia

Polysaccharides are often suspected for inhibiting chalk recrystallisation. Well known is the dual role of polymers in crystallisation control. They act as inhibitors when free in the solution, but when immobilized at surfaces, they can promote mineralization. This duality is shown in [1] where calcite growth, initially inhibited by alginate, resumed after alginate immobilization at the surface. Independent of supersaturation, induction time for resuming calcite growth drastically increases (Fig.1) when adsorbed concentration approaches

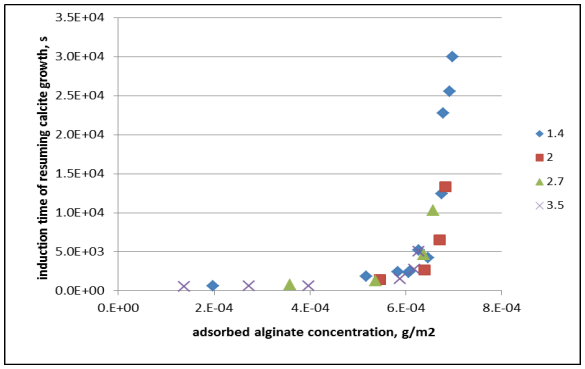

Figure 1. Induction time for calcite growth to resume after inhibition as a function of adsorbed alginate concentration for a series of solution supersaturations.

its maximum 7.5E-4 g/m^2. At maximal adsorption, alginate can no longer serve as a good template for calcite overgrowth. Alginate molecules spread and arrange in flat positions at the surface, where all their carboxylic groups are occupied in binding on Ca^{2+} that is part of the mineral structure, thus retarding ion transport to the surface. Under these conditions, diffusion becomes rate determining for calcite growth. Because of extremely low supersaturation, this is not the case when alginate inhibits calcite recrystallisation and the overall process proceeds in the surface kinetics range. This is the reason why the relative inhibition of calcite recrystallisation is much lower than that of calcite precipitation.

Direct Measurements of Isotopic Fractionation Factors of Water Vapor over Ice for Temperatures below 235 K

KARA LAMB[1*], BEN CLOUSER[1], LASZLO SARKOZY[1], ERIC STUTZ[1], BENJAMIN KÜHNREICH[2], JANEK LANDSBERG[3], JAN HABIG[4], NARUKI HIRANUMA[4], STEVEN WAGNER[2], VOLKER EBERT[5], ERIK KERSTEL[3], OTTMAR MÖHLER[4], HARALD SAATHOFF[4] AND ELISABETH MOYER[1]

[1]Department of the Geophysical Sciences, University of Chicago, Chicago, IL, USA (*correspondence: karalamb@uchicago.edu)
[2]Center of Smart Interfaces, Technische Universität Darmstadt, Darmstadt, Germany
[3]J. Fourier Laboratoire Interdisciplinaire de Physique, University of Grenoble, Grenoble, France
[4]Institute for Meterology and Climate Research, KIT, Karlsruhe, Germany
[5]Physikalisch-Technische Bundesanstalt, Braunschweig, Germany

The use of the isotopic composition of water vapor as a tracer for convective and microphysical processes is complicated by the fact that isotopic fractionation factors have not previously been directly measured at the temperatures characteristic of much of the upper troposphere (< 235 K). Instead, fractionation factor values used in models are extrapolated from measurements made at higher temperatures [1, 2]. We report on the first direct determination of the equilibrium fractionation of HDO/H2O between water vapor and ice at temperatures below 233 K, obtained during the ISOCLOUD measurement campaign at the AIDA cloud and aerosol chamber. The ISOCLOUD campaign involved a series of adiabatic expansion experiments over a range of temperatures between 190 and 233 K, during which measurements were made of water vapor and total water (vapor + ice) and their isotopic compositions. Modeling of vapor sources, sinks and ice cloud formation during the expansion experiments then allowed determination of the degree of preferential condensation of the heavier isotopologues.

The Nd isotopic composition of seawater is widely used as a tracer for ocean circulation, as each individual water mass is tagged with a characteristic Nd isotope fingerprint. The reconstruction of past water mass configurations and ocean circulation are useful to understand the role of the ocean in past climate change and hence comprehend the future evolution of climate. Even though the Nd isotopic composition is often assumed to be an ideal ocean circulation tracer, our understanding of the modern cycle of Nd in the ocean is still poor. Indeed, while the continents are assumed to be the major source of Nd in the ocean, it is not yet clear how exactly water masses acquire their Nd isotopic composition.

The goal of the present study is to investigate whether Nd isotopes in seawater behave conservatively along the flow path of North Atlantic Deep Water. The samples measured to address this question were collected in 2010 on the Pelagia during the first two legs of the Dutch GEOTRACES Atlantic Ocean transect (Iceland to Brazil). Twelve seawater profiles were analysed for their Nd isotopic compositions and concentrations. Each profile comprises 10 to 12 depths, providing a better depth resolution than previous studies and covering some areas that have never been investigated for Nd isotopes or concentrations.

The new results will be discussed in the context of previously published Nd data, constraints from physical oceanography, and other proxy data collected on the same samples.

High-precision atmospheric helium isotope measurement in volcanic areas

T.F. LAN[1]*, J.C. MABRY[1], B. MARTY[1], P. BURNARD[1], E. FÜRI[1], J.M. DE MOOR[2], T.P. FISCHER[2] AND G.M. MCMURTRY[3]

[3]Dept. Oceanography, University of Hawaii, Honolulu, USA

(*correspondence: tflan@crpg.cnrs-nancy.fr)

Current helium isotope analysis is sufficient to distinguish numerous geological end members, but determining the subtle isotopic variation in the air still poses a challenge to modern analytical techniques. The newly designed helium isotope measuring system, CRPG air-line, has reached the required precision to distinguish subtle differences in atmospheric helium isotopic ratios [1]. This technique marks a milestone for opening up new research directions for helium isotope study. Giving such high measuring precision, investigating geographical and temporal helium isotopic variation is within reach.

With this measuring system, we have identified that the average atmospheric helium isotopic ratios of the Big Island (Hawaii) and Afar region (Ethiopia) are 2.1-2.7 per mil higher than that in Nancy, France. Further investigation is needed to explain the cause of the difference, but comparing atmospheric helium isotopes from different tectonic settings is intriguing and may shed light on atmospheric helium dispersion patterns. Etna is an ideal place to study atmospheric helium isotopes since it has been constantly active and it offers various degassing mechanisms, such as: plumes, fumaroles, faults, and soil degassing. In June 2012, we took air samples from various sites, including the summit craters, fumaroles, Pernicana fault area, Paternò and Vallone Salato. We also took plume samples by flying through the trail on a gyroplane.

The $^{3}He/^{4}He$ ratio of the plume is 2.156±0.006 R_A (ratio normalized to atmospheric ratio of Nancy), while the ratio of the crater air is similar to that of Nancy. This indicates that the plume is the major helium degassing outlet of Etna, and helium seems to concentrate in the plume column rather than dispersing at the crater area. We will present the results of atmospheric helium isotope measurement of samples from Hawaii, Ethiopia and Etna; and hopefully will propose a model to elucidate the helium flux from Etna plume.

Hydrothermal origin of the Paleoproterozoic xenotimes from the King Leopold Sandstone of the Kimberley Group, Kimberley, NW Australia: Implications for a ca 1.7 Ga far-field hydrothermal event

Z.W. LAN[1]*, Z.Q. CHEN[2], X.H. LI[1], B. LI[3] AND D. ADAMS[4]

State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (*correspondence: lzw1981@126.com)

[2]State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan 430074, China

[3]Centre for Exploration Targeting, ARC Centre of Excellence for Core to Crust Fluid Systems, The Univeristy of Western Australia, WA6009, Australia

[4]Centre for Microscopy, Characterisation and Analysis, The University of Western Australia, WA6009, Australia

New xenotime overgrowth ages are obtained from the Paleoproterozoic King Leopold Sandstone of the Kimberley Group, NW Australia. The concordant age of 1679 ± 13 Ma can be equated with the *ca* 1.7 Ga xenotime overgrowth ages within errors obtained from the Warton and Pentecost Sandstones of the same group and the ca 1.7 Ga zircon U-Pb ages from the Dingo Granite in northern Australia, and together they are consistent with the age of Capricorn orogeny. These ages are much younger than the robust SHRIMP ages (1790 ± 4 Ma) obtained from zircons from the Hart Dolerite intrusions, and thus indicate that the xenotime overgrowths recorded in the Kimberley Group are unlikely to be diagenetic in origin, but may have been resulted from a post-depositional hydrothermal event. The *ca* 1.7 Ga age could point to a common hydrothermal event possibly associated with the low temperature far-field Dingo Granite intrusion during Capricorn orogeny in the Paleoproterozoic Australia. The hydrothermal origin of the xenotime overgrowths is also supported by its mineral chemistry characterized by LREE depletion, MREE-HREE enrichment, higher Zr content, and lower U, Fe, and Lu contents. The differing U and Th concentrations suggest a differing chemical pore fluid would have been responsible for the formation of xenotime overgrowths from the King Leopold, Warton, and Pentecost Sandstones as the zone of xenotime precipitation was reached by siliciclastic sediments.

Regional geochemical mapping at high density sampling: Various criteria in representation of Romagna Apennines, Northern Italy

V. LANCIANESE[1]* AND E. DINELLI[1]

[1]I.G.R.G, Università di Bologna, via S.Alberto 163, 48100 Ravenna (*correspondence: valerio.lancianese2@unibo.it)

Geochemical mapping is a fundamental tool in environmental monitoring and land management. For this reason, regional-, national- and global-scale geochemical mapping projects have been carried out in some countries since the late 1960s. The surveys had sample densities ranging from 1 site per 1 Km^2 to 1 site per 18000 Km^2 and each research group used different representation techniques.

In the Romagna Apennines (Northern Italy) has been conducted an high density stream sediment geochemical survey (1 sample per 5 km^2): 770 samples were collected in a regional-scale area (4125 km^2) and analysed for 30 elements by X-ray fluorescence spectrometry on the fraction < 180μm. In the area industrial settlements and largest towns are in the plains, agricultural areas in the hills and a wooded mountainous area is common in the upper reaches of the major streams. The area has a complex geology characterized by different geological units: Messinian gypsum, Plio-Pleistocene marls, chaotic clays with extensive outcrops of quartz-rich sandstones, carbonatic sandstones and limestones, and the extensive Serravallian-Tortonian Marnoso-arenacea Formation. In data interpretation different techniques were applied: EDA [1], IDW interpolation and Sample Catchment Basin (SCB) mapping approach [2,3]. EDA highlights very well the control of geological units and different background values using major elements. IDW interpolation point out the nature of some anomalies (Zn, Sr, V, Cr) showing the spatial distribution of geochemical data. Otherwise SCB mapping technique is useful in geochemical maps of Cu, Pb, Ba, S because identifies the effects of human activities localized along the valleys.

This study shows how in an area characterized by multiple factors, chemical elements can not be represent properly with a standardized mapping technique. Indeed, the use of different mapping techniques point out peculiarities useful for interpretation of the effect of geology or of the human impact.

A precise climatic sequencing of the penultimate glacial termination

A. LANDAIS[1,*], G. DREYFUS[1], E. CAPRON[1], J. JOUZEL[1], V. MASSON-DELMOTTE[1], D.M. ROCHE[1], F. PRIE[1], N. CAILLON[1], J. CHAPPELLAZ[2], M. LEUENBERGER[3], A. LOURANTOU[2], F. PARRENIN[2], D. RAYNAUD[2] AND G. TESTE[2]

[1]LSCE, CEA-CNRS-UVSQ, 91191 Gif sur Yvette, France (*correspondence: amaelle.landais@lsce.ipsl.fr)
[2]LGGE, CNRS-UJF, St Martin d'Heres, France
[3]Oeschger Center, Bern, Switzerland

Based on marine and terrestrial archives, a general mechanism has been proposed for the sequence of events over terminations involving interactions between millennial and orbital scale variability and atmospheric teleconnections. In this classical view, the occurrence of an Heinrich event in the first part of the deglaciation leads to a synchronism between Northern Hemisphere cooling (Heinrich Stadial), Asian monsoon dynamics (weak monsoon interval), CO_2 rise and Antarctic warming, the end of the HS being associated with an abrupt recovery of monsoon activity and Antarctic temperature maximum. Here, we provide new high resolution gas records ($\delta^{15}N$, $\delta^{18}O_{atm}$, CO_2) over the strong Termination 2 on the EPICA Dome C ice core and show a highly detailed sequence of events over this deglaciation with no relative chronological uncertainties between the records. We show a clear decoupling between Antarctic temperature and CO_2 increases 2000 years before the end of this deglaciation. This decoupling is synchronous with a clear change in the low latitude hydrological cycle (resumption of monsoon activity), in $\delta^{13}C$ of CO_2 and probably a partial recovery of the Atlantic Meridional Overturning Circulation.

Sulfur cycling in a karstic catchment: constraints from isotopes of dissolved sulfates

Y.-C. LANG*, H. DING, C.-Q. LIU AND Z.-Q. ZHAO

State Key Laboratory of Evironmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: langyc822@163.com)

Sulfur cycling in karstic catchments in southwest China is active and has been demonstrated to be coupled with carbon cycling. Therefore, many studies have been carried out to characterize the geochemical charateristics of sulfur cycling in a karstic catchment and to understand its effects on carbon cycling. In order to understand geochemical characteristics of dissolved sulfates in diverse aquatic system of a small karstic catchment, we carried out a research on variations in sulfur isotope composition of dissolved sulfate in precipitation, streams, springs, a well, and subsurface flow in the Mulian catchment of Northern Guangxi, China. This study area with a karstic landform of typical peak clusters depression is located in 24°44' N and 108°19' E, and covers about 1.14 km^2. Sixty water samples were collected for sulfur isotope analysis in the catchment in summer 2007, including rainwater, well water, spring water Other samples were collected from and the stream waters..

The average $\delta^{34}S$ value of SO_4 is -8.4‰ (n=7) in rainwater during sampling period. The one spring flowing through the clastic rocks has the highest average $\delta^{34}S_{SO4}$ value (-5.3‰, n=9), while the other spring flowing through the carbonate rocks has the lowest average $\delta^{34}S_{SO4}$ value (-9.1‰, n=2). There exists a positive correlation between $\delta^{34}S$ value and $1/SO_4$ for sampled seven rainwaters. The data distribution of all samples can be explained in terms of three-end member mixing. The three main sources include precipitation, the sulfate in soil, and oxidation of sulfide minerals in coal seams, which indicate that the sulfur cycling might have been coupled with carbonate weathering.

Modeling of copper and cobalt fractionation in soils: A useful tool to predict edaphic factors influence upon Cu and Co accumulation in two metallophytes

BASTIEN LANGE[1,2,*], MICHEL-PIERRE FAUCON[1], GREGORY MAHY[3], PETRU JITARU[1] AND OLIVIER POURRET[1]

[1]HydrISE, LaSalle Beauvais, Beauvais, France (*correspondence : bastien.lange2@lasalle-beauvais.fr)
[2]Laboratoire d'Ecologie végétale et Biogéochimie, Université Libre de Bruxelles, Bruxelles, Belgium
[3]Université de Liège, Gembloux Agro-Bio Tech, Unité Biodiversité et Paysages, Gembloux, Belgium

In Katanga (Dem. Rep of Congo), an original and unique metallophyte flora takes place on extremely copper and cobalt rich soils, deriving from Cu and Co outcrops. Among the present species, some are able to accumulate extremely high concentrations of Cu and Co in shoot, which are considered as Cu and Co hyperaccumulators. Still non-explained high variations of Cu and Co concentrations in shoot have been highlighted within this copper and cobalt flora. A good comprehension of the Cu and Co accumulation would go through a characterization of the Cu and Co speciation and bioavailability in soil. The objectives of the present study are to (i) examine variations of Cu and Co speciation in soils and Cu and Co concentrations in plants, (ii) determine which edaphic factors influence the Cu and Co accumulation in plants, and (iii) highlight the Cu and Co bioavailable fraction.

Two species have been selected as biological model: *Anisopappus chinensis* and *Crepidorhopalon tenuis*. Plant samples and soil samples (n=146) have been collected in seven pedogeochemicaly contrasted sites. Concentrations of Cu and Co in plants have been measured using ICP-MS and speciation modeling (WHAM 6.0) was performed to estimate Cu and Co speciation in soils. Huge variations in the Cu and Co fractionation in soils, as well as huge variations in the Cu and Co concentration in plants have been highlighted among and within the different sites and populations. Copper is mostly bind to organic matter (OM) and Fe oxides. Oppositely, Co occurs as ionic species and has strong affinity for Mn oxides. Copper accumulation variations are mostly explained by Cu adsorbed onto Mn oxides whereas Co accumulation variations are mostly explained by Co ionic species and Co adsorbed by OM. Bioavailable Cu and Co concentrations seem to correspond not only to the Cu and Co ionic species content but also part of linked Mn oxides and OM, for Cu and Co, respectively. Eventually, this latter fraction can be mobilized and / or absorbed by plants.

Why do some andesite stratovolcanoes evolve to erupt rhyolite and/or rhyodacite and others do not?

R.A. LANGE[1], H.M FREY[2] AND C.M. HALL[1]

[1]Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI, 48107, USA (*correspondence: becky@umich.edu)
[2]Department of Geology, Union College, Schenectady, NY, 12308, USA

If rhyolite/rhyodacite liquid commonly forms as an interstitial melt in crystal-rich andesite/dacite magmas in sub-volcanic chambers in the upper crust, an outstanding question is why segregation and eruption of the interstitial liquid occurs in some cases but not others. An example of this variation is seen among five andesite volcanoes along the western Mexican volcanic arc, spanning >150 km of arc length; three have explosively erupted rhyodacite and/or rhyolite (Volcáns Ceboruco, Tepetiltic and San Juan) and two have not (Volcáns Sanganguey and Tequila). Hypotheses for why some andesite volcanoes erupt rhyolite/rhyodacite and others do not include: (1) the effect of mafic magma recharge, which drives the differentiating magma back to more evolved compositions and prevents the formation and extraction of interstitial rhyolitic melt; (2) segregation of interstitial melt from a crystallizing magma requires compaction and thus crystal-rich (50-70%) conditions (e.g., Dufek and Bachmann, 2010) and/or gas filter-pressing (e.g., Sisson and Grove, 1999), and the time interval in which the magma spends under these optimal conditions for melt segregation may be variable, thus limiting the ubiquity of this process; and (3) extraction of interstitial melt may be most efficient during partial melting (vs. crystallization) because of the increase in volume associated with the crystal-liquid phase change, which causes the interstitial melt to be over-pressurized (vs. under-pressurized); however, this requires an influx of hot new magma into a sub-solidus system to transfer the heat and volatiles necessary to drive partial melting of adjacent wallrock. In this study, we use a combined geochemical and $^{40}Ar/^{39}Ar$ geochronology study to test which of the three models best explains the eruptive history of Volcán Tepetiltic, an andesitic stratovolcano (~42 km^3) that explosively erupted zoned crystal-poor rhyodacite-rhyolite (4-8 km^3) after a 180 k.y. hiatus in volcanic activity from the central vent. The explosive eruption was synchronous with an episode of basaltic andesite volcanism (~9 km^3) from three vents along the flanks Volcan Tepetiltic. Thus all three mechanisms can be tested against each other.

New insights into the evolution of the Finero Mafic Complex

A. LANGONE[1*], M.R. RENNA[2], M. TIEPOLO[1], A. ZANETTI[1], M. MAZZUCCHELLI[3] AND T. GIOVANARDI[3]

[1] CNR-IGG-Pavia, Pavia, Italy, langone crystal.unipv.it
[2] Dip. di Fisica e Sc. della Terra, Univ. di Messina, Italy
[3] Dip. Sc. Chimiche e Geologiche, Univ. di Modena e Reggio Emilia

The Finero Complex outcrops as an antiform in the northern sector of the Ivrea-Verbano Zone (Southern Alps). The antiform core is constituted by a mantle unit surrounded by a cumulitic sequence, i.e. the Finero Mafic Complex (FMC) [1,2]. The complex is divided in three units: a) the Layered Internal Zone (LIZ), in tectonic contact with the mantle unit; b) the Amphibole Peridotite (Amph-Pd); c) the External Gabbro. Owing to the lack of a detailed petrochemical characterisation of the FMC, we performed new major and trace element (LA-ICPMS) analyses on representative samples from the LIZ and Amph-Pd. The LIZ mainly consists of Grt-hornblendites and Hbl-gabbros, with minor anorthosites and pyroxenites. The Amph-Pd is mostly made up of Amph-bearing harburgites and dunites (Ol: Fo_{87-82}), with recrystallisation fronts along which the peridotites become modally-dominated by Amph. The Al_2O_3 content is up to 11 and 18 wt% in Cpx and Amph, respectively: it increases from the peridotites (Amph-Pd) through gabbros to the hornblendites and pyroxenites (LIZ). In the garnet-free pyroxenites and hornblendites from LIZ, Amph and Cpx have slightly LREE-depleted patterns with flat HREE (at 2 CI in Cpx) and marked positive Eu, Sr, Pb and U anomalies. Similar features are shown by the Cpx and Amph from the associated gabbros, they differ in having HREE-depleted patterns, thereby indicating chemical equilibration with garnet. Cpx and Amph from the Amph-Pd have variable LREE-enriched spoon-shaped patterns, with nearly flat HREE-pattern and positive Eu, Sr and U anomalies. The LREE gradient can be explained by interaction with percolating LREE-enriched melts, dominated by ion exchange processes. Amph-enriched peridotites, which contain the highest LREE contents are a proxy for the composition of the percolating melts. The new data suggest that the LIZ and Amph-Pd units may have crystallised from melts of cognate origin with a clear crustal component. However, the recrystallisation of the Amph-Pd cannot be explained by a closed-system evolution, pointing to significant changes in the composition of the uprising mantle melts.

Syn to post-eruptive crystallization of phenocrysts in pahoehoe "cicirara" lavas from Mount Etna volcano (Italy)

G. LANZAFAME[1*], S. MOLLO[2], G. IEZZI[3], C. FERLITO[1] AND G. VENTURA[2]

[3]Dipartimento INGEO – Ingegneria e Geologia, Università G. d'Annunzio, Via Dei Vestini 30, I-66013 Chieti, Italy (g.iezzi@unich.it)

At Mount Etna volcano (Italy) lavas with large plagioclase phenocrysts (PI > 40 vol.%) have been erupted during historical and pre-historical periods. If phenocrysts had crystallized inside a magma chamber or within the feeding system, viscosity would not have allowed the magma to reach the surface or at most would have produced volcanic domes. Instead, these plagioclase rich lavas, named locally as "cicirara", present wonderful pahoehoe morphologies with ribbons ropy structures and pressure ridges, which are definitively incongruous with an intratelluric growth of the phenocrysts. We have studied the mineral compositional variations and textural features, i.e., size frequency and crystal size of the one of the most basic cicirara lava. Our findings underline that only a small amount (10–15 vol.%) of crystals equilibrated at 12 km of depth, whereas most of the phenocrysts have grown at the surface and that emplacement of low-viscosity pahoehoe lavas is therefore driven by the low degree of undercooling associated with a rapid rise to the surface of poorly degassed magmas. In these conditions the growth of the phenocrysts occur mainly after the eruption when the lava is emplaced, thus reconciling the apparent paradox of pahoehoe morphology and high PI.

Four Cycles of Oxygenation in the Phanerozoic

R.R. LARGE[1], J.A. HALPIN[1], L.V. DANYUSHEVSKY[1], V.V. MASLENNIKOV[2], S. BULL[1], D. GREGORY[1], T.W. LYONS[3] AND E. LOUNEJEVA[1]

[3]University of California, Riverside, California, USA (timothy.lyons@ucr.edu)

Sedimentary pyrite captures trace elements (TE) from the oceans and tracks variations in their seawater concentrations through time [1]. LA-ICPMS analysis of sedimentary pyrites, based on newly developed standards, has enabled the development of temporal ocean concentration curves for 22 TE [2].

Our results show that TE variations over the last 700 million years of ocean history have been strongly cyclical. We interpret these cycles to indicate that the Late Neoproterozoic to Phanerozoic oceans went through dramatic changes in mean oxygen content. Four major cycles are recognised: Late Cryogenian to Late Ordovician, Early Silurian to late Devonian, Early Carboniferous to Late Permian and Triassic to Quaternary. Oxygen maxima, indicated by Se, U and Mo proxies, occur at 540, 390, 310 and 0 Ma, supporting previous models [3, 4]. Oxygen minima, indicated by trace element drawdown, occur at 700, 455, 365 and 200 Ma. Extended periods of low oxygen in the oceans have led to extreme deficiency of some elements that are critical for life. The periods of extreme Se depletion coincide with the mass extinction events at end Ordovician, Late Devonian and the Triassic-Jurassic boundary, suggesting that Se-deficiency in the oceans may be a contributing cause of marine mass extinctions.

Parkinsonism is a neurodegenerative disorder, and propagates from the loss of dopaminergic cells due to oxidative stress. Disordered copper metabolism may be important in the causation of Parkinsonism, as the main Cu carrying enzyme, caeruloplasmin, is key in handling oxidative stress and is involved in the synthesis pathway of dopamine [1, 2].

The human Cu metabolism of ten Parkinsonism patients was compared to ten healthy controls with the aid of a stable ^{65}Cu isotope tracer. The analyses of blood serum $^{65}Cu/^{63}Cu$ ratios yielded individual isotopic profiles spanning four days. The use of multiple-collector inductively coupled plasma mass spectrometry and the associated sample preparation techniques [3] is necessary to detect the small differences in Cu metabolism between subjects with Parkinsonism and controls.

The isotopic profiles indicate that the Cu metabolism is less controlled in patients with Parkinsonism. In addition, modelling suggests that (i) 30% of the subjects affected by Parkinsonism have abnormally large Cu stores in tissues and (ii) the absorption of Cu in the gut may control subsequent Cu metabolism. This pilot investigation supports full-scale medical studies into the Cu metabolism of those with Parkinsonism [4].

Geochemical evolution and bioenergetic potential of shallow-sea hydrothermal fluids from Panarea Island (Italy)

DOUGLAS E. LAROWE[1], ROY E. PRICE[1,*] AND JAN P. AMEND[1,2]

[1]Dept. of Earth Sciences, University of Southern California, Los Angeles, CA, USA
[2]Dept. of Biological Sciences, University of Southern California, Los Angeles, CA, USA
[*]Corresponding author: royprice@usc.edu

The shallow-sea hydrothermal fluids off Panarea Island, Italy are hot (up to 135 °C), acidic (pH 1.9-5.7), and sulfidic (up to 1 mM). Vent and pore fluids at three sites were sampled and analyzed for major and minor elements, redox-sensitive compounds, and strontium isotopes. These data were used to describe the geochemical evolution of the fluids and to evaluate the catabolic potential of 61 inorganic redox reactions for *in situ* microbial communities. Based on the geochemical data, the fluids divide into three distinct types, all depleted in Mg^{2+} and SO_4^{2-}. Types 1 and 2 are much more saline than seawater, but to different degrees, whereas Type 3 fluids are seawater-like with respect to most major ions. Type 1 fluids are interpreted to be derived from a very high salinity hydrothermal reservoir fluid, while Type 2 results from the discharge of a lower salinity reservoir fluid which has perhaps undergone phase separation. Type 3 fluids may result from hydrothermal alteration of seawater in the shallow subsurface by discharging gases. Gibbs energies (ΔG_r) of redox reactions that couple potential terminal electron acceptors (O_2, NO_3^-, Mn^{IV}, Fe^{III}, SO_4^{2-}, S^0, CO_2,) with potential electron donors (H_2, NH_4^+, Fe^{2+}, Mn^{2+}, H_2S, CH_4) were evaluated at *in situ* temperatures and compositions. Per mole of electron transferred, the range of ΔG_r spans from near 0 to -120 kJ $(mol\ e^-)^{-1}$. When these Gibbs energies of reaction are normalized per kilogram of hydrothermal fluid, sulfur oxidation reactions are the most exergonic, while the oxidation of Fe^{2+}, NH_4^+, and Mn^{2+} are moderately energy yielding. The results of these calculations are consistent with available molecular microbiology (16S rRNA) data, which suggest that aerobic oxidation of H_2S may be the most common metabolism in the hydrothermal springs near Panarea.

New Sr-Nd-Pb isotopic data on Graciosa island lavas (Azores)

P. LARREA[1,2]*, E. WIDOM[2], C. GALÉ[1], T. UBIDE[1], M. LAGO[2] AND Z. FRANÇA[3]

[1]Department of Earth Sciences, Universidad de Zaragoza, Spain (*correspondence: plarrea@unizar.es)
[2]Department of Geology & Envirnmental Earth Science, Miami University, Oxford, OH, USA
[3] Observatório Vulcanológico e Geotérmico dos Açores, São Miguel, Portugal

The Graciosa island belongs to the Central Group of the Azores archipelago, to the east of the Mid-Atlantic Ridge. Three main volcanic complexes are recognized, in order of decreasing age: the Serra das Fontes Volcanic Complex (620±120 Ky [1]) composed of basaltic effusive products, the Serra Branca Volcanic Complex (350±40 Ky [1]) which presents trachytic products and the most recent Vitória-Vulcão Central Volcanic Complex formed by basaltic to trachytic terms and divided into two units: Vitória and Vulcão Central, being the latter the youngest volcanic unit [2].

A selection of nine lavas from the three volcanic complexes (basalt to trachyte compositions) have been analyzed for Sr-Nd-Pb isotopic systems. They display a small variability of $^{87}Sr/^{86}Sr$ (0.703356 and 0.703576) and $^{143}Nd/^{144}Nd$ (0.512883 to 0.512964) isotope ratios, and the Pb-Pb isotope ratios correlate positively ($^{206}Pb/^{204}Pb$ from 19.419 to 20.096; $^{207}Pb/^{204}Pb$ from 15.588 to 15.659; $^{208}Pb/^{204}Pb$ from 39.038 to 39.520). These new Sr, Nd and Pb isotopic data suggest the involvement of two mantle components: a depleted MORB and an enriched HIMU.

The oldest samples (Serra das Fontes, Serra Branca and Vitoria Unit) of the northern half of the island have homogeneous isotopic ratios with a high influence of the MORB mantle component. In contrast, the youngest samples from the southern part of the island (Vulcão Central Unit) present more radiogenic isotopic compositions. This suggests that during the formation of Graciosa island, the composition of the mantle and/or conditions of melt generation varied with time, as recently reported in other islands from central Azores [3].

Formation timescales of pallasite meteorites inferred from the Mg isotope composition of olivine

K.K. LARSEN*, M. SCHILLER, C. PATON AND M. BIZZARRO

Center for Star and Planet Formation, University of Copenhagen, Øster Voldgade 5-7, DK-1350, Copenhagen K, Denmark (*correspondence: kirstenl@snm.ku.dk)

Early formed meteoritic materials with significantly sub-chondritic Al/Mg ratios are not influenced by in-growth of ^{26}Mg from the decay of ^{26}Al ($t_{1/2}$ ~ 0.73 Myr) and thus should record deficits in the mass-independent component of ^{26}Mg (μ^{26}Mg*) inherited from the source reservoir at the time of formation. This provides a means to define their formation timescales. Moreover, potential stable isotope variability in magnesium (μ^{25}Mg) can be used to track genetic relationships between early solar system reservoirs. Pallasite meteorites, consisting of large mm- to cm-sized olivine crystals (Al/Mg ~ 0) set in evolved iron–nickel metal, are ideally suited to constrain the timing of asteroidal accretion and differentiation in the early solar system. Using improved methods for high-precision Mg-isotope measurements [1], we have extended our search for deficits in pallasite meteorites [2] to diverse main group pallasites (PMGs), two pyroxene pallasites, the ungrouped Zinder and Milton pallasites and two pallasites from the Eagle Station grouplet (PESs), including 20 distinct olivine crystals from Eagle Station.

Apart from PESs, all pallasite meteorites studied here have μ^{25}Mg values that are identical to that of Earth's mantle. The PESs have μ^{25}Mg systematically lighter than PMGs and Earth's mantle; defining a weighted mean of -183 ± 23 ppm (relative to DSM-3). This composition is similar to that of the bulk Allende meteorite, supporting the view that PESs formed from a CV chondrite-like precursor [3]. Considerable variability is observed in μ^{26}Mg*, with PMGs, pyroxene pallasites and Zinder having consistently negative μ^{26}Mg* and PESs displaying positive μ^{26}Mg* values. Individual olivine grains from the Eagle Station pallasite have μ^{26}Mg* values ranging from +1.3 ± 1.5 ppm to +14.8 ± 2.0 ppm, plausibly related to igneous evolution on the Eagle Station parent body. Such excesses may record an evolutionary history of a magmatic reservoir with super-chondritic Al/Mg ratio while ^{26}Al was still extant. Model ^{26}Al-^{26}Mg ages constrain the differentiation of the parent bodies of PMGs, PESs, the Vermillion and Yamato8451 pyroxene pallasites as well as Zinder to <2 Myr after solar system formation.

Detritus-feeders play a key role for stimulating microbial activity in arctic peatlands but their nutritional requirements are poorly understood. We investigated whether a dominant detritivore in arctic peatlands, the enchytraeid worm, can overcome amino acid limitations in their nutrient poor diets by supplementation from bacterial symbionts. With a new isotopic tool for identifying bacterial synthesis of indispensable amino acids (IAAs) *in situ*, we demonstrated that enchytraeids feeding on hardly digestible diets derived nearly all IAAs from symbiotic bacteria; however, it was considerably less for enchytraeids feeding on easily digestible diets. We also found evidence for substantial bacterial IAA supplementation among enchytraeids dwelling in arctic peatlands. Although symbiotic synthesis and subsidy of IAAs to hosts is well known in herbivore specialists, this study provides the first evidence for substantial symbiotic IAA supplementation among soil detritivores. Our findings suggest that digestibility and initial microbial degradation of soil litter rather than nutritional qualities such as IAA composition determine its suitability as a food resource for enchytraeids. Recent observations and climate change projections for northern high latitudes indicate wetter and warmer conditions, which would be likely to stimulate enchytraeid activity by longer seasons and increased access to older stocks of decomposing litter.

Rates of low-pH biological Fe(II) oxidation in the Appalachian Coal Basin and the Iberian Pyrite Belt

LANCE N. LARSON[1], JAVIER SANCHEZ-ESPANA[2] AND WILLIAM BURGOS[3]

[1]Department of Civil and Environmental Engineering, Penn State University, USA, lnl5053@psu.edu
[2]Instituto Geológico y Minero de España (IGME), Ríos Rosas, 23 28003 Madrid, j.sanchez@igme.es
[3]Department of Civil and Environmental Engineering, Penn State University, USA, wdb3@psu.edu

Low-pH Fe(II) oxidation can be exploited for the treatment of acid mine drainage (AMD). However, natural or engineered terraced iron formations (TIFs) are underutilized for AMD treatment because of uncertainties with respect to treatment performance. To address this problem we measured the rates of Fe(II) oxidation multiple times at seven sites in the Appalachian Bituminous Coal Basin and three sites in the Iberian Pyrite Belt (IPB). Longitudinal geochemical transects were measured downstream of emergent anoxic AMD sources. Water velocities were measured at each sampling location and used to transform concentration versus distance profiles into concentration versus travel time for kinetic analysis of field data. Both zero-order rates and first-order rate constants were used to compare Fe(II) oxidation kinetics. Zero-order Fe(II) oxidation rates ranged from $8.60 – 97.0 \times 10^{-7}$ mol L^{-1} s^{-1} at the Appalachian sites and $13.1 – 67.9 \times 10^{-7}$ mol L^{-1} s^{-1} at the IPB sites. In contrast, first-order Fe(II) oxidation rate constants ranged from 0.035 – 0.810 min^{-1} at the Appalachian sites and 0.003 – 0.010 min^{-1} at the IPB sites. The fastest zero-order rates of Fe(II) oxidation were measured at two sites (one in Appalachia and one in IPB) where little to no oxidative precipitation of Fe(III) occurred. Laboratory-based rates of Fe(II) oxidation were measured with TIF sediments and emergent AMD collected from the seven Appalachian sites. A zero-order laboratory-based removal rate for Fe(T) was used to calculate performance criteria of 2.6 – 8.7 g Fe day^{-1} m^{-2} (GDM) for both natural and engineered TIFs. These GDM values could be used to size TIFs for AMD treatment.

Alteration and fluid flow in large continental hydrothermal systems

P.B. LARSON

School of the Environment, Washington State University, Pullman, WA 99164-2812 USA
(correspondence: plarson@wsu.edu)

Large volumes of hydrothermally altered rocks are found in calderas and around shallow plutons in the continental crust. The alteration is the product of water/rock interaction in hydrothermal systems that are convectively driven by cooling plutons, and record mass and heat flux through the shallow crust. They often host hydrothermal mineralization. O and H isotope ratios have been used to map large hydrothermal systems at the 23 Ma Lake City caldera and the 3-4 Ma Rico hydrothermal systems, CO, in Eocene hydrothermal systems, Idaho Batholith, ID, and in the active Yellowstone system, WY, all in the USA. These studies define a general architecture for continental hydrothermal systems.

Gradual variations of O isotope ratios in the altered rocks are observed both laterally and vertically, with lower values in central hydrothermal upflow zones with higher tempertures and enhanced fluid flux, and deeper where temperatures are higher. Fluids in deeper (more than 4km) portions of the systems can include a significant magmatic component near intrustions, where they are related to the formation of porphyry deposits. Fluids in shallower portions are dominated by meteoric ground waters. Thermal profiles in the shallowest (less than about 300 meters) epithermal near-surface environments are controlled by the hydrostatic boiling curve. In all cases, fractures and other permeable zones control the most important fluid flow paths.

Argillization and acid-sulfate alteration are widspread within a kilometer or so of the paleosurface, where boiling in rising fluids can be important. Propylitization is dominant in deeper parts of the systems, and potassic and quartz-sericite-pyrite porphyry-style alteration is prevalent near some deeper intrusions. The most important mass chemical effect of propylitic alteration is hydration. Although mineral reactions are pervasive in those altered rocks, major element concentrations suggest that their flux is minimal in the propylitic environment. Ba and Sr are generally added. Leaching of nearly all components, sometimes extreme, is characteristic of shallow alteration. Diffusion models of O isotope ratio profiles in altered feldspar phenocrysts at Rico suggest a hydrothermal duration on the order of about 100,000 years, whereas the Yellowstone system has been active for at least 400,000 years, although we do not know if it's activity has been continuous or intermittant.

Pre-Hallandian metamorphism in the Sveconorwegian Province – its implication on the tectonic evolution of the Baltic Shield.

S. Å. LARSON[1]* AND E-L. TULLBORG[2]

[1]Department of Geology, Earth Sciences Centre, Göteborg University, Box 460, SE-405 30 Göteborg, Sweden, svenake@gvc.gu.se

[2]Terralogica AB, Gråbo, Sweden,

It has long been debate whether the Sveconorwegian Province in SW Sweden has suffered pre-Sveconorwegian (>1.1 Ga) metamorphic imprints. However, today it is agreed upon that the pre-Sveconorwegian Hallandian (~1.45 Ga) event has influenced this province. Any older metamorphic events have not been revealed by using U-Pb geochronology on minerals hitherto.

In this study we have taken use of intrusive relations to find suitable samples in order to constrain metamorphic events. Ion-probe dating of zircon and titanite was carried out from different rock types of the Sveconorwegian Province in SW Sweden, both west and east of a N-S trending, Sveconorwegian shear zone, the Mylonite Zone. Intrusion and metamorphic ages were dated for both veined and gneissic rocks as well as for corresponding crosscutting younger rocks. In this way the formation of veins was constrained on both sides of the Mylonite Zone.

To the east in the easternmost part of the Eastern Segment formation of early veins were formed between 1.66 Ga - 1.53 Ga, and anatectic, granitoid magmas related to basic intrusions were formed at 1.53 ±0.03 Ga. To the west (Western Segment), the formation of early veins and folding is constrained between 1.61 Ga and 1.52 Ga, and formation of pegmatite related to basic intrusions to 1.54 ±0.02 Ga. Here also zircon growth indicates a Sveconorwegian thermal event in contrast to what was found in our samples from the easternmost Eastern Segment.

The findings of Pre-Hallandian (>1.45 Ga) metamorphism and magmatism across the Mylonite Zone, separating the Western and Eastern Segments of the Sveconorwegian Province in Sweden suggest that these parts of the Baltic Shield were united at least at ~1.54 Ga. Thus, it is suggested that the Mylonite Zone is a Sveconorwegian terrane boundary rather than a Sveconorwegian suture.

Modeling inverse adsorption isotope effects for CO_2 and CH_4 from experimental and field data

TOTI LARSON[1] AND JEIMIN LU[2]

[1]Department of Geological Sciences, The University of Texas at Austin, Austin, Texas, USA.

[2]Bureau of Economic Geology, The University of Texas at Austin, Austin, Texas, 78713, USA.

Transport of CO_2 and CH_4 through porous media is affected by diffusion, gas-liquid partitioning, advection and adsorption processes. Adsorption, diffusion, and gas-liquid partitioning processes are affected by isotope substitution. Although considerable effort has been placed on understanding stable isotope effects associated with diffusion and gas-liquid partitioning, significantly fewer results have been measured for adsorption carbon isotope effects of CO_2 and CH_4 on geologically relevant substrates, temperatures and pressures. Early work by Bruner *et al*.. (1966), Van Hook (1967) and Corcia and Liberty (1969) explored hydrogen isotope adsorption isotope effects for methane on dry and wet glass columns with limited carbon isotope results. Here we report experimentally measured carbon isotope fractionations for CO_2 on illite and quartz substrates at 298K using a 1-D column apparatus as well as preliminary field results of methane carbon isotope values from the caprock of a natural gas reservoir. Observed adsorption isotope effects are compared to diffusion effects conducted in unpacked 1-D columns. Results are modeled using an analytical solution to a coupled advection-diffusion-adsortpion transport model. Measured diffusivities from diffusion experiments are in excellent agreement with binary diffusion constants calculated for $^{13}CO_2$-Helium and $^{12}CO_2$-Helium using the Fuller Equation whereby the ratio of diffusivities between $^{13}CO_2$ and $^{12}CO_2$ is 0.99909. In contrast to diffusion where $^{12}CO_2$ preferentially populates the front of the chromatographic peak, adsorption of CO_2 and CH_4 has the opposite effect whereby preferential adsorption of $^{12}CO_2$ is observed, resulting in the 'front' of the chromatographic peak becoming enriched in $^{13}CO_2$. Similar observations are made for methane in a shale adsorption-dominated system whereby methane furthest from the reservoir is approx. 15 permil heavier than the reservoir gas. This inverse chromatographic effect for CO_2 and CH_4 is modeled well using the Rayleigh Equation (α=1.0086) and the transport equation (retardation factor=0.999). These results demonstrate the importance of understanding adsorption isotopic effects and potentially offers a tool to quantify surface area and/or transport distance in geological reservoirs.

Vanadium leaching from converter lime and speciation in soil: a long-term field study

M.A. LARSSON[1],M. D'AMATO[2], F. CUBADDA[2], A. RAGGI[2], I. ÖBORN[1] AND J.P. GUSTAFSSON[1]

[1]Department of Soil and Environment, Swedish Univeristy of Agricultural Sciences, Box 7014, 750 07 Uppsala, Sweden (*correspondence: maja.larsson@slu.se)

[2]Department of Food Safety and Veterinary Public Health, Istituto Superiore di Sanità, Viale regina Elena 299, Rome, 00161, Italy

Vanadium, V, is a redox-sensitive metal that is mainly used within the steel industry. Under environmental conditions, it mainly exists in oxidation states +4 and +5 [1]. Under aerobic conditions vanadium prevails as the pentavalent oxyanion vanadate, $H_2VO_4^-$. Vanadate is thought to be the most toxic vanadium form due to its strucural similarity to phosphate [2].

In the mid-1980's, a field trial was set up in a pine forest in the south of Sweden. Granulated converter lime, containing high concentrations of vanadium, was added in different concentrations (0, 2, 7 and 10 tonne ha^{-1}). 25 years later, soil samples from the mor and from the top 20 cm of the mineral layer were taken at the site. The soils were analyzed for total and dissolved vanadium concentrations. Further, the redox form of the vanadium bound to the soils was analysed using X-ray absorption near edge sructure (XANES) spectroscopy. Quantification of vanadium(IV) and vanadium(V) in the soil extracts was made with EDTA complexation followed by measurements with HPLC coupled ICP-MS [3].

The total soil vanadium concentrations generally decreased with depth, indicating some downward transport of vanadium in the profile. XANES spectra in the mor layer show similarities to reference samples of V(IV) bound to organic matter. Further down in the mineral soil, the XANES spectra suggests vanadium(V) binding to soil constituents containing aluminium. The speciation analysis of the $CaCl_2$-extracts showed a higher fraction of V(IV) in samples with higher concentrations of organic matter such as in the mor samples. The extracts of the mineral soils had a larger fraction of V(V).

Processed controlling recent lava fountaining activity on Mt. Etna, revealed using remote sensing measurements of volcanic gases

ALESSANDRO LA SPINA[1], GIUSEPPE SALERNO[2] AND MICHAEL BURTON[3]

[1]INGV Osservatorio Etneo, Italy, salerno@ct.ingv.it
[2]INGV Osservatorio Etneo, Italy, laspina@ct.ingv.it
[3]INGV Pisa, Italy, burton@pi.ingv.it

Open-Path Fourier Transform Infrared (OP-FTIR) spectroscopy is now an established methodology for measuring volcanic gas compositions remotely. Here we present and interpret OP-FTIR measurements collected on Mt. Etna, before, during and after a series of lava fountains which were observed between 2011 and 2013. We combine our results with quantifications of SO2 flux, allowing the fluxes of multiple volcanic gas species to be constrained, including H2O, CO2, SO2, HCl, and HF. These results allow an interpretative framework to be established, in which we use clearly observed geochemical precursors to the lava fountain activity to constrain the magma dynamics which produce the eruptive activity.

Thermoddem: an example of alive thermochemical database

LASSIN A.[1], BLANC P.[1], ANDRE L.[1], MARTY N.[1], PARMENTIER M.[1], MOYARD S.[2], AZAROUAL M.[1], PIANTONE P.[1], GAUCHER E.C.[1], KERVEVAN C.[1] AND TOURNASSAT C.[1]

[1]BRGM, 3 av. C. Guillemin, B.P. 36009, 45060 Orléans, France
[2]CASPEO, 3 av. C. Guillemin, 45060 Orléans, France

The basic goal of the Thermoddem thermochemical database [1] (http://thermoddem.brgm.fr/) is to gather standard thermodynamic data regarding chemical compounds encountered in most water-solid-gas systems, with a specific concern for environmental issues, cement phases and clay minerals. The construction of the database (since 2006) relies on a careful selection of published experimental data, constrained by a rigorous internal consistency. Data selection combines both solubility and calorimetric data in order to strengthen the coherence of the data set. A particular effort is paid to identifying the source of every data. Some examples will be presented for illustration.

A major objective of thermochemical databases (TDB) is to be integrated into coupled reactive transport modelling codes. Therefore, it is of key importance to provide database formats adapted to the most widely used calculation codes and to make them freely available on the Internet. In addition, Thermoddem includes mineralogical and geological information to help the modeller to define and to select the geochemical reactive system in agreement with the problematic to handle.

Geochemical and reactive transport modelling covers a wide range of temperature and pressure conditions, numerous reactive mechanisms (aqueous complexation, surface complexation and ionic exchanges, dissolution/precipitation or degassing reactions, kinetic processes, bacterial activity), and various contexts (dilute/saline waters, isobaric/anisobaric conditions). Models implemented in calculations codes for describing the different geochemical mechanisms evolve with time and new concepts are perpetually developed. Alive TDB have to adapt to these evolutions as for Thermoddem, which is this way developed. However one has to acknowledge that, despite the wide use of thermochemical databases, there is still a need for gathering a community that would actively contribute to help improving these tools. Furthermore a better scientific recognition could help supporting their development and maintenance.

How depleted is the upper mantle? Constraints from elemental-Os isotope correlations in abyssal peridotites and ocean island xenoliths

J.C. LASSITER*[1] AND B.L. BYERLY[1]

[1] Jackson School of Geosciences, University of Texas at Austin, Austin, TX, USA (* lassiter1@jsg.utexas.edu)

It is generally accepted that the convecting upper mantle is depleted in incompatible trace elements as a result of prior melt extraction. However, the amount of melt depletion that has occurred and the extent to which this has effected the major element composition of the mantle is less certain. *Workman & Hart* [1] estimated the composition of MORB-source mantle utilizing both MORB and abyssal peridotite (AP) compositional trends and inferred a relatively fertile bulk composition (e.g., Al_2O_3 > 4 wt.%) consistent with minor long-term melt depletion of ~3-4%, assuming a primitive mantle Al_2O_3 content of ~4.4 wt.% and that the melt extracted had a roughly MORB-like composition. *Walker et al*.. [2] also inferred limited long-term melt extraction (2-3%) based on Os-isotope systematics of ophiolite chromitites.

We have examined correlations between indices of peridotite fertility (Al_2O_3, spinel Cr#) and Os-isotopes in both APs and ocean island peridotite xenoliths (OIPs) to better constrain the average $^{187}Os/^{188}Os$ of the upper mantle, the average age of melt depletion, and the extent of melt depletion required to generate the observed major element-isotope correlations. APs and OIPs have statistically indistinguishable average $^{187}Os/^{188}Os$ (0.1244 versus 0.1245), and are considerably less radiogenic on average than chromitites derived from modern ophiolites (~0.1281; [2]). Both APs and OIPs display positive global correlations between fertility indices and $^{187}Os/^{188}Os$. The Al_2O_3-$^{187}Os/^{188}Os$ trends of both suites define aluminachron "ages" of ~1.5 Ga, similar to the average T_{Ma} ages of both populations. Combined, these trends suggest upper mantle peridotites have an average $^{187}Os/^{188}Os$ of ~0.1245 and the average age of melt depletion is ~1.5 Ga. If extraction of oceanic crust is the primary mechanism for depleting the upper mantle, then the degree of MORB melt extraction required to generate an average upper mantle Os-isotope value consistent with APs and OIPs is ~10-12%, significantly greater than previuos estimates of upper mantle depletion. During mantle upwelling, the degree of melt generated from a mantle packet is a function of initial fertility. MORB therefore oversample fertile components in the mantle, which likely accounts for the apparent conflict between our estimate of average mantle peridotite fertility and that of [1].

Reduction of aqueous U^{VI} by Fe^{II}: Effect of Ti^{IV} on the speciation of U^{IV}

DREW E. LATTA[1], CAROLYN I. PEARCE[2], KEVIN M. ROSSO[1], EDWARD J. O'LOUGHLIN[1], KENNETH M. KEMNER[1] AND MAXIM I. BOYANOV[1]

[1] Biosciences Division, Argonne National Laboratory, Lemont, IL 60439 USA
[2] Physical Sciences Division, Pacific Northwest National Laboratory, Richland, WA 99352 USA

The solubility and mobility of uranium, a radionuclide contaminant at many sites, is highly dependent on its valence state and speciation. Transformation of aqueous U(VI) to U(IV) under the (bio-)reducing conditions found in many subsurface environments can decrease U solubility due to the precipitation of U(IV) dioxide (uraninite), a process that has been studied extensively for uranium remediation. However, recent evidence suggests that U(VI) reduction can produce complexed U(IV) species in the solid phase, such as U(IV)-phosphate precipitates or surface-adsorbed U(IV) atoms. The molecular speciation and the stability of non-uraninite U(IV) phases is poorly understood, even though this knowledge is essential in predicting uranium behavior at contaminated sites or in the design of nuclear waste repositories.

As part of understanding uranium transformations under iron reducing conditions, we examined the reduction of U(VI) by Fe(II) in the presence of Ti(IV). Ti(IV) is commonly present in natural magnetite and has been observed in the magnetic sediment fraction at the Hanford nuclear site. Titanium-doped magnetite nanoparticles of varying Ti content ($Fe_{3-x}Ti_xO_4$, $0<x<0.5$) were synthesized and reacted with aqueous U(VI) in the presence and absence of bicarbonate. Analysis of the solids by U L_{III} edge x-ray absorption spectroscopy (XANES and EXAFS) indicated that Ti incorporation did not affect the ability of magnetite to reduce U(VI) to U(IV). Reactions with pure magnetite resulted in the formation of uraninite (dioxo-bridged UO_2). In contrast, reactions with Ti-doped magnetite resulted in a phase that lacked dioxo bridges between the U(IV) atoms. The latter phase was distinct from the U(IV) mineral brannerite (UTi_2O_6), suggesting that U(IV) was stabilized as a mononuclear surface complex. To understand the nature of Ti-complexed U(IV) species, U(VI) was co-precipitated with Fe(II) in the presence of carboxyl-functionalized microbeads and increasing amounts of Ti(IV). Analysis of the resulting solids indicated complete reduction of U(VI) to U(IV) and the formation of an inner-sphere U(IV)-Ti complex at Ti:U ratios as low as 1:1. The refined U(IV)-Ti distance of 3.43 Å suggests the formation of a bidentate corner-sharing complex between Ti octahedra and U(IV).

Active Carbon Cycling in Deep Subsurface Fracture Environments: Insights from RNA, Lipid and Isotopic Analyses

[8]Beatrix Au Mine, South Africa

This study undertook identifying 1) the metabolically active microbial communities of deep fracture water by comparison of cDNA (from RNA = active community) and DNA (total community) sequences; and 2) the C source of the active microbial community by comparing the compound specific $\delta^{13}C$ and $\Delta^{14}C$ of the PLFA and the $\Delta^{14}C$ of the DNA with the $\delta^{13}C$ and $\Delta^{14}C$ of the CH_4, DIC, DOC and the $\delta^{13}C$ of the organic acids. In this talk we will present this data for a borehole located at 1.3 kmbls. in the Beatrix Au Mine.

Comparison of the cDNA and DNA results for both Archaea and Bacteria indicates that the composition of the active community differs from that of the total DNA community. *Methanobacterium* is part of the active community, though in low abundance compared to the Bacteria. *D. audaxviator* found in both DNA and cDNA nifH results indicating that N_2 is occurring *in situ*. cDNA library also yielded pmoA gene indicating that active methanotrophy is also occurring.

The $\delta^{13}C$ and $\delta^{2}H$ of the CH_4 is consistent with methanogenesis. The $\Delta^{14}C$ of the PLFA agrees with the $\Delta^{14}C$ of the DNA and along with the $\delta^{13}C$ of the PLFA and the $\Delta^{14}C$ of the CH_4 indicate that the active microbial community is obtaining most of its carbon from the CH_4.

Polyelectrolyte injection increases mobility of nanoscale zero-valent iron in carbonate sand

S. LAUMANN, V. MICIĆ AND T. HOFMANN*

Department of Environmental Geosciences, University of Vienna, Vienna, Austria (*correspondence: thilo.hofmann@univie.ac.at)

The limited mobility of nanoscale zero-valent iron (nZVI) remains one major obstacle to widespread utilization of this agent for *in situ* groundwater remediation [1]. The nZVI mobility is strongly affected by aquifer heterogeneities, which include mineralogical variations [2]. In our previous study we showed that the presence of carbonates in porous aquifers significantly reduces the nZVI mobility [3]. New strategies are therefore required to improve the nZVI mobility in such porous media. This might be achieved by increasing the repulsion between nZVI and the porous media, which can be provided by the injection of anionic polyelectrolytes in the subsurface. We tested this hypothesis by studying the effects of various co-injected polyelectrolytes (natural organic matter, humic acid, carboxymethyl cellulose, and lignin sulfonate) on the mobility of polyacrylic acid coated nZVI in two model porous media; quartz and carbonate sand.

The results demonstrated that co-injection of the chosen polyelectrolytes at concentrations of 50 mg L^{-1} does not influence the nZVI mobility in quartz sand. This can be explained by the highly negative surface charge of quartz (-40 mV), which prohibited any surface interactions with the negatively charged polyelectrolytes. Contrarily, in less negatively charged carbonate sand (-10 mV) the co-injection resulted in an increased nZVI mobility. We related this to polyelectrolyte adsorption onto the carbonate surface. Lignin sulfonate was selected to further investigate the effect of increasing polyelectrolyte concentrations (10, 25, 50, 250, and 500 mg L^{-1}) on the nZVI mobility in carbonate sand. At concentrations above 10 mg L^{-1} an increase in nZVI mobility was observed. Furthermore, the nZVI transport distance was almost doubled when the particles were co-injected with 500 mg L^{-1} lignin sulfonate.

Overall, the results indicated that polyelectrolyte adsorption onto the carbonate sand reduces the nZVI deposition onto aquifer grains and consequently promote its mobility, an effect which is more pronounced with higher concentrations of co-injected polyelectrolyte.

Metal-silicate partitioning of the HSE at high pressures and temperatures in S-bearing systems

VERA LAURENZ[1]*, DAVID C. RUBIE[1] AND DANIEL J. FROST[1]

[1]Bayerisches Geoinstitut, Universität Bayreuth, Universitätsstrasse 30, 95440 Bayreuth, Germany *(correspondence: vera.laurenz@uni-bayreuth.de)

The highly siderophile elements (HSE - Os, Ir, Ru, Rh, Pt, Pd, Re, Au) are unique geochemical tracers of Earth's accretion and differentiation history. From high pressure-high temperature experimental work it is known, that the HSE were effectively scavenged from the Earth's mantle during core formation, leaving the mantle strongly depleted in HSE. After core formation was complete, a "late-veneer" of highly oxidized, chondritic material then delivered a small amount of HSE back to the mantle [1]. However, the observed HSE abundances of the primitive upper mantle cannot be reproduced by any known meteorite group, questioning how the HSE abundances were established. A possible clue to this problem could lie in the effect of S on metal-silicate partitioning of the HSE: As S is known to strongly influence the partitioning behaviour of chalcophile trace elements such as Mo or Ni, it may also have played an important role for the behaviour of the HSE, especially during the late stages of accretion and core formation.

In order investigate if sulfur has an effect on the behaviour of the HSE during core formation, we studied the metal-silicate partitioning of Pt, Pd and Ru in S-bearing systems under high pressure-high temperature conditions. A molten peridotite was equilibrated with a S-bearing Fe-HSE-alloy at pressures from 6 to 18 GPa and temperatures between 2200 °C and 2400 °C in a multianvil apparatus. Sulfur concentration in the alloy varied between 5-15 wt. %. Quenched metal and silicate were analyzed by electron microprobe (major elements) while trace element concentrations were determined using LA-ICP-MS.

Results indicate that Pd and Ru, the two most chalcophile HSE, become significantly less siderophile with increasing S-content of the metal. In contrast, Pt being less chalcophile shows only a small effect. These results indicate that, besides pressure and temperature, composition also has a significant effect on the partitioning behaviour of HSE. The presence of sulfur may induce HSE fractionation during core formation and might be responsible for observed HSE abundances in the Earth's mantle.

Denitrification rates in riparian wetlands of the Seine River are influenced by carbon quantity rather than quality

ANNIET LAVERMAN[1] CHRISTELLE ANQUETIL[2] AND SYLVIE DERENNE[2]

[1] UMR 7619 Sisyphe, UPMC, CNRS, Paris
[2] UMR 7618 Bioemco, UPMC, CNRS, Paris

Benthic denitrification in riparian zones or adjacent wetlands of the Seine River could significantly improve its water quality. The goal of this study was to investigate the potential for denitrification and the factors affecting *in situ* denitrification rates with special emphasis on the role of organic matter. We measured denitrification potentials in sediments collected from four sites along the Seine River during three different seasons. Sediment characteristics (C_{org}, C:N ratio, bioavailable carbon and chlorophyll content) were determined and the sedimentary organic matter was analyzed at the molecular level (^{13}C NMR and pyrolysis coupled with gas chromatography-mass spectrometry).

Denitrification rates showed large spatial and seasonal variations. They were significantly correlated with sedimentary chlorophyll concentrations, but not with biodegradable carbon, measured as the decrease in total organic carbon under oxic conditions. Algal C most likely served as a carbon source for this process. The addition of carbon, either in the form of simple organic molecules (acetate, lactate), reed or algae always increased the denitrification rates, indicating a strong carbon limitation in these sediments and a lack of discrimination against the carbon source. The latter was confirmed through examination of the molecular structure of the sedimentary organic matter from four sites. Indeed the sediments which exhibit the highest denitrification rates show the most similar organic matter chemical structures. Moreover, incubation of sediments for two months under denitrifying conditions did not induce any significant change in the chemical structure of the organic matter although the latter was contrasted from one site to another one.

Fluxes of fine particles over a semi arid pine forest: possible effects of a complex terrain

AVI LAVI[1], DELPHINE K. FARMER[2,3], ENRICO SEGRE[4], TAMAR MOISE[1], EYAL ROTENBERG[1], JOSE L. JIMENEZ[2] AND YINON RUDICH[1*]

[4] Department of Physical Services, Weizmann Institute of Science, Rehovot, 76100 Israel (enrico.segre@weizmann.ac.il)

Semi-arid forests are of growing importance due to expected ecosystem transformations following climatic changes. Size-resolved flux measurements of atmospheric aerosols (0.25-0.65 μm) were conducted for the first time in such an ecosystem in the Yatir forest in southern Israel, using an optical particle counter and eddy covariance methodology. Both downward and upward fluxes were observed. Upward fluxes were not associated with a local particle source. Moreover, the flux direction correlated strongly with wind direction suggesting topographical effects. The measured effect of topography on the deposition velocity (V_d) is greater as particle size increases, as had been shown in modeling and laboratory studies [1, 2] but had not been demonstrated yet in field studies. We therefore suggest that a complex terrain and a patchy fetch affect the expected dependence of V_d on particle size and cause the observed upward particle fluxes. This hypothesis is consistent with the observed relationship between V_d and the friction velocity, the topography around the flux tower, and the observed correlation of flux direction with wind direction. The averaged V_d for 0.25-0.28μm particles (3.8±4.5 $mm \cdot s^{-1}$) is similar to previous particle deposition velocity measurements in mid and northern latitude coniferous forests.

Low Concentration Soil Exposure to ZnO Nanoparticles by Stable Isotope Labelling

A. LAYCOCK[1,3], M. DIEZ ORTIZ[2], F. LARNER[1], A. DYBOWSKA[3], E. VALSAMI-JONES[3,4], C. SVENDSEN[2] AND M. REHKÄMPER[1,3]

[4] Geography, Earth & Env Sci, U Birmingham B15 2TT, UK

The tracing of engineered nanoparticles (NPs) in the environment is hampered by analytical limitations. In particular, difficulties lie in the detection of these materials against the natural background of elements and NPs found in complex systems. To overcome these problems excessive dosing is often employed in exposures, calling into question the relevance of findings. The novel application of stable isotope labelling in conjunction with high precision isotope ratio measurements can overcome these shortcomings.

Presented here are results obtained for the exposure of the earthworm *Lumbricus rubellus* to isotopically labelled ZnO NPs in soil. To this end, ZnO NPs were synthesised using Zn enriched to 99.5% in the Zn-68 isotope relative to the natural abundance of 18.8%. The introduction of this enriched isotope into the experimental system creates distinct non-natural deviations in the diagnostic isotope ratio $^{68}Zn/^{66}Zn$. Precise determination of isotope ratio changes then enables accurate detection and quantification of the isotope label in the components of the exposure system.

The study compares dietary vs. dermal uptake of ^{68}ZnO NPs and soluble ^{68}Zn from soil by *Lumbricus rubellus*. Exposures were performed simultaneously in triplicate with earthworms being sampled at 4, 8, 24, 36, 48 and 72 hours. The labelling method allows use of an environmentally relevant exposure concentration of 4 µg/g ^{68}Zn against a natural Zn background content of up to 1.7 mg/g. After 4 hours of dermal exposure, the enriched ^{68}Zn contributes about 0.02% to the total Zn concentration of an exposed earthworm but this already produces a sufficient deviation in the diagnostic $^{68}Zn/^{66}Zn$ ratio to be detectable when measured by high precision multiple-collector ICP-MS.

For the exposures with ^{68}ZnO NPs and soluble ^{68}Zn, our data reveal that dermal ^{68}Zn uptake accounted for less than 10% of the worms total uptake, with dietary ^{68}Zn uptake being by far the most important route. In both cases, the uptake rates determined for ^{68}ZnO NPs and soluble ^{68}Zn are identical, within error. This indicates that Zn from both nano and ionic based exposures display similar bioavailability.

Substantial changes in the salinity and paleo-hydrology of the late Quaternary Dead Sea revealed in the ICDP deep drill

B. LAZAR*[1], O. SIVAN[2], G. ANTLER[3], Y. YECHIELI[4], E. LEVI[1], I. GAVRIELI[4] AND M. STEIN[4]

Vertical profiles of chloride (Cl^-) and oxygen isotopes ($\delta^{18}O$) of Lake Lisan the late Quaternary precursor of the Dead Sea were established from analyses of pore-fluids that were extracted from cores drilled during the ICDP campaign in the deep basin of the Dead Sea at water depth of 300 m. The pore fluids data provide the first direct measurements of the composition of the Dead Sea deep brine that was evolved over the past several glacial interglacial intervals. Specifically, pore fluid profiles suggest that during the last glacial (70-14 ka BP) Cl^- concentrations at the bottom of the lake were not more than 2/3 of their present values and $\delta^{18}O$ reached values higher than 6.7 ‰. The low chloride values of porewaters indicate that during MIS2 the deepest part of Lake Lisan was significantly less salty than the present Dead Sea. This is compatible with the heaviest $\delta^{18}O$ values that could be produced by evaporation of the waters at the shallow southern lake margins. Continuous turbulent mixing of such an evaporated solution with the lower brine across the epi/hypolimniom interface, led the dilution of the latter and the buffering of the Sr/Ca ratios and radiocarbon reservoir ages in the epilimniom[1]. However, upon the abrupt decline of the lake to minimum levels (below 450 m bmsl)[2] e.g. at ~14-13 ka (the Bolling-Allerod period), the bottommost brine retained its highest salinity, lowest $\delta^{18}O$ and highest Sr/Ca ratios.

The Miscellaneous Crenarcheotal Group (MCG) represents a frequently detected and widespread phylum-level lineage of Archaea. Their members are as yet uncultivated and hence little is known about their metabolism or their biogeochemical role in the environment. Recently, single cell genomic sequencing of one MCG cell indicated a role in protein remineralization [1]. A characteristic feature of MCG is their wide intra-specific diversity. Up to 17 subgroups of MCG based on 16S rRNA sequences have been documented [2]. In order to expand the search on potential metabolisms of the MCG, sediment cores were sampled in the White Oak River estuary (North Carolina, USA) in October 2010; these sediments have been previously shown to be strongly enriched in members of the MCG. The archaeal diversity of these sediments was screened with 16S rRNA gene libraries, accompanied by detailed geochemical analysis. Apart from one shallow sediment sample (10 cmbsf) the MCG dominated all samples, and all 17 MCG subgroups were detected. A sample at 46 cmbsf was chosen for 454 pyrosequencing using genomic DNA. Sequence read assembly yielded approximately 34,000 contigs, 15 of which contained more than 6000 bp. Many of the top contigs belonged to the MCG Archaea. Of the ten 16S rRNA archaeal sequences retrieved from the reassembled contigs, nine were affiliated with MCG and belong to six different MCG subgroups. Metagenomic characterization of archaeal community members revealed a variety of novel organic matter utilization genes including; proteases, amino acid transporters, nucleases, and lipid degradation.

[5]Institute of Inorganic Chemistry SB RAS

Quasi-synchorous hydrothermal activity is critical for high Ge contents in coal [1]. The mechanism of Ge accumulation remians unknown and has been suggested to be associated mainly with sorption from thermal waters bearing 100-150 ppb Ge.

We discuss the geochemistry of a cyanobacterial community at the Uro vent in the Baikal rift and compare element abundances in its waters with those in shale [2] and brown coal [1]. The Uro community contains 350 ppm Ge (average dry-weight contents, up to 1000 ppm), which is about that in the highest-Ge coal. The Uro thermal water composition is remarkable by elevated Be, Sr, Cs, Ga, Mo, and W. Trace elements in the community have implications for the general composition of the water but not for the abundances of elements in it. Bacteria may accumulate little (Cs, Rb, Mg, Sr, K, Ca, Si, V, U, Sb) or zero (Li, Na) amounts of some elements, or be poorer in others than the water (e.g., Mo and W). The living matter of the community hyper-accumulates Ge from water with only 3.4 ppm germanium. Thus, in order to infer the water composition from buried fossils (i.e., to do inversion), one has to take into account the mobility of elements, as well as their different sorption/accumulation by bacteria. The composition of the Uro community is typically thermofilic. Syngenetic hydrothermalism may induce formation of cyanobacterial mats, along with peat generation. Therefore, accumulation by the cyanobacterial community may be the agent responsible for high Ge in coal. As our study shows, Ge contents in the hot spring water may be not very high, within a few ppm.

The work was supported by grant 11-05-00717 from RFBR and was performed as part of Integration Project SB RAS 94.

Biomorphic structure of rich ores at the Tomtor REE deposit

E.V.LAZAREVA, S.M.ZHMODIK, A.V.TOLSTOV, B.L. SHERBOV AND N.S.KARMANOV

[1]Institute of Geology and Mineralogy SB RAS, Pr. Koptug, 3, Novosibirsk, 630090, Russia (*lazareva@igm.nsc.ru)

The Tomtor Paleozoic complex of ultramafic alkaline and carbonate rocks covers about 250 km^2 in northern Yakutia (Russia). It has a zoned structure with a carbonatitic core surrounded by ultramafite and foidolite and an alkaline-nepheline syenite periphery [1, 2, 3]. All rocks are weathered, the weathering profile upon P-REE carbonatite being the thickest and consisting of four layers: kaolinite-crandallite, siderite, goetite, and francolite (from top to bottom) [3]. Mineralization is the highest in redeposited and altered thinly bedded aphanitic kaolinite-crandallite ores, of slope-wash-lacustrine origin, with chemogenic phosphate [3] and Nb, Y, Sc, and REE enrichment. The richest ores are natural concentrates of Nb (up to 24%) and REE (to 39%) [1, 2, 3].

Monazite, pyrochlore, and crandallite-group minerals (goyazite, georceixite, and florencite) are main opaque phases in the rich ores. Pyrochlore occurs as euhedral cracked grains of sodic compositions, with Sr-Ba substitutions. Fine colloform aggregates of crandallite minerals make up the groundmass. Monazite exists as aggregates of 800-1200 nm long tubes, 300 nm in diameter, which perfectly correspond to pseudomorphs coating bacterial cells (monazite sheaths). Lanthanum phosphate precipitation on *Pseudomonas aeruginosa* cells was reported from experiments [4, 5].

Thus the high mineralization at Tomtor may be due to microbially mediated alteration of eluvium. Microbial fossils in the Tomtor ores were reported earlier [6] but no further study ever followed for the lack of solid proof. Prolific accumulation of monazite was possible in water of a persistent hot spring where hydrothermalism maintained a microbial community that concentrated trace elements.

The work was part of Integration Projects SB RAS #40, 94.

[5]Stroud Water Research Center, Avondale, PA, USA, shicks@stroudcenter.org, davemont@stroudcenter.org

Between 1929 and 1950, mercury (Hg) was extensively used by the DuPont plant in the production of rayon acetate fiber in Waynesboro, VA and released into the South River. The contamination of Hg was discovered in the 1970s and remains elevated in water, soil, sediments,and biota.

The major objective of this study is to investigate Hg dynamics within the floodpliain soils at South River Mile 3.5. Our over-arching hypothesis is to test if leaching of bank soils is a significant source of dissolved or colloidal inorganic Hg (IHg). The hypotheses on Hg loading mechnism include: (1) bank soil inundation is due to horizontal flow through a highly transmissive gravel zone at the base of the bank, vertical drainage of precipitation, and upgradient groundwater flow; (2) drainage occurs mainly through gravel zone wetting an organic rich soil; (3) hydraulics facilitate the downward or upward movement of the capillary fringe affecting soil redox potential, mineral dissolution, and leaching of IHg into dissolved/colloidal phases that are either directly transported to the river or methylated within the saturated zone of the bank and subsequently released.

This investigation will demonstrate preliminary data from a number of state-of-the-art in-situ monitoring sensors, such as custom-designed redox probes, soil moisture and temperature probes, pressure transducers installed at the site; and soil and pore-water chemistry. The sensors are used to characterize geochemical gradients and how they change over time, and to enable targeted sampling at Hg loading hot spots.

In situ measurements of Cu isotopes in Cu sulphides

M. LAZAROV[1]*, I. HORN[1], S. WEYER[1] AND A. PAČEVSKI[2]

[1] Institute für Mineralogie, Leibniz Universität Hannover, Callinstr. 13, 30167 Hannover, Germany (*m.lazarov@mineralogie.uni-hannover.de)
[2] Faculty of Mining and Geology, University of Belgrade, Dusina 7, 11000 Belgrade, Serbia

Previous investigations observed Cu isotope fractionation in hydrothermal or porphyry ore deposites in the order of 2‰ [1, 2]. If such Cu isotope variations occur within a single ore body or mineralisation vein, they likely point to changes of the redox conditions or salinity of hydrothermal fluids [2, 3], rather then source heterogeneities. To distinguish these processes we are developing a method of in situ copper isotope analyses by femtosecond LA-MC-ICP-MS.

Initial tests were conducted using in-house standards of Cu metal, brass and Cu-sulphide minerals (chalchopyrite, covelite and enargite) that are homogeneous regarding their major elements. For comparison, the copper isotope composition of these in-house standards was also analysed by solution MC-ICP-MS. In both cases in-house standards were measured relative to the Cu (NIST976) standard while Ni (NIST986) was used to monitor instrumental mass bias [3]. For replicated analyses of metal in-house standards relative to NIST976, in both laser ablation and solution modes the precision of <0.05‰ for $\delta^{65}Cu_{NIST}$ was achieved. Replicated LA-MC-ICP-MS analyses of minerals relative to NIST976 or in-house standards of the same mineral, revealed reproducibility variations for $\delta^{65}Cu$ of ~0.2‰. The laser ablation analyses of the in-house mineral standards agreed within 0.15‰ ($\delta^{65}Cu$) with those obtained by solution analyses. The larger scatter of the mineral standards (relative to metals), obtained by laser ablation, likely indicates Cu isotopic heterogenities within the analysed minerals.

First in situ Cu isotope measurements of samples from the Bor hydrothermal ore deposit (East Serbia) reveals differences of ~0.35‰ in $\delta^{65}Cu$ between chalcopyrite in veins and those dispersed as small grains. These systematic variations likely imply a change in the composition of hydrothermal fluids.

[4]Dep. of Mineralogical and Petrological Sciences, University of Torino, Italy

The large amount of non-biodegradable sulfonamide antibiotics used in hospitals, feedstocks and in fish farming cause their occurrence in the aquatic environment resulting in the dramatic emergence of antibiotic resistance in fish pathogens and in the transfer of these resistance determinants to bacteria in land animals and to human pathogens [1]. In Italy, it was found that sulfamethoxazole (SMX) is one of the most abundant residual drug in surface waters [2]. Recently, it has been proven that high-silica zeolites (Y, ZSM-5 and MOR) are environmentally compatible adsorbents able to effectively remove sulfamethoxazole when dissolved in aqueous matrix [3]. The effective incorporation of this pollutant inside the zeolite cavities has been demonstrated by combining diffraction and spectroscopic techniques [3].

In this work, the thermal regeneration of hydrophobic high-silica ZSM-5 and hydrophobic high-silica zeolite Y after sulfamethoxazole adsorption was investigated using *in situ* high-temperature synchrotron X-ray powder diffraction (GILDA, ESRF) to monitor the structural modifications induced by heating. The evolution of the structural features was followed both in temperature ramp (25-575°C, heating rate 10 °C/min) and in isotherm mode (120 minutes at 575 °C) by full profile Rietveld refinements.

Structure refinements demonstrate that the thermal regeneration accompanied by the full degradation of SMX is completed at about 575 °C and it does not affect the crystallinity of the sorbing materials. These results indicate that high-silica zeolite Y and high silica ZSM-5 are affordable materials for water clean-up and drug delivery.

Connecting bacterial ROS cycling to the production of Mn oxides

D.R. LEARMAN[1*], T. ZHANG[2], P.F. ANDEER[2] AND C.M. HANSEL[2]

[1]Department of Earth and Atmopheric Sciences and Institute for Great Lakes Research, Central Michigan University, Mount Pleasant, MI, 48859 U.S.A. (*correspondance: deric.learman@cmich.edu)

[2]Marine Chemistry and Geochemistry Department, Woods Hole Oceanographic Institution, Woods Hole, MA 02543, U.S.A.

Reactive oxygen species (ROS) can drive the cycling of numerous important elements in the environment. Previously we have shown that the bacterium, *Roseobacter* sp. AzwK-3b, governs the oxidation of Mn(II) via enzymatic production of superoxide. Another ROS, hydrogen peroxide, is also important in this pathway. In fact, in reactions with only Mn(II) and abiotically generated superoxide, we find superoxide alone is not enough to produce Mn(III,IV) oxides. The scavenging of hydrogen peroxide (via the addition of catalase) is required to generate Mn oxides abiotically. Thus, *R*. AzwK-3b must produce superoxide and also scavenge hydrogen peroxide to form Mn oxides. To obtain a greater understanding of biological factors involved in this process, proteins were extracted from *R*. AzwK-3b cultures and examined for their connection to Mn(II) oxidation. Similar to the pathway identified in experiments with *R*. AzwK-3b whole cell cultures and cell-free filtrate, Mn(II) oxidation within soluble protein extracts is initiated by superoxide. Further, an in-gel Mn(II) oxidation assay revealed a protein band that could generate Mn oxides in the presence of soluble Mn(II). This Mn(II)-oxidizing protein band was excised from the gel and the peptides were identified via mass spectrometry. An animal heme peroxidase was the predominant protein found in this band. This protein is homologous to the animal heme peroxidases previously implicated as a Mn(II)-oxidizing enzyme within the *Alphaproteobacteria*, *Erythrobacter* SD-21 and *Aurantimonas manganoxydans* strain SI85-9A1. For *R*. AzwK-3b, the mechanism(s) of Mn(II) oxidation by this animal heme peroxidase is unknown, but may include scavenging of hydrogen peroxide, generation of superoxide, or production an organic ligand involved in Mn(III) complexation. Interestingly, the *Alphaproteobacteria, Ruegeria* sp. TM1040, is also known to generate extracellular superoxide but does not oxidize Mn(II) to Mn oxides. Interestingly, the genome of *Ru*. TM1040 does not contain an animal heme peroxidase, which further suggests an important role for this protein in the formation of Mn oxides.

Enzymatic contraints on the global S cycle: *the fractionation factors of Dsr*

WILLIAM D. LEAVITT[*1], INÊS C. PEREIRA[3], ALEXANDER S. BRADLEY[3], WEIFU GUO[4] AND DAVID T. JOHNSTON[1]

Coupling quantitative geochemical models with enzyme and whole cell observations informs our interpretation of the environmental histories encoded in the geological S isotope records. Much of this preserved record is driven by the central biochemical machinery of microbial sulfate reducers (MSRs) – linking sulphate reduction to organic matter oxidation. Our present understanding of MSR sulfur isotope fractionation stem from a series of robust cellular-scale (*in vivo*) studies [c.f., 1]. Still, biogeochemical models of the S cycle lack fundamental constraints on the fractionations associated with enzymatic S transformations within the MSR pathway, rendering our best models semi-quantitative. Inspired by the early carbon isotope work on RuBisCO and the influence those studies hold on our understanding of the global carbon cycle, we extend our recent open-system *in vivo* [2] and preliminary pure-enzyme (*in vitro*) experimental work. This study is part of a broader effort to precisely calibrate the S-isotope effects associated with *in vivo* sulphate and *in vitro* sulfite reduction, each underpinned by the MSR enzyme dissimilatory sulfite reductase (Dsr).

To provide fundamental boundary conditions for the network fractionation models of MSR, we performed *in vitro* closed-bottle sulphite reduction experiments with purified DsrAB protein. From these experiments we measure the isotopic composition of all S pools: sulfane and sulfonate moieties in reduction products trithonate and thiosulfate, residual, and initial sulphite. From here we apply a modified Rayleigh model to calculate the enzyme-specific isotope fractionation factors for DsrAB ($^{33}\lambda_{Dsr}$, $^{34}\alpha_{Dsr}$). We repeat this procedure over a range of experimental conditions, including temperature and host species. Isotope and mass balance is conserved in all individual experimental volumes allowing us to directly calculate fractionation factors. Interestingly, the major isotope fractionation factors ($^{34}\alpha_{DsrAB}$) we most often observe are significantly smaller than predicted those from equilibrium estimates, but readily fit with indirect estimates from a seminal study by Jørgensen [3].

Nitrogen biogeochemical cycling in ferruginous Lake Pavin

OANEZ LEBEAU[1*], VINCENT BUSIGNY[1*], DIDIER JEZEQUL[1], CARINE CHADUTEAU[1], SEAN CROWE[2] AND MAGALI ADER[1]

[1]Univ. Paris Diderot-IPGP, Sorbonne Paris Cité, UMR7154 CNRS, Paris, France *correspondence: olebeau@ipgp.fr
[2] Nordic Center For Earth Evolution, University of Southern Denmark, Odense, Denmark

Over geological timescales, the Earth's oceans were affected by several periods of total or partial anoxia. The timing, causes and consequences of ocean oxygenation are intimately linked to paleo- N cycling. Studies on modern analogues are essential for interpreting biogeochemical signals recorded in ancient sediments. Lake Pavin (French Massif Central) is permanently stratified with anoxic Fe-rich deep waters (from 60 to 92m depth) overlain by oxic shallow waters (from 0 to 60m depth) and can be regarded as an analogue for the ocean during periods of redox stratification with ferruginous deep waters. Such ferruginous conditions were prevalent during the Precambrian and may also have been important during Phanerozoic Ocean Anoxic Events (OAEs). In order to determine if the primary N isotope signatures are preserved or modified in this type of environment, we analyzed bulk N isotope compositions in 6 sediment cores from different depths in Lake Pavin: in the oxic zone (31.5, 26.8 and 19.5m depth), at the oxic-anoxic boundary (60m depth), at the peak of H_2S production from SO_4^{2-} reduction (65m depth) and at the bottom of the lake (90m depth). Complementary analyses of sediment traps set up at 4 different depths in the water column (25, 56, 67 and 88m depth) provide a reference frame for organic matter deposited in the sediments and allow us to test diagenetic N evolution in the water column. For the traps and cores of the anoxic layer, the N isotope composition is not significantly affected by diagenetic processes with $\delta^{15}N_{tot}$ values around -1 ‰. Such unusually low $\delta^{15}N$ values suggest a dominance of N_2-fixers in the water column, which is expected in a stratified system where nitrate is strongly depleted by denitrification at the redox boundary and N_2 is the major source of N for organisms living in the photic zone. For each core of the oxic layer, $\delta^{15}N_{tot}$ increases with depth within the sediment, from values as low as -3.3 ‰ up to +0.3 ‰. These variations are not compatible with purely oxic diagenesis but require a migration of the sediment oxycline through time, possibly due to an increase in the organic matter flux associated with eutrophication in Lake Pavin.

Stretching, Coalescence and Mixing in Porous Media

TANGUY LE BORGNE[1], MARCO DENTZ[2] AND EMMANUEL VILLERMAUX[3]

We study mixing in heterogeneous permeability fields, whose structural disorder varies from weak to strong. We propose a unified framework to quantify the overall concentration distribution predicting its shape and rate of deformation as it progresses towards uniformity in the medium. The concentation field is represented by a set of stretched lamellae whose rate of diffusive smoothing is locally enhanced by kinematic stretching. Overlap between the lamellae is enforced by confinement of the scalar line support within the dispersion area. Based on these elementary processes, we derive analytical expressions for the concentration distribution, resulting from the interplay between stretching, diffusion and random overlaps, holding for all field heterogeneities, residence times, and Peclet numbers. We discuss consequences for effective chemical reaction kinetics in heterogeneous media.

Rare earth elements in lake sediments in Poland

DARIUSZ LECH, IZABELA BOJAKOWSKA AND DOROTA KARMASZ

Polish Geological Institute – National Research Institute (izabela.bojakowska@pgi.gov.pl)

127 sediment samples were collected from profundal zones of 87 lakes of the following lakeland areas: Greater Poland, Pomerania, Masuria and Łęczna-Włodawa. In the samples the content of REE, Sc and Y were determined by ICP-MS method, the content of Ba, Cr, Co, Cu, Pb, Zn, Ni, V, Sr, Ca, Mg, Fe, Mn, K, Na, P and S - by ICP-OES method, after aqua regia digestion, Organic carbon were also determined (TOC) by means of coulometric titration method

The REE content in analyzed sediments ranged from 4.40 to 127.44 mg/kg, the average content was 35.78 mg/kg while the geometric mean - 24.68 mg/kg. The average REE contents of individual elements were as follows: La - 6.65 mg/kg, Ce - 15.43 mg/kg, Pr - 1.74 mg/kg, Nd - 6.93 mg/kg, Eu - 0.26 mg/kg, Sm - 1.36 mg/kg Gd - 1.24 mg/kg, Tb - 0.17 mg/kg, Dy - 0.92 mg/kg, Ho - 0.17 mg/kg, Er - 0 , 45 mg/kg, Tm - 0.06 mg/kg, Yb - 0.35 mg/kg and Lu - 0.05 mg/kg. The concentrations of rare earth elements in studied lake sediments are comparable to the concentrations found in sedimentary rocks. REE concentrations in the sediments are most similar to their concentrations in limestone rocks; however they are lower in comparison to the REE concentrations in sandstones and clay rocks. The results showed differences in the content of REE in lake sediments in various parts of Poland. The geometric mean of REE content in the lake sediments of Pomeranian, Greater Poland and Łęczna-Włodawa Lake Districts were similar and were respectively 21.70, 20.70 and 21.50 mg/kg, while the sediments of Masuria Lake District had a higher geometric mean of REE content – 29,54 mg/kg.

The content of REE in lake sediments shows a strong correlation with the Al (r = 0.96), K (r = 0.96) and Mg (r = 0.86) contents, a high correlation with the Fe (r = 0.68), a significant correlation with the P (r = 0.42), S (r = 0.40) and organic carbon (r = 0.38) contents. Among the trace elements analyzed REE concentrations showed a very strong correlation with the concentration of Ni (r = 0.92), V (r = 0.94), Co (r = 0.94) and poor correlation with the content of Zn (r = 0.31), Pb (r = 0.34), and Cu (r = 0.33). REE contents in sediments also showed a negative high correlation with calcium (r = -0.79) and strontium content (r = -0.53).

Redox in silicate melts: in-situ XAS investigation of 2 redox couples

M. LECONTE[1], P. M. MARTIN[2], D. TESTEMALE[3], C. PETITJEAN[4] AND D. R. NEUVILLE[1]

[1]CNRS-IPGP, Géochimie&Cosmochimie, Paris Sorbonne Cité, 1 rue Jussieu, 75005 Paris, France.

[3]Institut Néel, Département MCMF, 38042 Grenoble, France.
[4]Institut Jean Lamour, BP 70239, 54506 Vandoeuvre, France.

The silicate melts are important materials for earth sciences, in particular for the volcanology and mass transfers and also for glass industry (glass making, ceramics and nuclear waste management). Such melts are very complex materials generally containing more than ten oxides. The presence of multivalent elements within the glass compositions can significantly affect both glass properties (rheological properties [1] for example) and technological processes. In particular in the field of nuclear waste storage where solubility, crystallization and incorporation of heavy elements are of prime importance. Consequently, the control of oxydoreduction reactions proves to be necessary for managing both vitrification processes and structural changes intervening in temperature within glasses. Magnien *et al*.. [2] have shown that redox can be control at high temperature by diffusion of O_2 and O^{2-} whereas at low temperature, around the glass transition temperature by diffusion of cations according with Cook and Cooper [3]. But all these studies are made with only one redox couple, but what happens by mixing redox couple?

XANES spectroscopy is a powerful tools to investigate valence, coordination number, short and middle range order in mineral, glass and melts.

We have investigated redox of Cr and Ce silicate glass and melts at high temperature by using XANES at the Cr K-edge and Ce L3 edge. These results represent a first step to understand mixing redox couple in silicate melts and how they interact at different temperature and under different control atmosphere. These results will be present and discuss.

Genetic relationship between Ag-(Pb-Zn) mineralization and W-specific Mesozoic magmatism in the Nanling belt (China) based on data from the Wutong deposit

P. LECUMBERRI-SANCHEZ[1]*, R.L. ROMER[2], V. LÜDERS[2] AND R.J. BODNAR[1]

[1]4044 Derring Hall, Virginia Tech, Blacksburg, VA 24061, USA (*correspondence: pilar@vt.edu)
[2]GFZ, Telegrafenberg, D-14473, Potsdam, Germany

More than 50 % of the world's total reserves of tungsten are in China, and most tungsten deposits are located in the Nanling range (Cathaysia block, southeast China). This study explores the genetic relationship between W-specific magmatic events and shallow (W)-Ag-Pb-Zn deposits in the Nanling range based on data from the Wutong deposit, Guangxi Province.

Because the temperatures obtained from mineral thermometry and homogenization temperatures of fluid inclusions are the same (~300°C), the fluid inclusion homogenization temperatures are interpreted to be approximately equal to the trapping temperatures, indicating formation at low pressures, i.e., slightly above the liquid-vapor curve. This, in turn,indicates that the deposit formed at relatively shallow levels. The C-O-S-Sr-Pb isotopic composition of minerals indicate that one single fluid was responsible for mineralization. The chemical composition of fluid inclusions indicates that the fluid evolved from a fractionated magma. Therefore, the Wutong deposit is likely to represent the shallow expression of a magmatic-hydrothermal system. The Sr-Pb isotopic data indicate that the magmatic fluids are associated with melting of crustal rocks of the Cathaysia block.

The age of the Wutong mineralization, obtained from hübnerite dating, is Late Yanshanian (Cretaceous). Most Ag-Pb-Zn deposits in this region are typically attributed to Late Jurassic mineralization. In contrast, Wutong is a Cretaceous system formed during the Cretaceous mineralization peak in south China. As this relatively shallow hydrothermal system is related to deeper magmatism, Cretaceous mineralization is not limitted to the western limit of Cathaysia but may extend eastward at least to the Nanling range. Furthermore, regional grouping of the age of granite-related magmatism indicates that the same kind of crustal source has been melted repeatedly, possibly in different tectonic settings.

The turnover time of organic carbon in boreal riparian zones – A hydrological approach

J. L. J. LEDESMA[1*], T. GRABS[2], K. H. BISHOP[1,2] AND S. J. KÖHLER[1]

[1] Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), P.O. Box 7050, 750 07 Uppsala, Sweden (*correspondence: jose.ledesma@slu.se) (Kevin.Bishop@slu.se, Stephan.Kohler@slu.se)
[2] Department of Earth Sciences, Uppsala University, P.O. Box 256, 751 05 Uppsala, Sweden, (Kevin.Bishop@geo.uu.se, thomas.grabs@geo.uu.se)

Boreal regions are large stores of organic carbon (OC). The majority of the OC found in boreal inland waters is allochthonous, i.e. originally from terrestrial sources. Allochthonous carbon is especially dominant in headwater streams, which also show high concentration and fluxes. The link between the terrestrial and the aquatic compartments in these headwaters is dominated by organic matter-rich riparian zones (RZ). RZ have been described as near-infinite organic matter sources [1] [2] because large amounts of OC originate here and are exported to streams by lateral fluxes. But, how long can RZ sustain the high lateral OC fluxes in boreal catchments? To answer this question we estimate the turnover times of OC in 13 RZ profiles in a boreal catchment in northern Sweden by comparing pools and lateral fluxes. The lateral fluxes can be mathematically estimated using the Riparian Flow-Concentration Integration Model (RIM) approach [3] [4], in which lateral discharge and concentration profiles in the RZ are combined. Our calculations with this approach indicate that 90% of the lateral OC fluxes come from a 36 ± 18 cm (± SD) shallow soil layer accounting in all the 13 studied riparian profiles. Preliminary analyses suggest long turnover times of OC in these 'active' layers. That would imply that there is no long term supply shortage. The results from this study will have implications for the global carbon cycle in relation to human perturbations.

Archean cherts: are they reliable paleo-seawater proxies?

MORGANE LEDEVIN[1]*, NICK ARNDT[1] AND ALEXANDRE SIMIONOVICI[1]

[1]ISTERRE, BP53, 38041 Grenoble Cedex 9, France (*correspondence: morgane.ledevin@ujf-grenoble.fr)

Archean cherts represent some of the oldest sedimentary rocks on Earth. It is commonly thought that they could be useful paleo-environment indicators, assuming that the silica phase retained the composition of the fluid from which it precipitated. In this study, we conducted geochemical and isotope analyses of three types of cherts (seawater-derived precipitates, fracture-filling cherts and silicified sediments) from the Barberton greenstone belt (3.5-3.2Gy), South Africa, in order to test their reliability for paleo-environment studies.

We show that Archean cherts are a mixture of (*1*) a silica phase that has extremely low concentrations of trace elements and contributes only SiO_2 to the bulk composition, and (*2*) another phase that dominates the trace element composition and varies from site to site. We calculated that 3-4% of phyllosilicate, 20% of carbonaceous matter and only 2% of carbonate is enough to control the chert chemistry and mask the silica composition. Carbonate-rich cherts could be of interest because this phase has long been known to retain oceanic fluid chemistry.

Because the silica phase is easily contaminated, the use of cherts for paleo-environment reconstructions is seriously limited and requires high purity precipitates. Massive white chert layers at Buck Reef have SiO_2 close to 100wt% and extremely low concentrations in all the trace elements. We argue that these chemical features are the sole reliable criteria available for now to recognize a pure precipitate, i.e. one that lacks continental contributions, but that they are not sufficient to rule out a possible hydrothermal contribution. Otherwise, only systematic field and petrographic studies can help to distinguish the various chert types, as their composition does not depend on the formation process.

The high purity white cherts from Buck Reef display strong LREE depletions, positive La anomalies and superchondritic Y/Ho ratios that resemble modern seawater. However, these commonly used proxies for the recognition of seawater-derived precipitates fail to distinguish the origin of the silica, these characteristics being similar to those found in hydrothermal, metamorphic and pegmatitic quartz. An unusual feature is the strong positive Sm-anomalies of these samples which have never been observed in any other terrestrial rock.

Prediction of Effects of Acetogens on Hot Spring Biogeochemistry

BRADY D. LEE[1], JOHN E. ASTON[1], MICHELLE H. LEE[2] AND WILLIAM A. APEL[1]

[1]Idaho National Lab, P.O. Box 1625, Idaho Falls, ID 83415, Brady.Lee@inl.gov

[2]Pacific Northwest National Lab, P.O. Box 999, MSIN K3-62, Richland, WA 99352 USA, Hope.Lee@pnnl.gov

Acetogens are a broad category of obligately anaerobic bacteria that are found in a variety of ecosystems and are able to use diverse electron donors and acceptors. Activity of acetogens has been studied in many terrestrial environments, but the activity of acetogens in hot spring environments is not well understood. For this reason, acetogens in hot spring may have a wider impact on hot spring geochemical cycles and microbial populations, beyond just acetogenic activity. One method to predict the impacts of versatile metabolisms on the flow of energy and material through microbial systems is metabolic stoichiometric modeling, which extracts systemic information from molecular-level network structure and conservation relationships, depending on electron donors and acceptors in the growth environment. To test this hypothesis, an intitial model has been constructed from the annotated genome of the well-studied acetogen, *Moorella thermoacetica*, and the output data have been sorted against various cellular strategies, including maximal efficiency of biomass yield per substrate, and substrate consumption in the presence of high exogenous concentrations of produced metabolites. Output from such models has successfully predicted substrate concentrations that yield elevated ethanol production, as opposed to acetate, when *M. thermoacetica* was grown on CO_2 and H_2. This research has shown the utility of metabolic modeling in predicting electron donor and acceptor use and production of organic acids and alcohol in the *M. thermoacetica*. These types of models will help to predict the effects of acetogenic activity on the overall biogeochemistry in hot spring environments.

Carbon isotope and lipid biomarker stratigraphy from organic-rich strata through the Neoproterozoic Shuram excursion in South Oman

C. LEE[1], D. A. FIKE[2], G. D. LOVE[1], A. L. SESSIONS[3], J. P. GROTZINGER[3], R. E. SUMMONS[4] AND W. W. FISCHER[3]

[1]University of California, Riverside (clee093@ucr.edu)
[2]Washington University St Louis
[3]California Institute of Technology (wfischer@caltech.edu)
[4]Massachusetts Institute of Technology

The regulation of oxygen levels in Earth's atmosphere and oceans is inextricably linked to the carbon cycle. Carbon isotope ratios of carbonate and sedimentary organic matter provide first order insights into the operation of the carbon cycle in the geologic past. During the Ediacaran period, the ~580 Ma 'Shuram Excursion' (SE) records a dramatic, systematic shift in $\delta^{13}C_{carbonate}$ values to as low as *ca*. -12‰, lasting potentially millions to tens of millions of years in duration and constitutes the largest carbon isotope excursion known in the record [1]. The extremely negative carbon isotope values in carbonate challenges our understanding of the ancient carbon cycle and is difficult to rationalise *via* uniform carbon cycle principles. Several hypotheses have been developed to explain this behaviour, all of which make different predictions for the abundance, structure, and isotopic composition of organic carbon through the excursion [1,2,3,4].

For a direct test of these ideas, we report paired organic and inorganic stable carbon isotope ratios in addition to detailed lipid biomarker stratigraphic records from a subsurface well drilled on the eastern flank of the South Oman Salt Basin, Sultanate of Oman. This well captures thermally immature and organic-rich Nafun Group strata traversing the SE, yielding variable but primary biomarker characteristics typical of Neoproterozoic rocks from this region [5].

Despite the high organic matter contents, the carbon isotopic compositions of carbonates do not covary with those of organic phases. Furthermore, lipid biomarker data reveal that organic matter composition and source inputs varied stratigraphically, reflecting biological community shifts in non-migrated, syngenetic organic matter deposited during this interval. Together these observations imply that carbonate-organic isotopic decoupling during the SE is not a result of mixing of fossil or exogenous carbon sources (either DOC, detrital, or migrated) with syngenetic organic matter.

Mineralogical characterization of chrysotile-containing soils

CHAEHYANG LEE[1], JAEBONG PARK [2], SEKWHAN SONG[3], HOJU LIM[4] AND YUL ROH[5*]

[1]Chonnam National University, Gwangju, Korea, (chwish@nate.com)
[2]Chonnam National University, Gwangju, Korea, (20548pjb@chonnam.ac.kr)
[3]Joongbu University, Chungnam, Korea, (shsong@joongbu.ac.kr)
[4]National Institute of Environmental Research , Incheon, Korea, (limhoju@gmail.com)
[5]Chonnam National University, Gwangju, Korea, ([*]correspondence: rohy@jnu.ac.kr)

Asbestos-containing soils occur mainly at ultramafic rocks and hydrothermally altered carbnate rocks in S. Korea. Remediation of asbestos-containing soils is considered a high priority by the Korean Government because these soils, if left untreated, represent a hazard to the environment and human health. The objective of this study was to show physicochemical and mineralogical characterization of asbestos-contaminated soil can direct the development of remediation strategies.

Two sites (Hongseong and Gapyeong, S. Korea) at abandoned asbestos mines were selescted for soil and mineralogical characterization. At each site, samples were taken at soil surface. Soil preparation consisted of sieving air-dried soil through a 2-mm sieve. The sieved soils (< 2-mm) were used for soil characterization and mineralogical analysis. Following particle size fractionations, mineralogical characterization was investigated by TG-DTA, XRD, PLM, SEM and EDS analyses. Point counting was used to quantify asbestos in the whole soil and size fractionated samples.

The soil color of the both sites was gley. The soil texture of the Hongseong and Gapyeong soils was loamy sand and sand, respectively. XRD, PLM, SEM and EDS analyses showed that the fibrous chrysotile was observed at both soils, and both fibrous chrysotile and the needle or straight-shaped tremoilte asbestos existed in Gapyeong soils. Hongseong soils contained 4.8% asbestos in sand fraction and 2.5% asbestos in silt fraction. And Gapyeong soils contained 6.6% asbestos in sand fraction and 1.7% asbestos in silt fraction. Therefore, the soils of the both sites were designated as asbestos-containing materials (greater than or equal to 1%) according to the criteria of the U.S. EPA. TG-DTA showed that chrysotile and tremolite asbestos in soil at both sites were transformed to forsterite and diopside with the temperatures about 810°C and 1060°C, respectively. These results indicated that thermal treatment of asbestos-containing soils was effective for phase transformation of the asbestos in soils.

A case study for soil erosion in the Han river buffer zone, South Chuncheon, Korea

DAL-HEUI LEE[1], SUNG LAE CHUNG[2], WOO YOUNG CHOI[3] AND SEUNG HEON CHAE[4]

[1][215 Anyang Megavalley, Gwanyang-dong 799, Dongan-gu, Anyang-si, Gyunggi-do, Korea, dalheui@yonsei.ac.kr
[2, 3, 4][215 Anyang Megavalley, Gwanyang-dong 799, Dongan-gu, Anyang-si, Gyunggi-do, Korea, sj9171@chol.com]

The objective of this study is to report the relative importance of soil management on organic content of the sediment in relation to soil erosion. The rainfall simulation experiments were carried out under different rainfall kinetic energies and geotechnical conditions. The three soil sampling sites were located on the adjacent farms of the riparian buffer zone of the Han River, Korea. Rainfall simulations were carried out within three months after soil sampling. Lechler full cone nozzles (type 460.648.30.cc) based on measurements using a Distromet Joss-Waldvogel Disdrometer. Tap water with an electric conductivity of 105 uS cm^{-1} was used for each test. The implications of the results will aid the development of models aimed at predicting organic content due to soil erosion. The test results showed that geotechnical conditions and rainfall conditions, such as the ground slope, the compaction ratio, rainfall intensity and duration of rainfall are main factors for soil erosion. However, soil texture was determined to be the most important soil variable influencing soil erosion. Apparently, the severity of soil erosion did not exclusively determine the amount of nutrients lost in runoff from agricultural land.

Metal stable isotopes in Lake Baikal sediments

DER-CHUEN LEE[1,*], HSIN-TING LIU[2] AND SHUN-CHUN YANG[3]

[1]Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan, ROC, dclee@earth.sinica.edu.tw (* presenting author)
[2]Dept. of Earth Sciences, Nat. Normal Univ., Taipei, Taiwan, ROC, 49444039@ntnu.edu.tw
[3]Dept. of Geological Sciences, Nat. Taiwan Univ., Taipei, Taiwan, ROC, d98224001@ntu.edu.tw

Metal stable isotopes of Fe, Zn, Mo, and Cd, have been analyzed for the authigenic portion of a gravity core from Lake Baikal, Russia, in order to study the sources and sinks for these trace metals in the Lake Baikal, the largest fresh water lake in the world, and as potential proxies for the past climate changes in the region [1]. A ~ 3 meters gravity core (GC-99; 52°05'23"N, 105°15'24"E) sampled near the bore hole of BDP-99 in Lake Baikal is used in this study. The core was sampled per cm continuously, and one sample was analyzed for every 10 cm throughtout the entire core in this study. A series of leaching procedures were used to remove the carbonates, and to collect the authigenic fractions for study. Double spike technique is used for all four metal stable isotopic measurements.

In general, significant variations are observed yet no correlation is found among these four metal stable isotopes and their respective elemental concentrations. Direct ^{14}C-dating is currrently undertaken, however, using the sedimentation rate of a nearby sediment core, the 3 m GC-99 seems to have recorded the past ~ 23 ka of sedimentation history of Lake Baikal, with a shift of sedimentation rate at ~ 100 cm that has marked the YD event at ~ 12 ka. The same depth also marked the significant shift of δ^{97}Mo/^{94}Mo from -0.5 ‰ in the deeper depth to ~ -2.2 ‰ in the upper 100 cm. Simlar shifts from relatively constant at -0.7 ‰ in the deeper depth to more variable, 0 to -1.5 ‰, in the upper 100 cm is also observed for δ^{56}Fe/^{54}Fe. Less pronounced but nonetheless similar shfts also observed for Cd and Zn isotopes. While the vairations of Cd, Zn, and Fe (to some degrees) isotopes are mostly likely reflect the biological activities, booming of diatoms, the isotopic vairations of Mo and Fe (to a lesser degree) can only be explained by the changing of the redox states, towards more oxic from YD event to the present, in Lake Baikal, if the sedimentation rate is indeed correct. Nevertheless, this study marks the first time the metal stable isotopes can be used to study the connections between the local climate events and Lake Baikal using the sedment records. More data, in particular, the chronology and detailed chemical and mineralogical compoisitions of the sediment cores are needed in order to better constrain the relationship between the Lake Baikal and regional climate changes in the past.

Geochemical processes of soil and groundwater contamination by Cr(VI) from natural sources

GIEHYEON LEE*, SEONYI NAMGUNG AND YEONJIN LEE

Department of Earth System Sciences, Yonsei University, Seoul, Korea (*correspondence: ghlee@yonsei.ac.kr)

Soil and groundwater contamination with hexavalent chromium (Cr(VI)) is of serious concern especially in industrialized areas over the world as Cr(VI) is the 2nd most common inorganic contaminant. Reduction of Cr(VI) to Cr(III) followed by its precipitation as or directly to $Cr(OH)_3(s)$ is generally the best strategy for Cr(VI) removal because this process substantially alleviates both the toxicity and mobility of Cr. Thereby, processes and mechanisms for Cr(VI) reduction by various reductants have been extensively investigated. Besides the anthropogenic contamination, natural Cr(VI) contamination of soil and groundwater without any anthropogenic source has been reported over the world. Since Cr commonly exists as a trace constituent of various rock forming minerals in the oxidation state of +III, the oxidation processes of Cr(III) would likely be responsible for the natural Cr(VI) contamination processes. We have investigated the potential reaction pathways of Cr(III) oxidation to elucidate the geochemical processes of natural Cr(VI) contamination.

In this study, we examined the oxidation of $Cr(OH)_3(s)$ by birnessite. These two solid phases are those of the most common solid phases of Cr and Mn, respectively, under the near surface environmental conditions. $Cr(OH)_3(s)$ oxidation was examined with solid suspensions containing $Cr(OH)_3(s)$ and/or birnessite (1.0 g/L of each solid) fixed at pH 7 – 9 with buffers. Sparingly soluble $Cr(OH)_3(s)$ was readily oxidized by birnessite and released substantial amounts of dissolved Cr(VI) in the mixed suspensions. The apparent rate and extent of $Cr(OH)_3(s)$ oxidation increased with increasing pH. The oxidation was catalyzed by reaction intermediate during the early stage of reaction (ca. 10 h) at all pHs. At pH 7 the production of Cr(VI) reached plateau in about 10 d but was continued for 33 d at higher pHs until the experiments were ceased. In addtion, the processes of $Cr(OH)_3(s)$ oxidation by birnessite were substantially accelerated in the suspensions open to the atmosphere compared to those purged with N_2. The geochemical processes inhibiting or accelerating $Cr(OH)_3(s)$ oxidation under the experimental conditions will be discussed.

Age and geochemical constraints on the genesis of Late Cenozoic volcanic rocks in central Myanmar

HAO-YANG LEE[1]*, SUN-LIN CHUNG[1], HSIAO-MING YANG[1], CHIU-HUNG CHU[1], CHING-HUA LO[1] AND A.H.G. MITCHELL[2]

[1]Department of Geosciences, National Taiwan University, Taipei, Taiwan
(*correspondence: haoyanglee@ntu.edu.tw)
[2]Consulting Geologist, 20, Dale Close, Oxford OX1 1TU, UK

The central Myanmar basin in which Late Cenozoic volcanism occurred is marked by the existence of the dextral Sagaing fault linking the eastern Himalayan Syntaxis in the north and the Andaman Sea in the south. Here new and comprehensive age results of the volcanic rocks from volcanoes of Mt. Popa, Monywa and Singu are roported. They display two distinct stages of eruptions, including a mid-Miocene stage from ca. 14 to 13 Ma and a Quaternary stage <1 Ma, with a pronounced >10-m.y. magmatic gap in between. While calc-alkaline rocks showing arc-like lava features are abundant, an apparent change in magma composition is observed between these two stages. The mid-Miocene rocks are dominated by intermediate compositions (SiO_2 = 53-61 wt.%) and typical of high-K calc-alkaline nature. They exhibit similar Nd isotope ratios (ε_{Nd} = +2.6 to +1.4), suggesting a juvenile mantle origin possibly related to the subduction of the Indian oceanic slab beneath Asia. The Quaternary rocks, however, are mainly basaltic compositions but show heterogeneities. There are (1) high-Al basalts with high-K calc-alkaline geochemistry: ε_{Nd} = +3.1 to +2.1, (2) absarokites: Al_2O_3 = 13-15 wt.%; MgO = 10-12 wt.%; $\varepsilon_{Nd} \approx$ +3.5, and (3) intra-plate alkali basalts: K_2O = 2.6-3.5 wt.%; ε_{Nd} = +1.6 to +0.9. We interpret the long magmatic gap as a consequence of transition of the Indian oceanic slab from oblique convergence/subduction to stike-slip movement. It took place in the mid-Miocene, when the dextral motion of the Sagaing fault system initiated and opening of the Andaman Sea began. All these processes were related to the India-Asia collision that caused plate reorganization and eventually "rollback" of the Indian oceanic slab in this region since 1 Ma. Thus the Quaternary volcanism renewed owing to rise of the geotherm resulted from upwelling asthenosphere and small-degree melting of different domains of pre-Miocene subduction-related enriched mantle beneath central Myanmar.

Temporal variation of compositions of volcanic gas and hot springs in the Tatun Volcano Group, Taiwan

HSIAO-FEN LEE[1]*, TSANYAO FRANK YANG[2], HSIN-YI WEN[2] AND CHENG-HORNG LIN[1]

[1] Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan. (*correspondence: hf_lee@earth.sinica.edu.tw, lin@earth.sinica.edu.tw)

[2] Department of Geosciences, National Taiwan University, No. 1, Sec. 4, Roosevelt Road, Taipei 10617, Taiwan. (tyyang@ntu.edu.tw, d99224009@ntu.edu.tw)

The Tatun Volcano Group (TVG), where the geothermal and seismic activities are still very strong, is located in the northern Taiwan. In the past decade, gas samples have been collected monthly to analyze the compositions and isotopic ratios. The results show a similar composition as those of low-temperature fumaroles in other parts of the world. H_2O is the major species of these gas samples, and CO_2 is the dominant component after de-watering[1]. The high $^3He/^4He$ ratios (4.7~6.7 R_A) [2,3] indicate a mantle-derived degassing source in origin. The carbon isotopic values of CO_2 also exhibit a magmatic source. Since August 2004, progressive increases of HCl concentration and SO_2/H_2S ratio have been observed at Da-you-keng, the most active hydrothermal area in TVG. These variations are accompanied by rising temperature of fumaroles. From 2006 to 2009, increases of S_{total}/CO_2 ratio have been observed in many fumaroles simultaneously. The H-O isotopic values of condensed water of fumaroles from Da-you-keng and Hsiao-you-keng fall in the range away from the meteoric water line, indicating a magmatic water source. Meanwhile, the rest of data from other fumaroles are similar with previous published data of hot springs[4], which are clearly derived from meteoric water in origin.

To survaillence the potential magmatic activity of TVG, an observatory is established in October 2011. We have been collecting/analyzing the volcanic gas samples regularly, as well as the water samples from two hot springs weekly. Compare with the previous data, no significant variations of the geochemical compositions have been found in the past year until now.

[4]Jet Propolsion Laboratoty, Pasadena, CA, US: john.r.worden@jpl.nasa.gov

Observations show that heavy oxygen isotope composition in precipitation ($\delta^{18}O_p$) increases from coastal southeastern (SE) China to interior northwestern (NW) China during the wet season, contradicting expectations from simple Rayleigh distillation theory. Here we employ stable isotopes of precipitation and vapor from satellite measurements and climate model simulations to characterize the moisture processes that control Asian monsoon precipitation and relate these processes to speleothem paleoclimate records. We find that $\delta^{18}O_p$ is low over SE China as a result of local and upstream condensation and that $\delta^{18}O_p$ is high over NW China because of evaporative enrichment of ^{18}O as raindrops fall through dry air. We show that $\delta^{18}O_p$ at cave sites over southern China is weakly correlated with upstream precipitation in the core of the Indian monsoon region rather than local precipitation, but it is well-correlated with the $\delta^{18}O_p$ over large areas of southern and central China, consistent with coherent speleothem $\delta^{18}O_p$ variations over different parts of China. Previous studies have documented high correlations between speleothem $\delta^{18}O_p$ and millennial timescale climate forcings, and we suggest that the high correlation between insolation and speleothem $\delta^{18}O_p$ in southern China reflect the variations of hydrologic processes over Indian monsoon region on millennial and orbital timescales. The $\delta^{18}O_p$ in the drier part (north of ~30ºN) of China, on the other hand, has consistently negative correlations with local precipitation and may capture local hydrologic processes related to changes in the extent of the Hadley circulation.

Treatment of fluoride containing acid wastewater using red mud

JUNG-HWA LEE, JAE GON KIM*, CHUL-MIN CHON AND IN-HYUN NAM

Korea Institute of Geoscience and Mineral Resources, Daejeon 305-350 Korea (ljh@kigam.re.kr, jgkim@kigam.re.kr*, femini@kigam.re.kr, nih@kigam.re.kr)

Capacity of red mud for the fluoride(F) removal and acid neutralization for the wastewater from a semiconductor manufactor was investigated using a batch experiment. The red mud was characterized for the chemical and mineralogical compositions using XRF and XRD, respectively. The pH was determined with 1red mud and 10distilled water after 24 hrs reaction. The point of zero charge(PZC) was determined with a potentiometeric method. Red mud and wastewater was mixed at 0 – 25% of red mud. The suspention was reacted and the pH and F concentration of the solution were determined.

The red mud contained 34.3% of Fe_2O_3, 25.8% of Al_2O_3, 9.96% of SiO_2, 7.08% of Na_2O, 6.07% of TiO_2, and 5.07% of CaO. Hematite, boehmite, zeolite, quartz, anatase and calcite were indentified as major minerals of red mud. The pH and PZC of red mud was pH 12.4 and pH 9.2, respectively.

The pH sharply increased and the F concentration decreased for initial 2 hrs of the reaction and then showed a stady state for all red mud content. The pH increased from 1.7 to 8.8 with increasing the red mud content. The F concentration decreased from 2,600 to 31 mg L^{-1} with increasing to 7.5% of red mud. The F concentration of the solution was not significantly changed with increasing red mud content at > 7.5%.

The alkalinity of red mud neutralized the acidic wastewater. The F removal rate was increased with increasing content of iron oxides as major solid phases for the F adsorption at < 7.5% of red mud(pH 7.1). No significant change of F removal rate with increasing red mud content at > 7.5% might be due to the increased surface charge of iron oxide along with increased solution pH. The capacity of neutralization and F removal of red mud indicated that red mud can be utilized as a treatment agent for F containing acidic wastewater.

Hydrogeochemical characterization of urban groundwater in Seoul (South Korea) using Self-Organizing-Map technique

KYUNG-JIN LEE, KYOUNG-HO KIM AND SEONG-TAEK YUN*

Korea University, Depatment of Earth and Environmental Sciences and KU-KIST Green School, Seoul, South Korea styun@korea.ac.kr (* correspondence)

Degradation of urban groundwater quality is serious in some metropolitan cities such as Seoul, South Korea. In Seoul, depression of groundwater levels by over-pumping is considered as a major cause of groundwater contamination. In this study, we investigated spatial variations of groundwater level (i.e., drawdown) and hydrochemistry in Seoul. Field measurements and water sampling were made in 2003 and 2004 for this study. The average and maximum groundwater depths were 13.3 m and 73.3 m, respectively. The average and maximum concentrations of Cl, NO_3, and SO_4 as the potential indicators of anthropogenic contamination were high (45.5 and 189.8 mg/L, 24.8 and 528.1 mg/L, and 40.1 and 128.1 mg/L, respectively). Based on the Hierarchical Cluster Analysis (HCA) and Self Organizing Map (SOM) technique, four main clusters of groundwater samples were derived. Cluster 1 has the lowest concentrations of most solutes and represents the non-polluted groundwater; Cluster 2 contains relatively low concentrations of most solutes except NO_3; Cluster 3 and Cluster 4 are highly enriched in solutes (esp., Ca, Mg, Cl, SO_4) because of anthropogenic contamination. Cluster 3 has the high NO_3 but low HCO_3 concentrations, while Cluster 4 is opposite. The relationship between groundwater quality and groundwater depth was further evaluated by SOM. However, there is a weak correlation between spatial distributions of classified groups and groundwater depth data because of high heterogeneity of urban groundwater. On the other hand, the use of geo-SOM method showed a rather spatially classified water chemistry.

Evaluation of prokaryotes and community dynamics in Alvord Desert Hot Springs

M. HOPE LEE AND TIMOTHY MAGNUSON[123]

[1]Pacific Northwest National Laboratory, 902 Battelle Blvd, Richland, WA 99352; hope.lee@pnnl.gov
[2]IdahoState University, 921 S.8th Street, Pocatlelo, ID 83209; magntimo@isu.edu

The Alvord Desert, located in southeastern Oregon, is composed of springs which are near neutral and/or basic, and are driven by tectonic dilation of range-front faults. The thermal springs within the Alvord Desert discharge sodium-bicarbonate-chloride type water and maintain high concentrations of sulfate and chloride. Microbiological enrichments have resulted in the culturing of several organisms with biogeochemical significance including sulfate-reducing bacteria, and YeAs-1, a novel arsenic-reducing Archaea. Strain AlSe is a novel selenium-reducing thermophilic bacterium that is only 96% similar to *Carboxydocella thermoautotrophica*,; AlSe has the ability to utilize organic carbon. A strain of Thermus spp., OPOC, was isolated, and can oxidize As(III) and reduce As(V), as well as respire on Fe(III). Zymography and proteomics confirms the expression of both arsenite oxidase (Aio) and respiratory arsenate reductase (Arr), as well as large-mass c-type cytochromes that may serve as electron transport components for Fe(III) respiration. Aerobic prokaryotes, including multiple species of *Anoxybacillus,* methanogen and methanotroph organisms have also been isolated. Together these efforts show that this ecosystem maintains a broad diversity of uncultivated microorganisms and metabolic pathways. It is expected that with continued mining of organisms, there is potential for discovering novel metabolisms that have significant implications for next-generation technologies, including carbon sequestration, biofuels, and the development of bioconversion processes yet to be conceived.

Age, geochemistry and Sr-Nd-Pb isotopes of alkaline lavas from Northern Victoria Land and Ross Sea Region, Antarctica

MI JUNG LEE*[1], JONG IK LEE[1], TAEHOON KIM[1] AND JOOHAN LEE [1]

[1]Division of Polar Earth System Sciences, Korea Polar Research Institute (KOPRI), Incheon 406-840, Korea, mjlee@kopri.re.kr, jilee@kopri.re.kr, tkim@kopri.re.kr, joohan@kopri.re.kr

We present new K/Ar ages, geochemical and isotope results (Sr, Nd, Pb) on submarine basalts dredged from Victoria Land Basin of the Ross Sea, Antarctica. Subaerial samples were also collected from two areas near Mt. Melbourn in Northern Victoria Land for comparison. The volcanic rocks studied are alkaline raging from basanite to trachybasalt. Chemically, they show the OIB-like patterns of trace element distribution and are characterized by a prominent depletion in K and Pb relative to other highly incompatible elements when normalized to primitive mantle. K/Ar ages of basalts from group A in Mt. Melbourn area range from 0.16 to 0.33 Ma and those of group B are from 1.25 to 1.34 Ma. The K/Ar determination result for submarine lavas also shows similar ranges of eruption ages from 0.46 to 0.57 Ma. In spite of their distinctly different ages of group A and B subaerial samples from Mt. Melbourn area, they show similar geochemical and isotopic features indicating common mantle sources and magma processes being shared in their magma generation. The Sr, Nd and Pb isotopic compositions of the group A and B basalts from Mt. Melbourn area display a range of values for $^{87}Sr/^{86}Sr$ (0.70306 to 0.70398), $^{143}Nd/^{144}Nd$ (0.51284 to 0.51293) and $^{206}Pb/^{204}Pb$ (18.498-19.667). They show a considerably higher range of $^{206}Pb/^{204}Pb$ contrast to limited compositional variations of $^{87}Sr/^{86}Sr$ and $^{143}Nd/^{144}Nd$. Submarine lavas dredged from Victoria Land Basins (VLB) show slightly higher ratios of $^{206}Pb/^{204}Pb$ (18.935-19.852) and less radiogenic $^{87}Sr/^{86}Sr$ (0.70299-0.70340) and $^{143}Nd/^{144}Nd$ (0.51290-0.51297) isotope compositions compared to group A and B Mt. Melbourn basalts. The $(La/Yb)_N$ in submarine lavas ($[La/Yb]_N$ = 15.4 – 19.9) are slightly higher than those in group A and B volcanics ($[La/Yb]_N$ = 9.8– 15.7), suggesting lower degrees of partial melting in submarine lavas. The stronger HIMU signature (higher $^{206}Pb/^{204}Pb$ and less radiogenic $^{87}Sr/^{86}Sr$ and $^{143}Nd/^{144}Nd$ ratios) in submarine lavas appears to be related with smaller degrees of partial melting of them, suggesting preferential sampling of the HIMU component in small degrees of melts in the Cenozoic NVL magmatism.

Cooperative and competitive adsorption of amino acids with Ca^{2+} on rutile

NAMHEY LEE[1], DIMITRI A. SVERJENSKY[2,3] AND ROBERT M. HAZEN[3]

[1] Earth Science Division, Lawrence Berkeley National Laboratory, Berkeley, CA, USA, nlee@lbl.gov
[2]Department of Earth and Planetary Sciences, Johns Hopkins University, Baltimore, MD, USA
[3]Geophysical Laboratory, Carnegie Institution of Washington 5251 Broad Branch Rd., NW, Washington D.C., USA

Amino acids are highly soluble in water and do not spontaneously organize themselves. For these molecules, it has been recognized that mineral surfaces may potentially have played an important role in their selection, organization and concentration in the prebiotic era. Here, we investigated the adsorption of the oppositely charged amino acids glutamate and lysine with and without the addition of Ca^{2+}. Without Ca^{2+}, glutamate shows maximum adsorption at a pH of ~4 and lysine shows maximum adsorption at a pH of ~9.4. In comparison, with Ca^{2+} present, glutamate showed maxima adsorption at both pH ~4 and ~10, whereas lysine showed no adsorption at all. These dramatic effects can be described as cooperative adsorption between glutamate and Ca^{2+} and competitive adsorption between lysine and Ca^{2+}. Surface complexation model calculations indicate a purely electrostatic origin of these effects. Adsorption of Ca^{2+} at high pH makes the rutile surface more positive, attracting glutamate and repelling lysine. The cooperative or competitive effects show that biomolecules can participate in complex adsorption behaviour. A fundamental understanding of amino acids speciation and coordination chemistry to oxide mineral surfaces may provide valuable insight into biomaterial and bimolecular interactions and the fate of organic acids in natural environments, as well as the possible role of mineral surfaces in the chemical evolution of biomolecules in the origin of life.

Biogeochemical control on the dissolution/precipiation of fine suspended solids from mine drainage

SANGHOON LEE[1], MINAH OH[2], JAIYOUNG LEE[2] AND DUCKMIN KIM[3]

[1] Department of Environmental Engineering, Divison of Biotechnology, The Catholic Unviersity of Korea (slee@catholic.ac.kr)
[2]Department of Environmental Engineering, University of Seoul
[3]Mine Reclamation and Technology Center, Mine Reclamation Corporation

Mine drainage discharges fine suspended solids (SS), as well as trace metals. Although many abandoned mining sites adapt sand filter beds to treat the SS, improved system is still in demand, as often long-term operation clogs either the sand media or the porous filter installed underneath of the bed, dramatically degrading treating capacities. The first approach was to find better filtering mediums. Fly ash, mine tailing aggregates, metal scraps and the mixed medium were compared with the current sand bed filters in the laboratory, using the mine drainage from the field. Batch and column test of 7 days revealed sand media still outperformed to other candidates. Mixing with anthracite or activated carbon on the sand filter also improved the treatability, extending to some heavy metals, as well.

Possible bioleaching of the suspended solids was also investigated to ameliorate the system by manipulation the dissolution/precipitation processes associated with the solids in the filter media. The redox transformation and biogeochemical interactions of heavy metals in the solids were examined using facultative anaerobic bacterium *Shewanella* sp. (HN-41) in batch mode and with small scale columns. This is a preliminary study carried out to determine if such process is instrumental in preventing the coagulation of solid precipitates on the sand media and the porous media. In addition, bioleaching of the metals from the suspended solids is also considered. The organism HN-41 was not influenced by pH ranging from acidic to neutral and was able to metabolize all the metal elements from the suspended solids, with high contents of metals.

Evaluating the fate of chlorinated ethene (TCE) around the near-stream zone

SEONG-SUN LEE [1*], HUN-MI KIM[1], DUGIN KAOWN[1] AND KANG-KUN LEE[1]

[1]School of Earth Environmental Science, Seoul National University, Seoul 151-747, Korea (*correspondence : soon3311@snu.ac.kr), tweety1@snu.ac.kr, dugin1@snu.ac.kr, kklee@snu.ac.kr

The fate of chlororinated ethens in a near stream zone was evaluated using concentration of each component, hydrogeochemical data, microbial data and carbon isotope data. Temporal and spatial monitoring investigation show that a trichloroehylene (TCE) plume was originated from a small source zone in an industrial complex and is discharging to a stream. Groundwater geochemical data around the stream showed a region of depleted dissolved oxygen. Mass discharge of contaminants computed across transect lines showed that TCE mass discharge decreases along the groundwater flow path, whereas *cis*-DCE and VC mass discharge increases across the transect line located near the stream. TCE molar fraction is high ranging from 83 to 90% of total VOCs at a well located near the source zone. However, in the region downgradient of the source zone, molar fractions of *cis*-DCE and VC increase indicating biodegradation of TCE. The degree of chlorinated ethene transformation varies spatially due to local conditions. Reductive dechlorination likely dominated in the anaerobic region of the aquifer where TCE level was observed to decrease with simulaneous increase in *cis*-1,2-dichloroethene (*cis*-DCE) and vinyl chloride (VC). Groundwater along the transect nearest to the stream has concentrations of *cis*-DCE and VC decreased below detection limits, presumably due to anaerobic biotransformation processes at the near-stream zone. The increase in ferrous iron and manganese and decrease in TCE around the stream zone also are related with the biotransformation. Microbial community around the near-stream zone was analyzed to identify organisms which are responsible for the biodegradation. Carbon isotope ($\delta^{13}C$ of TCE, *cis*-DCE and VC) data were used to estimate the origin of contaminants source and the evidence of biodegration around the near-stream zone. TCE isotope values (from -19.21‰ to -17.78‰) around the near-steram zone are more enriched in $\delta^{13}C$ than the $\delta^{13}C$ around the source zone (-24.45‰). These isotope results also showed the evidence of biodegradation around the stream zone. Those data and analyses indicate the contaminant plume around the stream zone have been naturally attenuated by active anaerobic biotransformation processes.

Late Ordovician volcanic rocks in South Korea: Speculation on the cause of Paleozoic regional unconformity in Sino-Korean craton

SEUNG RYEOL LEE[1*], DEUNG-LYONG CHO[1], JOONBEOM PARK[2] AND HEEJAE KOH[1]

[1]Korea Institute of Geoscience and Mineral Resources, Daejeon 305-350, Korea (*correspondence: leesr@kigam.re.kr)

[2]US Army Corps of Engineers Far East District, Seoul 100-195, Korea

One of the distinct geologic features that distinguishing Sino-Korean block (SKB) from other east Asian blocks (e.g., South China block (SCB), Tarim block etc.) is a regional unconformity between Upper Ordovician and Middle-Upper Carboniferous on the SKB [1, 2]. The Korean Paleozoic, as a part of Sino-Korean sedimentary system, are mostly distributed in two relatively large sedimentary basins, the Taebaeksan and Pyeongnam basins, and consist of lower and upper Paleozoic strata with a great unconformity between them. The unconformity period is conventionally thought to be of non-deposition, but the cause of the unconformity is still ambiguous.

The Oknyobong Formation (OFm), consisting of volcanoclastics, tuffs, basalt and rhyolite, overlies Cambro-Ordovician strata in Taebaeksan basin [3]. It was considered to be Late Jurassic-Early Cretaceous stratum, based on incorrect age data [3]. In this study we reported SHRIMP U-Pb zircon ages and geochemical data for the volcanic rocks from the OFm. SHRIMP U-Pb zircon ages of 452.5 ± 3.2 (2σ) Ma and 445.0 ± 3.7 (2σ) Ma were obtained from two felsic volcanics, indicating that the OFm is of Upper Ordovician in age. Petrological and geochemical features suggest that the OFm extruded at the within-plate tectonic environment.

The Upper Ordovician within-plate volcanic activity, confirmed by the OFm, is coeval well with the Ordovician (~470 Ma) kimberlite volcanism in SKB, suggestive of regional lithosphereic uplift at that time [4]. Therefore epeirogenic uplift from mantle plumes (or hotspot epeirogeny) is suggested as a possible cause of the regional development of middle Paleozoic unconformity in SKB.

Hindcast study of aerosol optical depth using retrieval of geostationary satellite over East Asia

S. LEE[1], C. H. SONG[1], M. E. PARK[1], R. S. PARK[1], J. LEE[2] AND J. KIM[3]

[1]School of Environmental Science and Engineering, Gwangju Institute of Science and Technology (GIST), Gwangju, 500-712, Korea (noitul5@gist.ac.kr, *correspodence to chsong@gist.ac.kr)

[2]Aerosol and Cloud Group, NASA JPL, Pasadena, and JIFRESSE, UCLA, L.A., CA, USA

[3]Institute of Earth, Astronomy, and Atmosphere, Brain Korea 21 Program, Department of Atmospheric Sciences, Yonsei University, Seoul, Republic of Korea

Compared with the aerosol optical depth (AOD) retrievals from polar orbiting satellites, the AOD retrievals from geostationary satellites have a high temporal and spatial resolution. Because the number of AOD retrievals from geostationary satellites is increased, a better initial condition can be prepared for better aerosol forecast or hindcast. We carried out a hindcast study of AOD over East Asia to test the effects of the initial conditions prepared the AOD data from a geostationary satellite. The retrievals from the Geostationary Ocean Color Imager (GOCI) on board the Communication, Ocean, and Meteorological Satellite (COMS) were used in this study, and the retrieved AOD data were assimilated with the AOD values simulated by the Community Multiscale Air Quality Model (CMAQ). We assimilated the two data via an optimal interpolation (OI) technique, and the OI parameters of observation and modeling errors were calculated to minimize the variance of differences between assimilated and AERONET AODs. The AERONET AODs were selected within the period of Distributed Regional Aerosol Gridded Observation Networks DRAGON in Asia (DRAGON-ASIA) campaign, and were also used for comparison with the results of hindcast studies. The 6-hour hindcast result in selected days using the GOCI retrievals showed improved AOD distributions, compared with the AOD data from DRAGON-ASIA AERONET sites. Also, using GOCI and TERRA MODIS AOD retrievals, spatial coverage of satellite retrieval can be increased. 12-hour hindcast was also carried out using the combined GOCI-MODIS data sets.

Multi-component silicate glasses and melts under compression

SUNG KEUN LEE[1]

[1]School of Earth and Environmental Sciences, Seoul, 151742, Korea, sungklee@snu.ac.kr

Probing the pressure-induced structural changes and the extent of disorder in multi-component aluminosilicate glasses and melts at high pressure relevant to earth's inteiror remains challenge in mineral phsyics and high temperature geochemistry. Most of the previous studies focused on the pressure-induced bonding transition in rather simple model melts (e.g., from single-component, to ternary). Recent advances in element-specific experimental probe of local structures including non-resonant synchrotron inelastic x-ray scattering (IXS) and solid-state NMR unveil previously unknown structural details of the structural changes in the diverse multi-component silicate glasses under static and dynamic compression. This progress allows us to establish a systematic relationship between pressure, temperature, composition, and melt (and glass) structures. Here, we presnet an overview of the recent progress and insights by IXS and NMR into electronic structures of multi-component silicate glasses at high pressure. IXS study using shock compressed basaltic glasses allowed us to constrain topology-driven densification upon dynmaic compression. Contrary to an expected complexity in densification for multi-component silicate glasses, high-resolution O-17 NMR spectra for quaternary Ca-Mg- and Ca-Na aluminosilicate glasses quencehed from melts at high pressure demonstrate that the pressure-induced changes in melt structures show a simple densification trend where all the experimental non-bridging oxygen (NBO) fractions at high pressure converge into a single decaying function, regardless of composition. Additonally, detailed Al-27 NMR studies of aluminosilicate glasses showed that the fraction of $^{[5,6]}$Al at a given pressure vary nonlinearly with variations of NBO/T. $^{[5,6]}$Al fraction increases with decreasing degree of melt polymerization from NBO/T=0 to partially depolymerized melts. Then it gradually decreases with further increase in NBO/T. A new scheme of pressure-induced structural transitions in silicate melts involving $^{[4]}$Al-O-$^{[4]}$Al also includes the formation of $^{[4]}$Al-O-$^{[5]}$Al. We finally show how these new structural information can be utilized to help elucidate connections between the microscopic signatures of anomalous and non-linear changes in the macroscopic properties of the corresponding liquids as well as natural magmatic processes in the Earth's interior.

Variations of soil C and N along a South-North Transect in East Central Asia: Implications for climate change

XINQING LEE, LIKE ZHANG, DAIKUAN HUANG, LU HU, JIANZHONG CHENG, BING WANG, BIN FANG, FANG YANG AND TSERENPIL SHURKHUUA

State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, 46 Guanshui Road, Guiyang 550002, Guizhou, China. Email: lee@mail.gyig.ac.cn

The feedback of soil organic matter to global warming is important for modeling future climate change. No consensus, however, has been reached on this issue partly because the temperature sensitivity of soil organic carbon(SOC) is affected by a variety of factors such as water availability and the associated change in soil N contents. To elucidate the links between the C stock and environmental factors, we assessed the spatial variation of C and N content in the topsoil, and the concomitant changes of temperature, water availability and alkalinity in a mega-transect in East Central Asia, which is characterized by large environmental changes.

Totally 210 sites were sampled at 6 replicates using a corer along the transect. Soil C and N content and soil alkalinity change dramatically in the transect. SOC and soil organic nitrogen(SON) increases with water availability while decreases with temperature, both are associated so closely with each other that their molar ratio, C/N, is generally invariant about 12 except in the agro-pastoral transitional zone in north China. Soil pH increases with temperature and decreases with water availability. NH4+-N, which is the primary inorganic N in the soil, basically varies with SON, indicating its provenance, but is also subject to modification by soil alkalinity. NO3–-N, though derived primarily from nitrification of NH4+-N, does not follow its precursor because of precipitation leaching and re-deposition.

Statistic analyses indicate that SOC and SON contents in East Central Asia should have been influenced negatively by recent warming, which, albeit occurring primarily in the winter half year, strengthens the evaporation and enlarges the difference of wet and dry seasons, and thus reducing soil annual water availability while increasing soil alkalinity. The accelerated decomposition of SOC stock, in association with the increased soil alkalinity, enhamces transformation of SON to to NH4+. The increased N mineralization, however, may not necessarily promote net primary production because of the decreased water availability and increased soil NH3 volatilization.

Pressure-induced insertion of xenon into a small-pore zeolite natrolite

DONGHOON SEOUNG,[1] YONGMOON LEE,[1] HYUNCHAE CYNN,[2] WILLIAM EVANS,[2] THOMAS VOGT,[3] CHI-CHANG KAO AND YONGJAE LEE,[1,*]

[1]Department of Earth System Sciences, Yonsei University, Seoul, Korea [yongjaelee@yonsei.ac.kr]

[2]Condensed Matter and Materials Division, Lawrence Livermore National Laboratory, Livermore, USA

[3]NanoCenter & Department of Chemistry and Biochemistry, University of South Carolina, Columbia, South Carolina, USA

[4]SLAC National Accelerator Laboratory, Menlo Park, California, USA

We report here a novel mechanism of xenon incorporation into a zeolite at moderate upper mantle PT conditiions. When silver-exchanged natrolite, Ag16Al16Si24O48 ·16H2O, a small pore auxetic zeolite is compressed under xenon medium to ca. 1.7 GPa and heated to ca. 250 degrees celcius, significant amount of xenon is incorporated into the natrolite channel via desorptiion of water molecules and charge dispropornation of silver cations, resulting in ca. Ar8Al16Si24O80 · 8Xe. This material is recovered to ambient conditions with ca. 4% larger unit cell compared to the starting material. This process has been monitored by in situ high-pressure synchrotron XRD, and the presence of xenon and the formation of charge-disproportionated silver metal nano particles have been confirmed by XRF chemical analysis and TEM imaging from the recovered sample. Xenon incorporation under moderate pressure into Auxetic framework silicate such as natrolite is an important and overlooked confinement mechanism of heavy noble gases in geochemical environment.

Attenuated total reflection-infrared spectroscopy: a tool of choice for investigation of the sorption of oxyanions

G. LEFEVRE[1]

[1]LECIME, UMR7575 CNRS-Chimie ParisTech, 75005 Paris, France (*correspondence : gregory-lefevre@enscp.fr)

Attenuated Total Reflection-Infrared spectroscopy (ATR-IR) is a fast-expanding spectral techniques to *in situ* studies of the solid/solution interfaces. Several optical materials can be used as ATR crystal, but the range of probed frequency is always limited above around 700 cm^{-1}). The observation of sorbed heavy metals is therefore not possible since absorption bands of surface complexes would take place below this limit, contrary to most of oxyanions due to their polyatomic structure [1]. The first studies showed the adsorption of model ions (sulfate, carbonate) onto metal oxides, then several pollutants have been investigated (AsO_4^{3-}, SeO_4^{2-},…), along with other mechanisms, as ion exchange, have been followed.

Examples amongst our recent results are presented, as the study of sorption of molybdate and tungstate ions onto hematite. Thus, the use of ATR-IR to characterize surface complexes with tungstate ions is presented for the first time to the best of our knowledge. From the comparison of spectra of solution species as monomeric and polymeric geometries, the inner-sphere behaviour of tungstate has been deduced. A first try with perrhenate ions has been performed, confirming the formation of outer-sphere complexes.

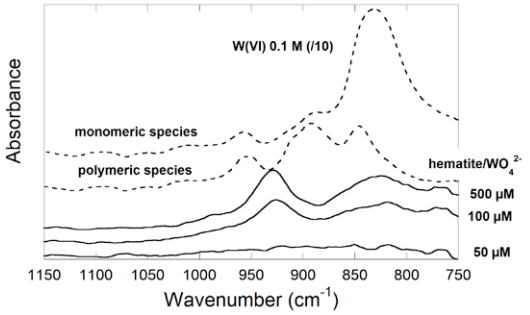

Figure 1. Spectra of tungstate solutions and adsorbed tungstate ions at pH 8.4.

Stable soil carbon decomposition is more sensitive to temperature. Evidence from long term bare fallow experiments

LEFEVRE R.[1], BARRÉ P.[2], BARDOUX G.[1], CHRISTENSEN B.T.[3], GIRARDIN C.[1], HOUOT S.[4], KÄTERRER T.[5], MOYANO F.[1], VAN OORT F.[6] AND CHENU C.[1]

[4] INRA, EGC, Grignon, France
[5] SLU, Uppsala, Sweden
[6] INRA, Pessac, Versailles, France

The impact of climate change on the stability of soil organic carbon (SOC) remains a major source of uncertainty in predicting future changes in atmospheric CO_2 levels. One unsettled question is whether the mineralization response to temperature is the same for labile and stable SOC pools. Long-term (>25 years) bare fallow experiments (LTBF) in which the soil is kept free of any vegetation, represent a unique research platform to examine this issue as with increasing duration of the treatment, the proportion of stable SOC relative to total SOC increases.

We used soils from LTBF experiments situated at Askov (Denmark), Grignon (France), Versailles (France) and Ultuna (Sweden). We used archived soils sampled at the start of the experiments and after 25, 50, 80 and 52 years of bare fallow, respectively, when the soils had became enriched in stable SOC. Samples were incubated at 4, 12, 30 and 35 °C and evolved CO_2 was monitored. We calculated the activation energy of SOC after the same amount of respired C at the different temperatures. The activation energy was always higher for samples more concentrated in stable C, implying a higher temperature sensitivity of stable C compared to more labile C. Hence, assuming the same temperature sensitivity for different soil carbon pools in simulation models appears inappropriate.

Temporal evolution of the oxygen depletion in the bottom water of the Lower St. Lawrence Estuary: from 1930 to 2100

Historical records reveal that the dissolved oxygen concentration has progressively decreased in the bottom water of the Lower St. Lawrence Estuary (LSLE) during the last century and reached the severe hypoxic threshold in the 1980s where it has hovered ever since. We recently demonstrated that the physics of the system, both benthic and pelagic respirations, as well as the modification of chemical properties of the water mass entering the Laurentian Channel (originating from the North Atlantic Ocean), are the main causes of the oxygen depletion in the LSLE. Climate models forecast a strong deoxygenation of the subsurface water in the North Atlantic Ocean over the next century, that may further decrease the oxygen supply into the Laurentian Channel. We used four climate scenarios (rcp2.6, rcp4.5, rcp6.0 and rcp8.5, labeled according to the additional radiative forcing level in 2100 with atmospheric CO2 concentrations reaching 421, 538, 670 and 936 ppm respectively) to estimate the oxygen concentration in the North Atlantic Ocean and at the entrance of the Laurentian Channel. By applying these estimated oxygen concentrations at the boundary condition of a bidimentional model validated for the 2002-2011 period, we forecast the evolution of hypoxia in the LSLE. We also estimate the contribution of the physics of the system, respirations and chemical properties of the source water to the oxygen depletion.

Coupled cycling of Fe and C_{org} in submarine hydrothermal systems: Modeling approach.

LOUIS LEGENDRE[1,2], CHRISTOPHER R GERMAN[3] AND SYLVIA G. SANDER[4]

[1]Université Pierre et Marie Curie Paris 6, Laboratoire d'Océanographie de Villefranche, France (legendre@obs-vlfr.fr)
[2]CNRS, Laboratoire d'Océanographie de Villefranche, France (legendre@obs-vlfr.fr)
[3]Woods Hole Oceanographic Institution, MA 02543, USA (cgerman@whoi.edu)
[3]University of Otago, Dunedin, New Zealand (sylvia.sander@otago.ac.nz)

We investigated the fate of dissolved Fe released from hydrothermal systems to the overlying ocean using an approach that combined modelling and field values. We based our work on a consensus conceptual model developed by members of SCOR-InterRidge Working Group 135. This model was both complex enough to capture the main processes of dissolved Fe release from hydrothermal systems and chemical transformation in the hydrothermal plume, and simple enough to be parameterized with existing field data. It included the following flows: Fe, water and heat in the high-temperature vent fluids, in the fluids diffusing around the vent, and in the entrained seawater; Fe precipitated in sulfides near the vent, and in particles onto the sea bottom away from the vent; and Fe dissolving into deep-sea waters. Through trials and errors, we transformed the conceptual model into equations, which were parameterized with field data. We used the resulting set of equations (model) to explore various scenarios of Fe emissions and transformations. The modelling exercises suggested that hydrothermal systems may play significant roles in the global biogeochemical Fe cycle.

Alteration of amorphous Fe-silicate in meteorites

C. LE GUILLOU [1], R. DOHMEN [1], T. MÜLLER [1], C. VOLLMER [2], D. ROGALLA[3] AND H. W. BECKER[3]

[1]Ruhr-Universität Bochum, Inst. für Geologie, Mineralogie and Geophysik., 44780, Bochum, Germany
[2]Universitat Münster, Inst. für Mineralogie, 48149 Münster.
[3]RUBION facility, Ruhr-Universität Bochum, Germany.

Serpentine is ubiquitous in carbonaceous chondrites and likely the result of a hydrothermal reaction of amorphous precursors (at <100°C) as indicated by replacement textures in fine-grained matrices. To constrain the temperature and timescales of aqueous alteration, we study the mechanisms and kinetics of Fe-rich amorphous silicate serpentinization. Our approach is a combination of a novel experimental setup and multiple analytical techniques. A thin (~ 1 μm) layer of amorphous "$FeMgSi0_4$" is deposited on a substrate using a pulsed laser deposition system (laser ablation / deposition from the plasma). The film is reacted in deionized water (60°C to 190°C, 2h to 2 weeks, water to rock ratios of about 300). The geometry is ideal to follow the evolution of the reaction front by FIB/TEM, Rutherford Back Scattering (major elements composition) and Nuclear Reaction Analysis (water content) with nm scale depth resolution.

Our results reveal a systematic sequence of hydrated amorphous layers from the surface towards the pristine material: (1) silicon oxide (<50 nm); (2) a fibrous and porous layer with a composition close to Mg-serpentine; (3) thin (< 20 nm) Fe-oxide; (4) a compact layer with a composition close to Fe-serpentine. Depth profiles reveal that all layers are hydrated (10-15 wt. %). Layer boundaries are sharp. The formation sequence likely results from kinetically-controlled, interfacial dissolution-precipitation front, as previously described in glass alteration experiments. The Fe/Mg fractionation between layers may be due to the higher solubility of Mg, first leached and later precipitated after fluid had reached saturation.

Our findings of amorphous and hydrated Fe-rich silicates with a stoichiometry close to serpentine are to some degree comparable to observations made in chondrites. It may point towards shorter hydrothermal episodes as initially thought in chondrites.

Effect of coarse marine aerosols on stratocumulus clouds

Y. LEHN[1], I. KOREN[1*], O. ALTARATZ[1] AND A. KOSTINSKI[2]

[1]Dept. of Environmental Sciences, Weizmann Institute, Rehovot 76100, Israel (*correspondence: ilan.koren@weizmann.ac.il, yoav.lehahn@weizmann.ac.il, orit.altaratz@weizmann.ac.il)
[2]Department of Physics, Michigan Technological University, 1400 Townsend Drive, Houghton, MI 49931-1200, USA (alex_kostinski@mtu.edu)

In contrast to fine anthropogenic aerosols (radii ~< 0.5µm), large aerosol particles are thought to enhance cloud droplet growth, promote precipitation formation and reduce cloud albedo. While shown in models, the impact of coarse aerosols on marine stratocumulus clouds lacks observational evidence. Combining satellite data from AMSR-E and MODIS, we link the amount of wind induced coarse marine aerosols (CMA), with droplet size of marine stratocumulus clouds over the southeastern Pacific.

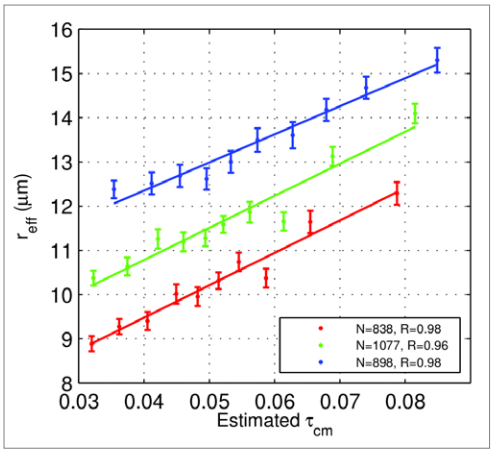

Figure 1. r_{eff} vs. τ_{cm} in a southeastern Pacific marine stratocumulus cloud field. Data are plotted for different ranges of LWP (25-50, 50-75 and 75-100 gr/m^2, red, green and blue, respectively).

For constrained meteorological conditions, approximately 1/2 of the change in droplet effective radius (r_{eff}) is attributed to increase in CMA optical depth (τ_{cm}), as surface winds intensify. Accordingly, a twofold increase in τ_{cm} is associated with a 1.4µm +/-0.11 increase in r_{eff}. Our results suggest that any attempt to quantify the impact of anthropogenic and biogenic marine aerosols on marine boundary layer clouds, should take into account the opposing effect of wind induced coarse marine particles.

Ore deposits related to felsic magmatism through time

B. LEHMANN

Mineral Resources, Technical University of Clausthal, D-38678 Clausthal-Zellerfeld, Germany

Shallow magmatic-hydrothermal ore systems, such as copper porphyries, molybdenum porphyries and tin-tungsten ore systems, as well as their epithermal superstructures, form at high level in orogenic belts (≤ 4 km) and have the same age distribution as their low-grade or non-metamorphic host environment, i.e. ≥ 90 % of their resources are of Phanerozoic age [1]. This is different from orogenic (mesothermal) gold deposits which form at deeper levels in metamorphic terrain (in a continuum of 2-20 km), with only about 50 % of gold resources of Phanerozoic age [2]. Rare-metal pegmatites (Ta-Sn-Li) form mostly in medium-grade metamorphic terrain (staurolite-kyanite stable), with spodumen present (≥12 km depth). Such relatively deep tectonometamorphic basement terrains are much less sensitive to erosional dispersion than the shallow orogenic domains and their ore deposits (and Ta resources) are dominantly of Precambrian age.

However, it is striking that major tantalum resources in western Australia (Greenbushes district, Yilgarn craton; Wodgina district, Pilbara craton) are all of Archean age, with about 2.8 Ga for the Wodgina and 2.5 Ga for the Greenbushes rare-metal pegmatite, respectively. The substantial rare metal enrichment in these pegmatites requires about 1000 times larger cogenetic peraluminous granite systems and an environment favorable for extreme reaction progress of magmatic fractionation processes, i.e. a reasonably thick continental crust. Further back in time, the giant Mesoarchean Witwatersrand gold-uranium placer province can be traced back to an Early Archean source domain of granitic affinity [3], underlining the presence of felsic magmatism with efficient metal enrichment already at ~3.1 Ga, although this domain has not survived tectonic diffusion.

The direct evidence of evolved felsic magmatism and related Ta ore formation in the Archean, and the indirect evidence for granite magmatism and large-scale hydrothermal Au-U ore formation in the Early Archean point to significant volumes of continental crust for that time. This is in accord with models of crustal evolution which suggest higher rates of crust generation in the Archean than in later times [4].

Hydrocarbon Generation and Accumulation in the Unconventional Petroleum System of the Silurian Shale, Lublin Basin, Poland

ERIC LEHNE [1*], OLIVER SCHENK [2], KENNETH PETERS [3] AND ARTUR STANKIEWICZ [4]

[1*] Schlumberger DBR Edmonton, ELehne@slb.com
[2] Schlumberger, SIS Aachen, OSchenk@slb.com
[3] Schlumberger, SIS Mill Valley, KPeters2@slb.com
[4] Schlumberger, RSA Paris, AStankiewicz@slb.com

As natural gas demand increases worldwide, exploration for gas is increasingly focused on unconventional reservoirs, such as shale gas formations. The economic value of shale gas plays is determined by reservoir and completion quality. Reservoir quality parameters include porosity, permeability, clay content, cementation factors, the diagenetic history and other factors that affect the storage and deliverability of fluids contained in the pores of those rocks. Organic geochemistry input parameters for reservoir quality assessment take account of the fluid types in shale gas plays, their compositional characteristics, and the evolutional generation history of hydrocarbons in such systems.

We constructed a numerical model for the petroleum system of the Silurian Shale to integrate parameters that influence generation and migration/accumulation of hydrocarbons in the Lublin Basin. The Silurian strata in Poland are at present the target of intensive shale gas exploration, due to relatively high total organic carbon content (TOC), and good hydraulic fracturing and production potential based on its silica content. The Silurian Shale is a marine (Type II) source rock with hydrogen index (HI) below 600 mg/g and TOC up to 12%. Vitrinite macerals from vascular land plants are absent in these shales. Thus, the visible reflectance equivalent (VRE) based on analyses of bitumen was used to calibrate the heat-flow. The reflectance data suggest that the Silurian shale is within the gas generation window in the study area.

Cyberinfrastructure Vision for Geochemistry, Petrology, and Volcanology

K. LEHNERT[1] AND L. HSU[1]

[1]Lamont-Doherty Earth Observatory, Palisades, NY, USA

Grand challenges in geochemistry and petrology, such as understanding the composition of and extent of fluxes between Earth's major reservoirs (core, mantle, crust, biosphere and hydrosphere), or the relationship between geologic processes and societal issues such as natural hazards and resources, require access and integration of large amounts of data and their seamless integration into dynamic models. Progress in scientific research will be greatly accelerated with a cyberinfrastructure that is guided by a community-endorsed vision. Recently, the geochemistry and petrology community has been charged with identifying key scientific and technical challenges, and next steps toward realizing the vision.

Scientific challenges are substantial in high impact, global scale research that currently is impeded by the dearth of accessible, integrated data, especially between terrestrial and marine data resources, thermodynamic models, experiments, and analytical data; lack of consistent coverage of geochemical sample specimens from geologic terrains of interest; lack of widespread sample curation and online sample catalogs; and lack of basic knowledge and communication within and outside the community.

The scientific challenges are augmented by technical challenges related to the discoverability, interoperability, and standardization of the geochemical, petrological, kinematic, and thermodynamic data currently in existence.

Steps have been proposed to reach the goal of science-supporting cyberinfrastructure in geochemistry: Data and metadata should be captured at the point of acquisition in a way that they can seamlessly be managed throughout their life cycle, including upload to repositories. Systems should be in place to promote spatial contextualization of analysis through sample registration, imagery, and links between samples (hand samples, thin sections, splits, etc.) and analytical data. Historical data should be properly brought into the integrated system. The community, especially early career scientists, must work together to produce the cultural shift to social networking, virtual collaboration, and sharing of data and knowledge.

With broad community participation and feedback, an integrated infrastructure can be lead more comprehensive, well-informed, and high impact scientific advances.

Anthropogenic impact on forest soil - Pollution with PAH, PCB and OCP in Germany

P. LEHNIK-HABRINK[1*], B. AICHNER [1], B. BUSSIAN[2], S. HEIN[1] AND CH. PIECHOTTA[1]

[1] Federal Institute for Materials Research and Testing, D-12489 Berlin, Germany (*correspondence: petra.lehnik-habrink@bam.de)

[2] Federal Environmental Agency, D-06844 Dessau, Germany

While organic pollutants have been extensively studied in urban and agricultural areas, data from forested regions are relatively rare.

Within the framework of a forest soil inventory in Germany polycyclic aromatic hydrocarbons (PAH), polychlorinated biphenyls (PCB) and organochlorine pesticides (OCP) were analyzed in 1500 soil samples taken from 3 soil horizons at 447 sites. An analytical protocol was developed and validated for the simultaneous extraction and measurement of all analytes in humic rich soil at trace level range [1]. In line with the monitoring campaign a comprehensive quality assurance concept was implemented to guarantee constant analytical measurement conditions for two years.

At most sampling sites pollutant concentrations gradually decrease with depth. Only few spots showed highest concentrations in the upper mineral soil. In the O-horizon the sum concentrations of 16 PAHs range from 104 to 14.000 μg/kg, of 6 PCBs from <1 to 106 μg/kg and the sum of DDT and metabolites range from <1 to ca. 4.000 μg/kg.

The observed concentration of PAH, PCB and OCP reflect an ubiquitous background contamination at most sites. Relatively high concentrations of PAH and PCB are related to industrial areas and peak concentrations only of PAH are associated with open cast mining of brown coal areas. The spatial distribution of the contents of DDT and metabolites in German forest soils can clearly be attributed to historic application.

Retention and mobility of heavy metals in the carbonate-rich sulfide tailings in Dachang mine (Guangxi, China)

LIANGQI LEI[1], CIAN SONG[1] AND LIYAN YANG[2]

[1]Earth Science Faculty, Guilin University of Technology, China; e-mail: leilq@glut.edu.cn; songcian@glut.edu.cn;
[2]Law school, Guangxi Normal University, China; e-mail: yangliyan891139@hotmail.com

The tailings in Bali impoundment of Dachang tin-polymetallic sulfide mine, which is located at Guangxi Zhuang Autonomous Region of P. R. China, are rich in carbonate($CaCO_3$ 30.2 wt%; $CaMg(CO_3)_2$ 4.4 wt%) and sulfide(Total-S 15.7 wt%). By observing and sampling successively on a plumb profile of the tailings pile and using the modified BCR (European Community Bureau of Reference) procedure for element extraction, and the secondary mineralogy and the element geochemistry etc, we have gained following conclusions: (1)Most of pyrrhotite, galena, calcite and sericite, while part of sphalerite, arsenopyrite and pyrite, were consumed in the tailings by oxidation. Sulfide oxidation resulted in generating acid mine drainage, as well as releasing heavy metals (such as Zn, As, Cd, Pb). Zinc and As were moved out from the tailings more easily and larger in quantity than Cd and Pb. (2)A hardpan with greater thickness, cemented by secondary gypsum and lepidocrocite, was formed on the tailings surface due to long-term oxidation. The hardpan could be concentrated with heavy metals which released from the original tailings through oxidation. Zinc and As appeared as active acid extractable speciation in the hardpan were prone to remigration and released in large amounts, implying that both may be key factors of heavy metals pollution in Dachang mine district. And Pb and Cd may cause less impact for the mine environment due to their lower contents as acid extractable speciation in the hardpan. However, the condition of the tailings stacking would be changed if the tailings were restored by coverage (resulted in reducing environment) or phytoremediation (resulted in development of organic matter). In these cases, heavy metals (As□Pb□Zn and Cd), which appeared as Fe-Mn oxide bound speciation and sulfide/ organic bound speciation in the tailings, may be removed and produce the environmental effect.

Consequently, the carbonate-rich sulfide tailings may be similar to many other types of sulfide tailings in retention and mobility of heavy metals. It means the carbonate-rich sulfide tailings may also have the potential of releasing heavy metals.

The early Paleozoic magmatic arc of the Central Tianshan, NW China

RUXIONG LEI[1] AND CHANGZHI WU[2]

[1] Key Laboratory of Western China's Mineral Resources and Geological Engineering Ministry of Education, College of Earth Sciences and Resource, Chang'an University, Xi'an 710054, China,
email: ruxionglei@chd.edu.cn
[2] State Key Laboratory for Mineral Deposit Research, School of Earth Sciences and engineering, Nanjing University, Nanjing 210093, China

Located in the Xinjiang province, NW China, the Central Tianshan zone is an important component of the Central Asian Orogenic Belt (CAOB) and crucial linkage between the Siberian, Kazakhstan, Turpan-Hami and Tarim blocks, and played a key role in the crustal evolution and collisional tectonics of the CAOB. We studied a series of the early Paleozoic igneous rock of the Central Tianshan in an attempt to understand the magmatism and tectonic setting of the early Paleozoic Central Tianshan. LA-ICP-MS zircon U-Pb dating yields 424.9±5.8 Ma for the Xingxingxia granodiorite, 445.3±4.6 Ma for the ore-bearing granite of Tianhudong Fe-Mo ore deposit, 466.7±4.2 Ma and 452.0±2.8 Ma Ma for the meta-volcanic rocks hosting the Tianhu iron deposit in the Central Tianshan. Geochemical analyses show these rocks are generally enriched in large ion lithophile elements (LILE) such as Rb, Ba, Sr and LREE, but depleted in typical high field strength elements (HFSE) such as Nb, Ta, Ti, Y and HREE, consistent with the geochemical characteristics of typical arc igneous rock, indicating these rocks have genetic relations to volcanic arc and have been formed in a magmatic arc environment. This is also demonstrated by a number of early Paleozoic granites with ages mainly between 470 and 420 Ma which have been defined by high-precision zircon U-Pb chronology recently in Central Tianshan, such as the Hongliuhe pluton (441.4±1.6 Ma), the north Xiaoyanchi monzodiorite (427±8 Ma), the East Tianhu gneissose granite (466.54±9.8 Ma), the mylonitized Tianger granite (441.6±3.8 Ma), and the Gangou granite (428±10Ma). The geochemical and isotope features of all these granites also show calc-alkaline arc affinity. Combined with the regional geological characteristics and all the available data, it is suggested that the Central Tianshan was a magmatic arc during the early Paleozoic. The mechanism of the early Paleozoic Central Tianshan arc can be ascribed to the southern subduction of the ancient Tianshan ocean located between the Tuha block and Tarim block.

[3]Department of mineral exploration,Henan Huatai Zijin Mining Industry Co., Ltd,LuoYang, 471700,China

Luyuangou gold deposit is located in the north slope of the xionger mountains,eastern Qinling,China,which belongs to the western Henan broken-dermatofibrosarcoma area,southern margin of Northe China platform.According to the type of mineralization,the characteristics of mineral assemblasges and the interpenetration relation between different mineral,the mineralization can be divided into three stages:Quartz-pyrite stage(I):gangue minerals was the milky white massive quartz,metal mineral was the pyrite,which

The main stage of gold mineralization.In this stage,the quartz mostly smoke gray,cut through the early quartz veins.Metal sulfide was disseminated and cloddy.which composed of pyrite,galena,sphalerite,chalcopyrite.Native gold mainly concentrated in the vein quartz,metal sulfides.Fine-grained dust-like characteristics of this stage pyrite.Carbonate stage(III):The last phase of mineralization.The combination of vein quartz,calcite and fluorite mineral appears.Poor mineralization.The existing gold body occur in the capacity seam fault invariably.The gold body assumes layered,stratiform and lenticular outputs.The boundary of ore body relys on chemical analysis to be delineated.

The BSE and EDS were used to study the Regularity of gold mineralization.the histogram shows three peak interval,0-10%,40-50% and 60-100%,which shows there are at least three types of Au migration and aggregation.Further investigation of ore-forming elements shows,the content of Au in gold-silver ore can be high;gold telluride ore Au content is generally not more than 40%;This shows that the combination between elements and substances allocation mechanism affects the occurrence of mineralization and ore-forming efficiency.Also shows that the multi-mode,multi-stage mineralization superimposed is the main characteristic in Alteration-Type Gold Deposit In Eastern Qinling,China.

This research is financially supported by the special Fund Basic Scientific Research of Central Colleges and the Special Fund of Basic Research Support Program of Chang'an University (Grant No.CHD2009JC159).

Do pyrolytic biomarker fragments retain some diagnosticity?

ARNE LEIDER[1] AND CHRISTIAN HALLMANN[1,2]

[1] Max-Planck-Institute for Biogeochemistry, 07745 Jena, Germany, (aleider@bgc-jena.mpg.de, challmann@bgc-jena.mpg.de)

[2] MARUM, University of Bremen, 28334 Bremen, Germany

The detection of early life signatures based on lipid biomarkers in the sedimentary record is frequently hindered by an intense thermal history of the sediments, which causes cracking of parent biomarker molecules [e.g., 1]. Specific degradation products of hopanes and steranes might however still carry diagnostic value for the reconstruction of past biota when found in mature oils and sediment extracts. Laboratory studies investigating the thermal stability of kerogens and authentic biomarker standards during pyrolysis revealed some characteristic alteration products [e.g. 2, 3] but it is not known if these compounds are unique to their precursors.

We here investigate this question with heating experiments using biomarker standards (steranes and hopanes) under different time and temperature conditions as well as in the presence of a carbonaceous catalyst. Preliminary results show that e.g. 5α-cholestane undergoes conversion to a series of benzenes, naphtalenes, biphenyls and diphenylmethanes at 350°C in the presence of activated carbon but diamondoid hydrocarbons, which are used to evaluate the thermal maturity in crude oils and condensates [e.g. 4], were not generated. Comparison of larger biomarker fragments to cracking products of spiked oils will reveal how unique they are. Such data might extend molecular geobiological approaches to basins that were hitherto precluded by their thermal maturity.

Origin of brines associated with the Bou Azzer silver deposit, Anti-Atlas, Morroco: A LA-ICPMS study of individual fluid inclusions

M. LEISEN[1-2*], M-C. BOIRON[1], S. ESSARAJ[3] AND J. DUBESSY[1]

[1] GeoRessources, Université de Lorraine, Vandoeuvre les Nancy, France
[2] present adress : Andean Geothermal Center of Excellence (CEGA), Universidad de Chile, Santiago, Chile (*mleisen@ing.uchile.cl)
[3] Faculté des Sciences et Techniques, Département de Géologie, BP 549, Marrakech, Morroco

Determination of major and trace element concentrations including metals in fluids associated with ore deposits is essential to evaluate contrasting genetic models. Such information can be obtained by LA-ICPMS analysis of individual fluid inclusions as they represent remnants of the hydrothermal fluids responsible of ore deposition. Previous studies have determined Br and Cl concentrations in high-salinity fluid inclusions using standard multi-element solutions loaded in silica glass capillaries [1] or by using scapolite solid standards [2, 3, 4]. In this work, all metal concentrations have been calibrated using NIST 610 glass. Concentration of all elements in the fluid inclusions have been calculated as described by Leisen *et al*.. (2012) [5].

Fluid inclusions associated with silver mineralisation in the Bou Azzer deposit (Anti-Atlas, Morroco) are Na-K-Ca chloride brines (Na: 30,000-60,000 ppm, K: 11,000-27,000 ppm, and Ca: 12,000-85,000 ppm). Ag content ranges from tens to hundreds of ppm. Cl/Br molar ratios range from 300 to 1,000. The Cl/Br ratios determined here are in good agreement with previously published data obtained by crush-leaching techniques [6]. The chemical characteristics of the fluid inclusions indicate that the fluids originated from evaporates that later migrated through basement rocks during a major extentional episode. These geochemical signatures do not support an epithermal model as previously suggested by Levresse *et al*.. (2004) [7].

Boron behavior during silicate weathering: clues from bulk mineral and intracrystaline investigations

D. LEMARCHAND[1]*, A. VOINOT[1,2], P. FLORIAN[3], D. NEUVILLE[4] AND M-P. TURPAULT[2]

[1]LHyGeS/CNRS, Univ. Strasbourg, France (*correspondence: lemarcha@unistra.fr)
[2]BEF, INRA Champenoux, France
[3]CEMHTI/CNRS, Orléans, France
[4]IPGP/CNRS, Paris, France

How to model the behavior of a trace element in the mineral structure? What can trace elements actually tell us about the weathering conditions and history of their host mineral? In the present study, we have analyzed a series of common silicate minerals (biotite, muscovite, albite, K-feldspar) handpicked in different soil horizons developped on a granite bedrock (Morvan, France). The chemical and mineralogical weathering gradient shown by those minerals is compared with their respective B and $\delta^{11}B$ signatures. Our results evidence an excess B solubility compared to major elements in both micas, whereas it shows a relative accumulation in albite. Beside, major elements and B show parallel evolutions in K-feldspar, which is diagnostic of a stoichiometric mineral dissolution.

In order to investigate whether these distinct B behaviors are related to the B atomic environment in those minerals, we have performed solid-state ^{11}B NMR (SSNMR) analyses in similar silicate minerals. As far as we know, these SSNMR ananlyses are the first ones performed on such low B silicate samples (10-100 ppm). The SSNMR spectra in a B-rich plagioclase (labradorite) clearly shows a well-organized environment for B atoms but they are found in both trigonal and tetrahedral coordination whereas the mineral structure only presents tetrahedral sites. The presence of trigonal B implies the disruption of one of the tetrahedral-O bond, which should necessarily change the energy state of the B local environment. The SSNMR spectra of pristine albite and muscovite clearly demonstrate that B in those minerals is also present in both the trigonal and tetrahedral coordination, but not in well-organized environments, typically not in substitution of Si or Al in the crystal structure but rather located in crystal defects (i.e. in those crystal positions expected to be the most reactive ones).

These new observations may allow the determination of distinct B energy states in crystallographic sites and study of the differential B mobility may help characterizing processes of non-stoichiometric mineral dissolution.

The copper deposit of Gaoua, Burkina Faso: A Paleoproterozoic porphyry deposit

E. LE MIGNOT[1,2]*, L. SIEBENALLER[3], D. BEZIAT[4], S. SALVI[4], A.-S. ANDRE-MAYER[1], L. REISBERG[2] AND G. VELASQUEZ[4]

[1] GéoRessources, Université de Lorraine, BP239, 54506 Vandoeuvre-lès-Nancy, France (*correspondence: elodie.le-mignot@univ-lorraine.fr)
[2] CRPG/CNRS, 54501 Vandoeuvre-lès-Nancy, France
[3] IRD GET, 31400 Toulouse, France
[4] GET, Université Paul Sabatier, 31400 Toulouse, France

The copper occurrence of Gaoua is located in the Boromo-Goren greenstone belt, southern Burkina Faso. In this deposit, copper mineralization is predominantly present in the form of chalcopyrite and is hosted in Paleoproterozoic volcanic and plutonic rocks of andesitic to dioritic composition.

Geochemical analyses of the host diorite and andesite suggest an island arc setting for the formation of these rocks. Brecciation is widespread, accompanied by abundant chalcopyrite ± anhydrite in the matrix, as are quartz ± carbonate veins, which commonly form stockwerk-like networks. Microthermometric analyses of fluid inclusions indicate high temperature (>400°C) and high salinity fluids (>30% wt% eq. NaCl), related to hydrothermal fluid circulation contemporaneous to diorite intrusion and andesitic volcanism. The above data suggest that the copper mineralization formed in a porphyry-type context.

Pyrites and molybdenites associated with the porphyry mineralization were dated by the Re-Os method. The resulting isochron yields an age of 2170 ±40 Ma, corresponding to a pre-Eburnean magmatic accretion event. Paleoproterozoic porphyry deposits are very rare since they form at shallow depths and, therefore, are very sensitive to erosion. Nevertheless, the high Re and radiogenic Os contents, together with the low common Os contents of the dated pyrites and molybdenites, argue for the reliability of the data.

FT-ICR Mass Spectrometric and Density Functional Theory studies of Solvated Cerium Chloride Clusters

KONO H. LEMKE[1] AND YIN ZHAO[1]

[1]Department of Earth Sciences, University of Hong Kong, Pokfulam Road, Hong Kong, SAR, China (kono@hku.hk)

The molecular-scale speciation of cerium in aqueous fluids (bulk liquid and vapor phase) is a primary field of interest with important implications for our understanding of the transport and deposition of REE's in the Earth's crust. Mass spectrometric and quantum chemical studies of cerium chloride solutions can provide important insight into the composition, structure and energetic properties of molecular cerium species, and as such, deliver new information with respect to the distribution and abundance of such materials in aqueous fluids.

Here we present results from electrospray ionization (ESI) Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometric experiments of cerium chloride complexes and clusters in the gas-phase, in particular, clusters of the general form $[Ce_mX_n]^+$ (X=Cl, OH, O) and corresponding micro-solvated species. We also report equilibrium geometries and associated energetic properties using M06/cc-pVXZ-PP (X=D,T) level theory in combination with quasi-relativistic effective core potentials for Ce. Ion cluster experiments have been conducted on a custom-modified Bruker-Daltonics 7T FT-ICR mass spectrometer with temperature-control, ESI capability and pulsing valves facilitating ion-solvent reactions. Molecular species identified upon electrospray ionozation of aqueous $CeCl_3$ include *a*) $[CeCl_2]^+(H_2O)_n$, $[CeClOH]^+(H_2O)_n$ and $[Ce(OH)_2]^+(H_2O)_n$ with n=0-4; *b*) polynuclear $[Ce_mCl_{3m-1}]^+(H_2O)_n$ with m=1-5 and n=0-4 *c*) mixed polynuclear $[Ce_mCl_{3m-2}OH]^+$ and $[Ce_mCl_{3m-3}O]^+$ with m=1-5 and *d*) larger solvated clusters of the general form $[Ce_mCl_{3m-4}O]^{+2}(H_2O)_n$ and $[Ce_mCl_{3m-4}O]^{+2}(H_2O)_n$ with m≤6 and up to six water molecules. We also conducted mass spectrometric experiments in which the concentration-dependence (1-20mM; pH 5.2-6.9) of the cerium cluster distribution was probed. Results from these concentration-dependent experiments demonstrate that cerium chloride clustering increases with $CeCl_3$ concentration, in other words, at higher $CeCl_3$ concentrations (lower pH) more cerium chloride is present as polynuclear chlorocerate. With respect to solution pH, it is likely that the emergence of clusters with bridging hydroxo groups, e.g. $[Ce_mCl_{3m-2}OH]^+$ arises as a consequence of the partial hydrolysis of $[Ce_mCl_{3m-1}]^+$ clusters, in particular, in the acidic pH range. Last but not least, the observed correlation between ion mass spectra and solution content appears to demonstrate that dinuclear clusters are intermediates on the way from the $[CeCl_2]^+$ complex to the formation of larger "bulk-like" chlorocerate clusters. In conclusion, results from our ESI mass spectromentric and DFT study strongly point toward molecular clustering being an important factor in understanding Ce speciation in aqueous fluids.

Geochemical Sample Analysis by Microwave Plasma Atomic Emission Spectrometry

T. D. HETTIPATHIRANA* AND J-P LENER

Agilent Technologies, 679 Springvale Road, Mulgrave VIC 3170, Australia (*correspondence: terrance_hettipathirana@agilent.com)

We present the results for a wide range of geochemical Certified Reference Materials (CRM) analyzed using a novel Microwave Plasma - Atomic Emission Spectrometer (MP-AES) developed by Agilent Technologies. This instrumental technique uses microwaves to generate an atmospheric pressure N_2-plasma and a conventional ICP-OES sample introduction system. Emission line measurement is performed using a Czerny-Turner monochromator and charge-coupled device system.

We have successfully analyzed base metals (Ag, Cu, Ni, Mo, Pb, and Zn) and platinum group metals (Au, Pd, and Pt). Figure 1 depicts a comparison of Certified and MP-AES results for the determination of Au in geochemical CRMs.

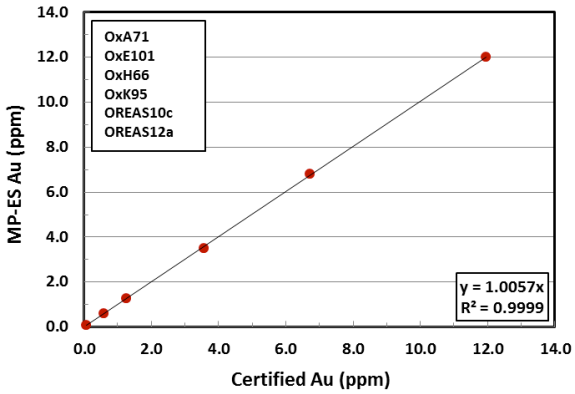

Figure 1 Comparison of Certified and MP-AES results for geochemical CRMs indicates excellent correlation.

The above results indicate that MP-AES is a very powerful technique for a wide variety of geochemical sample analysis. A highly robust atmospheric pressure plasma is generated by using N_2 and therefore the running cost is considerably lower compared with alternative techniques. MP-AES uses no flammable gases making the routine operation much safer than flame atomic absorption spectrometry.

Power of a new ICP-MS, ICP-QQQ: Application of the MS/MS reaction cell to two challenging analysis

LENER JEAN PIERRE[1] AND NAOKI SUGIYAMA [2]

[1]Agilent Technologies (jean-pierre.lener@agilent.com)
[2]Agilent Technologies (naoki_sugiyama@agilent.com)

A new type of ICP-MS, the Triple Quadrupole ICP-MS (ICP-QQQ) was applied to two challenging analysis. The ICP-QQQ provides MS/MS reaction cell that outperforms existing reaction cell ICP-MS. The MS/MS configuration unique to ICP-QQQ solves a problem of conventional reaction cell, complexity of chemical reaction in cell, allowing use of full potential power of reaction cell to remove spectra interference. The first quadrupole placed in front of cell removes undesired ions, allowing only ions having selected mass to enter the cell. It makes chemical reaction in cell simple and hence consistent regardless of sample matrix.

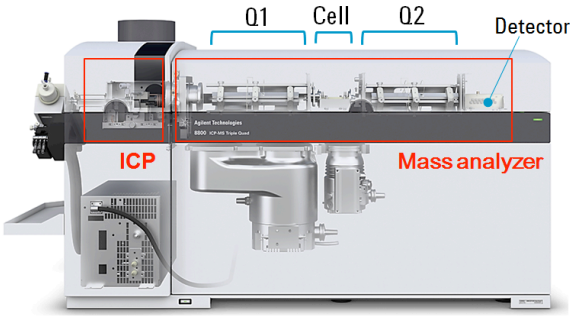

Figure 1: Configuration of ICP-QQQ

One analysis we applied ICP-QQQ is trace rare earth elements (REEs) measurement in REE materials such as gadolinium oxide, where interferences of GdH^+ with Tb^+ and GdO^+ with Yb^+ are problem. The other analysis is trace analysis of noble metals, Ru, Rh, Pd, Ag, Os, Ir, Pt and Au in complex matrix such as Cu, Zn, Ni, Sr, Rb, Zr, Nb, Mo, REE, Ta, W, Hf and Hg. Oxide, argide, atomic and double charged ions of the matrix elements interfere with isotopes of analyte. MS/MS mass shift method was used: analyte ions converted to molecular ions such as oxide ions via chemical reaction is detected on the different mass free from interference. The method successfully measured analyte at trace level in matrix, demonstrating excellent analytical performance of the ICP-QQQ.

Predicting the depth of the lithosphere-asthenosphere boundary from surface heat flow in the Carpathian-Pannonian region: the role of pargasitic amphibole

ISTVÁN KOVÁCS[1], LÁSZLÓ LENKEY[2], LÁSZLÓ OROSZ[1], JOLÁN ANGYAL[1] AND ZSUZSANNA VIKOR[1]

[1] Geological and Geophysical Institute of Hungary, H-1143, Srefánia út 14, Budapest, Hungary
2 Eötvös University, Budapest, Hungary, H-1117, Pázmány Péter sétány 1/c

It was shown recently (Green *et al*.., 2010) that pargasitic amphibole is the most important water bearing phase in the upper mantle. Its melting and instability at 3 GPa (~ 90 km of depth) or ~1050 °C lead to a significant drop in the water storage capacity of the upper mantle. The melt or free fluid forming during the decomposition of pargasite weakens considerably the rheology of the upper mantle resulting in lower seismic velocity, higher conductivity and stronger anisotropy.

If this petrologic model is correct, then we should see geophysical anomalies at ~90 km depth globally, expect places where the heat flow is high. In this areas, where the heat flow is higher than ~60-70 mW/m^2 -considering an average continental geotherm - the temperature may exceed the pargasite stability at ~1050 °C in a depth shallower than 90 km. The Carpathian-Pannonian region (CPR) which is characterized by high heat flow, and both geophysical and geological data are abundant, is an excellent natural laboratory to test such a petrophyscial model. Depth of the 1050 and 1100 °C isotherm was calculated beneath the CPR from heat flow data and compared the depth of major geophysical anomalies indicating the lithosphere-asthenosphere boundary.

Paleoredox chemistry of Cenomanian–Coniacian black shales at high paleolatitudes: Implications for the extent of anoxia during OAE2

M. LENNIGER[1]*, H. NØHR-HANSEN[2], L. V. HILLS[3] AND C. J. BJERRUM[1]

[1] Department of Geosciences and Natural Resource Management and Nordic Center for Earth Evolution (NordCEE), University of Copenhagen, 1350 Copenhagen, Denmark (*correspondence: mal@geo.ku.dk)
[2] Geological Survey of Denmark and Greenland (GEUS), 1350 Copenhagen, Denmark
[3] Department of Geoscience, University of Calgary, AB T2N 1N4 Calgary, Canada

Cretaceous oceanic anoxic events (OAEs) have been studied in detail during the last decades. OAE2 is of particular interest as it reflects one of the largest perturbations of the global carbon cycle in the Mesozoic. It is characterised by a widespread deposition of organic rich sediments which is reflected by a positive carbon isotope excursion (CIE) in the terrestrial and marine record. Whereas the paleoredox conditions in low and mid-paleolatitudes are well constrained for OAE2, data from high paleolatitudes are still scarce.

The paleoceanographic response at high paleolatitudes during OAE2 is here characterized by samples from Axel Heiberg Island in Canada. Preliminary palynological analyses indicate a Late Cenomanian–Coniacian age for the section. Bulk organic carbon isotope data have been corrected using the hydrogen index (Rock Eval pyrolysis) to account for changes in organic matter sourcing. Our corrected isotope record correlates in detail with the European carbonate reference curve and confirms our biostratigraphic model. Iron speciation (Fe_{HR}/Fe_T and Fe_{Py}/Fe_{HR}) data point to anoxic but non-euxinic conditions at high paleolatitudes during OAE2. Furthermore the Sverdrup Basin was intermittently suboxic to anoxic (ferruginous) throughout most of the latest Cenomanian–Coniacian. Despite very high TOC (>10%) and hydrogen index values, molybdenum concentrations are relatively low during OAE2 but increase after the event. This suggests a global drawdown of the seawater molybdenum reservoir caused by the widespread extent of ocean anoxia/euxinia in the Cretaceous oceans during OAE2.

Biological controls on oxygenation in the Neoproterozoic and Paleozoic

TIMOTHY M. LENTON[1]

[1]University of Exeter, Exeter, UK, t.m.lenton@exeter.ac.uk

The deep oceans were finally oxygenated during the Late Neoproterozoic, and this is widely attributed to a rise in atmospheric oxygen. However, existing data suggests there followed a de-oxygenation of the ocean across the Precambrian-Cambrian boundary. Only later in the Paleozoic did the deep ocean recover a fully oxygenated state. What biogeochemical mechanisms could explain these changes?

It is hypothesised that increases in phosphorus weathering, either due to greening of the land [1] or the aftermath of glaciations [2], fuelled organic carbon burial and thus a Neoproterozoic increase in atmospheric oxygen. However, sustained changes in silicate weathering flux are prevented by the well-known regulator of atmospheric CO_2 and temperature. Thus, increases in phosphorus weathering can only be sustained long enough to affect atmospheric oxygen if there is selective weathering of phosphorus relative to bulk rock (by biology) [1], or a shift in the balance of CO_2 sinks from seafloor weathering to continental weathering [3].

Hence it is worth considering if the Neoproterozoic oxygenation of the ocean could have happened without a rise in atmospheric oxygen. A possible scenario invokes the evolution of eukaryotes in the surface ocean producing larger particles that sank faster [4]. This would have shifted oxygen demand away from the bottom waters of continental shelves (where the majority of phosphorus burial and recycling occurs) to greater depth. Oxygenation of the shelves would have increased the efficiency phosphorus removal from the ocean (in organic matter and adsorbed to iron oxyhydroxides) thus lowering global productivity and lowering oxygen demand in the deep ocean, oxygenating it. The net effect on organic carbon burial is uncertain because less export production was counteracted by faster sinking to sediments.

The subsequent early Paleozoic de-oxygenation of the ocean could be explained by the evolution of animal bioturbation lowering the C/P burial ratio of organic matter in sediments and thus lowering atmospheric oxygen [5].

The later rise of land plants, selectively weathering phosphorus and producing recalcitrant high C/P biomass, increased organic carbon burial and atmospheric oxygen, finally producing a persistent oxygenation of the ocean.

Orientation-dependent REE^{3+} luminescence: a possible artifact in luminescence imaging

C. LENZ[1]*, C. REISSNER[1], D. TALLA[1,2] AND L. NASDALA[1]

[1] Institut für Mineralogie und Kristallographie, Universität Wien, Althanstraße 14, 1090 Wien, Austria (*correspondence: christoph.lenz@univie.ac.at)

[2] Institute of Geological Sciences, Masaryk University, Kotlářská 2, 61137 Brno, Czech Republic

Luminescence imaging is a sensitive tool for revealing internal zoning patterns of crystals and other geological samples, especially for species containing rare-earth elements (REE^{3+}) [1,2]. In addition to the traditional direct imaging methods, the hyperspectral mapping technique is used increasingly for this [3]. Quantifications of REEs from emission intensities have been proposed for several minerals [3–5]. Note, however, that the orientation-dependence of REE^{3+} emissions is often neglected by Earth scientists [4], even though the phenomenon is well known [5,6].

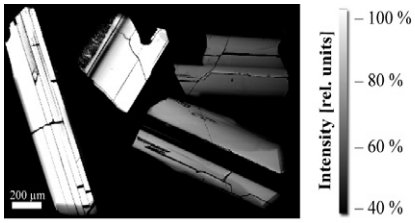

Figure 1: PL map (532 nm excitation with N–S polarisation) of the emission of Nd^{3+}, showing clear intensity differences among chemically uniform but randomly oriented crystals.

As an example, we have studied the orientation-dependence of the $^4F_{3/2} \rightarrow {}^4I_{9/2}$ emission of trace Nd^{3+} in zircon and xenotime–(Y) and their synthetic analogues. We found once again that the emission intensity depends strongly on the direction of the emitted light being analysed (CL and PL). In PL, the intensities observed are further affected by the polarisation of the incident laser beam relative to the crystal (compare Fig. 1).

Organic biomarkers in sediment from Admiralty Bay, Antarctica

LEONEL, J.[*1]; ARAÚJO, L. D.[1]; AND BÍCEGO, M. C.[1]

[1]Lab. de Quím. Org. Mar., IO-USP, 05508-120, São Paulo, Brazil.

[*]corresponding author: juoceano@gmail.com

The use of biomarker data as proxies reflecting recent environmental conditions is a well established geochemical tool. Therefore, this study aimed to get more detailed information on the source and composition of organic matter from surface sediments from Admiralty Bay and adjacent area of Bransfield Strait,Antarctica. Total organic carbon, carbon isotopic composition, *n*-alkanes and fatty alcohols were analyzed in sediment collected in four different isobaths (100m, 500m, 700m, and 1100m). Samples from all isobaths were characterized by low amounts of organic carbon (0.14 – 0.52%) and no significant variation among locations. Values of $\delta^{13}C$, ranging from -25.9 to -24.7, were similar to those from terrestrial inputs in tropical and subtropical areas. However, the low values of $\delta^{13}C$ in high latitudes can be related to the higher concentrations of dissolved CO_2 at low surface temperatures and slow growth rates infer small periods of light. In comparison with $\delta^{13}C$ found in phytoplankton (-28 to - 33‰) the values in sediment were higher probably due to the high contribution from krill faeces that are approximately 3-4‰ enriched compared to phytoplankton. Furthermore, the influence of a lateral influx of benthic macroalgae from the nearby shelf areas can also contribute to an enrichment of about 3‰. Average concentrations of *n*-alkanes (*n*-C_{12} to *n*-C_{36}) were 0.86 ug g^{-1}, 0.79 ug g^{-1}, 0.67 ug g^{-1}, and 0.17 ug g^{-1} at 100, 500, 700 and 1100 m, respectively, and its distribution varied among isobaths. Sediments from 100 m showed more *n*-alkanes with higher molecular weight, dominance of *n*-C_{29}, probably due to the input of *n*-alkanes from terrestrial adjacent areas, especially from grasses, lichens and mosses. On the other hand, at 500, 700 and 1100 m, the lower molecular weight compounds were the predominant *n*-alkanes showing marine influence. Normal alcohols (C_{12} – C_{30}) concentrations were 25 ng g^{-1} at 100 m, 76 ng g^{-1} at 500 m, 104 ng g^{-1} at 700 m and 158 ng g^{-1} at 1100 m, with predominance of the chain with 16 carbons in all samples. C_{16} level increased from 100 m to 1100 m, it is considered a typical marine compound since it is the most abundant homologue in phytoplanktons, while C_{18} appears to be less specific. The ratio low molecular over high molecular alcohols was above 3 in all samples, and also indicates a dominance of autochthonous productivity. The organic matter in the sediment from the Admiralty Bay and adjacent area of Bransfield Strait seems to be a mixture of both terrestrial and marine sources. However, further studies are necessary to fully understand the sources and distribution of organic matter in the region.

Biogeochemical types of lake sapropels in Siberia

G.A. LEONOVA*, V.A. BOBROV, S.K. KRIVONOGOV, A.A. BOGUSH, A.E. MALTSEV AND G.N. ANOSHIN

Institute of geology and mineralogy SB RAS, Koptyug Pr. 3, Novosibirsk 630090, Russia (*coresspondence: leonova@igm.nsk.ru)

We recognize three types of lake sapropels based on the paleolimnetic classification taking into account biological and chemical characteristics of sedimentation [1]. Molecular biomarkers were used as additional chemical criteria of origin of organics in sapropels [2]. Biological characteristics imply two types of sapropels: predominately macrophytic and planctonic and macrophytic. Combinations of biological and chemical characteristics imply three types of sapropels. Type 1, macrophytic with high Ca and low Fe, was found in West-Siberian lakes such as the whole Lake Beloye (Ca ~ 27%, Fe ~ 1.1%) [3] and near-shore zone of Lake Kirek (Ca ~ 18%, Fe ~ 3%) [4]. Type 2, planktonic and macrophytic with low Ca and high Fe, is characteristic for the central part of Lake Kirek [4]. Type 3, planktonic and macrophytic with low Ca and low Fe, was found in East-Siberian lakes, such as Lake Ochki (Ca ~ 0.43%, Fe ~ 0.67%) and Lake Dukhovoe (Ca ~ 0.86%, Fe ~ 2.7%) [5]. Formation of sapropels in certain lakes mostly depends on physic-chemical characteristics of their waters, i.e., mineralization, chemical class, pH, Eh and on dominated producers of the organic matter [5]. West-Siberian lakes mostly belong to the calcium hydrocarbonate class, have low or medium mineralization and alkalescent pH; macrophytes are the main producers of the organic matter. These conditions suggest formation of high-calcic sapropels. East-Siberian lakes show dominated planktonic sapropel production, whereas their hydrochemistry vary from little mineralized calcium hydrocarbonate alkalescent (Lake Dukhovoe) to ultra-fresh sulphate Ca-Na highly acidic (Lake Ochki) classes. These conditions suggest formation of low-calcic sapropels. This research was supported by the SB RAS Integration Project no. 125 and RFBR 11-05-00655.

Dating the collapse of the Scandinavian Ice Sheet using CH_4-derived carbonate crusts from the Barents Sea

AIVO LEPLAND[1,2]*, SHYAM CHAND[1], DIANA SAHY[3], STEPHEN R. NOBLE[3], DANIEL J. CONDON[3], TÕNU MARTMA[2], JON HALVARD PEDERSEN[4], SIMONE SAUER[1], HARALD BRUNSTAD[4] AND TERJE THORSNES[1]

[4] Lundin Petroleum, Oslo, Norway

Assessment of the potential impact of past CH_4 discharge from CH_4 hydrate reservoirs into the atmosphere is hindered by the lack of robust age constraints on the timing of such fluxes. Authigenic carbonates formed in shallow sediments can be related to CH_4 fluxes to the ocean-atmosphere via stable isotope analyses and can be dated by using U-daughter decay (e.g., Teichert *et al*.., 2003) affording the opportunity to constrain the absolute timing and estimate the rates of CH_4 release.

CH_4-derived carbonate crusts exhibiting characteristic ^{13}C-depleted isotopic signatures were collected from several seepage sites of the Barents Sea. The U-Th dating results of early generation aragonite cementing sandy and gravelly sediments constrain the main event of CH_4 discharge and crust formation to a time interval between c. 14 and 11 ka, continuing until c. 9 ka constrained by late stage cavity filling aragonite. These U-Th dates indicate that the carbonate crust formation in the Barents Sea was coincident with the deglaciation of the area and collapse of the Scandinavian Ice Sheet. The CH_4 flux for the carbonate crust formation was likely provided by the dissociation of CH_4 hydrates that extensively formed in underlying sediments during the last glacial period (Chand *et al*.., 2012), but became unstable due to depressuring effects of retreating ice sheet and related isostatic rebound. Ice core records from Greenland and Antarctica demonstrate two CH_4 concentration peaks at ca. 15-13 ka and 11-8 ka, overlapping with the crust formation episode. Such temporal coincidence implies the involvement of destabilised, sediment hosted CH_4 hydrates influencing atmospheric CH_4 and global climate during the last degalciation.

The oldest possible morphological evidence for life are 3.4-3.5 Gyr old. Distinguishing geochemical biosignatures in organic matter preserved in such ancient rocks remains difficult due to alteration by deep burial and to the abundance of hydrothermal systems that could have produced abiogenic organics. Microbial morphologies are in general simple and, especially when degraded, can be difficult to distinguish from migrated hydrocarbons precipitated along grain boundaries of variable shapes. Abundant cell-like organic microstructures have been recently reported in the 3.4 Gyr old Strelley Pool Formation from Western Australia. We measured carbon isotope ratios and H/C in situ (with a 15 μm spot) in these organic microstructures using Secondary Ion Mass Spectrometry (SIMS) and characterized the structure of organic matter using Raman spectromicroscopy. Coordinated Raman spectromicroscopy and SIMS carbon isotope measurements distinguished the indigenous cell-like structures and kerogen from late migrated bitumen. SIMS revealed carbon isotopic and H/C heterogeneities between spherical and lenticular cell-like structures and kerogen clots, and internal heterogeneties in lenticular structures. Heterogeneities can be explained by selective diagenetic preservation of the distinct isotopic fractionations inherited from different precursor biomolecules. These results support the interpretation of biogenicity of morphologically cellular structures in the Strelley Pool Formation.

Interactions between chemical inhibitors, scale formation, corrosion and microbes at geothermal plants

LERM, S.[1], WESTPHAL, A.[1], EICHINGER, F.[2], HUENGES E.[1] AND WÜRDEMANN, H.[1]

[1] Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany. Email: wuerdemann@gfz-potsdam.de

[2] Hydroisotop GmbH, Woelkestr. 9, 85301 Schweitenkirchen, Germany. Email: fe@hydroisotop.de

Chemical inhibitors are used to prevent scale formation and corrosion that adversely affect the reliability and economic efficiency of geothermal plants. However, knowledge about inhibitor efficiency with respect to chemical fluid composition, temperature and fluid abundant microorganisms is required. In addition, to be sufficiently effective, inhibitors have to be stable in the geothermal plant and the near wellbore area but for ecological reasons also degradable. Since microorganisms, such als sulfate reducing bacteria (SRB), are involved in scaling and corrosion processes, the influence of the inhibitor supply on the microbial community composition should be investigated.

Thus, lab-scale experiments with fluid samples from different geothermal plants in Germany were performed. As fluids from the North German Basin, the Upper Rhine Graben and the Molasse Basin have a significantly different chemical fluid composition that leads to a region-specific formation of scales, different inhibitors were tested. In order to investigate the interactions between microbes and reservoir rock material, fluids were incubated with rock material from outcrop analogues.

First results show the degradability of the supplied inhibitors that was indicated by the production of CO_2 in the gaseous phase of the vessels. Particularly, a correlation between the CO_2 yield and the inhibitor concentration illustrated the substrate-dependent activity of microorganisms.

The influence of inhibitor supply on the microbial community composition in fluids was shown for a bypass system at a geothermal plant in the Styrian Basin. At this plant, supply of a nitrate-based inhibitor led to a reduced diversity and abundance of SRB and a higher abundance of nitrate reducing bacteria. This corresponded to a reduced content of corrosive H_2S in fluids.

3D fluid distribution in subducted slabs: new constraints on H_2O cycling

V. LE ROUX[1], G. GAETANI[1], J. SLAUGENWHITE[2] AND K. MILLER[3]

[1]Woods Hole Oceanographic Institution, 266 Woods Hole road, Woods Hole MA 02543 USA. vleroux@whoi.edu; ggaetani@whoi.edu

[3]University of Maryland, College Park MD 20742 USA. kjmiller944@gmail.com

Large amounts of H_2O are carried into trenches via subduction of the sediments, basaltic crust and uppermost mantle that make up the oceanic lithosphere. A major question is how much of this subducted H_2O is released into the overlying mantle wedge, promoting melting, and how much is carried deeper into the mantle. This depends, at least in part, on whether H_2O is able to form an interconnected network among the mineral grains that make up the rock down to very low fluid fractions. In order to achieve connectivity and allow the fluid phase to escape, a minimum amount of fluid (critical porosity) is required when dihedral angles are more than 60 degrees. We investigated the distribution of seawater in simplified sediment analogs (i.e. quartz for siliceous sediments; calcite for carbonate sediments), in natural clays (kaolinite and montmorillonite) and in bulk eclogite. Experiments were performed in a piston-cylinder apparatus at 2 GPa and 650°C. Fluid fractions ranged from ~10% to ~1% to determine the porosity at which connectivity of the seawater network is lost for each rock type.

We used synchrotron X-ray microtomographic techniques (at Argonne National Laboratory, IL) to obtain 3-D images of the pore space network in order to constrain the grain scale distribution of fluids in a subducted slab. This nondestructive 3-D imaging technique has a spatial resolution of 0.7 μm and provides quantitative information on geometrical parameters of fluid topology, such as porosity, dihedral angle distribution, fluid channel sizes and connectivity. The geometrical parameters were extracted using the VSG Avizo® software. This study lays the groundwork for determining the 3-D grain scale distribution of fluids in a range of subducted lithologies. Results from this study provide important new insights into the amount of fluid that can be transported into the deep mantle by subduction.

Influence of surface conductivity on the apparent zeta potential of amorphous silica nanoparticles

P. LEROY[1]*, N. DEVAU[1], A. REVIL[2,3] AND M. BIZI[1]

[1] BRGM, 3 Avenue C. Guillemin, 45060 Orléans, France (*correspondence :p.leroy@brgm.fr).

Zeta potential is a physico-chemical parameter of particular importance in describing ion adsorption and double layer interactions between charged particles [1]. However, for metal oxide nanoparticles, the conversion of electrophoretic mobility measurements into zeta potentials is a complex problem. This complexity arises because of their high surface electrical conductivity, which is inversely proportional to the size of the particle [2].

To describe the electrochemical properties of amorphous silica nanoparticles, we use a basic Stern model whose parameters are independently adjusted by potentiometric titration and electrophoretic mobility measurements at high salinity (10^{-1} M NaCl) [3]. At low ionic strengths, because of the strong retardation and relaxation effect due to charged counter-ions at the silica/water interface, amplitude of the predicted zeta potential is significantly higher than that of the apparent zeta potential estimated with electrophoretic mobility measurements and Smoluchowski equation. Electrophoretic mobilities are calculated using Henry's electrokinetic model [4] with the predicted specific surface conductivities and zeta potentials. The very good agreement between calculated and measured electrophoretic mobilities confirms that the magnitude of the true zeta potential corresponds to the magnitude of the electrical potential located at the outer Helmholtz plane. Therefore, the assumption of the presence of a stagnant diffuse layer at the amorphous silica/water interface is not required. This study was done within the framework of the NANOMORPH Project (ANR-2011-NANO-008) coordinated by BRGM.

With the successful landing of the Mars Curiosity Rover in August 2012, we now have the most capable geochemical laboratory ever to travel to another planet roving Mars' Gale crater. The geochemical instrument suite includes the Chemistry Camera (ChemCam), which uses a laser to vaporize geologic targets and performs atomic emission spectroscopy on the vapor from distances of up to 7m. This provides a geochemical surveying capability that enables rapid identification of unique specimens and accumulation of a large set of rock and fines compositions as the rover traverses. The Alpha Particle X-ray Spectrometer (APXS) provides high quality "bulk" elemental analyses for major, minor and a few trace elements through a touch deployment on the surface of a rock or soil, and is an upgraded version of similar instruments previously flown to Mars. The addition of x-ray diffraction through the Chemistry and Mineralogy (CheMin) instrument and volatile, isotope, and organic analyses with the Sample Analysis at Mars (SAM) instrument suite, give Curiosity the capability to assess the geochemical history of the planet more deeply than previously possible.

Both CheMin and SAM accept sieved fines from either Curiosity's scoop or drill. To date, sampling has occurred at the Rocknest aeolian drift deposit and a fine-grained mudstone called John Klein. At Rocknest, CheMin found a mix of primary igneous minerals and amorphous materials. SAM found that Rocknest fines contain significant bound volatiles that can be released upon heating, largely associated with the amorphous material. Because APXS and ChemCam data support the fines being representative of those found at other sites on Mars, Curiosity results show that martian fines are a good source of water, CO_2 and other volatiles that could be leveraged by living organisms, including future human explorers. At John Klein, early results are consistent with an ancient aqueous habitable environment. Analyses of isotopes and organics also provide exciting windows into martian habitability and volatile evolution. These early geochemical results will be discussed.

Continental lithosphere removal by drip and delamination processes

ALAN LEVANDER[1]* , MAXIMILIANO BEZADA[2], EUGENE D. HUMPHREYS[2], , JENIFFER MASY[1] AND BRANDON SCHMANDT[3]

[1] Rice University, Houston Texas, USA 77251 (*correspondence alan@rice.edu)

[3] University of New Mexico, Albuquerque NM, USA 87131

We present evidence for convective removal of continental lithosphere beneath the western U.S., the western Mediterranean, and the southeastern Caribbean. All three locales are associated with subduction, the first through hydration weakening of overlying lithosphere during Laramide-age flat slab subduction, the latter two by recent or ongoing subduction that includes involvement of the adjacent continental margins. In the western U.S., the Precambrian continental lithosphere beneath the western Colorado Plateau, the Rio Grande Rift, and likely the northern Wasatch Front are experiencing thermo-chemical edge convection that removes most or all of the lithospheric mantle and can reach depths as shallow as the lower crust. Extensive basaltic volcanism accompanies this process, as vertical asthenospheric flow gradients and melt generation help destabilize the lithosphere. In the western Mediterranean, slab rollback and delamination of continental mantle beneath the Alboran crust have also removed the mantle lithosphere beneath the adjacent Iberian and Moroccan margins. Southern Spain and northern Morocco are sites of extensive mid-Cenozoic to modern basaltic volcanism. In the western Mediterranean, however, melt generation may be a consequence of rather than the cause of lithosphere removal. In the southeastern Caribbean, at the southernmost corner of the Antilles subduction zone, Atlantic subduction beneath the Caribbean plate results in a tearing lithosphere that produces a large-scale ocean-continent transform fault system. Deeper levels of the South American continental lithosphere (≥ 75-100 km depth) south of the surface expression of the plate boundary are dragged along by the subducting Atlantic plate and descend into the mantle. Removal of lithosphere beneath the South American continental margin appears to trigger additional lithospheric instabilities within the continental interior. In contrast to both the western U.S. and the western Mediterranean, this process is almost amagmatic resulting from the relatively thick lithosphere that remains, precluding significant decompression melting. The range of subduction styles in which part or all nearby continental lithosphere is removed suggests a widespread process for recycling continental mantle.

The Effect of Chloride on the Dissolution Rate of Silver Nanoparticles and Toxicity to *E. coli*

CLÉMENT LEVARD[1,2,†*], SUMIT MITRA[1], TIFFANY YANG[1], ADAM D. JEW[1], APPALA RAJU BADIREDDY[2,3], GREGORY V. LOWRY[4] AND GORDON E. BROWN, JR.[1,2,5]

Pristine silver nanoparticles (AgNPs) are not chemically stable in the environment and react strongly with inorganic ligands such as sulfide and chloride. Understanding the environmental transformations of AgNPs in the presence of specific inorganic ligands is crucial to determining their fate and toxicity in the environment. Chloride (Cl^-) is a ubiquitous ligand with a strong affinity for Ag(I) and is often present in natural waters and in bacterial growth media. Though chloride can strongly affect toxicity results for AgNPs, their interaction is rarely considered and is challenging to study because of the numerous soluble and solid Ag-Cl species that can form depending on the Cl/Ag ratio. Consequently, little is known about the stability and dissolution kinetics of AgNPs in the presence of chloride ions. Our study focuses on the dissolution behavior of AgNPs in chloride-containing systems and also investigates the effect of chloride on the growth inhibition of *E.coli* (ATCC strain 33876) caused by Ag toxicity. Our results suggest that the kinetics of dissolution are strongly dependent on the Cl/Ag ratio and can be interpreted using the thermodynamically expected speciation of Ag in the presence of chloride. We also show that the toxicity of AgNPs to *E.coli* at various Cl^- concentrations is governed by the amount of dissolved $AgCl_x^{(x-1)-}$ species suggesting an ion effect rather than a nanoparticle effect.

Variations in triple oxygen isotopes in precipitation and river waters in the continental U. S.

NAOMI E. LEVIN[1]*, SHUNING LI[1], J. RENÉE BROOKS[2] AND JEFFREY M. WELKER[3]

[1]Department of Earth & Planetary Sciences, Johns Hopkins University, Baltimore, MD 21218, USA (*correspondence: nlevin3@jhu.edu)
[2]Western Ecology Division, US Environmental Protection Agency, Corvallis, OR 97333, USA
[3]Department of Biological Sciences, University of Alaska, Anchorage, AK 99508, USA

The triple oxygen isotope composition of water is an emerging tool in studies of hydrological processes because the $\delta^{18}O$-$\delta^{17}O$ relationship differs during kinetic and equilibrium isotope fractionation such that ^{17}O-excess is sensitive both to humidity at the site of evaporation and to secondary processes during moisture transport [1]. The utility of triple oxygen isotope measurements in hydrological studies is twofold: 1) they provide additional contraints on isotopic fractionation of precipitation when both ^{17}O-excess and *d-excess* can be measured and 2) they provide an additional understanding of hydrologic processes, such as evaporative effects, that are recorded in oxygen bearing minerals (*e.g.*, $CaCO_3$, SiO_2) and traditionally investigated with $\delta^{18}O$ alone.

Most ^{17}O-excess paleoclimate studies are based on high-latitude ice core records [2,3], but there is great potential to apply triple oxygen isotope approaches to climate proxies in low- to mid-latitude settings. A better understanding of ^{17}O-excess in meteoric waters in these settings is thus needed to develop ^{17}O-excess as a tool for probing the modern, past and possibly future hydrological cycle. Here we report ^{17}O-excess values of meteoric waters from the continental U.S. ^{17}O-excess values in weekly precipitation samples vary between -0.01‰ to +0.05‰. The lowest ^{17}O-excess values are from precipitation sourced in the Gulf of Mexico, whereas the highest observed ^{17}O-excess values are from precipitation that originates in the nothern Pacific Ocean. ^{17}O-excess values of surface waters are similar to or lower than those of precipitation in the main recharge season. We use our results to demonstrate the role of moisture source, transport effects, and post-precipitation processes on continental-scale ^{17}O-excess variation and to provide a framework for using triple oxygen isotope records as proxies for hydrological change.

The Formation of the Cores of the Giant Planets

H.F. LEVISON[1*], K. KRETKE[1], M.J. DUNCAN[2] AND H. NGO[2,3]

[1] Southwest Research Institute, 1050 Walnut St, Suite 400, Boulder, CO 80302, USA (*correspondence: hal@boulder.swri.edu)
[2]Department of Physics, Engineering, and Astronomy, Queen's University, Kingston, ON K7L 3N6, Canada
[3]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadenia, CA 91125, USA

It is ironic that the most massive planets in the Solar System had to have formed in the least amount of time. Jupiter and Saturn, for example, which are made mainly of hydrogen and helium, must have accreted this gas before the solar nebula dispersed. Observations of young star systems [1,2] show that gas disks, at least insofar as they are traced by the presence of dust, as well as accretion onto the star, have lifetimes of ~1-10 Myr. So, the gas giant planets had to form before this time.

Thus, one of the most challenging problems we face in our understanding of planet formation is how Jupiter and Saturn could have formed so quickly. In the core accretion model, which envisions that a large planetary embryo formed first by two-body accretion followed by a period of inflow of gas directly onto the growing planet [3,4], the main difficulty is in the first step. The accretion of a massive atmosphere requires a solid core ~10 M Earth-masses in mass [5,4,6].

We will present the most complete models of standard core formation to date and show that it is difficult to construct objects larger than ~2 Earth-masses before the disk dissipates [7]. We will also present some new simulations that include solutions that have previously been suggested, but to have yet been included in full simulations. These include planetesimal-driven migration [8] and pebble accretion [9].

The relative contribution of sedimentation and diagenesis in colour formation of Quaternary bottom sediments from the southern part of Mendeleev Rise and the continental slope of the East Siberian Sea

M.A.LEVITAN[1*], K.V.SYROMYATNIKOV[1], I.A.ROSHCHINA[1] AND R.STEIN[2]

[11] Vernadsky Institute RAS, Moscow 119991, Russia (* correspondence: m-levitan@mail.ru)

[2,2] AWI, Bremerhaven 12 01 61 – 27515, Germany

The goal of this study is to determine the relative contribution of both factors based on XRF study of sediments and field colour descriptions of sediment cores using Munsell Soil Colour Chart. Four studied sediment cores are located at the area of Southern Mendeleev Rise and continental slope of the East Siberian Sea . We paid special attention to amounts of Mn, Cu, Ni, Co, As, quartz; Mn/Al and Mn/Fe ratios. Quarts amount mimics the influence of terrigenous matter during glacial/interglacial cycles; As is concentrated in diagenetic Fe sulfides; other abovelisted elements and ratios reflect the relative contribution of sedimentation and diagenesis.

It's important to note that according to V/Cr ratio the studied sediments have been accumulated in the oxic environment. Our study allowed to constrain the consequence of sediment colours reflecting the increasing of diagenesis/sedimentation ratio: dark brown – yellow brown – olive brown – olive grey – grey – dark grey. Pink sediments should be considered separately due to specifics of their composition (abundance of dolomite) but they have been underwent to diagenetic processes as well. The significant role in diagenesis played the type and amount of labile organic matter, sedimentation rates and facies environments of sediments. These conclusions are confirmed by results of dispersion analysis based on 333 samples.

The geochemical history of the Dead Sea from dissolved chemical species and isotopes in pore waters

E. J. LEVY [1]*, O. SIVAN [1], Y. YECHIELI [2], I. GAVRIELI [2], B. LAZAR[3] AND M. STEIN[2]

[1] Dept. of Geology and Environmental Sciences, Ben Gurion University of the Negev, Beer-Sheva, ISRAEL 84105 (*correspondance: elanl@post.bgu.ac.il)

[2] Geological Survey of Israel, 30 Malkhe Israel St., Jerusalem, ISRAEL 95501

[3] Institute of Earth Science, The Hebrew University of Jerusalem, ISRAEL 91904

During the winter of 2010-11 an ICDP-drilling project exposed a 456m long water saturated core from the centre of the hypersaline Dead Sea (Israel). This research provides a unique perspective on the geochemical evolution of the lake from the analysis of dissolved chemical species and isotope proxies within the interstitial water gathered from the samples collected at intervals along the core. In this study we intend to present initial pore water results for major ion concentrations (Na^+, K^+, Ca^{2+}, Mg^{2+}, Sr^{2+}, Cl^-, Br^-, SO_4^{2-}) and corresponding ratios (Na/Cl (fig. 1), Mg/Ca (fig. 2), Sr/Ca, Na/K), the carbon system (dissolved inorganic carbon (DIC) and $\delta^{13}C_{(DIC)}$), $\delta^{34}S_{(SO4)}$ and $\delta^{18}O_{(SO4)}$. Discussion of results will take place during the conference.

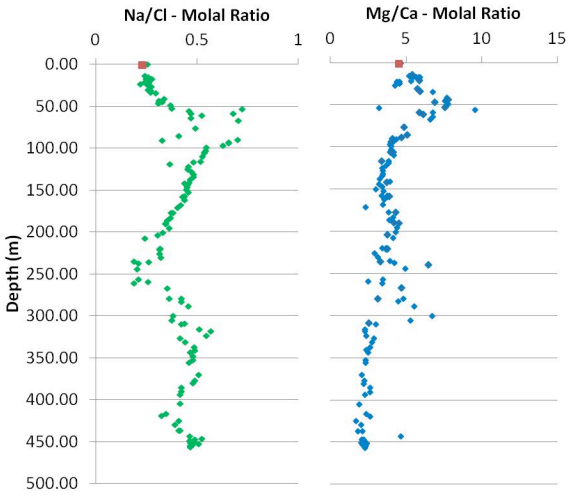

Figure 1 (top left) and figure 2 (top right): Molal ratios for Na/Cl and Mg/Ca from interstitial water concentrations. The depth is the length of the core in meters and the red squares indicate current Dead Sea water molal ratios.

[2] Duke University, Division of Earth & Ocean Sciences, Durham, NC, USA
[3] Hassan 1st University of Settat, Polydisciplinary Faculty of Khouribga, Khouribga, Morocco.

This study investigates water quality in Ziz basin, southeastern Morocco.

TDS and majors elements show a linear trend which suggests the coexistence of two end-members: (1) saline end-member dominated by Cl, SO4 and Na; and (2) fresh end-member dominated by Ca, Mg and HCO3. The main mechanisms of salinization are evaporation, dissolution of evaporates and carbonate formations within the study area.

Stable isotopes indicate that the High Atlas Mountains with high rainfall and low δ 18O and δ 2H values (-8.64to-8.31and -55.76 to -53.88) represent colder climate and constitute the major source of recharge to the basin. Also, the δ18O enrichment with respect to the Global Meteoric Water Line (GMWL) confirms that waters from downstream part have been diluted by shallow waters of meteoric origin.

The effect of the Three Gorge Reservoir on the water cycle and sediment transfer within the Changjiang catchment have been atttracting great interests for its environmetal significance. Data from Datong hydrologic station indicates the consierable decreae of sediment flux since 2003 due to the water impoundment of the Three Gorge Dam. Nevertheless, the relating water cycle in the catchment over the last ten years has rarely been studied.

H/O isotopes have been regarded as good tracers to identify different water sources for river/ocean, vapour and underground water. This study investigates the H/O isotope compostion in the mid-lower Chanjiang reaches (from Yichang to Nantong) in 2012 and 2013. The result based on the H/O isotope mass balance equation shows that the river discharge in Datong is roughly equivalent to the total flux of the mainstream at Yichang and of all the tributaries in the mid-lower reaches during the dry season, which means no or minor external input/output (underground water, precipitation) in the lower valley. Thus, the water contribution of each tributary to the Changjinag mainstream at Datong can be estimated quantitatively. The Changjiang upstream (above Yichang) contributes only ~24% to the total fluvial discharge to the East China Sea, while the Dongting Lake and Poyang lake contribute ~68% in together during the dry season. Addionaly, a weekly observation near Nantong reveals that the storage and discharge of the Three Gorge Reservoir has exerted a great influence on the water H/O isotope composition in the lower mainstram near the river mouth, while tidal influence is minor. Deuterium excess parameter in the mid-lower Changjiang river water exhibits smaller variability in recent years compared to that observed before the construction of Three Gorge Dam, which implies that the water cycle in the Changjiang catchment has been considerably changed in recent years. Overall, the Dongting and Poyang lakes now play an important role in regulating the Changjiang water discharge to the East China Sea in dry season. The variations of H/O isotopes in the Changjiang river water into the East China Sea clearly indicate the daming effect.

Modelling the atmospheric transport distance of PAHs at remote cold regions

CHONGYING LI[1,2], MEIHAN LI[3] AND CHAOQI YU[1]

[1] College of Materials and Chemistry & Chemical Engineering Chengdu University of Technology , Chengdu 610059 , China, lichy@cdut.edu.cn
[2] Mineral Resources Chemistry Key Laboratory of Sichuan
[3] College of Foreign languages and Cultures, Chengdu University of Technology , Chengdu 610059 , China , 317292496@qq.com

Long-range atmospheric transport (LRT) of polycyclic aromatic hydrocarbons (PAHs) means the contamination of remote regions such as high mountains. A simple model was developed to estimate the atmospheric transport distance of PAHs at high mountains, especially lighter PAHs like anthracene and phenanthrene.

This model was made by using the OH reaction rate constant difference between PAH isomers(anthracene and phenanthrene) based on considering isomers gas/particle partitioning, reaction with OH radicals, dry and wet deposition, air-surface exchange and dilution of atmospheric dispersion along transport path in atmosphere as follows.

$$D_t(km) = -\frac{6\times10^6}{C_{OH}(molecules\cdot cm^{-3})}\times windspeed(ms^{-1})\times\ln\left(\frac{C_{st}^A}{C_{st}^P}\times\frac{C_{g0}^P}{C_{g0}^A}\right)$$

Where D_t *(km)* is the transport distance .C_{OH} is the atmospheric [OH]. *windspeed* is the wind speed of the PAH-containing air masses.C^P_{g0}/C^A_{g0} is the diagnostic ratio(PHEN/ANTH) of anthracene and phenanthrene at emission source , and C^A_{st}/C^P_{st} is the diagnostic ratio (ANTH/PHEN) of anthracene and phenanthrene in snow at sampling location of cold regions.

The model can be used to predict the maximum transport distance and delineate a border of potential emission regions of PAHs at remote sampling sites. The model gave the origin of PAHs in snow at the typically sampling sites in cold regions in Europe and China under a wind speed of 60 m s^{-1} and 24 h atmospheric average [OH] of $0.3x10^6$ molecules cm^{-3} based on some published data. It is concluded that PAHs at the three sampling sites in Europe primarily came from Europe and Northern Africa at a distance of less than 3000Km and PAHs at the two sampling sites in China came from local regions at a distance of less than 1000Km which are similar to the reports in the literatures.

The marine biogeochemical carbon cycle modeling of Yangtze sea during the Ediacaran–Cambrian transition

DA LI[1*]

[1]State Key Laboratory for Mineral Deposits Research, Department of Earth Sciences, Nanjing University, Nanjing 210093, China (* lida@nju.edu.cn)

Earth's biosphere witnessed a revolutionary change from soft bodied animals to skeletal animals across the Ediacaran–Cambrian boundary and is associated with frequent large oceanic $\delta^{13}C$ oscillations. The $\delta^{13}C$ excursions are often interpreted to reflect changes in the global carbon cycle. We have reported a 300m-thick high-resolution carbonate $\delta^{13}C$ profile for the Ediacaran–Cambrian Xiaotan section, South China, showing a large negative excursion (N1, –12.2‰) in terminal Ediacaran and a sustained pre-'Tommotian' positive plateau (P4, up to +7.3‰) which coincides with the occurrence of the Watsonella crosbyi Assemblage SSF [1].

Here I used a simple numerical box model to simulate the $\delta^{13}C$ excursions of Xiaotan section in a straightforward way. Under non-steady-state conditions, the time-dependent changing rate of $\delta^{13}C$ of marine carbonate is determined by Formula 1. I initiated the forward modeling by giving the uncertain parameters steady-state boundary values (typical Neoproterozoic values). The P4 excursion can be replicated by transiently increasing the amount of organic carbon buried (F_{org}) by 4 fold for a duration of 1 M.yr and keeping for 5 M.yrs and then decreasing back to one tenth of the original F_{org}. These changes in F_{org} could be related to the introduced modern digestion innovations in Phanerozoic time, and the subsequent biological turnover. However, the N1 excursion cannot be replicated by changing F_{org} or M_0, or both. Instead, it can only be simulated by drastically decreasing δ_w to -13‰. Therefore, we must entertain the possibility that there was an isotopically light source of carbon to the surface ocean during the late Neoproterozoic, which could be the release of methane hydrates from an anoxic dissolved organic carbon-rich ocean or remineralization of old-time organic matters.

$$\frac{d\delta_0^C}{dt} = \frac{F_w^C(\delta_w^C - \delta_0^C) - F_{org}\Delta_C}{M_0^C} \qquad \text{Formula 1}$$

At the meantime, a backward modeling was tested by starting from the Xiaotan $\delta^{13}C$ profile. Using the best-fitted curve of the isotopic profile and the first-order derivative curve, unrealistic negative F_{org} values was generated, which also implied normal δ_w value could not generate N1.

Manganese and cadmium accumulated in tomato under greenhouse conditions

FEI-LI LI[1], ZAN-FANG JIN[1], DANIEL G. SHENG[2]

1 Coll Biol & Environ Eng, Zhejiang Univ Technol, Hangzhou 310032, China

2 Coll Environ Sci & Eng, Tongji Univ, Shanghai 200092, China

Greenhouse cultivation not only promotes vegetable production, but also alters soil pH, soil aeration, and even root microorganisms in the greenhouse, which affects heavy metal transport in vegetables. Field experiments were conducted. Soils and tomato plants were sampled at harvest and analyzed for concentrations of Mn and Cd as well as other properties.

As compared with open field, greenhouse cultivation significantly decreased soil pH, soil organic matter, and oxidation-reduction potential (ORP) ($p<0.01$). Total chlorophyll in greenhouse tomato laminae also decreased ($p<0.01$).

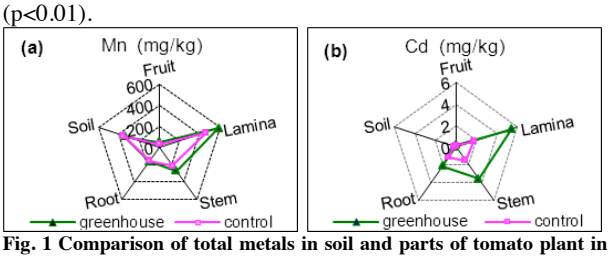

Fig. 1 Comparison of total metals in soil and parts of tomato plant in two cultivations

Mn and Cd concentrations in soil and parts of tomato plant were shown in Fig. 1. Mn and Cd concentrations in two cultivation soils had no significant difference. However, an obvious increase of metal concentrations in greenhouse tomato plant was clearly seen. Specifically, Mn concentrations in tomato root, stem, lamina and fruit increased with greenhouse cultivation by 5%, 27%, 28%, and 50%, respectively; the differences in two parts reached the significant levels ($p=0.009$ in lamina and $p=0.029$ in fruit). Cd concentrations in greenhouse cultivation increased in tomato root, stem, lamina, and fruit by 88%, 143%, 216%, and 27%, respectively, with all the differences being significant ($p=0.001$, $p=0.000$, $p=0.000$ and $p=0.049$, respectively). Lower pH and ORP in greenhouse soil were responsible for enhanced metal accumulation (Wang *et al*.. 2006). Correlation analysis showed that total chlorophyll in lamina was negatively correlated with Cd content, which was in accord with the report of a Cd inhibitory effect on chlorophyll formation (Stobart *et al*.. 1985). Mn and Cd concentrations in tomato fruit were below the limit for safe human consumption.

Greenhouse cultivation promoted heavy metal accumulation in vegetables. In other words, greenhouse cultivation may be a potential remediation of metal pollution.

Seesaw balance of Cenozoic carbon cycle

GAOJUN LI[1]

[1]MOE Key Laboratory of Surficial Geochemistry, Department of Earth Sciences, Nanjing University, 163 Xianlindadao Road, Nanjing 210046, China (ligaojun@nju.edu.cn)

It is generally accepted that decreasing partial pressure of atmospheric CO_2 (pCO_2) has caused the progressive cooling of Cenozoic climate. However, the reason behind the decline of pCO_2 is still unclear. BLAG model (Berner *et al*.., 1983, Am. J. Sci. 283, 641-683) proposes that the decrease of volcanic degassing is the primary driver for the long-term decline of pCO_2 through the negative feedbacks between pCO_2 and silicate weathering. However, the spreading rate of seafloor, which is believed as the major control of CO_2 degassing, seems to have remained relatively constant. The hypothesis of 'uplift driven climate change' proposes that tectonic uplift may have enhanced the sink of atmospheric CO_2 by silicate weathering, and thus produced the decline of pCO_2 (Raymo *et al*.., 1998, Geology 16, 649-653). However, increasing weathering sink of CO_2 could deplete atmosphere all of its CO_2 within several million years while holding volcanic outgassing constant (Berner and Caldeira, Geology 25, 955-956).

The fundamental difference between BLAG carbon model and the ‘uplift driven climate change’ hypothesis is related to the two extreme mechanisms that control the rate of silicate weathering, i.e., the weathering limited regime in BLAG model and the supply limited regime in ‘uplift driven climate change’ hypothesis respectively. Since both of the weatering regimes exist on earth, here based on reverse caclulation on the major carbon cycle fluxes, a seesaw balance of Cenozoic carbon cycle is proposed by combining the BLAG carbon model and the ‘uplift driven climate change’ hypothesis following the weatherability idea of Kump and Arthur (1997, Ruddiman, W. (Ed.), Tectonics Uplift and Climate Change. Plenum Publishing Co., 399-426). The seesaw balance model could solve both of the driver problem in BLAG model and balance problem in ‘uplift driven climate change’ hypothesis. Tectonic uplift will enhance the supply limited weathering consumption of atmospheric CO_2 in continents, which initialize the drawdown of pCO_2. The decline of pCO_2 will decrease the weathering consumption of atmospheric CO_2 in weathering limited regions (mainly basaltic islands) until the decrease of weathering limited weathering could compensate the increase of supply limited weathering, then reaches a new steady state.

Iodine speciation change by a Mn-oxidizing marine bacteria, *Roseobacter* sp. Azw-3k, through the production of reactive oxygen species

HSIU-PING LI[1], DANIELLE CREELEY[1], BENJAMIN DANIEL[1], RUSSELL GRANDBOIS[1], SAIJING ZHANG[1], CHEN XU[1], KATHY SCHWEHR[1], DANIEL KAPLAN[2], PETER SANTSCHI[1] AND CHRIS M. YEAGER[3*]

Iodine-129 is one of the most persistent radionuclides released from nuclear reprocessing facilities. With its longevity (half-life: 16 Myr) and biophilic nature (it accumulates in thyroid glands), iodine-129 is a potential human health threat. Thus, it is important to understand the behaviour of iodine in the natural environments. *Roseobacter* spp. are widely-distributed and comprise up to 15~20% of bacterial community in coastal/marine environments, and at least one member of this genus, *Roseobacter* sp. Azw-3k, facilitates extracellular Mn oxidation by releasing superoxide anions (O_2^-). We hypothesized that *Roseobacter.* sp. Azw-3k could mediate iodide oxidation through the production of extracellular superoxide anions and/or biogenic Mn(IV) oxides. Without Mn(II), Azw-3k cultures transformed ~90% of provided iodide (10 μM) into organo-iodine and iodate within 6 days, whereas in the presence of Mn(II), iodide oxidation only occurred after an initial period of Mn(IV) formation (~12 days). Heat-killed cells did not transform iodide. O_2^- production rates peaked at day 3, corresponding to early stationary phase of the cultures and the peak of iodide oxidation, and ceased after day 15. The results suggest that biogeneic O_2^-, but not biogenic Mn oxides, were involved in the iodide oxidation process. However, iodide oxidation also occurred in the presence of the O_2^- scavengers, Cu^{2+} and superoxide dismutase. Results suggest that Azw-3k-mediated iodide oxidation could be facilitated by two reactive oxygen species, O_2^- and its hydrolysis product, H_2O_2.

Poorly-crystalline Fe(Mg) Silicates involved in early fossilization of microbes in modern microbialites

JINHUA LI[*1], NINA ZEYEN[1], KARIM BENZERARA[1], SYLVAIN BERNARD[2] AND OLIVIER BEYSSAC[1]

[11]IMPMC - ERC Calcyan, CNRS & UPMC, 75005 Paris, France, *correspondence: jinhua.li@impmc.upmc.fr

The search for the oldest traces of life has been a long-term challenge partly because of the difficulty to distinguish abiotic artefacts from biogenic traces. One way to improve our capability to detect traces of life is to study the fossilization processes affecting microorganisms in modern environments. Here, we studied the early fossilization of microorganisms in modern microbialites from, hyperalkaline crater lakes in Mexico, which might be good analogues for some Archean deposition environments such as Tumbiana.

Scanning electron microscopy (SEM) and energy dispersive X-ray (EDX) microanalyses on polished petrographic sections showed textures reminiscent of stromatolitic laminations and domal microstromatolites, consisting mainly of alternating aragonite and iron (sometimes magnesium)-rich silicates. Diverse microfossils of unicellular eukaryotes (e.g., diatoms) and prokaryotes were observed to be morphologically well-preserved by the precipitation of iron- or magnesium-rich silicates. The structural and chemical features of these potential fossils were further studied down to the nm-scale using a combination of focused ion beam (FIB) milling, transmission electron microscopy (TEM) and scanning transmission X-ray microscopy (STXM) at the C K-edge and Fe $L_{2,3}$-edges. The Fe(Mg)-rich silicate was characterized as a poorly-crystalline talc-like phase containing mixed-valence iron. Compared with the aragonite-dominant part, the Fe(Mg)-Si-rich laminations are richer in fossil microbes . Altogether, our results indicate that poorly-crystalline Fe(Mg) silicates can play an important role in the early stages of microbial fossilization.

Uranium transport and deposition in iron oxide copper gold deposits (IOCG's): An experimental approach

KAN LI[1], JOËL BRUGGER[2,3], ALLAN PRING[2], YUNG NOGTHAI[1], BARBARA ETSCHMANN[2], JING ZHAO[1] AND EDELTRAUD MACMILLAN[3]

[1] School of Chemical Engineering and [3]School of Earth and Environental Scinces, the University of Adelaide, 5005 Adelaide, Australia. Email: kan.li@adelaide.edu.au.
[2]Mineralogy Department, SA Museum, 5000 Adelaide, Australia.

Iron oxides Copper gold type deposits in southern Australia often contain quantities of uranium, both at economic and the subeconomic level. Olympic Dam (OD) is the largest U resources in the World, but uranium also at Prominent and Moonta where the uranium is subeconomic and a problem in ore concentrates. In South Australian IOCG deposits the ores are unusually oxidised, consisting of hematite, with bornite, chalcopyrite and pyrite as the main sulphide minerals. The uranium occurs in a variety of 'primary' minerals including uraninite and brannerite and these minerals exhibit a remarkably diverse range of textures suggesting extensive remoblization.

We initiated an experimental study of hydrothermal mineral reactions in the Fe-Cu-S-U system, focusing in particular on the fate of U during sulphidation reactions. Much of the U in these IOCG deposits is secondary (either remobilised, or added in hydrothermal events postdating Fe-Cu mineralization). Applying the principles of interface coupled dissolution-reprecipitation reactions, we were able to reproduce the IOCG mineral assemblages experimentally by reaction of a Cu-rich fluid with hematite. When U is added to the system as uranyl salt or UO_2(s), U precipitates during the sulphidation reaction. Synchrotron experiments were used to characterize the nature of the U in the ores as well as of U precipitated during sulphidation reactions, information critical for deciphering the mechanism of U scavenging. This information improves our understanding reactions at interfaces with conditions far-from-equilibrium in controlling metal endowment.

The characteristics of an old gas reservoir in Sinian strata, central Sichuan basin, south China

L. LI*, Z. C. WANG, T. S. WANG AND H. JIANG

PetroChina Research Institute of Petroleum Exploration & Development,Beijing,China
(*correspondence:liling5551@126.com)

The study region is an important exploration area which has great prospect in Sichuan basin. By analyzing the formation conditions, accumulation periods and characteristics of Sinian gas reservoir in this area, we found that the natural gas is mainly oil cracking gas and the main source rocks were black sapropelic shales at the bottom of Qiongzhusi formation in Lower Cambrian, followed by dark algae dolomite and shale in the third member of Dengying formation. The formation of effective reservoir was controlled by supergene karstification and sedimentary facies. The reservoir was widely distributed with large thickness but strong heterogeneity. The area located at the east high point of an ancient uplift in a long period, whose structual evolution was inherited. It developed large-scale low-amplitude anticline in this region, and the trap formed by top of Sinian System could be 1128km^2, whose closure was over 200 meters [1]. The trap had strong oil and gas capability.

Analysis of the structural evolution history of the region and thermal history of the source rocks showed that: the source rocks in the 3rd member of Dengying Formation started to generate a large sum of hydrocarbon from the Ordovician to Silurian, the liquid hydrocarbon generated accumulated in top of ancient uplift to form paleo-reservoir; the structural uplift at end of the Silurian terminated the first stage of hydrocarbon generation. They entered the second stage of hydrocarbon generation from the Late Permian. While source rocks in Qiongzhusi formation entered the main phase of hydrocarbon generation from the Triassic to the Middle Jurassic, the hydrocarbon accumulated in the weathered crust of Dengying formation at top of ancient uplift to form paleo-reservoir. They entered the main stage of gas generation from the Late Jurassic to the Early Cretaceous, the liquid hydrocarbon of paleo-reservoir cracked to gas, which accumulated as present gas reservoir [2]. The homogenization temperature of fluid inclusion in Sinian carbonate of this area also supported this view.

High-precision collision-cell MC-ICPMS analysis of Ca isotopic ratios (including ^{40}Ca)

QIONG LI*[1], MATTHEW THIRLWALL[1] AND WOLFGANG MÜLLER[1]

[1]Dept. of Earth Sciences, Royal Holloway Univ. of London, Egham, Surrey, UK. TW20 0EX
qiong.li@rhul.ac.uk

Ca isotopic ratios have traditionally been measured by TIMS due to its high sensitivity and a precision of ~0.1 ‰ (2sd) in $\delta^{44/40}$Ca has been achieved using double spike techniques [1,2,3]. Compared with TIMS, Ca isotope analysis by MC-ICPMS faces three big challenges: 1) interference of $^{40}Ar^+$ from the plasma on $^{40}Ca^+$; 2) high background noise due to scattered ^{40}Ar which can severely affect the low-abundance Ca isotopes; and 3) the presence of hydrocarbon interferences especially for the minor isotopes. Earlier MC-ICPMS work avoided some of these issues by presenting data as $\delta^{44/42}$Ca, instead of $\delta^{44/40}$Ca, with 0.1-0.2‰ (2sd) precision using sample-standard bracketing [e.g. 4].

We report Ca isotopic measurements using an IsoProbe MC-ICPMS operated in collision/reaction cell mode using a $10^{10}\Omega$ resistor for ^{40}Ca. A flow of H_2 (0.8 ml/min) through the collision cell eliminates ^{40}Ar interference on ^{40}Ca via charge transfer and enables precise measurements of ^{40}Ca. Blanks (2% HNO_3, $2x10^{-13}$ A ^{40}Ca) and Ca samples (1 ppm, $4x10^{-9}$ A ^{40}Ca) show a residual ^{40}Ar intensity of ca. $4x10^{-14}$ A, implying negligible Ar interferences on measured ratios.

Internally ^{44}Ca/^{40}Ca-normalized ^{42}Ca/^{40}Ca and ^{43}Ca/^{40}Ca ratios of Ca-isotope standard SRM915b within a day yield 2sd of 72 ppm and 260 ppm respectively after correction for Sr^{2+} interference. Identical normalized ^{42}Ca/^{40}Ca and ^{43}Ca/^{40}Ca ratios are obtained for natural apatite and aragonite without chemical separation, and form the basis of an accurate double spike correction. We are currently investigating the use of a ^{43}Ca-^{46}Ca double spike (DS) for mass bias correction of solution mode analyses, and are comparing results of this with data obtained in both solution and laser-ablation (LA) modes [5] using sample-standard bracketing. Alternating with unknown samples, six sets of measured Ca isotope ratios obtained by laser abation of a SRM915b pellet agree within the internal error (2se = 0.2‰) over a 6-hour period.

Seasonal variations of chemical weathering rates and CO_2 consumption in Yangtze River basin

S.L. LI, Y. CHEN*, J. CHEN, AND J.F. JI

The MOE Key Laboratory of Surficial Geochemistry, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, China
(*Correspondence: chenyang@nju.edu.cn)

Continental erosion controls atmospheric CO_2 levels on geological timescales through silicate weathering. Rivers play an important role in long-term carbon cycle by transporting rock weathering products to oceans. The Yangtze River (Changjiang) is the largest river in Asian and drains the tectonic uplifted Himalaya and Qinghai–Tibet Plateau which are of especial importance because of the possible connections with late Cenozoic climate change.

In this study, water samples of the Yangtze River were collected at Nanjing twice a month from May, 2010 to April, 2011. Major ions (Cl, SO_4, NO_3, Ca, Mg, K, Na, Sr) in the dissolved load were determined. There were linear correlations between Ca/Na ,1000*Sr/Na, HCO_3/Na and Mg/Na. Na-normalized ratios of major ions were used in an inverse model to calculate the contribution of the six end-members(i.e. atmosphere, industry pollution, agriculture pollution, carbonates weathering, silicates weathering and evaporates dissolution). Results show that in the monsoon season (May-August) carbonate weathering contributed more to the dissolved load than in the dry seasons. Almost 60% of major ions were derived from carbonates weathering while carbonates contribution reduced to near 40% in dry seasons. The variation of contributions from silicate weathering shows an opposite trend, that means it is low (about 1%) during the monsoon season but can increase astonishingly to 32% in dry seasons. In the whole year, carbonates weathering and silicate weathering consumed $8.32*10^{11}$mol and $1.61*10^{11}$mol CO_2, respectively in the Changjiang basin.

Late Mesozoic A-type magmatism in Hailar basin, NE China: Constraints on the evolution of the Mongol-Okhotsk Ocean

S.-Q. LI [A], F. CHEN [A]*, E. HEGNER [B] AND J.-D. WU [A]

a: Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China

b: Department of Earth and Environmental Sciences, Universität München, Theresienstr. 41, München, Germany

The northeastern China situated between the Siberian and Sino-Korean (North China) cratons was characterized by widespread volcanism and well developed extensional basins in the period of Late Mesozoic. In the north-west of Hailar basin which located west part of NE China there exposes a suit of A-type rhyolitic rocks that had been rarely noticed. Major and trace element, Sr-Nd-Pb and zircon U-Pb data are presented for this special profile. Furthermore general I-type volcanic rocks from mafic to felsic aged 160~120 Ma also selected and performed for comparing.

The first U-Pb Zircon ages that constrains the timing of emplacement of the A-type rhyolites as Early Cretaceous (125±3~136±4 Ma), and the zircon ages range from 158±6~125±3 Ma indicate complicated magma chamber evolution and mixing process. All the volcanic rocks belong to high-K calc-alkaline series. The mafic-felsic rocks show enrichment of LILE and LREE, and depleted in HFSE and HREE compared to the A-type rhyolites with higher HFSE, HREE contents and no negative Nb-Ta anomalies. All the volcanic rocks show slightly depleted to enriched isotopic features. These data suggest that basaltic-andesitic rocks in Hailar basin were generated by fractional crystallization of melts partial melting from the enriched lithospheric mantle which had been metasomatised by previous slab subduction of the Paleo-Asian Ocean and the Mongol-Okhotsk Ocean, whereas the andesitic-rhyolitic magmas were produced by the melting of lower crustal mafic and felsic granulites, respectively. Accordingly we suggest the A-type rhyolites are generated by high-temperature partial melting of lower continental crust which depleted by previous I-type melts extraction and the anhydrous melting with high F contents increased the HFSE contents in the melt. Considering the evolution of the Mongol-Okhotsk Ocean, this A-type magma event provides evidence for the slab break-off process of the Mongol-Okhotsk Ocean.

Incorporation of trace metals into soil microcodium as a novel proxy for paleo-precipitation

TAO LI[1*] AND GAOJUN LI[1]

[1]MOE Key Laboratory of Surficial Geochemistry, Department of Earth Sciences, Nanjing University, 163 Xianlindadao Road, Nanjing 210046, China
taoli.es.nju@gmail.com(*presenting author);
ligaojun@nju.edu.cn

Trace element compositions of carbonates have been successfully applied to reconstruct the paleo-environments under which they are precipitated. However, information on the incorporation of trace metals into the authigenic carbonates in soil is rare. Major challenges come from the impurity of soil carbonates and thus comtamination of trace metals by other mineral phases.

Here we present trace element compositions of microcodium found in Chinese loess. Microcodium is formed by the replacement of bio-residues by soil solution, which is very easy to identify and pick. We have observed large variation in the Mg/Ca and Sr/Ca ratios of microcodium in the Holocene soils across Chinese Loess Plateau, which reflects large variation in corresponding composition of soil solution. Rayleigh fractionation associated with the precipitation of secondary carbonate is responsible for the compositional variation of soil solution. The extent of Rayleigh fractionation is significantly correlated to precipitation amount (Fig. 1). The incorporation of trace metals in microcodium may serve as a novel proxy for paleo-precipitation. Initial application of the new proxy indicates clear glacial-interglacial changes of precipitation amount on Chinese Loess Plateau.

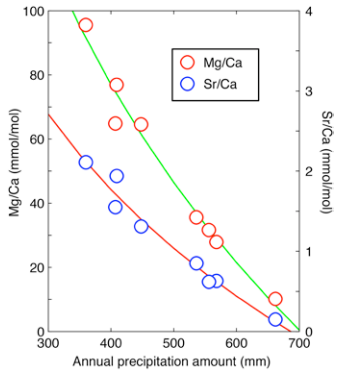

Fig. 1. Holocene calibration curves for the Mg/Ca and Sr/Ca ratios of microdium as proxies for precipitation amount.

$^{40}Ar/^{39}Ar$ Phenocryst-Matrix isochron dating on Quaternary volcanic rocks

WEI-RAN LI[1*], JIAN-QING JI[1] AND JING ZHOU[1]

[1]Peking University, School of Earth and Space Sciences, Beijing, China, *lwr@pku.edu.cn

A big challenge of K-Ar and $^{40}Ar/^{39}Ar$ dating is to obtain precise ages of Quaternary volcanic rocks with low K and high Ca content. To date these rocks, isochron method has been widely used on matrix with phenocryst removed. However, if argon isotope concentrations of matrix are too close, isochron ages may be unreliable. To solve this problem, we have developed a Phenocryst-Matrix isochron method to get more reliable results. This method is based on initial $^{40}Ar/^{36}Ar$ values of phenocryst and matrix tested uniform. To determine it, we propose to compare the uniformity of initial $^{36}Ar/^{38}Ar$ values of phenocryst and matrix before samples are irradiated by neutron. If the initial $^{36}Ar/^{38}Ar$ values are uniform, the initial $^{40}Ar/^{36}Ar$ values are supposed to be uniform. Here we dated young volcanic rocks from Lei-Zhou area in Southeastern China, and obtained five isochron ages that range from 0.05Ma to 0.35Ma with relatively large error. Considering these unreliable results and tested uniform initial $^{36}Ar/^{38}Ar$ values of phenocryst and matrix, Phenocryst-Matrix isochron method was applied for all the samples of this area (shown in the figure below), yielding an age of 0.18±0.03 Ma, which fits well with stratigraphic time.

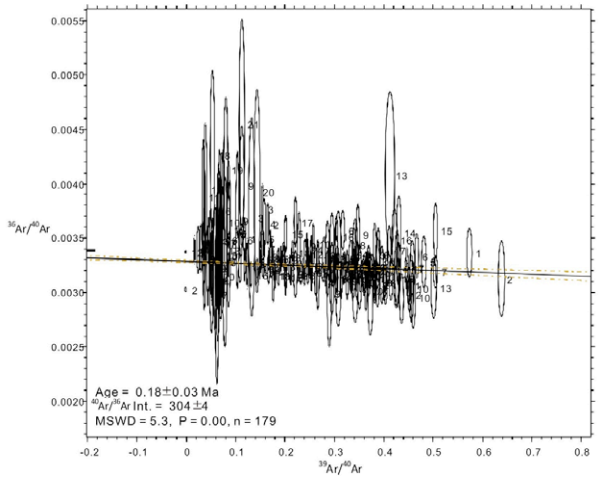

Figure 1: $^{40}Ar/^{39}Ar$ Phenocryst-Matrix isochron for all the samples from Lei-Zhou area.

Sulfur isotopic compositions of total suspended particulates (TSP) in Chengdu, Southwest China

X.D. LI[1]*, Z. YANG[1,2], B.J. LIU[1], L.J. WU[3] AND B.L. WANG[1]

[1]Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, PR China (*correspondence: lixiaodong@mail.gyig.ac.cn)

[2]Graduate University of Chinese Academy of Sciences, Beijing, PR China

[3]College of Environment and Civil Engineering, Chengdu University of Technology, Chengdu, Sichuan, PR China

The sulfur isotopic compositions were analyzed to discuss the source and transformation process of sulfur in total suspended particulates (TSP) that collected from a megacity, Chengdu, SW China where atmospheric particulate matters, a major air pollutant, currently affect air quality of this city.

The annual variations of $\delta^{34}S$ values of TSP from 2005 to 2010 were little and the data were concentrated within 5.3~5.8‰. The seasonal variations of $\delta^{34}S$ values of TSP were obvious, and the order was winter (6.6‰) > spring (5.2‰) > autumn (5.0‰) > summer (4.5‰) which is similar to the concentrations of sulfate in TSP. The $\delta^{34}S$ and sulfate content of TSP were higher in winter and spring that probably be associated with high-sulfur coal combustion, and lower in summer and autumn which might be affected by biogenic sulfur which having light $\delta^{34}S$. Under different weather conditions as foggy, cloudy, sunny and rainy days, the changes of $\delta^{34}S$ values were not obvious except that higher data in the rainy days, and there is no correlation between the $\delta^{34}S$ values and sulfate content of TSP. In the rainy days, the gaseous sulfur dioxide having light $\delta^{34}S$ values dissolved in rain by liquid-phase oxidation reaction, which led to the collected TSP being little affected by gaseous SO_2 and the sulfur in TSP were more from the particulates having heavy $\delta^{34}S$ values resulted from coal combustion. Consequently, the $\delta^{34}S$ values of TSP were probably higher in the rainy days.

The mass rations of $[SO_4^{2-}]/[NO_3^-]$ in TSP decreased from 2005 to 2010, which indicated the atmospheric quality in Chengdu would be more affected by vehicle exhaust while the pollution control in coal combustion are stepped up.

Controlled bio-inspired synthesis of composites: a close simulation of biomineralization process

XUAN QI LI[1] AND NICO SOMMERDIJK[1]

[1]Laboratory of Materials and Interface Chemistry
And Soft Matter CryoTEM Research Unit
Department of Chemical Engineering and Chemistry
Eindhoven University of Technology

Many structural biomaterials, biopolymers as well as biominerals, derive their mechanical properties from a complex hierarchical fibrillar organization. An intriguing example is the Stomatopod Dactyl club that consists of an impact resistant calcium phosphate-chitin composite structure. The chitin matrix has a highly expanded helicoidal organization.

In nature, biominerals often grow at controlled reacting conditions, such certain pH value, temperature, concentrations of reactants and also reaction rate. However, most bio-inspired mineralization studies cannot control those parameters during the reaction.

In this study, we investigated self-assembly and reaction process of chitosan and calcium phosphate in water solution, control the reaction parameters, and obtain ordered composite structures in a controlled biomimetic way. In addition, we investigated the interaction rules between biopolymers and minerals during assembly and mineralization process on the molecular level, which will be very helpful for biomineralization research and biomaterials synthesis. A controlled reaction system assisted by a titration setup was built up. The assembly process of chitosan, the nucleation and growth of calcium phosphate, and the formation process of chitosan/calcium phosphate biocomposites were investigated by the cryo-transmission electron microscopy (cryoTEM), Fourier transform infrared spectroscopy (FTIR), X-ray diffraction (XRD) etc.

A theoretical approach of isotope fractionation mechanism for thermal diffusion processes

XUE-FANG LI AND YUN LIU*

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, China.
Correspondence*: Liuyun@vip.gyig.ac.cn

Under thermal gradients, not only chemical compositions of a homogeneous system will be significantly changed between high temperature and low temperature ends, but also its isotopic compositions will be tremendously changed (e.g., Richter *et al*.. 2008, 2009; Huang *et al*.. 2010). However, the isotope fractionation mechanism of such thermal diffusion processes is still under debating. Dominguez *et al*.. (2011) used transition-state theory (TST) model to explain stable isotope fractionations in high-temperature silicate melts. They mainly considered the zero-point vibrational energy (ZPE) of diffusing species with different isotopes. Other kinetic energies were completely ignored even they are important under high temperatures. They also did not consider kinetic energies (ZPE, translational, rotational energies, etc.) for the activated complex at transition state. Their treatment resulted in an unusually large ZPE difference for different isotopologues, which was questioned by Lacks *et al*.. (2012a) for the unusually large wavenumber of a vibration. Lacks *et al*.. (2012b) proposed a new model based on Chapman-Enskog theory to treat the thermal diffusion processes and used a specially designed classical molecular dynamics (MD) method to treat temperature gradients. They concluded that the classical mechanical collisions maybe the essence reason of isotope fractionation, but not the quantum effect suggested by Dominguez *et al*.. (2011). They also found that heavier isotope systems (i.e. Fe, Ca, Mg) can be fractionated to larger extents than those of network formers but lighter isotope systems (i.e., Si, O). Until now, all theoretical studies are focused on high temperature conditions, there is no theoretical framework for systems with temperature gradients at low or medium temperatures.

Here, we propose a new theoretical model for dealing with isotope fractionation by thermal diffusion. We used a newly developed thermodynamic law which directly relates Soret coefficient to entropy (Duhr and Braun, 2006a; Duhr and Braun, 2006b). We have developed its counterpart for isotope fractionation treatment. By following this approach, we provide a unified equation for the calculation of isotope fractionation under thermal gradients for any temperature condition. Using high temperature silicate melts as examples, we test our equation and find out the relationship between isotope fractionation and temperature gradients.

Soil microbial species selection and activity influenced by semiconducting minerals

YAN LI[1] AND ANHUAI LU[2]*

[1]School of Earth and Space Sciences, Peking University, Beijing. (liyan-pku@pku.edu.cn)
[2]School of Earth and Space Sciences, Peking University, Beijing. (*correspondence: ahlu@pku.edu.cn)

Semiconducting minerals are a unique class that could absorb photons with energy equivalents to or higher than the bandgap to form negatively charged photoelectrons and positively charged photoholes in the conduction band (CB) and valence band (VB), respectively. There is a wide distribution of semiconducting minerals in natural soils, mainly including Fe and Mn oxides [e.g., hematite (Fe_2O_3), goethite (FeOOH), pyrolusite (MnO_2)]. The redox potential of their CB electrons ranges from -1.01 V to 0.28 V (*vs*. NHE). Natural microbes have evolved various strategies to acquire electron energy for maintaining metabolism. We predicted photoelectrons in the CB of semiconducting minerals is a natural solid phase electron source for microbes and make influences on microbial metabolism. We designed experiments in an electrochemical equipment to simulate the energy of CB electrons by setting the redox potential of electrodes similar to the CB potential of goethite. A natural soil microbial community was inoculated and the microbial community structure were analyzed by *16S ribosomal RNA* gene. The results indicated the soil microbial community at day 0 was diverse, and some species like *ChitinophageI*, *Psudomonas*, *Alcaligenes* and *Pedobacter* became enriched by day 5. By day 10, the *Alcaligenes* species constituted greater than 70% of the total bacterial population, in marked contrast to < 8% in the control with no applied electrode potential. Then, the growth of a pure *Alcaligenes* strain under three different electrode potential (-0.15 V, -0.06 V and +0.06V) was observed and its denitrification efficiency of nitrate was measured. Both were found to be closely related to the electrode potential. The quantity of the biofilm coated on the electrode and the nitrate reduction efficiency reached the highest at -0.15 V among three electrode potentials. In contrast, no biofiml formation or no reduction of nitrate were observed in the open circuit control. Therefore, photoelectrons probably led to the enrichment and selection of certain microbes such as *Alcaligenes* and also infulenced its denitrification activity.

A contrastive study of organic matter influences on the smectite illitization in Dongying Sag, China

YINGLI LI[1], JINGONG CAI[1*], SHOUPENG ZHANG[2] AND JUNFENG JI[3]

[1] State Key Laboratory of Marine Geology, Tongji University, Shanghai 200092, China ([*]correspondence: jgcai@tongji.edu.cn)
[2] Geological Scientific Research Institute, Shengli Oil Field Company, Sinopec, Dongying 257015, China
[3] State Key Laboratory of Surficial Geochemistry, Nanjing University, Nanjing 210093, China

Many factors such as temperature, pressure and time etc. can affect the smectite illitization in mudstone. Whereas the organic matter which owns important relationship with clay minerals has been easily ignored. For this point, samples respectively representing water-rock interaction system and water-rock-organic interaction system were selected here to make a contrastive study on the influences of organic matter during the smectite illitization in mudstone.

11 red mudstone (RM, 1000m-5300m) and 23 dark mudstone (DM, 2200m-3500m) samples from Dongying Sag were studied with X-ray Diffraction and pyrolytic analysis. Results show that RM had about 0.01-0.14%TOC (0.07% in average) while the latter had 0.17-6.75%TOC (2.16% in average). Obvious smectite illitization differences were also indicated. (1) Above 3100m: Illite proportion of RM (37-60%) was higher than that of DM (31-48%). Mixed-layered illite/smectite of RM was mainly R0, R1 patterns and that of DM was R0 pattern. Illite Crystallinity of RM (Kübler index, 0.40-0.76) was usually higher than that of DM (0.44-0.69). (2) Beneath 3100m: Illite proportion of RM (9-65%) turned significantly lower than that of DM (52-100%). Mixed-layered illite/smectite of RM turned to be mostly R3 pattern, while the DM being R1, R3 pattern. Simultaneously, the RM Illite Crystallinity (Kübler index, 0.61-0.69) got lower than that of DM (0.69-0.90). In short, the three mentioned parameters significantly inverted at the depth of 3100m. Considering their discrepancy in TOC content, it is thought that organic matter not only influenced the smectite illitization but also made this differently above/beneath 3100m. This could stimulate further study of smectite illitization especially under water-rock-organic matter interaction system.

Experimental study on gas generation potential of marine source rock with high maturity

LI YONGXIN[1], WANG ZHAOYUN[1], HU SUYUN[1] AND WANG HONGJUN[1]

[1] Research Institute of Petroleum Exploration and Development, PetroChina, *lyxin@petrochina.com.cn (*presenting author)

The ancient marine source rocks in basins of west China have endured lengthy process of thermal evolution, which makes them have a relatively high degree of maturity. According to analysis of available data, a fair number of liquid hydrocarbons, account for 40%-60% of total, still remain in source rocks within oil window. And these hydrocarbons can crack into gas at high mature stage, serving as an important source of some gas pools found in deep formations. In this way, the deep formations will have great resource potential. In order to assess the amount of dispersive liquid hydrocarbons resident in source rocks, a simulation of marine marl with low organic matter abundance under different fluid pressures were carried out.

The sample used in these experiments is from a core of Pando-X1 well from Madre de Dios Basin in Bolivia. It is of Devonian age, and at this locality it is thermally immature in the pre-oil generation. The collected sample is a marine marl with an organic carbon content of 0.95 wt %. The sample was crushed into gravel-sized chips. Reflectance measurements on vitrinite macerals found dispersed in the kerogen gave a mean %Ro of 0.59. All of the experiments were conducted in stainless-steel. The temperature is set at 290°C, 310°C, 330°C,350°C and 370°C, while the pressure obtained at each temperature was set at 10MPa and 20MPa respectively.

The results indicated that, the peak time of hydrocarbon generation and expulsion was around 310°C under the pressure of 10MPa, with the expulsive oil rate and the total oil yielding rate of 182.5mg/g and 193.4mg/g, respectively. Under 20MPa, the temperature corresponding to the hydrocarbon generation and expulsion peak was about 330°C, with the expulsive oil rate and the total oil yielding rate of 92.4mg/g and 111.4 mg/g, respectively. It has been suggested that, the increase of pressure represses the thermal evolution of organic materials. It enlarges the effective hydrocarbon expulsion stage of source rocks in addition to postponing the major expulsion period. As a result, the residence time of resoluble organic materials with large quantity has been enlarged, which provides material basis for the generation of gas during the high evolutionary phase.

Metal zoning feature and its Genesis of Bairendaba vein type ore forming system in Inner Mongolia, China

LI ZHENZHEN [1]*, CAI YUQI [1] AND LIU YIFEI [2]

[1] Beijing Reseach Institute of Uranium Geology, Beijing, 100029,China (*correspondence: leemimi@163.com)

[2] Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, 100037, China

Bairendaba Zn-Pb-Ag deposit is located in Inner Mongolia, China, and is a large scale vein type deposit with more than 4 000 tons of Ag and 2M tons of Zn+Pb.

The deposit is hosted in faults system of Carboniferous quartz diorite. There are More than 68 veins are found in the deposit, most of them are dip to the north. The No. 1 and No. 3 veins are the main orebodies and host more than 77% metal reserves of Bairenda[1]. Hydrothermal alterations closed to orebodies are well developed, including silicification, chloritization, epidotization and minor sericitization. The mainly ore minerals occurred in the deposit are marmatite, pyrrhotite, galena, with minor chalcopyrite, arsenopyrite, pyrite, Ag-bearing tetrahedrite and sulfosalts. The most common gangue minerals are quartz and fluorite.

The orebodies show obvious mineralization zoning feature, with Cu-bearing ores in the center and high grade Ag-bearing ores in the outer of the deposit. There is a systematic variation of metal grades, metal ratios and metal tonnage in the most economic No. 1 vein along its trend as it is divided into equidistant blocks by the cross sections.The tonnage and grade of zinc in each ore block decrease from west to east, the tonnage and grade of lead and silver of each ore block increase first and then decrease gradually. The Ag/Pb ratio of each block decrease first and then increases gradually, while the Ag/Zn and Pb/Zn ratios increase gradually all the time.

We propose that this metal zoning feature and systematic variation of metals is a reflection of decreasing temperature of ore forming system from west to east, and is the consequence of mixture of high temperature ore forming fluid with cold meteoric water in the fault system.

Black Carbon (BC) encompasses a variety of highly aromatic C forms including biochar, soot and graphite. Black C plays an important role in global warming and carbon cycling, and may act as a significant sink for green-house-gas CO_2 due to its long-term residence in the slower geological C pool. We explore high-resolution 3-D imaging using synchrotron-coupled Nano-Transmission X-ray Microscopy (TXM) and elemental mapping to describe the interplay of BC and mineral. Mineral particles of nano size are found in close association with both fresh and aged BC samples. Mineral of sheet layer is found important for the physical protection of BC. Our study provides the first direct description of BC physical protection by minerals, by far which is considered the most important mechanism for BC stabilization in environment.

Mercury Emission from Coal Fire and Spontaneously-ignited Gangue Hill and Distribution in Local Near-Surface Air in North China

HANDONG LIANG[1] AND YANCI LIANG[2]

[1]State Key Laboratory of Coal Resources and Safe Mining, Beijing, China, hdl6688@vip.sina.com (*presenting author)
[2]School of Chemical and Environmental Engineering, China University of Mining and Technology, Beijing

Underground coal fire is a global environmental and ecological hazard [1]. In China alone there are 84 coalfield in 13 provinces currently suffering from coal fire, with coal annual loss over 200 million tons. Coal gangue is a byproduct of coal mining and often piled up on site. There are estimated over 5,000 giant gangue hills located across China, with many of them reported spontaneous ignition [2]. These two source have no control or mitigation method of mercury emission, hence may bring mercury pollution on local environment and further contribute to global mercury inventory.

To study the mercury emission and diffusion pattern,a typical minig area with coal fire and gangue hill in Wuda coalfield, Inner Mongolia was chosen. Atmospheric mercury concentrations were measured at 1.2 m to ground surface by 10 m x 10 m grid in the prepheral area of fire zone and a giant gangue hill 6.7 km apart. Both results gave a prevalent mercury concentration of 40-50 ng/m^3, which is 30 times higher than the background level of atmospheric mercury (1.6 – 1.8 ng/m^3), and equal to previously reported atmospheric mercury concentration in the vicinity of mercury smelting factory [3]. The mercury concentraiton of ground vapor in a drilling hole -0.4 m to the surface in the vicinity of the gangue hill also fell in this range. The consistency of mercury content in two areas suggests that the mercury content may be the consequence of long-term accumulation and diffusion of gaseous mercury from multisites and multitype sources in the mining area rather than directly from the source. In addition, few vegetation were found in the mining area, and surface vegetation restored in correlation with the distance from the minig area. The exact influence range, the potential influence on remote populated area, and the potential impact on local vegetation of mercury emission from coal fire and spontaneous-ignited gangue hill still requires further insight.

An XPS study on the valence states of arsenic in arsenian pyrite: implications for Au deposition mechanism of the Yangshan gold deposit, Western Qinling Belt, central China

JINLONG LIANG[1]*AND WEIDONG SUN[2]

[1]Department of Geochemistry, Chengdu Univ. of Technology, Chengdu 610059, China (*correspondence: richardljl04@yahoo.com.cn)
[2]Guangzhou Institute of Geochemistry, the Chinese Academy of Sciences, Guangzhou 510640, China

The Yangshan gold deposit is a typical sediment-hosted disseminated type recently exploited in the Western Qinling Orogen, central China. Determination of gold chemical states is difficult due to its low concentrations of ppm level in the major Au carrier, arsenian pyrite. It is well known that the enrichment of Au in pyrite is usually associated closely with the enrichment of arsenic in the mineral.

Here we obtained pristine surfaces of arsenian pyrite from the Yangshan ore by sputtering with Ar^+ beam in the vacuum chamber of an X-ray photoelectron spectroscopy (XPS). The XPS results indicate that the predoinant state of arsenic is As^-, wherea As^{3+} is the oxided state likely formed during sample preparation, which only distributed on the surface.

The new observations suggest that the enrichment of Au in arsenian pyrite is not due to the double substitution of As^{3+} + Au^+ for 2 Fe^{2+} as previously proposed[1], but because significant substitution of As^- for S^- resulting in structure loosening facilitates Au entering the pyrite lattice[2].

Spontaneously-Ignited Gangue Hill – a Potential Source for Global Mercury Inventory

YANCI LIANG[1*] AND HANDONG LIANG[2]

[1] School of Chemical and Environmental Engineering, China University of Mining and Technology, Beijing. liangyc08@hotmail.com (*presenting author)
[2] State Key Laboratory of Coal Resources and Safe Mining, Beijing, China

Coal gangue is a waste mining material mingled with small amount of coal. It is of little value for reproduction and mostly piled up into gangue hills [1]. The total stock of coal gangue in China is documented over 5 billion tons to date with an annuanl increment of 2,000 million tons [2]. Due to the mingled coal content, gangue hill is believed to share a similar spontaneous ignition process to coal fire. In China, spontaneously-ignited gangue hill cases are quite common in coal mining areas [1,3].

Figure 1: landscapes of spontaneously-ignited gangue hill

This study focused on a giant gangue hill with a height about 50 meters in Wuda coal field , Inner Mongolia. Red clinkers were scattered on the surface, indicating multiple spontaneous ignition in history. Three large burning sites and several vents were around the hillside. Atmospheric mercury concentrations were measured on each burning sites and vents, and the average is 12,438 ng/m^3 (min: 319, max: 31,754, n=12), which is around 7,000 times of background level of atmospheric mercury (1.6-1.8 ng/m^3).

Gangue hills are prone to intermittent self ignition, which releases mercury both in coal and surrounding clay or rocks. The long-term mercury inventory from gangue hill and potential impact on local environment requires further study.

(*correspondence: Yu-Hsuan.Liang@earth.ox.ac.uk)

Molybdenum is a refractory and moderately siderophile element that is highly redox-sensitive and has mainly been used to study changes in marine sedimentary environments [1,2]. So far little is known about mass dependent isotope fractionation of Mo at high temperatures in the Earth, in particular during mantle processes.

We have analyzed 42 mafic (mainly MORB and OIB) and 7 ultramafic rocks from diverse locations, using a double-spike technique and MC-ICPMS. The $\delta^{98/95}$Mo values exhibit a significant range from +0.53 ± 0.21 to -0.56 ± 0.01‰ relative to NIST SRM 3134. The compositions of MORB (+0.03 ± 0.07‰, 2s.d.) and ultramafic rocks (+0.38 ± 0.15‰, 2s.d.) are each relatively uniform and distinct from each other, providing clear evidence of fractionation associated with partial melting. In contrast OIBs display significant variability within a single locality. The most extreme values measured are for nephelinites from the Cameroon Line and Trinidade, which also have anomalously high Ce/Pb [3] and low Mo/Pr relative to normal oceanic basalts [4]. The observed relationships between δ^{98}Mo and Ce/Pb, U/Pb, and Mo/Pr provide evidence that sulfide plays a critical role, not just in in fractionating chalcophile elements [5], but also in preferentially incorporating heavier Mo isotopes. Residual immiscible sulfide liquids lead to the eruption of magmas with relative light Mo isotopes and low Mo/Pr relative to the source composition. Therefore, the Mo isotopic compositon of the bulk silicate Earth and mantle will be best represented by values for peridotites.

Tectonic control on the distribution of Paleogene deep-lake syn-rift deposits in Qikou sag, Bohaiwan Basin, Eastern China

YUANTAO LIAO[1,2], HUA WANG[1] AND WENLI XU[1]

[1]Faculty of Earth Resources, China University of Geosciences, Wuhan, China, lyt706@gmail.com
[2]Key Labortary of Tectonics and Petroleum Resources, Wuhan, China

The tectonic control on subaqueous sediment routes and stacking patterns is not well understood although the resulting deposits may form potentially important hydrocarbon reservoirs. In this study, an area of lacustrine syn-rift succession in the Qikou sag is examined in detail to unravel the interplay between fault geometries evolution and sediment transport paths and infilling patters.

Qikou sag is a tpyical superimposed rift basin at the center of Bohaiwan Basin, Eastern China. Structurally, it is characterized by a linked system deep NEE-SWW striking half-grabens. This study focuses on the eastern part of the Qikou sag and it is bounded to the north by the overlapping Gangdong, Gangxi and Binhai normal faults. Syn-rift succession of the Qikou sag comprises Oligence Shahejie Formation (EsF), Dongying Formation (EdF) and is mostly dark-grey mudstone interbedded with fine to coarse-grained sandstone deposited by large-scale turbidity currents in deep-lake. Using strata pattern, fault activity hsitory, seismic attribute and heavy mineral analysis based on three-dimensional seismic and well logging data, our study demonstrate that the growth and propagation of main border normal fault segments associated with paleogeomorphology changes (particularly subaqueous relay ramps) have a marked influence on dispersal and localization of the turbidity currents during the syn-rifting phase. The main sediment supply is interpreted to be sourced from the basin marginal Cangxian uplift and the significant coarse-grained materials were transported to the deep-lake over long distance. In subqueous settings, however, no clear evidence of channel incision on the relay ramp is obseved, and turbidity currents are likely to by-pass the relay ramp and flow down the inner fault slope directly into the basin. Therefore, Locating subqueous syn-rift sediment and relating them with evolutional relay ramps need further investigation.

Over the last few decades subseafloor Carbon Capture and Storage (CCS) has been recognized as having great potential as an effective and safe method to reduce anthropogenic CO_2 emissions. However, the impact of any CO_2 seepage from a storage site on the marine environment is poorly understood. Released CO_2 will potentially dissolve into sediment pore waters, increasing the concentration of total dissolved carbonate and decreasing pH. As a consequence, metals may be released into pore waters and potentially into the water column. The effects of these changes to pore water chemistry on benthic ecosystems needs to be assessed.

To this end, we have analysed the chemical composition of pore waters, sediments, and the water column during a CO_2 release experiment that we carried out in Ardmucknish Bay, Scotland, as part of the 'Quantifying and Monitoring Potential Ecosystem Impacts of Geological Carbon Storage' (QICS) project. CO_2 gas was injected into the sediment 12m below seafloor at a known flow rate through a borehole drilled through the underlying bedrock. Sediment cores and water column samples were taken before, during and after the CO_2 release from 3 sites, at varying distances from the injection point.

Our data demonstrate that injected CO_2 was detected in the pore waters within 30 cm of the sediment-seawater interface within 33 days after the start of the CO_2 injection, but only at the site located closest to the injection point. As the CO_2 dissolved, concentrations of dissolved inorganic carbon (DIC) and total alkalinity (TA) increased and the $\delta^{13}C$ of the DIC decreased, reflecting the low $\delta^{13}C$ value of the injected CO_2 gas ($\delta^{13}C$= -26.6 ‰). Highest DIC concentrations (up to 30 mmol L^{-1}, compared with background levels of ~ 2.2 mmol L^{-1}) were observed 5 days after the injection had stopped. Pore waters with highest DIC concentrations also had enhanced concentrations of cations (e.g. iron, calcium) and nutrients. However, concentrations of all pore water consituents had returned to background values 18 days after the CO_2 injection was stopped.

Paired Sr Isotope ($^{87}Sr/^{86}Sr$, $\delta^{88/86}Sr$) Systematic of Sulfates and Pore Waters: New Perspectives in Marine Weathering, Seepage Signatures and Fractionation Processes

V. LIEBETRAU[1*], M. HAECKEL[1], A. EISENHAUER[1], H. VOLLSTAEDT[1], L. HAFFERT[1] AND C. HENSEN[1]

[1]Helmholtz Centre for Ocean Research Kiel (GEOMAR), Germany ([*]vliebetrau@geomar.de)

The simultaneous but independent determination of the conventional normalized radiogenic ($^{87}Sr/^{86}Sr$) and the fractionation reflecting stable ($\delta^{88/86}Sr$) Sr isotope ratio on pore waters, sediments and precipitates (e.g. carbonates and sulfates) opens a new perspective in the field of marine weathering and Sr contribution to the ocean chemistry.

As established tool in provenance studies on silicates and SIS-geochronology (Sr-Isotope-Stratigrapghy) of marine carbonates the radiogenic $^{87}Sr/^{86}Sr$ signature is in our approach directly combined with the isochemical stable Sr ($\delta^{88/86}Sr$) fingerprint of isotope fractionation, mainly due to water/rock-interaction and secondary precipitation processes.

One of our initial case studies, includes gypsum bearing sediments of active mud volcanoes (MV) and mounds from the Gulf of Cadiz (GoC). The Mercator MV is characterised by high $\delta^{88/86}Sr$ ratios of 0.72‰ for small ideomorphic (mm scale, most probably authigenic) and up to 0.92 ‰ for large (cm scale) heterogeneous gypsum crystals. The related pore water profile reflects also elevated signatures from around 0.7 ‰ at the crystals to 0.52 ‰ close to the sediment surface at $^{87}Sr/^{86}Sr$ ratios around 0.7105. Referred to NIST-SRM-987 the IAPSO seawater (SW) standard of this study plots on 0.39 ‰ (±0.03, 2SD) in $\delta^{88/86}Sr$ and on 0.70917(1) in $^{87}Sr/^{86}Sr$.

Potential explanation for the observed trend and PW signatures heavier than SW are (a) strong fractionation processes enriching light isotopes in secondary precipitates and remineralisation products and/or (b) preferential dissolution of mineral phases high in $\delta^{88/86}Sr$.

In order to develop a better understanding of isotope fractionation processes we conducted experiments providing contrary Sr and Ca isotope systematics for the precipitation of gypsum.

Whereas the precipitate is enriched in ^{88}Sr by more than 0.1 ‰ when compared to the initial fluid source, the $\delta^{44/40}Ca$ isotope signature is depleted as known for carbonates.

In contrast, Sr of biogene $SrSO_4$ dominated sulfates of acantharia follows the Ca fractionation systematic with a strong depletion of 0.3‰ in $\delta^{88/86}Sr$ compared to seawater.

Standing on Lal's shoulders: A look back and ahead at *in situ* cosmogenic nuclide production rate scaling

NATHANIEL LIFTON

Department of Earth, Atmospheric, and Planetary Sciences and Department of Physics, Purdue University, West Lafayette, IN 47907 [nlifton@purdue.edu]

Devendra Lal had a profound influence on the development of the field of cosmogenic nuclides – nuclides produced by the interaction of cosmic rays with matter. When he passed away on 1 December 2012 at the age of 83, the scientific community lost a creative and energetic advocate, whose wide-ranging interests led to pioneering atmospheric, terrestrial, and extraterrestrial applications of these nuclides. Although he made significant contributions to many fields, his landmark publication in 1991 (Lal, 1991) presented theoretical underpinnings of key terrestrial cosmogenic nuclide applications in a manner accessible to a broad audience. Lal (1991) thus stands out as the foundation for many of the cosmogenic nuclide techniques now widely used to study rates and magnitudes of geomorphic and geologic processes operating at or near Earth's surface.

A cornerstone of many of these applications is the ability to predict the production rate of a nuclide of interest anywhere on the Earth, through a procedure known as production rate scaling. The scaling model presented in Lal (1991) was a key contribution to this area, and is still among the most widely used. Subsequent studies presenting alternatives have pointed out various discrepancies between that model and measurements of atmospheric cosmic ray fluxes (e.g., Desilets and Zreda, 2003), yet those alternative models appear to have biases as well. A new model based on analytical fits to Monte Carlo simulations of atmospheric cosmic ray spectra, both of which agree well with measured spectra (Sato *et al*.., 2008), enables identification and quantification of the biases in previous models, and allows for a flexible framework for exploring the implications of potential future advances such as nuclide-specific scaling and time-dependent atmospheric reconstructions.

Compositional zoning of polyphase garnet in pelites as a consequence of three metamorphic events in Precambrian *P-T-t* history of the Yenisey Ridge, Siberia

I.I. LIKHANOV[1]* AND V.V. REVERDATTO[1]

[1]Sobolev Institute of Geology and Mineralogy, Novosibirsk, Russia (*correspondence: likh@igm.nsc.ru)

In situ U-Th-Pb geochronology of monazite and xenotime from different growth zones of the garnet porphyroblasts coupled with P-T path calculations derived from garnet zoning patterns records three temporally distinct events in the polymetamorphic history of the rocks, which differ in their ages, thermodynamic regimes and metamorphic field gradients. The first stage occurred as a result of the Grenville orogeny (1050-850 Ma) and was marked by LP zoned metamorphism at *c*. 4.8-5.0 kbar and 565-580ºC with gradient dT/dH=20-30ºC/km typical of orogenic belts. At the second stage, the rocks experienced collision-related (801-793 Ma) MP metamorphism at 7.7-7.9 kbar and 630ºC with dT/dH=10ºC/km. The final stage evolved as a syn-exhumation retrograde metamorphism (785-776 Ma) at 4.8-5.4 kbar and 500ºC with dT/dH=12ºC/km and recorded a relatively fast post-collisional uplift of the rocks to upper crustal levels in shear zones. The duration of thrust exhumation does not exceed 17 My, which implies an exhumation rate of 500-700 m/My. This is consistent with the rate of exhumation (400 m/My) calculated for coeval collision-related metamorphic events in the Yenisey Ridge [1] resulted from crustal thickening due to thrusting [2] and agrees with the results of thermomechanical numerical modeling (350 m/My) [3]. The final stages of collisional orogeny were followed by the development of rift-related bimodal Baikal-Yenisey dyke belt (790-780 Ma) along the western margin of the Siberian craton and the onset of Rodinia's breakup. Post-Grenville episodes of regional crust evolution are correlated with the synchronous succession and similar style of the later tectono-metamorphic events within the Valhalla orogen along the Arctic margin of Rodinia supercontinent [4] and support the spatial proximity of Siberia and North Atlantic cratons at *c*. 800 Ma, as indicated by the paleocontinental reconstructions of the Rodinia configuration in Neoproterozoic [5].

[3]Department of Applied Sciences, University of the West of England, Coldharbour Lane, Bristol BS16 1QY, U.K.

Anaerobic conditions in soils experiencing water saturation favour the production of methane (CH_4) [1], which may undergo subsequent oxidation by methanotrophs [2]. Here, we combine stable isotope probing and flux methods to trace the fate of ^{13}C-labelled methanogen substrates introduced to a peat and organic-rich water-saturated soil, in order to constrain production by methanogenic *Euryarchaeota* and its subsequent utilisation by CH_4-oxidisers. We monitor carbon flow by ^{13}C-analysis of *Archaea*-derived intact polar lipids, proposed to serve as a biomarker for extant methanogen biomass in this setting [3], and phospholipid fatty acids (PLFAs), in addition to the isotopic composition and flux of CH_4 and CO_2.

Enrichment in the $\delta^{13}C$ values of CH_4, and concurrently phospholipid-bound archaeol, confirm the *in situ* production of CH_4 and incorporation of ^{13}C into archaeal biomass by predominantly acetoclastic and, to a lesser extent, hydrogenotrophic methanogens. Utilisation of endogenous CH_4 by methanotrophs was traced by incorporation of ^{13}C-label in the isotopic values of CO_2. Enrichment of some PLFA lipids was also observed. At present, we are unaware of any other studies which have successfully involved the ^{13}C-labelling of intact archaeal lipids in the terrestrial realm.

Indium from the Lagoa Salgada Orebody, Portugal

LIMA A.M.C. [1], RODRIGUES B.C[1], OLIVEIRA A.,[2] AND GUIMARAES F. [2]

[1] Geology Centre of Porto, Porto, Portugal
[2] LNEG, S. Mamede de Infesta, Portugal

The Iberian Pyrite Belt is one of the most outstanding European ore province, hosting one of the largest concentrations of massive sulphides in the Earth's Crust. Lagoa Salgada orebody, the most northerly of the Iberian Pyrite Belt known so far, is a small massive sulphide deposit with an inferred mineral resource of 3.7 Mt. The orebody has been described as composed of a central stockwork zone – a thick Volcano Sedimentary Complex with more than 700m – and a massive sulphide lens in the northwest. It is covered by more than one hundred meters beneath sediments of the Sado Tertiary basin.

A Junior Exploration Company has implemented an exploration program with recent drilling holes in new areas of the northwest lens of the deposit. Different types of ores have been identified on preliminary metallographic study that have established five basic textural domains: (i) Massif pyrite; (ii) Banded texture with layers of sphalerite and, rarely, of sphalerite and galena; (iii) Secondary transformation of massif pyrite; (iv) Infilling veins texture; (v) Supergenic banded texture.

The ore mineralization assemblage is mainly composed of pyrite with minor sphalerite, tetrahedrite-tennantite, arsenopyrite, chalcopyrite, galena, stannite, cassiterite, and supergene minerals which are in different amounts represented throughout the basic textural domains.

Polished sections of massive sulphide ore samples were studied by Electron-probe microanalyses (EMPA). Most of the minerals phase are behind the detection limit of Indium values, however, related with banded basic textural domain (ii) it was identified one generation of sphalerite, with mean granular dimension of 20 micra included on recrystallized arsenopyrite, that have 23000 ppm of Indium. This value is four times more Indium content than the best average values of other studied sphalerite examples on the same orebody deposit, in recent published results. This discovery proves again the complexity of this deposit and highlights the needed of prospecting new areas inside the ore body with predominance of this generation of sphalerite.

Ongoing works will demonstrate the Lagoa Salgada orebody potential for this rare trace metal, that is used in high-tech applications and is critical for European Industry.

Heavy metal contamination in the semi-urbanised Laurel Creek Watershed, Waterloo (Ontario), Canada

ANA T. LIMA[1], GORDON S. GELLER[1], JON P. JONES[1], PHILIPPE VAN CAPPELLEN[1] AND HANS H. DÜRR[1]

[1]Department of Earth and Environmental Sciences, University of Waterloo, Canada, hans.durr@uwaterloo.ca

Metal pollution in our watersheds can have numerous and sometimes severe impacts on the health of organisms which interact with the affected water sources. Some metals are required for cellular growth and maintenance as micronutrients, but are toxic at larger doses, while others are not required and are toxic at even low concentrations. Anthropogenic activities provide pathways for these metals to enter waterways, including industrial activities, mining, and transportation. There is currently a limited amount of literature addressing metal budgets and pathways within individual drainage basins, leading to some limitations of the understanding of heavy metal sources and interactions within these basins. Here, we study Waterloo region, and specifically the Laurel Creek drainage basin (80 km2 basin area, population 123,500, precipitation 907 mm/year). The Laurel creek watershed has a myriad of land uses that makes it a perfect local setting for our metal budget approach. This tributary to the Grand River is divided in agricultural land (37% basin area), and a mosaic of residential (32% of basin), commercial (4.5% of basin), and industrial land (7% of basin), with some brownfields constituted of previously active tanneries. Extensive datasets, mostly at very high resolution, are available, both historical and current, including climate, GIS data on land use, drinking water, storm water management and sewage system, particulate levels, and measurements of various other factors influencing contaminant pathways, with ongoing sampling for many of these. Using the data available, along with an available water model and GIS processing, the aim is to create a water and metal budget, following the methodology first presented by [1]. The budget will focus on specific target heavy metals, such as copper, nickel, and cadmium. We anticipate that this work will introduce a more detailed conceptual model for heavy metals in urban settings, with a better description of some overlooked sources. This study will serve as a stepping stone for larger watershed studies.

Evaporation as the transport mechanism of metals in arid regions

ANA T. LIMA[1,2], ZEINAB SAFAR[1] AND J.P. GUSTAV LOCH[1]

[1] Department of Earth Sciences, Division of Geochemistry, Utrecht University, PO Box 80.021, 3508 TA Utrecht, The Netherlands

[2] Ecohydrology, Department of Earth and Environmental Sciences, University of Waterloo, Waterloo, Canada N2L 3G1

Arid regions are wide and vast areas of the globe with a relatively low population density. Arid regions are known for the deserts, the scarcity of fresh water and long periods of draught. The main climatic process that dictates water flow in soils in such areas is evaporation rather than precipitation e.g. [1]. While groundwater protection is a main issue in temperate regions, arid regions do not have such concerns when dealing with soil contamination. Contaminated sites are often not a priority, as its remediation, since there is no real scarcity of land for certain economic activities and overlooking how contamination of desert areas could ever affect human health.

This study tests the hypothesis of heavy metals coupled flow with the evaporating soil water in arid climates. Laboratory tests were performed to study the migration of heavy metals in an artificially spiked soil, using compressed air as evaporation driving force. A loamy and a sandy soil, collected near Al-Hasa, Saudi Arabia, are spiked with a heavy metal solution that is representative of a landfill leachate in developing country [1], and then used in this study. Main results show that while evaporation does transport heavy metals to the surface of a sandy soil, the loamy soil does not show the same trend. Therefore, contaminant accumulation predominates at the surface of sand soils in arid and semi-arid regions. Given that 90% of the land in Saudi Arabia, and for the most of arid regions, is sand, contaminated sand sites can pose a considerable hazard to the environment, especially biota, humans included. Ingestion or inhalation of sand particles from contaminated sites is a public health issue that should be assessed in arid regions. Sand and silt size particles from arid regions do travel long distances and may present an aerosol problem elsewhere. This is a source of atmospheric pollution that has been overlooked.

From grains to planetesimals in evolving protostellar disks.

D.N.C. LIN[123], Y. ZHANG[2], B. DAI[3], Y. FENG[3], J AND C. LI[3]

[1]University of California, Santa Cruz, USA
[2]KIAA and School of Physics, Peking University, China
[3]Physics Department, Tsinghua University, China

We model the properties of meteorites and protostellar disks in the context of the new planet-formation paradigm that planets and their building blocks may have migrated extensively. We suggest that CAIs condensed, with little age spread in a hot compact nebula formed by the infall of turbulent gas. Hydrodynamic drag led to the accumulation of meter-size particles near the inner boundary disk boundary beyond the stellar magneto- sphere where the first generation planetesimals and proto- planetary embryos formed. Earth-mass embryos migrated outwards to and stalled at a few AU's. They promoted the accumulation of later generation grains and planetesimals. In the solar nebula, embryos becomed cores of gas giants. Strong perturbation by emerging Jupiter and Saturn led to the wide-spread episodic melting and re-condensation of chondrules. In less massive disks, super-Earth embryos formed, and blocked the migration of grains and planetesimals to produce transitional disks. Super-Earths migrate to their present-day compact orbits during the disk depletion.

Electronic Spin Transitions of Iron and Geoelectrons in Earth's Mantle

J.-F. LIN[1]

[1]Department of Geological Sciences, Jackson School of Geosciences, The University of Texas at Austin, Austin, TX 78712 (*afu@jsg.utexas.edu)

Based on a pyrolitic compositional model, the lower mantle is mainly made of ferropericlase, aluminous silicate perovskite, and calcium perovskite. Silicate perovskite transforms into silicate post-perovskite structure just above the core-mantle region, the D" layer. The existence of iron in the lower-mantle minerals can affect a broad spectrum of the minerals' physical and chemical properties. In this presentation, I will address recent results and current understanding on the pressure-induced electronic spin-pairing transitions of iron and their associated effects on physical properties of host phases in lower-mantle minerals [1]. The spin crossover of Fe^{2+} in ferropericlase occurs over a wide pressure-temperature range extending from the middle part to the lower part of the lower mantle. Furthermore, a high-spin to low-spin transition of Fe^{3+} in the octahedral site of perovskite occurs at pressures of 15-50 GPa [2]. In post-perovskite the octahedral-site Fe^{3+} remains in the low-spin state at the pressure conditions of the lowermost mantle. These changes in the spin and valence states of iron as a function of pressure and temperature have been reported to affect physical, chemical, rheological, transport properties of the lower-mantle minerals. These effects of the spin transition can thus significantly affect our understanding of the deep Earth. I will present and evaluate the consequences of the transitions in terms of their implications to deep-Earth geophysics, geochemistry, and geodynamics [1-3].

The electrons of ferrous and ferric iron ions that occupy some of the lattice sites in mantle minerals become slightly polarized in the presence of the Earth's magnetic field. Using recent deep-Earth geophysics and geochemistry results, we have developed a model of the polarized electron spin density within the Earth. We have examined possible long-range spin-spin interactions between these spin-polarized geoelectrons and the spin-polarized electrons in recent particle physics experiments [4]. Such information might eventually help reconcile seismic observations and mineral physics data with geochemical models.

Precision maping and towcam aided study over geochemical anomalies of the Goodweather Ridge, Southwestern Taiwan

SAULWOOD LIN[1*], C.-W. HSU[1], I-JY HSIEH[1], HSIU-HUI CHANG[1] AND GERHARD BOHRMANN[2]

[1]Institute of Oceanograpny, National Taiwan University, Taipei, Taiwan (*correpondence: swlin@ntu.edu.tw)
[2]MARUM/ Center for Marine Environmental Sciences University Bremen, Germany

Very fine scale and detail bathymetric map could reveal a great deal of processes that may occur near the sea floor. This study used a MARUM SEAL 5000 AUV (Autonomous Underwater Vehicle) to obtain high-resolution depth variations on the sea floor and towcam aided piston coring to facilitate a better resolution of sea floor biogeochemical processes relate to methane gas venting.

Fine scale, high-resolution seafloor structures were obtained on the west of Good Weather Ridge by AUV mapping. A fault scarp previously draw based on seismic data at ridge slope is clearly visible from the AUV map, about 1-3 m deep and extending from south to the north about 4 km long. A series of micro-faulting branch structures appeared away from the ridge slope toward north. Another set of pockmarks, up to 7 m deep, 70 m in diameter, appeared on the surface indicating faulting extended from deep to sea floor. Large scale of authigentic carbonate buildups, and shallow SMI were observed. This study demonstrated that fine-scale mapping and towcam-aided sediment sampling could provide unprecedented details of sea floor features in corresponding to geochemical variations as a result of deep fluid venting.

Two Neo-Tethyan magmatic suites of distinctive geochemical features in Burma and southern Tibet: Zircon U-Pb and Hf constraints with regional tectonic implications

LIN, T.-H.[1], CHUNG, S.-L.[1], MITCHELL, A.H.G.[2], THURA OO[3], TANG, R.-T.[1] AND WU, F.-Y.[4]

[1] Institute of Geosicences, National Taiwan University, Tapei, Taiwan, tehsienlin@ntu.edu.tw
[2] Consulting Geologist, 20, Dale Close, Oxford OX1 1TU, UK
[3] University of Yangon, Kamayut Township, Yangon, Myanmar
[4] Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

The Neo-Tethyan subduction that operated before the India-Asia collision resulted in an Andean-type convergent margin in South Asia (Yin and Harrison, 2000; Chung *et al*.., 2005; Kapp *et al*.., 2005; Mo *et al*.., 2005), inducted arc magmatism distributing more than ~2,500 km that formed the Transhimalayan batholiths in the Lhasa terrane. Based on the age distribution and geochemical characteristics, the MMB may correlated northward to the Danxi Batholith, western Yunnan (Yang *et al*.., 2006; Liang *et al*.., 2008; Xu *et al*.., 2012), westward to the Bomi-Chayu Batholith (Chiu *et al*.., 2009; Lin *et al*.., 2012) and the Central Lhasa plutonic belt, which is a northern Transhimalayan plutonic suite typically has low and negative $\varepsilon_{Hf}(T)$ values suggesting involvement of old continental crust in the petrogenesis (Chu *et al*.., 2006, 2011; Chiu *et al*.., 2009; Zhu *et al*.., 2011); Comparatively, the Wuntho-Mokapalin arc in West Burma, characterized by high and positive $\varepsilon_{Hf}(T)$ values, with similar age and isotopic characteristics as the Lohit Batholith in the Eastern Himalayan Syntaxis, was proposed as the southward extension of the Gangdese Batholith, in general, has long been regarded as the main arc component produced by northward subduction of the Neo-Tethyan oceanic slab under the Lhasa terrane.

6 National Astronomical Observatories, CAS, Beijing, China
7 Guangzhou Institute of Geochemistry, CAS, China
8 National Institute of Polar Research, Tokyo, Japan

Organic carbon was found in Tissint, the new Martian meteorite fall [1], most filling fractures and a few entrained in shock-melt veins. The organic carbon is kerogen-like based on Raman spectra. Some organic carbon inclusions in the veins were transferred to diamond. The organic carbon has been analyzed with NanoSIMS 50L. The abundances of H, N, O, S, P , F and Cl relative to C of the organic carbon are comparable with coal. The organic carbon grains have $\delta^{13}C$ values of -13.0 ~ -33.3‰, δD values of up to +1183‰ and normal N isotopic compositions.

The organic carbon in Tissint is of Martian origin, based on the presence in the shock-melt veins, the formation of diamond and the D-enrichment. It formed by depositing from organic-rich groundwater on Mars. The petrographic settings and significantly light C isotopes of the organic carbon are consistent with a biogenic origin. Our observations of the organic carbon argue against an igneous origin [2]. The organic carbon couldn't originate from carbonaceous chondrites that impacted on Mars, because the chondritic kerogen has heavier N isotopes and relatively homogeneous H isotopes.

Precise Determination of B Isotopic Compositions in Low Concentration Carbonates and Fluids Using Micro-sublimation MC-ICPMS

YEN-PO LIN[1], CHEN-FENG YOU[1,2*] AND CHUAN–HSIUNG CHUNG [2]

[1]Department of Earth Sciences, National Cheng Kung University, Tainan, Taiwan
[2]Earth Dynamic System Research Center (EDSRC), National Cheng Kung University, Tainan, Taiwan (*correspondence: cfy20@mail.ncku.edu.tw)

Although the pH-dependence of boron (B) isotopic fractionation in marine carbonates has been widely used for pH reconstruction in ancient seawater, the available analytical techniques still exhibit large discrepancies. In this study, we evaluated systematically the B isotopic compositions in two reference materials, JCp-1 (porites coral) and JCt-1 (giant clam). A low blank boron separation procedure was evaluated using micro-sublimation technique [1], subsequently combined with MC-ICPMS isotopic measurement. The two carbonate standards were treated with oxidative cleaning (NaOCl) and without any prior cleaning for comparison. There is no major B isotopic difference between the two groups; however, the cleaned carbonates show slightly lower $\delta^{11}B$ with better precision. These $\delta^{11}B$ results agree well with literature values, but achieve with high throughput and high precision (2SD, 0.2 ‰).

Boron isotopic fractionation during sorption is rather significant in soils and river water. Our $\delta^{11}B$ technique was applied further for a better understanding of clay adsorption/ desorption behaviors of B in aqueous environments, as well as the associated isotopic fractionation during water/rock interaction. The calculated K_Ds and the degree of B isotopic fractionation showed significant variation among various minerals.

Higher oxygenation level after Sturtian glaciation meltdown despite varying local redox in Nanhua basin

HONG-FEI LING[1], XI CHEN[1], DA LI[1], G.A. SHIELDS[2], D. VANCE[3] AND L. OCH[2]

[1] Department of Earth Sciences, Nanjing University, China
[2] Department of Earth Sciences, University College London
[3] School of Earth Sciences, University of Bristol

Both of the major two oxygenation events occurred coincidently with severe glaciations in the early and late Proterozoic. Causal relationship was proposed that enhanced postglacial weathering input caused high rates of productivity and organic carbon burial and thus further oxygenation of the surficial Earth (Planavsky *et al*.., 2010). Here we present data of iron speciation, pyrite sulfur isotopes and Mo isotopes of black shales and Mn-rich carbonates of the basal Datangpo Formation immediately covering the Sturtian diamictite in Tongren County, South China, to constrain the oceanic redox condition in the aftermath of the glaciation. Our iron speciation data show anoxic condition of local seawater within the Nanhua Basin, while published data for samples in Minle County (Li *et al*.., 2012), ~70 km from Tongren, show euxinic condition, indicating heterogeneous redox in the Nanhua Basin. The $\delta^{34}S_{Py}$ values of our samples are between 20.6‰ and 59.3‰, similar to those of Minle area (38.6-57.3‰). Furthermore, our samples show a negative correlation between $\delta^{34}S_{Py}$ and pyrite-sulfur contents. Low S_{Py}, anomalously high $\delta^{34}S_{Py}$ and their correlation suggest a very low seawater sulphate content which limited pyrite formation, given ferruginous condition and relatively high organic carbon content. The δ^{98}Mo values range between which should be the lower limit of the coeval ocean values as Mo-isotope fractionation may have existed during deposition in ferruginous condition. However, the high end of our data is higher than those of euxinc black shales in mid-Proterozoic ($\delta^{98}Mo \leq 1.13$, Kendall *et al*.., 2011; and in pre-Sturtian Neoproterozoic ($\delta^{98}Mo \leq 1.19$ at 750Ma, Dahl *et al*.., 2011), suggesting a higher oxygenation level of the ocean after the Sturtian glaciation.

Destruction of the North China Craton Induced by Ridge Subductions

M.X. LING[1], W.D. SUN[1], F.Z. TENG[2], Y. LI[3], X. DING[1], X.Y. YANG[4], W.M. FAN[1] AND Y.G. XU[1]

[1] Guangzhou Institute of Geochemistry, CAS, Guangzhou 510640, China (mxling@gig.ac.cn)
[2] Department of Geosciences, University of Arkansas, Fayetteville, AR 72701, USA
[3] China Petroleum Pipeline Engineering Corporation Langfang 065000, China
[4] School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China

The destruction of the North China craton (NCC) has been attributed to a "top-down" rapid delamination or to "bottom-up" long-term thermal/chemical erosions, or hydration by subduction released fluids. Based on the distribution of one Jurassic and two Early Cretaceous adakite belts and the drifting history of the paleo-Pacific plate, here we propose that three ridge subduction events dominated the large-scale decratonization in the NCC. Both physical erosion (delamination) and magmatism (thermal/chemical erosions) induced by ridge subduction contributed to the destruction of the NCC, whereas the last ridge subduction at 130±5 Myrs was the key driving force that led to the final destruction, which mainly occurred in the Cretaceous. Integrated study of mineralogy, major and trace elements, as well as Mg isotopes, was conducted, which supports the ridge subduction model: The flat subduction of a spreading ridge had stronger physical erosion on the thick lithosphere mantle of the NCC. The final decratonization was triggered by the last ridge subduction, with both physical erosion (flat subduction) and thermal erosion (adakitic and A-type magmatisms). Given that ridge subduction occurred throughout Earth's history, the associated decratonization processes are presumably a common phenomenon that modified the chemical compositions of the continental crust.

The related paper was published in Journal of Geology (Ling, M.X. *et al*.., 2013. Destruction of the North China Craton Induced by Ridge Subductions. Journal of Geology, 121(2): 197-213).

The link between biotic and abiotic systems: How and why does gold accumulate in calcrete (caliche)?

M.J. LINTERN

CSIRO Minerals Downunder Flagship, 26 Dick Perry Avenue, Kensington, WA 6152, Australia (correspondence: lin082@csiro.au)

It is well known to mineral explorers that in drier parts of Australia Au accumulates in calcrete (caliche). Calcrete is a Quaternary aeoilan or marine addition to the soil yet it is strongly correlated with Au derived from the weathering of Archean rocks. Why this should be the case is not well understood..

Through a series of recent field observations, laboratory experiments and microanalytical techniques it will be demonstrated that the relationship between gold and calcrete is mediated by both biological and climatic mechanisms. We track the process by which Au becomes adsorbed by plant roots and is translocated to the canopies of large trees. From here the Au is transferred to the soil whereby organic processes involving bacteria, fungi and/or plant roots serve to complex and mobilise Au. Climate affects the uptake of Au in plants and causes it to accumulate in the pedogenic carbonate horizon of soil profiles.

It is important that we elucidate these abiotic-biotic processes if we are to identify the constraints on the Au-calcrete association. Mineral explorers may overlook Au deposits if they fail to understand mechanisms on how soil anomalies form above them.

Geochemical processes during weathering of natural volcanic glasses: comparison with experimental alteration

ANGELO LIOTTA[1], MICHEL DUBOIS[1] AND ARNAUD GAUTHIER[1]

[1] LGCgE, Université Lille 1, France angelo.liotta@ed.univ-lille1.fr

The objective of this research, currently in progress, is to study the weathering processes of glassy silicate materials, in order to understand the geochemical processes involved and the variation of mineral phases as a result of alteration.

The use of samples of natural glass of volcanic origin has allowed to obtain some powder or sections of fresh silicate glass that have been subjected to artificial alteration in the laboratory, in order to model the geochemical processes that have occurred.

Moreover, the study of naturally altered samples has allowed to observe the effects of weathering after a period of time corresponding to the age of the sample. Three samples were collected in the eastern Sicily, Italy. They include the rhyolitic obsidian of historical age coming from the island of Lipari (Aeolian Islands) in the southern Tyrrhenian Sea, connected to a complex subduction-related magmatism. The second one is a glassy salband from a basaltic dike outcropping in the western wall of the Valle del Bove (Etna), having an estimated age between 15 and 60 thousand years. The third sample is a glassy crust of tholeiitic pillow lavas from submarine eruptions of the upper Pliocene in shallow water environment in the northwestern Iblean Mountains.

The characterization of the samples was obtained by Raman spectroscopy, which showed the effects of the devitrification and the presence of some secondary minerals such as phillipsite and offretite, two varieties of zeolite found in the cavities of oldest basalts.

Samples have been altered from 1 to 100 days of experiment. Alteration experiments were conducted in pure water at 90°C; solid modifications were observed by SEM. The analysis showed the formation of an amorphous material surface characterized by a slight decrease in the content of silica, alkali and calcium, and by a marked increase in titanium (up to 3.17%) and iron (up to 16.21 %) contents.

All these results allow to test the geochemical modeling in the long term. Further analysis will be needed to reach a full understanding of the weathering of glassy materials, in order to prevent the environmental pollution caused by the alteration of vitrified metallurgical or radioactive waste.

Sulfur and Chlorine isotopes in volcanic products at Mt. Etna, Italy

M. LIOTTA[1,2]*, A.L. RIZZO[2], A. PAONITA[2], J.D. BARNES[3], A. CARACAUSI[2], R. CORSARO[4] AND M. MARTELLI[2]

[1]Dipartimento DiSTABiF, Seconda Università di Napoli, Caserta, Italy (*correspondence: marcello.liotta@unina2.it)
[2]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Palermo, Italy
[3]Department of Geological Sciences, University of Texas, Austin, Texas 78712, USA
[4]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Catania, Italy

Mt. Etna volcano is characterized by a persistent volcanic plume and by a complex fumarolic field. Two types of fumaroles were identified: low-temperature fumaroles, which are dominated by CO_2 with minor amounts of SO_2 and H_2S, and negligible chlorine contents, and high-temperature fumaroles, which are strongly air-contaminated and characterized by appreciable amounts of volcanogenic carbon, sulfur, and chlorine [1, 2].

Sulfur and Chlorine isotopic compositions ($\delta^{34}S$, $\delta^{37}Cl$) of fumarolic and plume gases collected at Mount Etna volcano during 2008–2011 are compared to those of volcanic rocks. While low-temperature fumaroles are affected by postmagmatic processes that modify the pristine isotopic signature of sulfur and remove chlorine [2], high-temperature fumaroles and plume gases allow to constrain the $\delta^{34}S$ of magmatic SO_2 to ~0 ± 1‰, being systematically 1–2‰ lower than that of S dissolved in Etnean melts [2].

Chlorine dissolved in rocks shows an isotopic composition partially overlapping with that of high-temperature fumaroles and plume gases defining a narrow range of $\delta^{37}Cl$ range of ~0 ± 0.7‰ for magmatic chlorine [3].

While sulfur fractionation ($\alpha_{gas\text{-}melt}$) depends on the speciation of sulfur, thus providing a useful information on the redox conditions of the Etnean plumbing system, chlorine hexibits neglegible fractionation during degassing of magmatic bodies. Accordingly, isotopic fractionation model for sulfur and chorine during magma degassing provide inferences on the mantle source of Etnean magmas and physico-chemical conditions in the shallower system.

Fossil fuel and biofuel emissions of particles in Africa are expected to significantly increase in the near future, particularly due to rapid growth of African cities. Air quality degradation is then expected with important consequences on population health and climatic/radiative impact.

In this work, we show the central role of black carbon to organic carbon ratios (BC/OC) to characterize African anthropogenic emissions and impacts:

- a new BC and OC African anthropogenic emission inventory adapted to regional specificities has been constructed for the years 2005 and 2030.

- BC and OC radiative impacts in Africa have been modeled with TM5 model and Penner *et al*.. (2011) radiative code for these inventories for 2005 and 2030 and for two emission scenarios: a reference scenario and a ccc* scenario including regulations. In this study we will show that enhanced heating is expected with the ccc* emissions scenario in which the OC fraction is relatively lower than in the reference scenario.

- results of short term POLCA intensive campaigns in Africa in terms of aerosol inflammatory impacts on the respiratory tract through in vitro studies. In this study, organic carbon particles appear more biologically active than BC particles.

Quite importantly, air quality improvement obtained through regulations in the ccc* scenario with higher BC/OC ratios are accompanied by stronger heating impact. BC/OC ratio variations may be considered as a standard reference index to study air quality, health and climatic impacts.

Geochemistry and crystal preferred orientation of upper mantle peridotite xenoliths from the Nógrád-Gömör Volcanic Field (Northern Pannonian Basin)

N. LIPTAI[1]*, L. PATKÓ[1], L. E. ARADI[1], CS. SZABÓ[1], I. J. KOVÁCS[2], K. HIDAS[3], GY. FALUS[2], O. VASELLI[4], A. TOMMASI[5] AND F. BAROU[5]

[4]Department of Earth Sciences, Florence, Italy
[5]Geosciences Montpellier, University of Montpellier, Montpellier, France

Information on the physical and chemical properties of the subcontinental lithospheric mantle can be obtained by the study of mantle rocks outcropped on the surface mostly as xenoliths or massive peridotite bodies. The Nógrád-Gömör Volcanic Field (NGVF) is one of the five occurrences in the Carpathian-Pannonian region where Plio-Pleistocene alkali basalts host upper mantle peridotite xenoliths. There is only a limited number of publications that provide basic petrographic and geochemical data about xenoliths in the area [e.g. 1, 2], and none of these contains analyses of crystal preferred orientation (CPO), which can be an important key to gain insight into the rheological conditions of the given mantle domain, and thus, the evolution of the Pannonian Basin.

Here we present major and trace element contents and CPO data of representative lherzolite xenoliths collected from different parts of the NGVF. The major goal is to depict an overall picture of CPO in olivines in the studied area and look into geochemical data to see if there is any link between them. Our results show that the xenoliths are geochemically similar, however, three types of olivine CPO can be distinguished, which correlate with localities, xenolith fabrics, and calculated equilibrium temperatures. This suggests that the studied xenoliths recorded the presence of various types of deformation events in the upper mantle beneath the NGVF, which occurred most probably during the Neogene evolution of the Pannonian Basin.

Chemical composition of apatite as a tool for modeling composite-pluton evolution using Polytopic Vector Analysis (PVA)

LISOWIEC K.[1], SŁABY E.[1], FÖRSTER H.-J.[2], GÖTZE J.[3] AND MICHALAK P.P.[3]

[1]ING PAN, Warsaw, PL *klisowiec@twarda.pan.pl*
[2]GFZ, Potsdam, DE, forhj@gfz-potsdam.de
[3]TUBAF, Freiberg, DE, *goetze@mineral.tu-freiberg.de*

Composite plutons are common constituents of the continental crust, therefore identification of their evolution path is crucial. Polytopic Vector Analysis (PVA) is used to define the number and composition of end-members from a data set representing a system formed by mixing of several different components. This approach is routinely applied to study whole-rock composition. We verified its applicability for mineral compositions. Apatite grains from a composite granitic pluton were studied with FE-EPMA and CL. The pluton formed by mixing of mantle- and crust-derived melts influenced by late-magmatic fluids, thus being a suitable example for a heterogeneous system. Apatites exhibit complex zoning in BSE and CL, pointing to rapid changes in melt composition. Variation in trace-element content demonstrates distinct trends that changed over time of formation of the pluton.

Polytopic Vector Analysis was applied to the whole rock and apatite major and trace-element compositions, in order to verify the record of a common differentiation path. The results of the PVA study performed for the whole rock are consistent with previous studies employing other modeling approaches and are in accord with the supposed magma-mixing model. Apatite composition does not reflect operation of this mixing model, especially in the case of REEs which exhibit chaotic distribution, likely resulting from local saturation of the melt. The results of the PVA of apatites from every stage of magma differentiation will be presented and the advantages and limitations of this approach will be shown.

Chalcophile and Highly Siderophile Element systematics in Mid-Ocean Ridge Basalts

MORITZ LISSNER[1*], STEPHAN KÖNIG[1], AMBRE LUGUET[1], PETRUS LE ROUX[2] AND ANTON LE ROEX[2]

[1] Steinmann Institut für Mineralogie, Universität Bonn, Germany mlissner@uni-bonn.de (* presenting author)
[2] Department of Geological Science, University of Cape Town, South Africa

Mid-Ocean ridge basalts (MORBs) constitute an exceptional window to investigate the chalcophile element (S, Se and Te) and the highly siderophile element (HSEs: Os, Ir, Ru, Pt, Pd, Re) signatures of the depleted MORB mantle (DMM), provided that the behavior of these elements during MORB evolution is entirely understood. Hence, we analyzed S, Se, Te, HSEs and ^{187}Os in 20 Southern Mid-Atlantic Ridge (SMAR) MORBs, which range in composition from typical N-MORBs to plume-overprinted E-MORBs [1].

All samples display positively-sloped CI-normalized HSE patterns (Pt_N/Ir_N=2.8-88.3, Pd_N/Ir_N=3.1-17.3, Re_N/Pd_N=40-270), with E-MORBs having higher Pt and Pd contents than N-MORBs. S, Se and Te concentrations range from 715-1143 ppm, 107-242 ppb and 1.63-9.46 ppb, respectively. S contents increase with decreasing Mg# and Se concentrations. Se and Te positively correlate with each other and with incompatible PGEs (Pt, Pd). In addition Se/Te increase with decreasing Te concentrations defining a clear non-linear trend. After filtering out possible effects of seawater alteration, volatilitization upon eruption and sulphide fractionation on S, Se, Te and HSE contents, the Se/Te and Pd/Ir ratios appear as indicators of the mantle source composition, correlating with discriminant parameters like La_N/Sm_N and Sr-Nd-Pb isotopic signatures. While both N- and E-MORBs are characterised by supra-chondritic Se/Te and Pd/Ir, N-MORBs generally show higher Se/Te but lower Pd/Ir (Se/Te=51-92 vs. 26-38, Pd_N/Ir_N=3.1-7.0 vs. 4.4-17.3). Partial melting modelling [2] performed to reconstruct the DMM composition, predicts an incompatible behaviour of both Se and Te during partial melting as well as chondritic abundances of Se, Pt and Ir but sub-chondritic Pd and Te contents in the SMAR mantle source. This ultimately supports supra-chondritic Se/Te and sub-chondritic Pd/Ir ratios in the MORB mantle source and has important implications on the Se, Te and HSE budget estimate of the Earth's primitive mantle.

Deep melting of subducted carbonate and carbonatite melt diapirs in the Earth's mantle

K.D. LITASOV[1,2]*, A. SHATSKIY[1,2] AND E. OHTANI[3]

[1]Sobolev Institute of Geology and Mineralogy, Novosibirsk, 630090, Russia (*correspondence: klitasov@igm.nsc.ru)
[2]Novosibirsk State University, Novosibirsk, 630090, Russia
[3]Tohoku University, Sendai, 980-8578, Japan

Minor amounts of alkalis (Na and K) can drastically reduce the solidus temperatures of carbonated silicate mantle, by as much as 400-500°C. Low-degree melting of carbonated peridotite and eclogite at pressures of 3-10 GPa produces Na- and K-bearing carbonatite melt. Mass-balance calculations of samples obtained below apparent solidi show clear deficits of alkalis suggesting the presence of minor alkali-rich liquid or solid carbonate phases. Here we determined the true solidi in Na- and K-bearing carbonated systems and report the stability of new alkaline carbonate phases [1]. Starting materials correspond to Na- and K-bearing Mg-Ca-carbonatite. Experiments were run at pressures from 3-21 GPa and 750-1450°C using multianvil apparatus.

Major carbonate phases in both the Na-carbonatite and K-carbonatite systems are aragonite and magnesite. Magnesite is a liquidus phase together with silicates. Aragonite contains significant amounts of Na_2O (up to 7 wt.%), K_2O (up to 1 wt.%), and MgO (up to 8 wt.%) in the Na-carbonatite system. The solidus temperature is defined by the stability of double carbonate phases. The solidus slope has a significant change between 6 and 10 GPa. Above 10 GPa the solidus becomes flat at a temperature near 1150ºC. In the Na-bearing system it may have a slightly negative slope above 15 GPa according to stability of K-Ca carbonate in this system. Several K- and Na-bearing double carbonates were observed in both the Na-carbonatite and K-carbonatite systems. The major phases observed in the experiments are $(K,Na)_2Mg(CO_3)_2$ and $(K,Na)_2Ca_4(CO_3)_5$. Low-degree partial melts are Na- and K-rich, for Na- and K-bearing carbonatite, respectively, due to early melting of double alkali carbonates.

According to solidi temperatures significant melting of subducting carbonates would likely occur at the transition zone depths Taking into account the amount of subducted carbonated (1-2 wt.% CO_2) in the top 500 m of model slab we proposed a model for mobile carbonatite melt diapirs, generating from the slab in the transition zone, migrating upwards, modifying and oxidizing possibly reduced mantle section [2], precipitating diamonds, creating enriched source regions, and initiating volcanism at the surface.

Calculation of mass (im-)balance in the oceanic cycling of Cu and Zn isotopes

S.H. LITTLE[1,2*], D. VANCE[1,2], T. W. LYONS[3] AND J. MCMANUS[4]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, Bristol, UK.

[2]Now at: Institute of Geochemistry & Petrology, Dept. of Earth Sciences, ETH Zürich, Clausiusstrasse 25, 8092 Zürich, Switzerland. *susan.little@erdw.ethz.ch; derek.vance@erdw.ethz.ch

[3]Department of Earth Sciences, Universit of California, Riverside, USA. timothy.lyons@ucr.edu

[4]Oregon State University, College of Earth, Ocean & Atmospheric Sciences, 104 CEOAS Admin. Bldg., Corvallis, OR 97331-5503, USA. mcmanus@coas.oregonstate.edu

The stable isotope systems of the transition metals are increasingly being developed as tracers for the paleoenvironment. However, as yet, controls on their modern cycling in the oceans are little known. In particular, constraints on their modern oceanic mass balance are sparse [1].

We present best estimates for the fluxes and isotopic composition of Cu and Zn for the known oceanic inputs (rivers, aeolian dust) and outputs to sediments (in normal marine and anoxic settings), the latter based on estimates for Mo, with Cu/Mo or Zn/Mo ratios of different types of marine sediments [2, 3]. For both Cu and Zn, the sum of the known input fluxes is greater than that of the output fluxes, i.e. the cycles are out of balance. This imbalance is also observed in the isotope ratios of sources and sinks. For δ^{65}Cu, we find flux-weighted outputs that are isotopically light (at ~0.3‰) compared to the inputs (at ~0.6‰). For δ^{66}Zn we observe the reverse, with a sink for Zn that is isotopically heavy (at ~0.7‰) compared to the input, the latter indistinguishable from detrital sediments (at ~0.3‰).

Taken at face value, these calculations require that the Cu and Zn cycles include an unidentified additional sink to achieve flux and isotopic mass balance. For Cu, this sink should be isotopically heavy (at ca. +2‰) while for Zn, a missing sink for light isotopes (at ca. -1‰) is implied. However, we consider these projected missing sink isotopic compositions to be implausible. Instead, we discuss the possibility of (an) additional source(s) of Cu and Zn, the presence of which would reduce the isotopic extremity of each missing sink. We suggest that one such source may be solubilisation of a portion of the large riverine particulate flux at the river-sea interface.

Differentiation of the mantle ultrabasic-basic magmas and diamond-forming carbonatite melts on experimental evidence

YU.A. LITVIN

Institute of Experimental Mineralogy, Chernogolovka, Moscow Region 142432 Russia (litvin@iem.ac.ru)

Generalized melting diagram-complex of upper-mantle peridotite-eclogite system

The diagram-complex consolidates garnet peridotite Ol-Opx-Cpx-Grt and four eclogitic simplexes. Primary komatiitic magma is formed under control of invariant peritectic Ol+Opx+Cpx+Gr+L linked with olivine eclogite simplex by univariant Ol+Cpx+Grt+L curve. Peridotite and silica-saturated eclogite compositions are separated by Opx-Cpx-Grt plane. Peritectic points of peridotite and Coes-eclogites (Coes+Opx+Cpx+Gr+L) are linked by univariant Opx+Cpx+Grt+L curve. While piercing the Opx-Cpx-Grt plane, the curve has temperature maximum known as thermal eclogitic barrier [1]. The barrier represents an insuperable obstacles for ultrabasic-basic magma both equilibrium and fractional differentiation.

"Peridotite-to-eclogite tunnel" mechanism against the thermal eclogitic barrier

Fractional crystallization of primary komatiitic magma is accompanied by increasing concentration of jadeite component at residual melts. This activates mechanism of ultrabasic-basic magma differentiation with formation of continuous peridotite-eclogite series. By experimental data, the differentiation is controlled by reaction of Ol- and Jd-components above 4.5 GPa [2]. As result Ol is disappeared and Grt formed. Liquidus reaction point Ol+Jd-Cpx = Grt+L operates effectively in Ol elimination along the univariant curve Ol+Cpx+Grt+L that brings residual melts compositions into the Cpx-Grt join. The join is a commonplace for all the peridotite and eclogite simplexes. Here "peridotite-to-eclogite tunnel" mechanism is proved and makes the round the thermal eclogitic barrier. As a result, it paves the way for continuous fractional crystallization of ultrabasic-basic magmas and transfer from Ol-bearing peridotite to Coes-bearing eclogite rocks. Differentiation of the carbonatite melts parental for diamonds and primary inclusions.

By experimental evidence, a changeable composition of the carbonatite parental melts for diamond and inclusions is based on $peridotite_{30}carbonatite_{70}$-$eclogite_{35}carbonatite_{65}$-carbonatite system [3]. Differentiation of parental melts is controlled by "peridotite-to-eclogite tunnel" mechanism associated with carbonatization of peridotitic Mg-components. Fractional differentiation is responsible for formation of diamond-hosted mineral inclusions for peridotite and eclogite parageneses. *Support*: RFBR grant 11-05-00401.

Graphic mehtod for estimating the biological absorbtion coefficient

YU.S.LITVINENKO

EcoGeoLit Ltd., Moscow, Russia (ecogoelit@mail.ru)

Fixed biological absorption coefficient values (Ax) as in relation of microelement contents in plants ashes to its content in the soil (Perelman, 1975) show overall biophilic qualities of chemical elments but not the accumulation dynamics in plants depending on the concentration of it in soil.

Such dynamics is shown on the plot of element concentration in plants (lnCv) against its concentration in the soil (lnCs).

Ax coefficients for selected intervals of Ni concentration in soils are tangents of the angle α between the graph and the x axis (fig. 1).

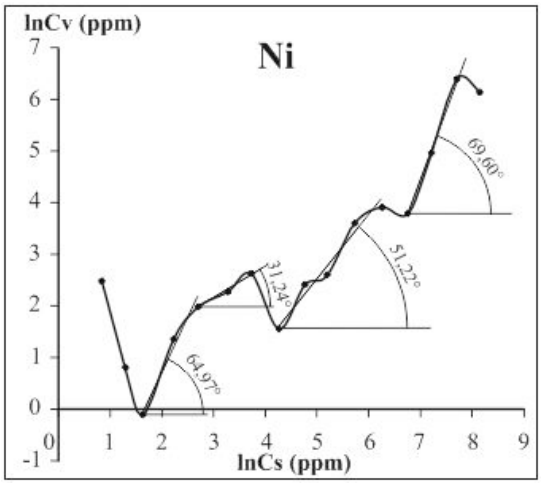

Figure 1: angle α of the plot of Ni concentration in moss against its concentration in the soil.

Upper Cretaceous Marine Source Rocks and its Contribution to Hydrocarbon Accumulations in Eastern Niger Basin, Niger

LIU BANG[1*] ,WAN LUNKUN[2] ,MAO FENGJUN[3] AND LIU JIGUO[4]

[1] Research Institute of Petroleum Exploration & Development, PetroChina, Beijing, P.O. Box 910, China (*correspondence: liubang@petrochina.com.cn)

[2] Research Institute of Petroleum Exploration & Development, PetroChina, Beijing, P.O. Box 910, China (wanlunkun@petrochina.com.cn)

[3] Research Institute of Petroleum Exploration & Development, PetroChina, Beijing, P.O. Box 910, China (maofengjun@petrochina.com.cn)

[4] Research Institute of Petroleum Exploration & Development, PetroChina, Beijing, P.O. Box 910, China (ljiguo@petrochina.com.cn)

The Eastern Niger Basin is a typical Mesozoic-Cenozoic intracontinental rift basin of the Central and Western African rift system, including Tenere and Termit depression. Using techniques of kerogen maceral analysis, rock pyrolysis and GC-MS for mudstone cuttings from Yogou and Donga formation of the Upper Cretaceous, this study investigates the origin, abundance, type and thermal maturity of organic matter. Kerogen macerals are dominated by amorphinite displaying no or weak fluorescence, and rock extracts have a regular sterane distribution of C_{29}>C_{27}>C_{28}. These characteristics suggest that the organic matter of the Upper Cretaceous mudstones originated mainly from land-derived plants. Rock-Eval pyrolysis data reveals that the Yogou Formation of the Upper Cretaceous generally have moderate to good hydrocarbon potential with kerogen predominantly Type II_2-III, while the Donga Formation are mainly bad-moderate source rocks with type III kerogen. T_{max} values indicate that the threshold depth for hydrocarbon generation of source rocks is about 2300m. Three-dimensional modeling of hydrocarbon generation suggests that petroleum in marine source rocks began to be generated in the Early Palaeocene. Peak generation took place from the Late Eocene to Early Miocenes, with thermally mature area covering most of the basin. Geochemical results of crude oils show that the majority of oil samples are characterized by Pr/Ph ratios below 1.5, high relative abundance of β-carotane and gammacerane, and dominance of C_{29} steranes over C_{27} steranes. Geochemical correlation analysis of oil and rock samples indicates that most of oils from the Eastern Niger basin were probably derived from the Upper Cretaceous marine source rocks.

Sr and Mg isotopes of Marinoan Cap dolostones: implication for glacial lake Harland?

CHAO LIU[1], FRANCIS MACDONALD[2], ZHENGRONG WANG[1] AND TIMOTHY RAUB[3]

[1] Yale University, New Haven, CT, USA, chao.liu@yale.edu, zhengrong.wang@yale.edu

[2] Harvard University, Boston, MA, USA, fmacdon@fas.harvard.edu

[3] University of St. Andrews, St. Andrews, Scotland, UK, timraub@st-andrews.ac.uk

Marinoan cap dolostones cap dolostones have been suggested to be formed in a lid of glacial-melt water on top of normal seawater (i.e., the "glacial lake Harland", [1]), which needs to be tested geochemically. In this study, Sr and Mg isotopes of the cap dolostones were investigated from three sections of Marinoan cap dolostones: Hay Creek Group (Canada), Ol member (Mongolia), and Nuccaleena formation (Australia). An incremental leaching technique[2] has been applied to these samples, in order to understand their diagenetic history and to constrain the Sr and Mg isotope compositions of penecontemporaneous seawater. Cap dolostones from Nuccaleena formation can be categorized into two groups based on their chemistry. Group-I samples are located in the bottom and top parts of the section, exhibiting $^{87}Sr/^{86}Sr$ values (~0.7075) similar to previously reported Marinoan seawater values [3], and $\delta^{26}Mg_{DSM3}$ increasing upwards from -2.14‰ to -1.75‰. Group-II samples are located in the middle part of the section, with elevated $^{87}Sr/^{86}Sr$ values (average of 0.7092±0.0003) and $\delta\delta^{26}Mg_{DSM3}$ values (average of -1.71±0.05‰). For Monglian cap dolostones, all samples exhibit similar $^{87}Sr/^{86}Sr$ values (average of 0.7091±0.0001) and$\delta^{26}Mg_{DSM3}$ values (average of -1.63±0.05‰) to group-II Australian cap dolostones. For Canadian cap dolostones, more elevated $^{87}Sr/^{86}Sr$ values (higher than 0.7200) are observed. However, they share similar$\delta^{26}Mg_{DSM3}$ values (~-1.60‰) to Mongolian samples and group-II Australian samples. These geochemical variations could be explained by glacial lake Harland model, i.e., the cap dolostones from Nuccaleena formation recorded seawater signals before, during and after the stage of glacial lake Harland, whereas those from Mongolia and Candada are formed exclusively during the stage of glacial lake Harland. However, other possibilities cannot be ruled out.

[1]Hoffman (2011) Sedimentology 58, 57-119. [2]Liu *et al*.., Chemical Geology, under review. [3]Halverson *et al*.., (2007) PAELEO 256, 103-129.

The Paleoproterozoic basin evolution in the Trasn-North China Orogen, North China Craton

CHAOHUI LIU[1] AND GUOCHUN ZHAO[2]

[1] Institute of Geology, Chinese Academy of Geological Sciences, Beijing 100037, China denverliu82@gmail.com

[2]Department of Earth Sciences, The University of Hong Kong, Pokfulam Road, Hong Kong *gczhao@icloud.com*

The Trans-North China Orogen (TNCO) has been recognized as a continent-continent collisional belt along which the Eastern and Western Blocks amalgamated to form the North China Craton. However, controversy has surrounded the timing and tectonic processes involved in the collision of the two blocks, ranging from the westward-directed subduction with final collision at ~2.5 Ga to the eastward-directed subduction with final collision at ~1.85 Ga. Detailed lithostratigraphic and geochronological analyses for the low-grade supracrustal successions in the TNCO has been carried out recently, which help us to examine current models. Lithostratigraphic data indicate that the Gantaohe, Jiangxian and Lower Zhongtiao Groups and lower parts of the Hutuo and Yejishan Groups are composed of metaclastic rocks, carbonates and metavolcanic rocks, interpreted as back-arc basin deposits, whereas the Dongjiao, Upper Zhongtiao, Danshanshi Groups and the upper parts of the Hutuo and Yejishan Groups consist only of metaconglomerates and metasandstones, interpreted as foreland basin deposits. For the Gantaohe, Hutuo and Yejishan Groups, we found major age U-Pb age peaks of detrital zircons at ~2.5 and ~2.15 Ga, which are consistent with ages of the lithological units in the middle sector of the TNCO. Besides the age peaks of ~2.5 Ga and ~2.15 Ga, detrital zircons from the Lower Zhongtiao, Upper Zhongtiao and Danshanshi Groups also gave an older age peak of 2.7 Ga, which is comparable with ages of the lithological units in the Taihua Complex. For the back-arc basin deposits, their maximum depositional ages were constrained at ~2.1 Ga, whereas the presence of ~1.85 Ga detrital zircons from the foreland basin deposits indicates that they were deposited after this time. At ~2.1 Ga, back-arc basins developed behind an "Andean-type" arc that were subsequently incorporated into the TNCO during the later collision. At ~1.85 Ga, the two blocks collided along the TNCO, resulting in the crustal thickening followed by rapid exhumation/uplift, which shifted the back-arc basins to foreland basins. Such a shift in the late Paleoproterozoic supports the model that the collision between the Eastern and Western Blocks occurred at ~1.85 Ga.

Existence of elevated $\delta^{18}O$ values in the lithospheric mantle: evidence from olivines in Sailipu mantle xenoliths, Tibet

CHUAN-ZHOU LIU[1], FU-YUAN WU[1] AND QIU-LI LI

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, 100029, Beijing.
chzliu@mail.iggcas.ac.cn

In southern Tibet Plateau, post-collisional Sailipu ultrapotassic lavas erupted at ca. 17 Ma entrain peridotite xenoliths of small sizes (<1 cm). It has been suggested that the Sailipu mantle xenoliths were derived from a relic of the thickened Asian lithospheric mantle, the lower portion of which has been delaminated by conective removal [1]. Clinopyroxene trace-element compositions, together with the ubiquitous presence of phlogopite, support that the Sailipu mantle xenoliths have been metasomatized by fluids/melts liberated from the subducted Neo-Tethys Ocean [1].

Olivines separated from Sailipu peridotite xenoliths have been analyzed for oxygen isotope using secondary ion mass spectrometry (SIMS). The studied olivines have Fo contents of 88-91, containing 0.04-0.08 wt.% CaO and 0.38-0.55 wt.% NiO. Such compositional characteristics are in stark contrast with olivine phenocrysts crystallized from the host lavas (Fo_{69-81}, 0.14-0.47 wt.% CaO and 0.13-0.28 wt.% NiO). Olivines in each sample display homogeneous oxygen isotope compositions, as both inter- and intra-grain variations are always less than the precision of the method (i.e., ~ 0.5‰). Olivines from eight samples with Fo of 87.7-89.1 have similar $\delta^{18}O$ values ranging from 5.22‰ to 5.41‰, which are well within the range of the upper mantle (5.18 ± 0.28‰) defined by olivines in mantle xenoliths from various settings [2]. In comparison, olivines from one sample with a Fo content of ~ 91.3 has the highest $\delta^{18}O$ values rangin from 7.42‰ to 8.92‰ (with an average of 8.03 ± 0.28‰), which are remarkably higher than the upper mantle values. Such heavy oxygen isotopes could result from metasomatism by slab-released fluids or melts, which commonly have elevated $\delta^{18}O$ values. Therefore, our results support the existence of high oxygen isotopes, at least locally, in the lithospheric mantle.

Multiple metamorphic events hidden in zircons from the Sanjiang complex belt, southeastern Tibetan Plateau

F.L. LIU, F. WANG, P.H. LIU AND C.H. LIU[1]

[1]Institute of Geology, Chinese Academy of Geological Sciences, Beijing, 100037, China

Analyses of mineral inclusions within complexly zoned zircons, combined with SIMS U–Pb ages for various domains within the zircons, provide evidence of the origin and multistage metamorphic evolution of the Sanjiang complex, southeastern Tibetan Plateau. Metamorphic zircons with high-pressure (HP) mineral inclusions in paragneisses, amphibolites and garnet pyroxenites, suggest they are formed at 650–720°C and ~14 kb. These HP zircons yield U-Pb ages of 249–230 Ma, indicating an Early–Middle Triassic HP metamorphic event within the Sanjiang complex belt. Two groups of Eocene–Oligocene metamorphic zircons are also present. One of the groups comprises homogenous zircons contain medium-pressure (MP) amphibolite-granulite facies mineral inclusions in paragneisses, amphibolites, and marbles. These assemblages are stable at peak P–T conditions of 720°C–760°C and 8.0–9.6 kb, and yield consistent Eocene ages (44–36 Ma). The second group is homogeneous and all zircons contain distinct low-pressure (LP) mineral inclusions in paragneisses, amphibolites and garnet pyroxenites, and marbles, recording post-peak P–T conditions of 700°C –750°C and 5.0–6.5 kb, and yielding younger Oligocene metamorphic ages (32–25 Ma). $^{40}Ar/^{39}Ar$ analyses of biotite, muscovite, and amphibole yield the youngest ages (25–14 Ma, Miocene) related to late cooling during retrogressive metamorphism under conditions of 520°C–620°C and 4.0–4.5 kb. These new data suggest a clockwise P–T–t path for the Sanjiang metamorphic complex, typical of continent–continent collision, indicating collision–subduction tectonism prior to the strong, left-lateral, ductile deformation along the Ailao Shan–Red River (ASRR) shear zone that started at ~32 Ma and lasted until 25 Ma, causing mid-crustal (18–25 km depth) high-temperature metamorphic conditions. Continued uplift, and a slowing of left-lateral ductile shearing occurred at ~25–14 Ma at a depth of 10–15 km and under relatively low-temperature conditions. This temporal and kinematic link between left-lateral shearing along the ASRR and the opening of the South China Sea supports the occurrence of the block extrusion of Indochina from Eurasia along lithospheric-scale strike-up faults.

Oxidization of chalcopyrite Mediated by *Acidithiobacillus ferrooxidans* and secondary minerals

HUAN LIU[1*], XIANCAI LU[1], BINGJIE OUYANG[1], XIANGYU ZHU[1], JUAN LI[1] AND JIANJUN LU[1]

[1]School of Earth Sciences and Engineering, Nanjing University, Nanjing, China, huanliu.earth@gmail.com (* presenting author)

Chalcopyrite is one of the most abundant copper mineral. The microbial oxidization of chalcopyrite in mining wastes is an important pathway for the release of heavy metals into surrounding environments. We performed an bath experiment to disclose the mechanism of chalcopyrite- *Acidithiobacillus ferrooxidans* in this study.

A strain of *Acidithiobacillus ferrooxidans* isolated from acid mine drainage of Shizishan Cu-Au mineral deposit, eastern China, was used to interact with hand-selected chalcopyrite particles from sulfide ores in this study. *A. ferrooxidans* were inoculated into three flasks each contains 300 mL sterilized 9K culture with 17 mM Fe^{2+}. Other flasks with same volumetric 9K culture were control groups without inoculation. After reacting for 5 days, 10 days and 20 days, samples were extracted and lyophilized for SEM observation and spectral analysis (FTIR, XRD, Raman and XPS). STXM coupled with NEXAFS analyzed the distribution of Fe and Cu in/on the cell. As for the reacted solution, ICP-OES was employed to determine the concentrations of Cu and Fe, while Ion Chromatography (IC) to measure the contents of $S_2O_3^{2-}$, SO_3^{2-} and SO_4^{2-}.

The results reveal the enhancement of oxidation of chalcopyrite by microbial mediation. Surface etching attributed to the adhesion of the cells on chalcopyrite results in various pits on chalcopyrite surface. Jarosite and elemental sulfur were identified as main secondary minerals. The concentration of Cu in solution increased in the beginning reaction days and decreased a little subsequently because of adsorption onto and coprecipitation into Fe(III) sulfate minerals. Base on the depth profiles of XPS analysis of reacted chalcopyrite particles, detailed information of oxidization processes of Cu, Fe and S can be acquired. From the surface to the depth, the content of Fe(III) decreases and Fe(II) increases. S was presented as sulfate and sulfur in the surface, and contents of reduced states increase in the deep. According the variation of their chemical states, the chemical mechanism behind the microbial oxidation was discussed, which will highlight the study on bioleaching technology for the processing of low-grade copper sulfide ores.

Control of gypsum-salt rock on source rock and reservoir in the Dongpu depression of Bohai gulf basin, eastern China

JINGDONG LIU[1]* AND YOULU JIANG [2]

[1]Wuxi Research Institute of Petroleum Geology, SINOPEC, Wuxi 214151, China (*correspondence: ljd840911@126.com)

[2]School of Geosciences, China University of Petroleum, Qingdao 266555, China (upcjyl@126.com)

Source rocks and gypsum-salt rocks of Dongpu depression distribute alternately in vertical, overlay in horizontal, which have a symbiotic relationship[1,2]. The source rocks in gypsum-salt and sand-shale transition zone have the highest organic matter abundance, and the nearer the distance from gypsum-salt rocks, the higher organic matter abundance the source rocks have. Organic matter types of source rocks in gypsum-salt zone and transition zone are mainly typeI and type II1 Kerogen, while that in sand-shale zone are mainly type II1 and typeII2 Kerogen. For the role of high thermal conductivity of gypsum-salt rocks, source rocks in the upper part of which has shallower threshold depth for oil generation, and that in lower part has deeper threshold depth, thateffectively expand the scope of the hydrocarbon generation window.

Sandstone in Dongpu depression is interfingered with gypsum-salt rocks in space[1]. By the compactness and high thermal conductivity of gypsum-salt rocks, the porosity of sandstone in the lower part of gypsum-salt rocks has larger porosity than normal sediment stratums. By the carbonate cementation and gypsum and salt rock grain infiltration, the porosity of sandstone in the lower part of gypsum-salt rocks performs first increases and then decreases with increasing depth, and the maximum porosity appears within a certain distance in the lower part of the gypsum-salt rocks..

Age of the Kelameili ophiolite in Eastern Tianshan: LA-ICP-MS U-Pb zircon Dating

JUNFENG LIU* AND YONG LI

School of Earth Science and Resources, Chang an University, Xi'an 710054, China (*correspondence: junfengliu@chd.edu.cn)

Being an important complex unit along the Kelameili default, Kelameili ophiolite mainly consists of serpentinized peridotite, pyroxenite, gabbro and silicolite, etc. It is located between the eastern Junggar (the North) and a southward subduction zone beneath the eastern Tianshan; the latter is defined by the Harlik-Danahu arc in the eastern Qinling Mountains, West China [1,2].

Determining the time of the Kelameili opholite is very important for understanding the evolution of Eastern Tianshan area. Previous dating results however, range from late Devonian to early Permian, displaying a large span. That led to various models to reconstruct the Tianshan orogenic belt in early Paleozoic.

Here we show LA-ICP-MS dating results for single zircon grains of gabbro from the Kelameili ophiolite, which yield 352 ± 3Ma. Those zircon grains are small in size (30-100μm) and idiomorphic. Cathodoluminescence images show obvious magmatic oscillatory zoning. The U and Th concentrations vary from 30ppm to 278ppm, with high Th/U ratios (> 0.3), also suggesting their typical magmatic origins. The new-determined age definitely indicates that the gabbro from the Kelameili ophiolite was formed in the early Carboniferous, which gives a valid constrain on the formation of the Kelameili ophiolite.

This work is supported by the Fundamental Research Funds for the Central Universities (CHD2010JC042).

[1] Ma *et al*.. (1997) *House of Nanjing Univ*., 2, 25. [2] Xiao *et al*.. (2004) *J. Geol. Soc*., London, 161, 339-342.

Petrology, P–T–t path, and geotectonic significance of high-pressure mafic granulites from the Jiaobei terrane, North China Craton

PINGHUA LIU , FULAI LIU [1], FANG WANG, JIANHUI LIU, HONG YANG, JIA CAI AND JIANRONG SHI

Institute of Geology, Chinese Academy of Geological Sciences , Beijing 100037, China (lph1213@126.com)

High-pressure (HP) mafic granulites in the Jiaobei terrane are composed predominantly of garnet–bearing mafic granulites, garnent–hypersthene granulites, and garnet amphibolites, and they are found as irregular lenses or deformed parallel dykes within tonalitic–trondhjemitic–granodioritic gneisses or granitic gneisses. The HP mafic granulites cantain four distinct metamorphic assemblages of which the early prograde assemblage (M_1) is represented by the cores of garnets, together with mineral inclusions of clinopyxene + plagioclase ± quartz, and it formed at 740–770 °C and 0.90–1.00 GPa. In contrast, the peak assemblage (M_2) consists of high-Ca cores in garnet, high-Al cores in clinopyroxene, and high-Na cores plagioclase in the matrix, which formed under P–T conditions of 850–880 °C and 1.45–1.65 GPa. The peak metamorphism was followed by near-isothermal decompression (M_3), which resulted in the development of orthopyroxene + clinopyxene + plagioclase ± quartz ± amphibole ± magneitite symplectites or coronas surrounding some garnet grains with P–T conditions of 780–830 °C and 0.65–0.85 GPa. Surrounding some garnet grains are symplectites of amphibole + plagioclase + quartz ±magneitite, which formed during a cooling retrograde stage (M_4) with P–T conditions of 590–650 °C and 0.62–0.82 GPa.. The combination of petrography, mineral compositions, metamorphic reaction history, thermobarometry, and geochronology defines a near-isothermal decompressional clockwise P–T path for the Jiaobei HP mafic granulites, suggesting that the Jiaobei terrane underwent initial crustal thickening, followed by relatively rapid exhumation, cooling, and retrogression. This tectonothermal path was probably generated by subduction and collision-related tectonic processes.

Iron isotope systematics of the Baima magmatic Fe-Ti-(V) oxide deposit, SW China

PING-PING LIU[1], MEI-FU ZHOU[2], BÉATRICE LUAIS[3], DAMIEN CIVIDINI[4] AND CLAIRE ROLLION-BARD[5]

[1]The University of Hong Kong, Hong Kong, China, liupp@hku.hk
[2]The Univeristy of Hong Kong, Hong Kong, China, mfzhou@hkucc.hku.hk
[3]CRPG, Nancy, France, luais@crpg.cnrs-nancy.fr
[4]CRPG, Nancy, France, cividini@crpg.cnrs-nancy.fr
[5]CRPG, Nancy, France, rollion@crpg.cnrs-nancy.fr

The Baima oxide-bearing mafic-ultramafic layered intrusion, SW China, provides an excellent opportunity to examine the controls of high temperature fractionation of Fe isotopes. The intrusion consists of a Lower zone of net-textured and disseminated oxide ores, a Middle zone of olivine gabbro and an Upper zone of gabbro. Fe isotopes (IRMM-014-normalized) have been measured by high- resolution MC-ICPMS (Neptune *Plus*) at the CRPG-Nancy, with a 2 sigma reproducibity of ≤ 0.08‰ [1]. Olivine has δ^{56}Fe values ranging from -0.01 to +0.11‰, clinopyroxene from +0.11 to +0.22‰ and titanomagnetite from +0.20 to +0.51‰. In $\delta^{56}Fe_{Cpx}$-$\delta^{56}Fe_{Ol}$ diagram, Baima samples plot on the primitive mantle end member of the mantle metasomatism trend, indicating the parental magma of the Baima intrusion is the partial melting equivalent of the mantle rocks. Fe isotopes of titanomagnetite-clinopyroxene and titanomagnetite-olivine pairs do not display linear correlations, strongly against simple fractional crystallization model.

Positive correlations of whole-rock TFe_2O_3 vs. δ^{56}Fe values of olivine, roughly constant δ^{56}Fe values of titanomagnetite from net-textured and disseminated oxide ores and an abrupt break of TFe_2O_3 content and $\delta^{56}Fe_{Mt}$ between oxide ores and mafic rocks would indicate that mechanisms for the Fe-Ti oxide ore genesis depend on the oxidation state of the magma chamber. Oxygen fugacity variations inferred from V contents of titanomagnetite indicate that the crystallization of low δ^{56}Fe titanomagnetite occurred firstly from a high fO_2 liquid, followed by the fO_2 dropped to the lowest with crystallisation of high δ^{56}Fe titanomagnetite on olivine gabbro and gabbro .

These results indicate the strong control of redox state of the magma on Fe isotopic signatures.

Anharmonic effects of equilibrium clumped isotope signatures for H_2O, H_2S, SO_2, NH_3 and CH_4

QI LIU AND YUN LIU*

Institute of Geochemistry, Chinese Academy of Sciences (*correspondence: liuyun@vip.gyig.ac.cn)

Geological application of clumped isotope techniques has been broadened, but the studied objects mainly remain CO_2, or O_2. There is an urgent need to include other species into the inventory of clumped isotope geochemistry. In this study, we provide equilibrium Δ_i values of several common gaseous molecules which can be potential targets for the clumped isotope study in future. For improving the calculation accuracy, theoretical treaments beyond the harmonic level by including several higher-order corrections to the Bigeleisen-Mayer equation are used. We have evaluated contributions from many higher-order corrections (e.g., AnZPE, AnEXC, VrZPE, VrEXC, QmCorr and CenDist) to calculate the anharmonic effects of vibration, vibration-rotation coupling, quantum mechanics and centrifugal distortion for rotation, etc., which are ignored in the Bigeleisen-Mayer equation for the calculation of reduced partition function ratios. All calculations are performed at MP2/aug-cc-pVTZ level and no frequency scale factor has been used. The computational details of these higher-order corrections can be found in [1].

Our results provide detailed temperature dependencies of clumped isotope signatures of those molecules. We also find AnZPE is the most significant correction at room temperature. VrZPE plays second important role at room temperature, but may contribute equally important to AnZPE at higher temperature. Other corrections can contribute a little only if hydrogen atom is involved. With the increase of temperature, contributions of AnEXC, VrEXC and CenDist will become larger; contributions from AnZPE and QmCorr will become smaller. Our results suggest anharmonic corrections can significantly improve the estimation of clumped isotope signatures especially when hydrogen atom is in the clumps (e.g., H_2O, H_2S, NH_3 and CH_4). Higher-order anharmonic corrections are therefore recommended to the theoretical study of clumped isotope fractionations.

[6]Department of Applied Geology, Curtin University, Perth, Australia
[7]ESRF, Grenoble, France

Gold transport and deposition in hydrothermal ore fluids is dependent on the identity and stability of predominating aqueous gold complexes. Gold(I) bisulfide (e.g., $Au(HS)_2^-$) and in some instances Au(I) chloride complexes are widely acknowledged to account for Au transport in ore fluids.

This study investigates the potential of the unconventional ligands Br^- and NH_3 to increase Au mobility. This was achieved by determining the predominant Au species in hydrothermal fluids with binary mixed ligands (Br^- - Cl^-, Br^- - HS^-, HS^- - NH_3), and measuring their structural properties using in situ Synchrotron X-ray Absorption Spectroscopy (XAS). The capacity of XAS to follow the progress of ligand exchange reactions was demonstrated at room temperature, where the $Au(III)Br_4^-$ complex was found to predominate in mixed Br^-/Cl^- solutions (Br^-/Cl^- = 0.1-1), with average ligand numbers derived from XAS in good agreement with a recent UV-Vis study (Usher *et al*.., 2009, Geochim. Cosmochim. Acta 73, 3359-3380). At temperatures up to 400 ºC and at 600 bar, the XAS measurements show that Au(I) – HS^- complexes are the only stable Au species in mixed HS^-/Br^- and HS^-/NH_3 fluids (HS^-/Br^- = 0.1; HS^-/NH_3 = 0.2), indicating that hydrosulfide is the most important ligand for Au transport in the hydrothermal fluid under our experimental conditions, i.e., hydrosulfide complexes outcompete bromide and ammine complexes in S-bearing fluids. These results are comparable to solubility and speciation calculations based on the available thermodynamic data.

Li isotope geochemical study on weathering of granite in Longnan, Jiangxi Province, South China

W.J. LIU[1], C.Q. LIU[12*], Z.Q. ZHAO[2], T. ZHAO[1], Z.F. XU[1], T.Z. LIU[2] AND L. HUANG[2]

[2] Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, 550002, China

Li isotope has been newly demonstrated to be a powerful tool in studying silicate weathering in a weathering profile, catchment, and even continental scale. In this study, we focus on variation in Li isotope geochemical features along soil and weathering profiles of three sites along a mountain ridge slope, which was developed on granite in Longnan, Jiangxi Province, South China. The studied profiles include JLN-S4 (mountain top, 120 cm deep soil profile); JLN-S3 (middle slope, 120 cm deep soil profile); and JLN-S1 (valley floor, about 1100 cm deep weathering profile). Li content and δ^7Li of bulk samples, along with major element composition and CIA (chemical index of alteration) values of the bulk samples from weathering and soil profiles were determined.

JLN-S4 profile samples have CIA values between 97.63 and 98.32,with δ^7Li values from -2.50‰ to -3.90‰; JLN-S3 profile samples have CIA values varing from 94.42 to 96.12 and δ^7Li values from -0.73‰ to -1.55‰; The weathering profile JLN-S1 at valley floor has a generally descending CIA values (57.77~92.44) with increasing depth. Its δ^7Li values vary with CIA, showing a two stage relationship: persistent increase from -14.92‰ to 0.66‰ when CIA increasing from 57.77 to 74.56, and δ^7Li variation in a range of -4.74~3.62‰, with no obvious relationship with CIA change. Li contents in JLN-S4 vary between 3.84 and 15.03 μg/g, in JLN-S3 between 1.43~8.03 μg/g, and in JLN-S1 between 6.95~22.27 μg/g. In JLN-S1, Li contents decrease with increasing CIA (57.77~74.56), no regular tendency in Li abundance was observed in samples with higher CIA values. Two granite bedrock samples have δ^7Li value of -0.23 and 0.39‰, Li abundances of 38.58 and 34.22μg/g, respectively.

The Li isotope geochemical features of the profiles in this study indicate that Li isotope behavior was dominantly determined by weathering extent during incipient weathering of granite, while much complicated factors, such as mineral phases, adsorption and desorption of different clay minerals control Li isotope geochemical features as weathering and pedogenesis progressing.

pH-Eh diagram of ore-forming elements from first principles molecular dynamics simulations

XIANDONG LIU[12], MICHIEL SPRIK[2], JUN CHENG[2], XIANCAI LU[1] AND RUCHENG WANG[1]

[1] State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093, P. R. China

[2] Department of Chemistry, University of Cambridge, Cambridge CB2 1EW, United Kingdom

pH-Eh diagram maps out the stable species of an aqueous elecrochemical system with respect to the activity of proton and electron under a certain T-P condition. Such diagram presents the fundamental properties of aqueous species, which is very useful for understanding numerous natural processes, such as transport and enrichment of elements. Research of aqueous speciation has heavily relied on solubility experiments and related thermodynamics calculations. Due to the experimental difficulty in high T-P conditions, first principles molecular dynamics (FPMD) simulations have been attracting more and more attentions.

FPMD based vertical energy gap method was an advanced technique developed recently by our group (Adriaanse *et al*.., 2012; Costanzo *et al*.., 2011), which combines electronic structure calculation, MD and free energy perturbation theory. With this method, one can evaluate the ingredients for making pH-Eh diagrams of aqueous complexes: acidity (p*K*a) and redox potential (pE). In this presentation, we will show the results of important ore-forming elements. The p*K*a case studies include H_2S_n/HS_n^-, Zn^{2+} and Cu^{2+}. The calculated redox couples are Cu^+/Cu^{2+} and Fe^{2+}/Fe^{3+}. Comparisons between the calculated and experimental values indicate a reasonable accuracy. Origins of the error such as density functionals and finite size effects will be discussed.

Roles of NH_4NO_3 and secondary organics in growing > 10 nm new particles to cloud condensation nuclei size in marine atmosphere

XIAOHUAN LIU, YUJIAO, ZHU, HE MENG, GAO HUIWANG AND YAO XIAOHONG

[1] Key Laboratory of Marine Environment and Ecology, Ministry of Education of China, Ocean University of China, Qingdao 266100, China

A Fast Mobility Particle Sizer was used to investigate new particle formation events over the marginal Sea in China during two cruise experiments in the falls of 2010 and 2011. New particles cannot grow over 30 nm in three out of four new particle formation events in 2010. The air quality modeling results showed that formation of secondary organics (SO) occurred through the events, formation of NH_4NO_3 was thermodynamically forbidden. SO was likely the major contributor to the growth of > 10 nm new particles. In one event, new particles grew over 50 nm (the threshold of particle acting as cloud condensation nuclei (CCN)) and the modeling results showed formation of NH_4NO_3 and SO being concurrently with the growth of > 10 nm new particles. However, the formation rate of SO in the event was significantly less than that in one out of the three events. Formation of NH_4NO_3 was proably the key factor in growing > 30 nm new particles to CCN size and formation of SO may play an important role in growing particles <30 nm. In 2011, a regional nucleation event was observed in the marine and coastal atmosphere and formation of NH_4NO_3 was identified from the modeling and was probably the key factor in growing > 30 nm new particles to CCN size.

Analyses of temporal and geographic distributions of the minerals of beryllium, boron, copper, mercury, and molybdenum reveal episodic deposition and diversification [*1-4*]. We observe statistically significant increases in the number of reported mineral localities and/or the appearance of new mineral species at ~2.85-2.6, ~1.95-1.80, ~1.10-0.90, ~0.60-0.50, and ~0.43-0.25 Ga—intervals that correlate with presumed episodes of supercontinent assembly and associated collisional orogenies of Kenorland (Superia), Columbia (Nuna), Rodinia, Godwana (Pannotia), and Pangea, respectively. In constrast, few deposits or new mineral species containing these elements have been reported from the intervals of supercontinent stability and breakup at ~2.5-1.9, ~1.8-1.2, 0.9-0.6, and 0.50-0.43 Ga. Variations in the details of these trends may reveal changing near-surface environments, including those associated with ocean chemistry and biological influences. For example, no mercury mineral localities or new Hg minerals are documented from 1.8-0.6 Ga. By contrast, we observe pulses of 14 new beryllium minerals associated with peralkaline complexes in southwest Greenland at 1.16 and 1.27 Ga.

[3]Key Lab of Western China's Min Resourses and Geological Engineering, Ministry of Education, Xi'an 710054,China

The gold deposit is on the north hillside of Xiong'er mountain in Luoning county, Henan province. which belongs to in the southern margin of north China platform. Taihua mountain group in Archaeozoic is crystalline basement, both Xiong'er mountain group and Nantianmen mountain group are sedimentary cover. Glided detachment faults formed between them.Super-Thin alteration-type gold deposit mainly distributed in the glided detachment tectonic zone. Metallogenic period is Yanshanian, and the characteristics of single ore veins are generally small in size, thin thickness and high grade.Generally they appear in groups. The formation of gold deposit closely connected with the detachment tectonic. The main metallogenic activities are controlled of the detachment faults' three cycle:1. The stage of thrust napping structure from north to south. The crust in the southern margin of north China platform was under the intensively constringent environment, developed a series of large scale overlap thrust napping structure and arose acidic magma's activity, at the same time,the thickness of crust became thicker, mantle material with high temperature and low density formed in upper mantle, they transported in the plastic state and arched up along upper mantle and lower crust;2. NS tensional rifting stage. The crust was on the tension releasing stage, the early thrust napping structure system and compressive detachment fault obtained a little tensional stress, brittle ductile occurred on the superficial crust. Mantle-derived mineral upwelling slowly along the detachment fault and secondary ore-transmitting structure. Thus large and super-large golden deposit Formed in PDZ (Principal displacement zone) , such as Kangshan, Hongzhuang and Shanggong golden deposits etc ; 3. WE thrust shear stage. At this stage brittle ductile broke and the crust shrank. Relative to superficial crust, pressure became bigger and temperature higher in the deep crust. Mantle-derived mineral accumulated rapidly along the gradient zone of pressure and temperature. At the same time, under the effect of atmospheric precipitation and retrograde metamorphism on the superficial crust, Ore mineral rapidly migrated, enriched, mineralized, and finally formed super-thin alteration-type gold deposit, such as Tantou, Nanping and Luyuan-Gou gold deposits, etc. This research is financially supported by the special Fund Basic Scientific Research of Central Colleges and the Special Fund of Basic Research Support Program of Chang'an University (Grant No.CHD2009JC159).

The heavy oil accumulation characteristics and exploration potential of Orinoco heavy oil belt in East Venezuela Basin

LIU YA MING

Research Institute of Petroleum Exploration and Development, Petrochina, Beijing, China
(*correspondence: liuyaming-hw@petrochina.com.cn)

The parte knowledge of no exploration needed in Orinoco heavy oil belt is popular. In fact its resource isn't distributed omnipresent, and the accumulation recognition need to be enhanced. Based on the theory of hydrocarbon accumulation, the heavy oil accumulation conditions and characteristics of Orinoco heavy oil belt are analyzed, and the exploration direction is pointed out in this paper.

Orinoco heavy oil belt is located in the foreland slope region with weak structural affection. The main source rocks are the neritic mudstone of upper Cretaceous Guayuta group, with a thickness of more than 500m, rich in organic matter (TOC weight of 0.25-6.6%)and high hydrocarbon potential. The main reservoirs are the Delta sandstones of Oficina formation in Miocene and the Merecure formation in Oligocene, sandstones distributed widely in the shape of sheet, reservoir thickness keep stable on the east-west direction, and thinning to the south gradually. The reservoir capability is excellent for shallow burial(200-2000m, average of 900m), high porosity(10-32%, average of 21%), and high permeability(20-5000mD, average of 430mD). The regional shale, intrabed shale, bitumen and underlying basement are sealing layers. The main trap type are lithologic stratigraphic traps. Faults, unconformities and connective sandstones formed excellent combination of oil migration pathways. biodegration occured during the long distance migration (50-200km) period in the late Miocene and main accumulation period in the Pliocene-Pleistocene are the main viscosifying factors. The gas chromatography analysis of saturated hydrocarbon components (C10+) of heavy oil from many samples showed the n-paraffins and isoprenoid have different degrees of consumption due to high level of biodegradation.

The accumulation model is long distance migration biodegradation and concentrated shallow burial. Source rocks, migration pathways and viscosifying mechnism controlled the heavy oil accumulation. The western part, the Oficina formation and stratigraphic related traps are the key points for exploration.

Stable isotope analysis of carbonates using Isoprime MultiFlow-IRMS

YAN LIU [12], JINCAI TUO[1*], CHENJUN WU[2] AND D RU CHEN[2]

[1] Key Laboratory of Petroleum Resources Research Institute of Geology and Geophysics Chinese Academy of Science Lanzhou, 730000, China (correspondence:jctuo@lzb.ac.cn)

[2] Graduate School of the Chinese Academy of Science, Beijing, 100039, China (yanliu@lzb.ac.cn)

Isoprime MultiFlow is the pretreatment device which can connect with Isoprime 100 (IRMS) for carbonates analysis. We found that the $\delta^{18}O$ values decreased when the CO_2 sample peaks increased higher in our experiments. The empirical linear regression of the $\delta^{18}O$ value was a function of the CO_2 quantity, which was useful to correct the deviation caused by the decreasing trend of $\delta^{18}O$ value. In addition, we tested the analysis linearity of IRMS and the fractionation of other interfaces. The results showed that the temperature of GC column in MultiFlow was significant factor for the variation of $\delta^{18}O$ value. Although the user guide recommended that 100°C was a sufficient setting for separating the gas species of interest, we found that 60°C for GC column was better to adjust the decreasing of $\delta^{18}O$ value. We inferred that the high temperature would cause the oxygen isotope exchange between CO_2 and the filler inside the GC column.

Fluid electrolytes of Mohailaheng Pb-Zn deposit in Tibetan plateau

YINGCHAO LIU [1], ZENGQIAN HOU [1], ZHUSEN YANG[2] AND SHIHONG TIAN [2]

[1]Institute of Geology, CAGS, Beijing 100037, China (lychappy@126.com)
[2]Institute of Mineral Resources,CAGS,Beijing 100037, China

The Mohailaheng deposit, located in the north eastern margin of Tibetan collisional orogen, is a MVT-like Pb-Zn deposit controlled by thrust nappe structures [1] in the 'Sanjiang' metallogenic belt. Ore bodies in this deposit are stratabound and hosted by Early Carboniferous limestone in the hanging wall of a Cenozoic thrust fault system. Five mineralization stages are recognized, including minerals such as sphalerite, galena, dolomite, barite, calcite and fluorite.

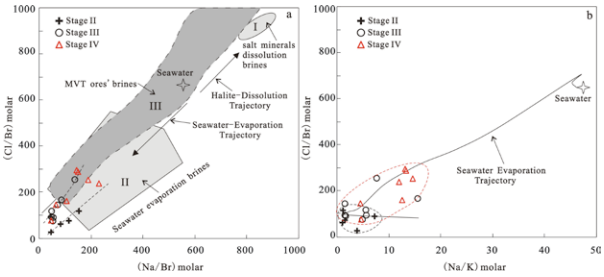

Fig.1 Binary plots of fluid inclusion electrolytes from the Mohailaheng deposit. (The field of I form [2], of II from [3], and of III from [4]. Seawater evaporation curves from [5].)

The solute compositions of ore-forming brines for the Mohailaheng deposit were measured from bulk extraction of fluid inclusions in barite, calcite and fluorite in different mineralization Stages. The Cl/Br and Na/Br molar of the solutes plot close to seawater evaporation line (Fig. 1a) and constrain the source of the ore-forming brine to evaporate seawater. Some Cl/Br and Na/K plot along but slightly above the seawater evaporation line (Fig. 1b) indicating seawater was evaporated beyond halite saturation. Some data in Fig. 1a plot in the compositional field for MVT basinal brines suggesting they all share a common origin. Other data out of MVT field in Fig. 1a may indicate other origins such as regional metamorphic fluid suggesting by microthermal work.

This work was supported by grants (Contract No. 2009CB421007, 2011CB403104 and J1314).

Boron isotopic composition in *Arctica islandica* shell: a potential historical, prehistorical and geological seawater pH indicator

YI-WEI LIU[1*], SARAH M. ACIEGO[1], ALAN D. AND WANAMAKER JR.[2]

[1] Earth and Environmental Sciences, University of Michigan, 1100 N. University Avenue, Ann Arbor, MI 48109, USA (*correspondence: liuyiwei@umich.edu; aciego@umich.edu)
[2] Department of Geological and Atmospheric Sciences, Iowa State University, Room 12, Science I, Ames, IA 50011-3212, USA (adw@iastate.edu)

Research on the ocean carbon cycle is vitally important due to the projected impacts of atmospheric CO_2 on global temperatures and climate change, but also on ocean chemistry. The actual influence of this CO_2 rise on the pH of North Atlantic seawater is largely unknown because of the dearth of instrumental records or reliable proxies. The long-lived bivalve mollusk *A. islandica*, common in the shelf seas of the temperate to sub-polar North Atlantic, is an excellent high-resolution marine archive with great potential for monitoring pH as well as other seawater properties. Boron isotopic composition ($\delta^{11}B$) in aragonite biogenic carbonate has been suggested to trace ambient seawater pH because marine carbonates will primarily incorporate $B(OH)_4^-$ into the carbonate structure during growth, in which the $\delta^{11}B$ is pH dependent. Here we aim to develop a $\delta^{11}B$ -pH transfer function in *A. islandica* to reconstruct mid to high latitude seawater pH record. An improved rapid throughput microsublimation technique coupled with Total Evaporation NTIMS method was conducted so that <1 ng boron could be measured. Reproducibility of boron isotopic composition of better than ±0.3‰ (2SE, n > 10) was achieved for a variety of isotopic standards and natural samples. We analyzed boron isotopic composition in the living shells reared at the Darling Marine Center, Maine, USA in which seawater temperature, salinity and pH were carefully monitored. During the experimental period (January 2010 to August 2010), the temperature raised from 2 to 18°C, with a 3 ppt salinity variation and a 0.2 pH unit change. Our pilot data suggest the the $\delta^{11}B$ value reflects the ambient seawater pH. This study will form the basis for reconstructing high-resolution seawater pH in the mid to high latitudes of the Atlantic Ocean through the living and fossil history of *A. islandica*.

On the test of a new volume variable cluster model method for stable isotope fractionation of solids: Equilibrium Mg isotope fractionations between minerals and solutions

YUN LIU

State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, China. (Liuyun@vip.gyig.ac.cn)

There is a tremendous interest in developing a cluster-model-based method of isotope fractionation calculation for solids because most of new techniques developed in modern quantum chemistry are for molecules which usually are represented by cluster models. The reason we developed this method is to remedy problems raised from a similar method used by Rustad and co-workers (e.g.,[1]), especially to enhance its implementation on isotope fractionation calculations between solids and aqueous species.

For the test of this so-called volume variable cluster model method (VVCM), we estimated Mg isotope fractionations between various silicate and carbonate minerals. We also study the Mg isotope fractionations between minerals and solutions. These cases usually are thought as the confusing part for isotope fractionation calculations because large disagreements exist among different theoretical groups (e.g., [1] and [2]).

Our results are very close to existing Mg and O isotope experimental data. Especially, for those mineral vs. solution cases, our results are better than previous theoretical estimations, suggesting very useful applications of this method in future.

4)Shunan Gas District of Southwest Oil and Gas Company , PetroChina,Luzhou,Sichuan,646000,China. snyangyang@ petrochina.com.cn

A Microbial mud mound in the Middle Permian Qixia Fm. in Sichuan basin,is first found.This mud mound is belong to Waulsortion ,and supported by mud,the primary builder is fungi.The species diversity is low,high species richness.The main lithology including bioclastic micritic limestone and Thrombolite.The Mud mound can be divided into mound-core,mound-flank,mound-base. Through a multidisciplinary approach, including carbonate petrology and geochemistry of the mud mound and unmound, we reconstruct the development history of the Microbial mud mound and characterize the formation and the evolution of the eastern portions of Sichuan basin. The results of geochemical analysis of the Qixia Fm. shows: all of the paleosalinity Z value greater than 122, $\delta^{13}C$ compositions range from 1.84‰ to 4.58‰(VPDB); δ18O compositions range from -6.33‰ to -4.42‰(VPDB);the Ancient water temperature values compositions range from 33.60℃ to 24.26℃;V/（V+Ni）values compositions range from 0.51228 to 0.77795. It shows that the environment of Qixia period were relatively deep water, hydrodynamic weaker, higher temperature, high salinity and anoxic. According to geochemical analysis,the Microbial mud mound growth environment is low dissolved oxygen content, the higher water temperature and the salinity is higher. After it dead,the water temperature are reduced and salinity began to increase which became a stable super salty hypoxia environment.

Origin and implications of $^{238}U/^{235}U$ variations in CAIs

B. D. LIVERMORE[1], J. N. CONNELLY[1] AND M. BIZZARRO[1]

[1]Centre for Star and Planet Formation, Natural History Museum of Denmark, University of Copenhagen, Copenhagen 1350 DK. Email: bettina@livermore.dk

Calcium-aluminum rich inclusions (CAIs) are submillimeter- to centimeter-sized inclusions that condensed from gas in the hot, inner region of protoplanetary disk and are a major constituent of carbonaceous chondrites. Believed to be the first formed solids in our Solar System, they have been a prime target for absolute Pb-Pb geochronology to establish the age of the Solar System [eg. 1] as well as a time anchor for several relative chronometers. It is now known that CAIs display significant variations in their $^{238}U/^{235}U$ ratio [2], a critical parameter in all Pb/Pb age calculations. Whereas this variation was first attributed to the decay of the short-lived radionuclide ^{247}Cm to ^{235}U [2], it is likely at least part of this variation is due to mass dependant fractionation that occurred during the CAI forming process [1]. Therefore, beyond the importance of this ratio for geochronology, understanding the origin of uranium isotopic variations in CAIs may offer insights into CAI forming processes and conditions.

Ten large CAIs have been selected for this study from the pristine carbonaceous chondrite (CV3) NWA 3118 [3], all with sizes large enough for accurate determination of their $^{238}U/^{235}U$ ratios. The sample has been cut dry into 3 mm slabs using a diamond wire saw and CAIs selected on the basis of their size have been imaged using a scanning electron microscope. Using the procedure of [1], U is separated from the samples and measured by HR-MC-ICP-MS using a Thermo-Fisher Neptune Plus. To determine the degree of mass-dependent isotope fractionation experienced by individual inclusions, stable Mg and Nd isotope composition are measured for each CAI and compared to the uranium isotopic ratios. Correlations between the Mg, Nd and U isotope ratios will support a model of mass-dependent fraction of U to explain the isotopic variations observed in CAIs from CV chondrites. A lack of correlation will support ^{247}Cm as the primary cause of U isotopic varibility. In addition, the CAIs measured for U isotopes will also be dated using the Pb-Pb system based on the Pb step-wise dissolution procedure by [1].

The relationship of goethite surface structure, habit and adsorption capacity

K.J.T. LIVI[1], M. VILLALOBOS[2], M. VARELA[3], M. VILLACÍS-GARCÍA[2], K. VACA-ESCOBAR[2] AND D. A. SVERJENSKY[4]

[1]HRAEM Facility, Dept. of Earth and Planetary Sciences, Johns Hopkins University, Baltimore, MD 21218 USA
[2] Environmental Bio-Geochemistry Group, Geochemistry Dept. Geology Inst., UNAM, CU México 04510, D.F.
[3]Oak Ridge National Laboratory, Oak Ridge TN 37831 USA
[4]Dept. of Earth and Planetary Sciences, Johns Hopkins University, Baltimore, MD 21218 USA

It is well established that the adsorption capacity of goethite (α-FeOOH) per m^2 increases significantly with decreasing specific surface area (SSA, determined by N_2-adsorption). For example, the adsorption of chromate increases three-fold as SSA decreases from 94 to 50 $m^2.g^{-1}$ [1]. This has led to recent explanations postulating the possible roles of different faces with different surface site densities and affinities [1-3]. The current model assumes that small particles with SSA > 80 m^2/g are "ideal" prismatic crystals elongated parallel to the **b**-axis (Pnma setting) with {101} and/or {001} forms [4]. It is assumed that the more reactive goethites, which have larger particles and SSA < 80 m^2/g, may have different crystal face distributions to the "ideal" crystals.

We report electron microscopy observations on a suite of synthetic goethites with SSA ranging from 40 to 100 $m^2.g^{-1}$. Transmission Electron Microscopy (TEM) confirms that the crystals are well-formed elongate blades: the 40 $m^2.g^{-1}$ and the 100 $m^2.g^{-1}$ crystals have length modes of about 1 μm and 100 nm, respectively. The 40 $m^2.g^{-1}$ sample has single-domain crystals elongated parallel to the **b**-axis as expected. However, the 100 $m^2.g^{-1}$ sample contains numerous crystals that have mosaic-domain structure and are instead elongated parallel to the [610] direction. Atomic-Resolution Scanning TEM analysis of the steps on the long edges of two crystals of the 40 $m^2.g^{-1}$ sample revealed only 66% terraces parallel to either {001} or {101} forms and 33% parallel to {210}. In contrast, steps on two crystals of the 100 $m^2.g^{-1}$ sample with [610] habit were 96% {210}-type and 4% {110}. The change in habit and increase in {210}-type steps in high SSA samples, although surprising, must now be taken into account in assessing the adsorption behavior of goethites.

Ferruginous (anoxic and iron-rich) conditions dominated ocean chemistry throughout much of the first 3.5 billion years of Earth history. Modern ferruginous water masses are rare, but detailed examination of these oddities, especially of photoferrotrophs and their Fe-reducing respiratory counterparts, could yield important insights into the early evolution of life on Earth. Here, we report pelagic photoferrotrophs from Kabuno Bay, DR Congo. Based on 16S rDNA, the Kabuno Bay photoferrotrophs are similar to laboratory cultures of *Chlorobium ferrooxidans*, the only member of the Chlorobi previously known to conduct photoferrotrophy. Photoferrotrophs comprised up to 38.3%, of the total microbial communinty and exhibited high rates of phototrophic ferrous Fe oxidation. Up to 60% of total depth integrated bacterial production was carried out at depths where photoferrotrophic GSB dominate. Microbial groups involved in methanogenesis and Fe-reduction also comprised large fractions of the microbial community within depth intervals domminated by photoferrtrophs. Microorganisms typically implicated in the sulfur cycle were only present at low relative abundances, and this is consitent with low measured rates of sulfate reduction and sulfide oxidation. Our findings in Kabuno Bay support models for early ocean ecosytems with primary production driven by photoferrotrophy and organic matter degradation channeled through both Fe-reduction and methanogenesis.

A meta-analysis reveals biases in methods to quantify marine microorganisms

KAREN G. LLOYD[1], MEGAN MAY[2], RICHARD KEVORKIAN[1] AND ANDREW D. STEEN[1]

[1]University of Tennessee, Knoxville, TN, USA
[2]Depauw University, Depauw, Greencastle, IN, USA

There is no universally-accepted method for quantifying specific microbial taxa in the marine subsurface, but this is a crucial first step in any analysis of sedimentary microbial ecology. The two most common methods are fluorescent in situ hybridization (FISH), often with catalyzed reporter deposition (CARD-FISH), and quantitative PCR (qPCR). We compiled sediment cell quantifications from published papers and defined yield as the sum of bacterial and archaeal FISH/CARD-FISH counts divided by total cell counts. We found that permeabilization with proteinase K results in higher yield, as well as higher percent archaea, than permeabilization with lysozyme or other methods, which may be explained by the fact that lysozyme hydrolyses peptidoglycan, which does not exist in archaeal cell walls. Studies in which the absence or near-absence of archaeal CARD-FISH signals have been used to argue for the dominance of bacterial activity in the deep subsurface (e.g. [1], [2]) used lysozyme, suggesting that the low abundance of Archaea in those studies may be artifactual. The ratio of qPCR-determined 16s rDNA copy numbers to directly-counted cells is highly variable, and is often outside of physiologically reasonable range of 1-10, suggesting that qPCR does not provide absolute quantification of specific taxa.

Improved multi-ion-counting capabilities for high sensitivity U-Pb LA-MC-ICP-MS zircon geochronology

N. S. LLOYD [1*] AND C. BOUMAN [1]

[1] Thermo Fisher Scientific, Bremen, Germany. (*correspondence: nicholas.lloyd@thermofisher.com)

The Thermo Scientific NEPTUNE *Plus* with Jet Interface option has been shown to significantly enhance LA-MC-ICP-MS sensitivity for hafnium isotope ratio analyses [1, 2], allowing precise and accurate Hf ratios to be determined from 25 μm diameter laser ablation spots (within 100 ppm 2RSD). The high sensitivity Jet and X-cones have also been used to enhance Hf isotope ratio sensitivity on a NEPTUNE *Plus*, whilst U-Pb ratios were analysed from a split flow to a Thermo Scientific ELEMENT XR [3].

In this poster we present U-Pb data from the NEPTUNE *Plus* with Jet Interface option. The sensitivity enhancement can be used to collect U-Pb ratios on Faraday cups from larger ablation spots, or for small spot sizes using multi-ion-counting. We use an array of new Compact Discrete Dynode (CDD) electron multipliers in combination with classical large-scale Secondary Electron Multipliers (SEM). The new CDDs have the same performance characteristics as the classical SEMs used in the NEPTUNE *Plus* and TRITON *Plus*.

The multi-ion-counting package allows for simultaneous analysis of ^{202}Hg, ^{204}Pb, ^{206}Pb, ^{207}Pb, ^{208}Pb and ^{238}U on the electron multipliers. If desired, also ^{232}Th and ^{235}U can be detected along on additional CDD multipliers. The detector catching ^{206}Pb is a dual detector; ^{206}Pb can be detected in either an SEM or Faraday. This setup gives full flexibility for the analysis of zircons, where ^{206}Pb is the most abundant Pb isotope.

This contribution will present U-Pb data on zircon standards as well as analytical and instrumental challenges relating to the laser ablation process, the plasma interface and the multi-ion-counting detectors will be discussed.

Arsenic release from red mud affected soil-water systems

CINDY L. LOCKWOOD[1*]; ROBERT J. G. MORTIMER[1]; DOUGLAS I. STEWART[2]; WILLIAM M. MAYES[3] AND IAN T. BURKE[1]

[1]School of Earth and Environment, University of Leeds, LS2 9JT, UK(*correspondence: ee09cll@leeds.ac.uk)

[2]School of Civil Engineering, University of Leeds, LS2 9JT, UK

[3]Centre for Environmental and Marine Sciences, University of Hull, Scarborough, YO11 3AZ, UK

Red mud is a highly alkaline waste product from bauxite ore processing. It contains elevated concentrations of several oxyanion forming elements such as Al, As, V and Mo that are mobilised at high pH. The tailings dam breach at Ajka, western Hungary, released ~1 million m^3 of toxic red mud into the Torna and upper Marcal valleys. As part of the initial clean-up, some thinner red mud deposits (< 5 cm) were ploughed into fields to prevent dust formation and some wetland areas were left untreated.

We used anaerobic microcosm experiments to determine the mechanisms of As release from red mud mixed with uncontaminated soils. Soils from unaffected locations in the Torna and upper Marcal valleys were mixed with Ajka red mud at two different ratios (9 % and 33 % red mud), with soil only incubations as controls. XAS spectroscopy and HPLC-ICP-MS was used to determine changes in As oxidation state.

After 180 days the water in soil-only control microcosms contained ~ 200 μg L^{-1} As, of which ~50% had been converted to As(III) as a result of microbial As(V) reduction. However, dissolved As concentrations in red mud effected systems reached only 100 μg L^{-1} after a similar time period, all as As(V), despite microbial Fe(III)-reduction being observed. When red mud is added to soils there is an initial rapid increase in dissolved As concentrations that correlates with microcosm pH. However, concentrations at equilibrium are independent of both microcosm pH and red mud loading and are ultimately controlled by the dissolution of inorganic-arsenate host phases from the red mud.

This study shows that although As in red mud is not bioavailable, the slow leaching of As from red mud / soil mixtures at circum-neutral pH will in time result in an overall increase in the amount of aqueous As(V) present in affected environments. In addition, the use of red mud as a soil amendment should be carried out with caution as even low loadings of red mud may result in As-release at problematic concentrations.

Mass Transfer of Fluids and Metals in the Deep Earth

M. LOCMELIS[1]*, M. L. FIORENTINI[1], T. RUSHMER[2], J. ADAM[2], F. ZACCARINI[3], G. GARUTI[3], M. TURNER[2] AND S. TURNER[2]

[1]CET/CCFS, The University of Western Australia, Perth, Australia (*Marek.Locmelis@uwa.edu.au)
[2]Dept. Earth and Planetary Sciences and CCFS, Macquarie University, Sydney, Australia
[3]University of Leoben, Austria

Mantle-derived fluids are generally considered to be involved in the transport and distribution of trace elements in the deep Earth. However, we lack a robust understanding of the processes that lead to mass transfer of fluids and metals between the mantle and the crust. In this study, we integrate a series of volatile- and S-bearing high P/T experiments with the analysis of rock samples collected from one of a series of Ni-Cu-PGE mineralized alkaline ultramafic pipes in the Ivrea-Verbano Zone (IVZ). This exhumed section of the critical crust-mantle interface shows tantalizing relationships between ultramafic fluid-rich rocks and metal-rich sulfide mineralization. Geothermometry suggests that the Valmaggia pipe was emplaced at a temperature of ~900-950ºC, close to the water-saturated peridotite solidus. The high P/T experiments support this observation, based on an H_2O-saturated run at 950ºC and 2 GPa that yielded a mineral assemblage remarkably similar to the pipe. High H_2O contents in the melt are also supported by SHRIMP-SI analysis of pyroxene that yielded 550 ppm H_2O, which corresponds to ~4 wt% H_2O in the melt. Whole-rock and laser ablation ICP-MS data of silicate phases from the pipe suggest that a juvenile, sulfur- and metal-bearing mantle fluid refertilized a depleted harzburgitic source at depth, causing partial melting. The evolving, volatile-rich melt then intruded the IVZ, most likely as a series of open-system feeder conduits and/or chonoliths that subsequently reached sulfide saturation and formed widespread Ni-Cu-PGE mineralization. This hypothesis is supported by isotopic data, which indicate that this alkaline pipe was emplaced slightly after the voluminous mafic magmatic event that underplated the lower crust in the IVZ during the late Carboniferous. The significant difference in epsilon Nd values between whole-rock (-3.1) and amphibole-phlogopite concentrates (respectively -1.0 and -1.6) at ca. 290 Ma indicates that multiple metasomatic events may have been responsible for the establishment of open conduits and the transfer of fluids and metals between the metasomatized lithospheric mantle and the lower crust.

Cation adsorption, hydrogen bonding structure and dynamics at the clay-water interface: MD simulations with new models of muscovite and montmorillonite

NARASIMHAN LOGANATHAN.[1*], BRICE F. NGOUANA W.[1] AND ANDREY G. KALINICHEV[1]

[1] Laboratoire SUBATECH (UMR-6457), Ecoles des Mines de Nantes, 4 Rue Alfred Kastler, La Chantrerie, 44307, Nantes Cedex 3, France (*loganath@subatech.in2p3.fr)

The structure of water films at charged clay surfaces is crucial factor in understanding and predicting the physico-chemical properties of the adsorbed aqueous species which can provide fundamental insights into mobility of contaminants in soils and subsurface environments. Concurrently, the ion-water interactions strongly depend upon both the nature of the charge-compensating ions and the clay substrate structure. Classical molecular dynamics (MD) computer simulations using CLAYFF forcefield [1] were performed for a series of monovalent cations at the surfaces of newly developed models of muscovite and montmorillonite. Atomic density profiles, near-surface atomic distribution maps and the structure and dynamics of the interfacial H-bonding network were analyzed in detail for both clay substrates. The energetics of surface complexation was quantified via the calculation of potentials of mean force for the adsorption processes. Only one stable adsorption site for cations is observed at the muscovite surface in contrast to two different adsorption sites in the case of montmorillonite. The local structural disorder of the substrate charge distribution is clearly responsible for the significant redistribution of water molecules at the interfacial region.

The lateral diffusion of H_2O molecules is 35% reduced at the surface of muscovite in comparison with the bulk liquid sate. The diffusion rate of aqueous species in disordered montmorillonite structure is similar to that in the ordered structure. The calculated hydrogen bond lifetimes between H_2O-H_2O pairs are lower than between H_2O and the bridging oxygens of the muscovite surface. The simulation results are compared with available experimental data and other simulations [2,3] to provide a reliable comprehensive molecular view of the structure and aqueous ion at the clay-water surface.

A new benthic Mg/Ca temperature calibration to reconstruct thermocline temperature variability in the Indonesian archipelago

E. LO GIUDICE CAPPELLI[1] *, A. HOLBOURN[1], W. KUHNT[1] AND M. REGENBERG[1]

[1] Institute of Geosciences, Christian-Albrechts-University, Kiel, Germany
(*correspondence: elgc@gpi.uni-kiel.de)
(ah@gpi.uni-kiel.de)
(wk@gpi.uni-kiel.de)
(regenberg@gpi.uni-kiel.de)

23 Multi-corer core tops representing a range of modern bottom water temperature (BWT) between 3°C and 8°C and covering a water depth between 500 and 2000 m were retrieved from the Makassar Strait (Indonesia) and the Timor Sea to produce a regional BWT calibration. Mg/Ca ratios of the benthic foraminifer *Hoeglundina elegans* show an exponential relation with temperature ($Mg/Ca=0.21e^{(0.23BWT)}$ $R^2=0.91$). This relationship differs significantly from previous calibrations [1, 2], but shows similarity to a later re-calibration [3]. We applied our calibration to sediment core SO18471, retrieved within the lower thermocline of the Indonesian Throughflow (ITF) outflow into the Timor Sea (9°21.987' S, 129°58.983' E, 485 m water depth, 13.5 m length). In core SO18471, we measured Mg/Ca ratios in ~10 tests of *H. elegans* in 10 cm intervals (~1-2 kyr time resolution) to reconstruct thermocline temperature variability. We based the age model on 5 AMS ^{14}C dates and on correlation of our benthic oxygen isotope curve to the Antarctic EDML1 ice core [4]. Preliminary results show that BWT varied from 5 to 10°C over the last 140 kyr (present day BWT is 8°C). During periods of relatively high sea level, thermocline waters cooled and freshened, suggesting a gradual shift from surface to thermocline dominated ITF. In contrast, during sea level lowstands, thermocline temperatures increased, supporting the hypothesis of a reduced thermocline flow during glacials. Although sea level variations appear to be the main control on ITF variability, changes in the global thermohaline circulation and the Australian-Asian monsoon were also influential. Our data suggest that cooling events in the Northern Hemisphere during MIS 3 led to a reduction in ITF intensity, resulting in higher thermocline temperatures in the Timor Strait.

Biogeochemical cycle of dissolved zinc and cobalt in the South Atlantic

M.C LOHAN[1*], N.J. WYATT[1], A.MILNE[2] AND E.M. WOODWARD[3],

[1]Marine Institute, Univeristy of Plymouth, Plymouth, Pl4 8AA, U.K. (*correspondence: maeve.lohan@plymouth.ac.uk
[2]SoGEES, University of Plymouth, Plymouth, Pl4 8AA
[3]Plymouth Marine Laboratories, Plymouth, PL1 3DH, U.K.

We report the first comprehensive dataset of dissolved zinc and cobalt along the South Atlantic 40ºS transect as part of the UK GEOTRACES programme. To date there is little understanding of the supply of Zn and Co which are essential requirement for phytoplankton growth, to this highly productive region. Surface concentrations of zinc and cobalt were extremely low with a pronounced subsurface minima (25pM and 10pM respectively) reflecting the biological uptake in this highly productive region. Prochlorococcus has an absolute cellular requirement for cobalt. Where the phytoplankton biomass was dominated by prochlorococcus, highest concentrations of cobalt were observed below chlorophyll max, indicating a biological control on the vertical flux of cobalt.

The vertical distributions of Zn and Co were similar to soluble reactive phosphorus. The ecological stoichiometry for dissolved Co and Zn ($Co:PO_4^{3-}/Zn:PO_4^{3-}$ ratio 1:1) suggests that both Zn and Co are influencing phytoplankton diversity.

A strong correlation was observed between zinc and silicate across the entire study region ($R^2 = 0.97$, $n = 460$). By utilizing Si* as a tracer for Subantarctic Mode Water, our data indicate that the preferential removal of Zn in the Southern Ocean prevented a direct return path for dissolved Zn to the surface waters of the South Atlantic at 40ºS, and potentially the thermocline waters of the South Atlantic subtropical gyre.

Diversity of microbial communities in sites of discharges gas-and-oil containing mineralized fluids in Lake Baikal

A.V. LOMAKINA[1*], T.V. POGODAEVA[1], I.V. MOROZOV[2] AND T.I. ZEMSKAYA[1]

[1]Limnological Institute, Siberian Branch of the Russian Academy of Sciences, Ulan-Batorskaya Street 3, Irkutsk, 664033, Russia (*correspondence: lomakina@lin.irk.ru)

[2]Institute of Chemical Biology and Fundamental Medicine SB RAS, 8, Lavrentiev Ave., Novosibirsk, 630090, Russia.

Natural discharges gas-and-oil containing mineralized fluids have been identified in different parts of the South and Central Baikal using different methods (De Batist *et al*.., 2002; Klerkx *et al*.., 2003; Khlystov 2006; Khlystov *et al*.., 2007; Kontorovich *et al*.., 2007; Granin *et al*.., 2010) have been found in. We study microbiol community in deep-water sediments of sites with high concentration of ammonium (up to 20 mg/L), bicarbonate ions (up to 183 mg/L), total Fe (4.7 mg/L) and methane. For detection representatives *Planctomycetes*, ANAMMOX group, methanotrophs bacteria and methanogenic archaea, and other bacteria dergading oil in surface and deep-water sediments of cold seeps with different hydrocarbon structure we using methods of molecular biology (PCR analysis, FISH, pyrosequsing). Comparative analysis of nucleotide sequences of Bacteria and Archaea of 16S rRNA gene fragments from the site of natural oil discharge, Gorevoi Utes (Central Baikal), has indicated different microbial composition in the studied samples. We have identified representatives of the phyla *Bacteroidetes, Proteobacteria* (β, γ, and δ), *Verrucomicrobia*, *Nitrospirae*, *Chloroflexi*, *Planctomycetes*, *Acidobacteria*, *Chlorobi*, and *Actinobacteria*. Using *Planctomycetes*-specific primers, we have obtained various representatives of the phylum, including the ANAMMOX group in sites of discharge gas-and-oil containing mineralized fluid: cape Gorevoi Utes and Posolskaya Shoal (South Baikal). Fluorescent in situ hybridization (FISH) with labeled oligonucleotide probes has confirmed the presence in the microbial community site of Posolskaya Shoal of *Planctomycetes* and the ANAMMOX group. Using *pmoA*-gene specific primers was obtaned in surface sediments representatives of types I, II methanotrophs.

Therefore, at the sites with cold seeps in Lake Baikal we have detected bacteria participating in methane (methanotrophs) and oil oxidation, and utilize ammonium.

Molecular scale speciation of U(VI) association with clay bacterial isolates

M. LÓPEZ-FERNÁNDEZ[1], I. SÁNCHEZ-CASTRO[1], A. AMADOR-GARCÍA[1], M. ROMERO GONZALEZ[2] AND M.L. MERROUN[1]*

[1]Department of Microbiology, University of Granada, Spain (*correspondence: merroun@ugr.es)

[2]Department of Civil and Structural Engineering, University of Sheffield, Sheffield, UK

Clay deposits have been studied in recent years as potentially host rock for deep geological disposal of radioactive wastes. A reliable performance assessment of these systems depends on better knowledge on the interactions of actinides with host rock natural microorganisms. The present work aims to characterize the speciation of U(VI) associated with highly U resistant bacteria isolated from Spanish clay deposits. The U(VI) bacterial interaction experiments were performed under physiological conditions. The speciation of U(VI) in U-loaded culture medium is complex and dominated by $(UO_2)_2CO_3(OH)_3^-$. Several spectroscopic and microscopic techniques indicated that the speciation of U(VI) changed drastically upon the addition of bacterial cells to U-loaded culture medium. Infrared spectroscopy analysis revealed that bacterial phosphate groups are involved in the coordination of U(VI) at these neutral conditions. X-ray absorption spectroscopy and time resolved laser induced fluorescence spectroscopy showed that U phosphate precipitation is the main interaction process. The U precipitates are localized at the cell surface as was demonstrated by TEM analysis. The biomineralization of U(VI) phosphates is seen as a detoxification mechanism of the cells to overcome the toxicity of this radionuclide. The results of this work will help in understanding the role of microbiological process in the chemical behavior of actinides in geological and environmental context for future nuclear waste disposals.

[5]Radiological Protection Institute of Ireland, Clonskeagh Square, Dublin 14, Ireland, Ireland (pmcginnity@rpii.ie).

In this work, ^{129}I concentrations in seawater samples from the Irish coast and from the Extended Ellet Line (from Scotland to Iceland) are presented, including both surface samples as well as two depth profiles at the Atlantic Ocean. The results aim to increase and update the information on the presence of this radionuclide in the Atlantic waters.

Surface water ^{129}I along the Irish coast, directly affected by Sellafield discharges, is 3.2×10^{10} at./kg in average Measured ^{129}I concentrations along the EEL are typically in the order of 10^{8} at/kg, slightly over the results obtained by Alfimov *et al*.. [1] in waters sampled nearby in 1999. Also, our results are about one order of magnitude lower than those previously found in the Irminger Basin [2] and in the Arctic Oceans [3].

The two EEL depth profiles show different shapes, as shown in figure 1. Profile 1 decreases with depth, due to dilution. However, profile 2 shows the highest ^{129}I levels in the deepest waters. The North Atlantic Deep Waters current from the Arctic Ocean Profile and enriched in ^{129}I was probably sampled in Profile 2

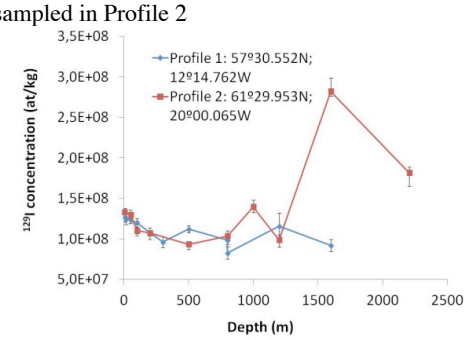

Figure 1.

The platinum behavior in the North Atlantic Ocean

Daniel Eduardo López Sánchez, Antonio Cobelo García

[1][Grupo de Bioxeoquímica Mariña, Instituto de Investigacións Mariñas de Vigo C/Eduardo Cabello, 6. C. P.: 36208. Vigo, Pontevedra, Spain]

We studied the water mass influence over the dissolved platinum levels and its behavior in the North Atlantic. 24 profile stations were sampled during the GEOTRACES cruise in early-spring 2010. 5 water mass were found in the profile: the North Atlantic Deep Water, Denmark Strait Overflow Water, Labrador Sea Water, Iceland and Scotland Overflow Water and Western North Atlantic Central Water. We found different platinum concentration within the different water masses. Platinum concentration increased with depth. The intermediate Atlantic water formation should have an influence on the higher platinum concentration, and could be used as a tracer. However, no significant statistical differences were observed.

[3]Swiss Federal Institute of Technology, Zurich, Switzerland
[3]Instituto Andaluz Ciencias de la Tierra, Granada, Spain.
[3]Dpt. Mineralogía Petrología, Universidad de Granada, Spain

Geothermobarometry in antigorite serpentinite is traditionally hampered by the lack of assemblages buffering the antigorite composition, and customarily relies on the conditions at which breakdown reactions occur of phases like brucite, diopside or titanian clinohumite and/or alternatively on associated mafic assemblages. The aluminium-content in antigorite may provide an independent constraint of the pressure-temperature conditions for serpentinite phase equilibria. Such information would permit a more precise estimation of the conditions for the subduction and exhumation structures recorded in serpentinite during orogenic cycles. Additionally, the relation between the Al-content and the modular structure in antigorite could be investigated more precisely without the need of indirect temperature constraints based on associated mafic rocks.

A model for the incorporation of alumina in FeO-MgO-Al_2O_3-SiO_2-H_2O (FMASH) serpentinites has been developed by considering ideal Tschermak ($Al_2Mg_{-1}Si_{-1}$) solid solution in antigorite [1]. In the assemblage antigorite-olivine-chlorite-fluid the Al-content of antigorite is buffered and temperature sensitive. This temperature sensitivity is the basis for a serpentinite geothermometer at greenschist, amphibolite and eclogite facies conditions. The buffer assemblage is stable in harzburgite bulk compositions for relatively moderate amounts of Al_2O_3 (> 1.8 wt. %) and is widespread in lherzolites protoliths, where it occurs together with diopside or, in a narrow higher temperature field, with tremolite.

The utility of the Tschermak solid solution model in antigorite has been applied to serpentinite samples from the Betics (Cerro del Almirez, Spain) and the Western Alps (Zermatt-Saas). Agreement with previous estimates of metamorphic PT conditions supports the reliability of this new geothermomether.

Quantifying effective ferric iron content in hematite-rich metapelites through phase equilibria modelling

D. LO PÒ[1]* AND R. BRAGA[1]

[1]University of Bologna, Piazza di Porta San Donato 1, 40126, Bologna, Italy
(*correspondence: deborah.lopo@unibo.it)

Iron is a common element in metapelites and is usually approximated to be entirely ferrous. Underestimating the ferric iron (Fe^{3+}) content, however, may result in erroneous whole-rock compositions and thus incorrect P-T estimates when dealing with Fe^{3+}-oxides-rich metapelites. A geothermobarometric-based approach to infer the rock Fe_2O_3 content is here presented using hematite-rich metapelites from Palaeozoic basement of the Pisani Mts. (Northern Apennines, Italy) as example. The paragenesis is represented by phengitic white mica, chlorite (XFe^{2+} = $Fe^{2+}/(Fe^{2+}+Mg)$ = 0.54), chloritoid porphyroblasts (XFe^{2+} = 0.86), quartz and rutile. Hematite is widespread in the matrix and locally forms mm-thick layers. Because of the lack of reliable Fe^{3+} recalculation scheme for major rock-forming minerals, thermodynamic modelling was first attempted assuming whole-rock total iron as FeO. This assumption failed to reproduce the observed paragenesis and mineral compositions. This mismatch suggested that a certain amount of bulk Fe_{tot} must be converted into Fe^{3+}, which is mainly contained in hematite. In order to calculate the Fe_2O_3 content a P-$X_{Fe^2O^3}$ ($X_{Fe^2O^3}$ = $Fe_2O_3/(FeO + Fe_2O_3)$) pseudosection was performed at a fixed T = 475 °C, estimated through the chloritoid-chlorite geothermometer [1]. XFe^{2+} in chlorite and chloritoid intersect in the field corresponding to the observed paragenesis, at P ≈ 9-10 kbar and $X_{Fe^2O^3}$ ≈ 0.6, which is the effective Fe^{3+} content needed to stabilise the observed paragenesis. The inclusion of Fe^{3+} in the modelling increases the whole-rock MgO/(MgO+FeO_{tot}) ratio, which in turn affects chloritoid and chlorite XFe^{2+}. The new P-T constraint agrees with available thermobaric conditions for the Alpine metamorphism in Northern Apennines recorded in Triassic metasedimentary cover, especially in the Verrucano facies rocks [2]. Our modelling suggests that the generally overlooked Northern Apennine Palaeozoic basement was deeply involved during the Paleogene collision between the Adria and Corsica-Sardinia microplates.

Highly siderophile elements and mantle heterogeneities: The interplay between accessory sulfides and trace minerals.

LORAND, J.-P.

LPGN, CNRS UMR 6112, University of Nantes, Nantes, France (jean-pierre.lorand@univ-nantes.fr)

Highly siderophile elements (HSE = Platinum-group elements, Au, Re, Se, Te) occur at ppb concentration levels in the Earth's upper mantle. The HSE are now currently used as geochemical tracers, owing to their wide range of compatibility. Accessory (<0.1 vol.%) Fe-Ni-Cu sulfides (BMS) are the main HSE carriers in the fertile upper mantle. In contrast to lithophile elements, the HSE are versatile elements which easily change their host minerals as a function of sulfur-saturation, redox conditions, pressure, fugacity of sulfur, melt compositions. Recent studies put strong effort to unravel which phases control the HSE budget of mantle rocks after partial melting, metasomatism and magmatic refertilization. Each stage generates specific interplay between BMS and a wide range of micron-sized trace platinum-group minerals (PGMs).

By progressively eliminating sulfur, adiabatic partial melting processes and porous flow percolation systems at high melt/rock ratios transfer the HSE systematic of mantle residues from the BMS to refractory monosulfides, and then to PGMs. The HSE may form their own minerals (refractory PGMs, i.e. Os-Ir-Ru alloys/sulfides; Pt-Ir-(Os) alloys) which carry the whole-rock HSE budget at the micron scale. The inhomogeneous distribution of these micron-sized PGMs may cause extreme nugget effects in the whole-rock budgets. They may also decouple elements that are usually considered to be proxies in sulphur-saturated conditions (e.g. Se and Te, Pt and Pd).

Magmatic erosion at the lithosphere-asthenophere boundary and magmas fluxing through the lithospheric mantle may completely rejuvenate the PGE budgets inherited from melting events. Melt/mantle reactions redistribute the HSE systematics into newly formed, metal-rich BMS, while generating a wide variety of Pt-Pd-Te-Bi microphases. Arsenic may also play an important role in the sub-arc mantle or in volatile-rich metasomatic processes, generating immiscible Ni-As-S liquids in the most As-rich environments. Refractory PGMs may survive these rejuvenation, dispersing the Os isotopic compositions of ancient melt depletion events on a regional scale through refertilized peridotites and melt vein-conduits (e.g. chromitites, pyroxenites). Thus, understanding mantle heterogeneities from whole-rock HSE systematics requires appropriate tools for evaluating the different HSE carriers and their origin.

Basalt weathering on Mars: insights from Li-isotope fractionation models

E. LOSA ADAMS*[1], C.G. LOZANO[1], P. DIZ[1], L.G. DUPORT[1], A.F. DAVILA[2] and A.G. FAIREN[3]

[1] Universidad de Vigo. 36200 Vigo. Spain. (corresponding author*: elosa@alumnos.uvigo.es)
[2] SETI Institute, Mountain View, CA 94043, USA.
[3]Cornell University. Ithaca, 14853 New York, United States

Lithium is incorporated as trace element in most of basalt bearing minerals, namely olivines, clinopyroxenes and plagioclase feldspars, where Li abundance lies in the order of 1-200 ppm depending on their source area. For modeling purposes, we assume an initial value of ^{7}Li = 5 ‰ that corresponds to the average isotopic signature of unweathered MORB basalts [1,2]. It is also assumed that dissolution of basalt leads to release of both isotopes, without significant isotope fractionation. Secondary minerals incorporate a significant fraction of the dissolved Li, with selective uptake of ^{6}Li by clays through cation exchange reactions [3].

Modelling clay–water Li isotope fractionation

Geochemical Models dealing with the selective uptake of each Li isotope by clays were achieved by implementing in the *Phreeqc* code a specific algorithm that splits the total amount of sorbed Li between ^{6}Li and ^{7}Li isotopes under the assumption that fractionation occurs following a Rayleigh distillation process. Li-isotopic signature in H2O resulting from weathering of basalt was analyzed in two scenarios: (1) at near equilibrium conditions and constant temperature, (2) along simultaneous freezing and evaporation buffered by a CO2 atmosphere. Resulting models were used to describe possible paths of Li isotopic fractionation and the extent of basalt weathering on early Mars conditions, as a function of supersaturation, temperature and evaporation rates. We suggest, using MSL capabilities for Li detection, to complete an initial screening for targets relevant for an eventual analysis of Li isotopes.

Thermodynamic data for cementitious systems: Katoite

B. LOTHENBACH[1]*

[1]Empa, Concrete & Constr. Chem., Dübendorf, Switzerland (*correspondence: barbara.lothenbach@empa.ch)

The formation of katoite, $3CaO{\cdot}Al_2O_3{\cdot}6H_2O$, is observed experimentally in hydrated calcium aluminate cements but generally not in hydrated Portland cements. Thermodynamical modeling of the stable phases in hydrated Portland cements without calcite predicts either the formation of katoite, $3CaO{\cdot}Al_2O_3{\cdot}6H_2O$ [1], or monosulfoaluminate, $3CaO{\cdot}CaSO_4{\cdot}Al_2O_3{\cdot}12H_2O$ [2-4], depending on which thermodynamic data are used.

A recent critical review of the thermodynamic data for katoite resulted in $\Delta_fG°$ = -5008.2 kJ/mol and $\Delta_fH°$ = -5537.3 kJ/mol [5] using an entropy of 422 J/mol/K and heat capacity of 446 J/mol/K from [6]. It was shown that some of the experimental solubility measurements have been performed on carbonated samples where monocarboaluminate had precipitated [5]. This resulted in too low $\Delta_fG°$ values for katoite in many databases [2-4] and thus to wrong predictions on the stability of katoite as shown in the figure below.

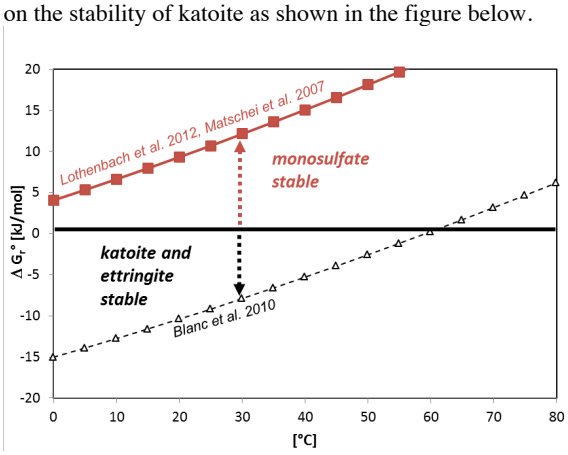

Figure 1: Influence of the stability of katoite on the stability of ettringite and katoite relative to monosulfate in hydrated Portland cements: $3CaO{\cdot}3CaSO_4{\cdot}Al_2O_3{\cdot}32H_2O$ + $2(3CaO{\cdot}Al_2O_3{\cdot}6H_2O) \leftrightarrows 3(3CaO{\cdot}CaSO_4{\cdot}Al_2O_3{\cdot}12H_2O)$.

Distinctive Composition and Genesis of Copper Ore-forming Arc Magmas

ROBERT R. LOUCKS[1]*

[1]Centre for Exploration Targeting & CCFS, School of Earth and Environment, University of Western Australia, Crawley, WA 6009, Australia
*email: Robert.Loucks@uwa.edu.au

In arc segments undergoing orogenic deformation, magma ascent to shallow depths is inhibited by horizontal compressive stress that hinders dyke propagation and that fosters development of subhorizontal magma chambers deep in the ductile lower crust. Experimental and field evidence shows that distinctive chemical features of Cu-ore-forming arc magmas develop in magma chambers near the Moho where country- rock temperatures on a normal arc geotherm are around 700-800°C, so magma chambers cool slowly and tend to last long enough to experience intermittent influxes of mantle-derived basaltic magmas that mix with residual magma already in the chamber, producing multiple cyclic units in stratified crystal cumulates on the magma chamber floor. Residual dacitic melt fractions eventually acquire extraordinary contents of dissolved H_2O (~10 wt%) and SO_3 and probably Cl by inheritance through many cycles of chamber replenishment and fractional crystallisation. Over many such cycles, residual magmas reach unusually high ferric/ferrous ratios, due to selective segregation of ferrous iron into cumulate silicates. The typically high oxidation states of Cu-ore-forming arc magmas is reflected in part by elevated V/Sc and Eu/Eu* ratios. This high oxidation state endows the magma with exceptional sulfur-carrying capacity, because sulfate is around 100 times more soluble (at anhydrite saturation) than sulfide (at pyrrhotite saturation) in magmas of dacitic to rhyolitic composition. The effects of high pressure and high content of dissolved H_2O are to retard plagioclase crystallisation and promote early and prolific hornblende cyrstallisation, which causes the ratios (Eu/Eu*)/Yb and Sr/Y to increase in residual melt as differentiation proceeds from basaltic to dacitic compositions.

Values of Sr/Y>35, (Eu/Eu*)/Yb>2, and V/Sc>10 at 58-70 wt% SiO_2 are typical of arc magmas parental to magmatic-hydrothermal copper ore deposits throughout Phanerozoic time, according to my compilation of compositions of ore-forming intrusives in >135 deposits. These ratios may be used to screen collections of whole-rock chemical analyses to identify igneous complexes that are prospective (fertile) for copper ore genesis. Hundreds of thousands of such analyses are available in published literature. I have compiled many.

Evolution of anthropogenic contamination in the Seine River (France) over the last 15 years revealed by boron isotope ratios

P. LOUVAT[1], D. GUINOISEAU[1], G. PARIS [1,2], J-B. CHEN[1,3], B. CHETELAT[1,3] AND J. GAILLARDET[1]

[1]Institut de Physique du Globe de Paris, Sorbonne Paris Cite´, Univ Paris Diderot, UMR 7154 CNRS, Paris, France
[2] GPS - Caltech, MC 131-24, Pasadena, CA 91125, USA,
[3]State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, CAS, Guiyang 550002, China

Boron is an ubiquist constituant of plants and materials and is widely used by human activities (borosilicate glasses and ceramics, detergents, fertilizers, cosmetics…). Boron has a relatively conservative behaviour within the hydrosphere, and its isotopic compositions are possible tracers of anthropogenic activities. Following the work by Chetelat and Gaillardet (Env. Sci. Tech. 2005) on boron isotopes as a probe for anthropogenic contamination in the Seine River (France), we investigate 3 other series of water samples collected in Paris (monthly between 2004 and 2007) and on the whole Seine Basin (at high- and low-water stages) between 2004 and 2012 that complement their 1994 series. $^{11}B/^{10}B$ ratios have been measured by MC-ICP-MS with d-DIHEN as sample introduction device (Louvat, Bouchez and Paris, Geostand. Geoanal. Res. 2011) after boron extraction on resin Amberlite IRA 743 (adapted from Lemarchand *et al*.., Chem. Geol. 2002). They are expressed in ‰, notation $\delta^{11}B$.

From 1994 to 2007, B concentrations ([B]) have been reduced by a factor of up to 2 for the Seine River in Paris, and the range of $\delta^{11}B$ variations restricted (2 to 9 ‰). On the whole Seine River Basin, [B] are the highest downstream from Paris, associated to the lowest $\delta^{11}B$. These characteristics are even more pronouced during low-water stage. There is however no marked evolution of [B] and $\delta^{11}B$ between the sampling session of 2004-2007 and the more recent ones of 2009 and 2011-2012.

Low $\delta^{11}B$ and high [B] are attributed to anthropogenic sources of boron within the Basin, which are increasing downstrean with increasing population density and industrial activities. Two hypotheses are tested to explain the variation of [B] and $\delta^{11}B$ in Paris between 1994 and 2006: i/ changing of the $\delta^{11}B$ signature for the plant treated waste waters from -10‰ to 0‰, ii/ decrease of the anthropogenic input of boron to the Basin.

A high T cell for the *in situ* study of flux-driven magmatic processes

M. LOUVEL[1*], D. TESTEMALE[1], E. LAHERA[1] AND J-L. HAZEMANN[1]

[1] Institut Neel, CNRS-Grenoble, F-38042 - Grenoble, France. *marion.louvel@grenoble.cnrs.fr

Aqueous fluids and vapors that exsolve from silicate melt as magma rises through the upper crust are of critical importance in volcanic arcs. They can for instance affect the dynamics of magma ascent and trigger eruption or favor the mobilization of metals as Cu, Au and Mo at the origin of the formation of porphyry ore deposits [1, 2]. Up to now, constraints on the nature of theses volatile-rich phases and their relation to silicate melts are mainly limited to the chemical analysis of volcanic fumaroles and the study of melt and fluid inclusions [3]. Furthermore, experiments investigating aqueous fluids or vapor phases in complex systems involving both fluids and melts are challenging, scarce and rely either on mass balance calculations [4] or synthetic fluid inclusions [5].

Here, we present an hydrothermal cell [6] developed to achieve P-T conditions relevant to the *in situ* study of magmatic-hydrothermal processes. This device enables visual monitoring of the high P-T sample but also Raman, X-ray fluorescence (SXRF) and X-ray absorption (XAS) measurements up to 950 °C and 1.5 kbar. Preliminary studies focused on determining 1) phase relations, fluid densities and volatiles speciation in H_2O-CO_2, H_2O-CO_2-NaCl and H_2O-CO_2-Hpg melt systems from 200 to 950 °C and 0.5 to 1.5 kbar and 2) the effect of pressure, temperature and fluid composition on the fractionation and speciation of Cu in fluid-melt systems.

Monodentate inner–sphere coordination of arsenate and phosphate anions, stabilized by hydrogen bonding, at the goethite/water interface

LARS LÖVGREN[*1], HANNA NELSON[1] AND STAFFAN SJÖBERG[1]

[1]Department of Chemistry, Umeå University, SE-901 87 Umeå, Sweden (*lars.lovgren@chem.umu.se)

We have previously described adsorption of arsenate to goethite (α-FeOOH) using a simplified surface complexation model including two surface complexes with arsenate anions [1]. ATR-FTIR studies have, however, shown that more than two complexes are formed [2,3]. Supported by this information new models are presented for surface complexation of arsenate and phosphate. Based on data from potentiometric titrations and batch adsorption experiments, combinations of complexes were tested. Different stoichiometries with corresponding charge distributions according to Pauling's valence bond theory were tested. A coordination mode considering monodentate inner-sphere binding to singly coordinated surface hydroxyl groups with hydrogen bonding to neighbouring triply coordinated surface oxygen were assumed. The resulting model consists of six ternary surface species which match data from both wet chemistry and spectroscopy. Four of the complexes involve a hydrogen bond between the arsenate (or phosphate) anion and a neighbouring surface site. In one complex the ligand acts as a hydrogen bond acceptor and in the other three as a hydrogen bond donator. Species with the same overall charge can be regarded as surface isomers.

Use of mobile laser-based methane analysers to target plume sampling for high-precision isotopic analysis

D. LOWRY[1], R. FISHER[1], J. FRANCE[1], M. LANOISELLÉ[1], G. ZAZZERI[1], E.G. NISBET[1], A.WELLPOTT[2] AND S. BAUGUITTE[2]

[1]Greenhouse Gas laboratory, Department of Earth Sciences, Royal Holloway, University of London, Egham, Surrey TW20 0EX, UK (d.lowry@es.rhul.ac.uk)

[2]Facility for Airborne Atmospheric Measurements (FAAM), Cranfield University, Cranfield, Bedford MK43 0AL, UK

Laser-based analysers are capable of very high precision methane concentration measurements, but are not yet close to matching the precision for isotopic measurement of methane by isotope ratio mass spectrometry. The challenge is even bigger for mobile platforms, such as aircraft, where a plume of methane may be encountered for as little as 5-seconds.

Real-time methane measurements have been made using mobile laser-based spectrometers on land, sea and air platforms, while steel flask and Tedlar bag sampling systems have been used to grab air samples from the identified plumes for later high precision isotopic analysis by IRMS. The rapid-response (1Hz or better) of the methane concentration measurements combined with fast-flow sampling pumps allows narrow plumes to be targeted for sample collection.

A 4WD vehicle is used to detect plumes from landfill sites, gas processing and distribution systems in the UK. A ship-based system is detecting emissions of methane near hydrate dissociation zones in the Arctic and outflow of biological plumes from South America into the Atlantic. The aircraft-based system has been used to target emission plumes from leaking gas rigs, wetlands and forest fires.

The IRMS systems at RHUL are capable of ±0.05‰ precision or better on triplicates using 75cc of air per analysis. Methane sources have very distinctive $\delta^{13}C$ signatures around -20‰ to -40‰ for combustion sources down to -60 to -80‰ for biological sources. The further away from the source that a plume is encountered the more diluted toward atmospheric background of -47‰ is the plume signal. This requires high-precision isotopic measurement to identify the source of the methane increment over background.

Although laser-based isotopic systems are starting to provide useful data at static ground-sites close to source emissions, the combination of laser-based concentration measurements and IRMS provides the best method to identify unknown methane sources, to understand distribution of sources at the regional scale and to tightly constrain the source isotopic signature of known sources.

Are there Unique "Nano" Effects from Exposure to Metal and Metal Oxide Nanoparticles?-Yes and No!

GREGORY V. LOWRY[1,2], RUI MA[1,2], CLEMENT LEVARD[3,2], BENJAMIN P. COLMAN[4,2], EMILY S. BERNHARDT[4,2], GORDON E. BROWN, JR.[5,2] AND MARK WIESNER[4,2]

[1]Carnegie Mellon University, Pittsburgh, PA 15213
[2]Center for Environmental Implications of Nanotechnology
[3]Centre de Recherche et d'Enseignement de Géosciences de l'Environnement, Aix-en-Provence, France
[4]Duke University, Durham, NC 27708
[5]Stanford University, Stanford, CA 94305

Engineered nanomaterials (ENMs) have novel properties relative to their bulk counterparts. This "uniqueness" is raising societal concerns about their potential for negative environmental effects. However, it is unclear if ENMs result in unique "nano" effects in the environment. Research in the Center for Environmental Implications of Nanotechnology is identifying cases where nanomaterial exposures indeed lead to unique "nano" effects compared to ionic controls, and cases where they do not, i.e. effects are predicted from existing geochemical principles.

The solubility of silver nanoparticles (Ag NPs) was independent of nanoparticle size down to 5 nm. Solubility increased with decreasing size, but in a manner predictable from thermodynamics. This indicated a constant surface energy and an absence of strain on the FCC structure of the particles. This was confirmed with X-ray absorption spectroscopy and by pair distribution function analysis of total X-ray scattering data. The toxicity of Ag NPs to four different organisms was fully explained by the availability of dissolved silver species in the exposure media. Despite the apparent "non-uniqueness" of Ag NPs, application of Ag NPs in biosolids to terrestrial plants resulted in an increase in N_2O flux from the system relative to biosolids and $AgNO_3$/biosolid controls. This behaviour may be a result of spatial and temporal uniqueness of Ag NPs, i.e. their distribution in the environment and their ability to afford sustained low-level release of Ag ion, rather than from a unique reactivity.

Photoelectrons from minerals and microbial world

ANHUAI LU [1]* AND YAN LI [2]

[1] School of Earth and Space Sciences, Peking University, Beijing. (*correspondence: ahlu@pku.edu.cn)
[2] School of Earth and Space Sciences, Peking University, Beijing. (liyan-pku@pku.edu.cn)

The Earth surface is a multiple open system. Semiconducting minerals, including many metal oxides and sulfides, are ubiquitous on Earth's surface and widely participate in redox reactions following photoelectron/photohole pairs excited by solar light. Microorganisms evolve various pathways to utilize extracellular electrons and to get energy. Recently, Lu[1] presented evidences demonstrating solar energy mediated by semiconducting mineral photocatalysis, promoted the growth of some nonphototrophic bacteria and revealed that the ternary system of microorganisms, minerals and solar light has played a critical role in the life history on Earth. Under simulated sunlight, photoelectrons generated from semiconducting minerals could be used by nonphototrophic microbes to support their metabolisms. The growth of microbe, closely related with the photon quantity and energy, and well fitted the light absorption spectra of the semiconducting mineral. The overall energy efficiency from photon to biomass was 0.13‰ to 1.9‰. Further studies revealed that in natural soil system, semiconducting mineral photocatalysis influenced the microbial community. This solar energy utilization pathway by nonphototrophic microorganisms mediated by semiconducting mineral photocatalysis extends our knowledge on the use of solar energy by nonphototrophic microorganisms, and provides a new concept to evaluate the life origin and evolution. The comprehending of non-phototrophic bacteria solar energy utilization conducted by semiconducting minerals in present environment will greatly help us to better understand the energy transform mechanism among interfaces of lithosphere, pedosphere, hydrosphere and biosphere.

Phases of gold and silver in the sediments in the Jidong gold ore concentration area, China

LU JILONG[1] SHI HOULI[1] HAO LIBO[1] ZHAO YUYAN[1A] AND LIU HONGYAN[2]

[1]College of GeoExploraion Science and Technology, Jilin University, Changchun 130026, China. lujl@jlu.edu.cn
[2]Center of Testing Science, Jilin University, Changchun 130026, China.

49 samples of sedment in Jidong ore concentration area, located in the subunit of the yanshan fold belt in north China platform - the middle of Malanyu uplift, were sampled and the different phases of gold and silver were analized. The results showed that eight phases of gold(soluble facies, surface adsorbing facies, organic facies, carbonate facies, natural gold facies, iron and manganese oxides facies, sulfide facies and residual facies) could be detected in the sediments and seven phases of silver(as same as phases of gold except natural gold facies) could be detected in the sediments. Au of sediments existed mainly in the phases of natural gold facies and sulfide facies in the gold abnormal area, while in the background area, mainly in natural gold facies and organic facies. But to the silver of sediments, both existed mainly in the sulfide facies and residual facies in gold abnormal area and the background area. Thus could be utilized in the evaluation of anomaly and be propitious to gold deposit exploraton in the area.

Pb and Zn Coprecipitation with Iron Oxyhydroxide Nano-Particles

PENG LU,[1] SHELLY KELLY[2] AND CHEN ZHU,[1]

[1]Department of Geological Sciences, Indiana University, Bloomington, 1001 E 10th Street, Bloomington, IN 47405-1405, chenzhu@indiana.edu
[2]Argonne National Laboratory, Biosciences Division, Argonne, IL 60439-4843, United States

Pb and Zn coprecipitation with Fe^{3+} was studied with sorption edge measurements, desorption experiments, paired coprecipitation – adsorption experiments for comparison, sorbent aging, EXAFS, High Resolution Transmission and Analytical Electron Microscopy (HR TEM–AEM), and geochemical modeling. Coprecipitation of Pb with ferric oxyhydroxides occurred at ~ pH 4 [1] and for Zn at pH ~5 [2], about 0.5-1.0 pH unit higher than Fe^{3+} precipitation. Coprecipitation is more efficient than adsorption in removing Pb and Zn from aqueous solutions at similar sorbate/sorbent ratios and pH. HRTEM of the Pb-Fe and Zn-Fe coprecipitates shows a mixture of 2 to 6 nm diameter 2-line ferrihydrite spheres. The co-refinement of the Pb LIII-edge and the Fe Kedge EXAFS spectra suggested that Pb formed a solid solution in the Pb-Fe coprecipitate [3]. Desorption experiments show that more Pb^{2+} was released from loaded sorbents collected from adsorption experiments than from Pb to Fe coprecipitates at dilute EDTA concentrations. Desorbed Pb^{2+} versus dissolved Fe^{3+} data show a linear relationship for coprecipitation desorption experiments but a parabolic relationship for adsorption experiments.

Based on these results, we hypothesize that Pb^{2+} was first adsorbed onto the nanometer-sized, metastable, iron oxyhydroxide polymers of 2-line ferrihydrite with domain size of 2–3 nm. As these nano-particles assembled into larger particles, some Pb^{2+} was trapped in the iron oxyhydroxide structure and re-arranged to form solid solutions.

Our study shows that coprecipitation and adsorption experiments resulted in different Pb and Zn incorporation mechanisms, which could result in different mobility, bioavailability, and long-term stability of trace metals in the environment.

Preliminary studies on physicochemical characterization of $PM_{2.5}$ collected in underground and ground-level rail systems Shanghai metro

SENLIN LU[1*] HAO XIAOJIE[1] LIU DINGYU[1] ZHANG RONGCI[1] YI FEI[1] GU YAN[1] LUO WENYUN[1*] LIN JUN[2] AND YONEMOCHI SHINICHI[3]

[1]School of Environmental and Chemical Engineering, Shanghai University, Shanghai 200444, China
[2] Shanghai Institute of Applied Physics, Chinese Academy of Sciences, Shanghai 201800, China
[3] Center for Environmental Science in Saitama, Saitama 374-0115, Japan

Metro systems are an important transportation mode in megacities across the word. Few works focused on fine particles in the atmosphere of metro. A campaign was conducted to investigate physicochemical characterization of ambient fine particles (PM2.5, D<2.5μm) in the atmosphere of underground and metro station of Shanghai rail system. Proton induced X-ray emission (PIXE) technique, field energy scanning electronic microscopy (FESEM) and synchrotron radiation X-ray absorption fine structure (XAFS) were employed to analyse chemical elements and microscopic characterization of $PM_{2.5}$. Our results showed that mass level of $PM_{2.5}$ in the air of underground of Shanghai metro system (42.17±23.74 μg/m^3) was higher than that of $PM_{2.5}$ collected out of metro station (21.54±6.86 μg/m^3). The $PM_{2.5}$ was mainly consisted by fly ashes, mineral particles. Al, Si, Ca, S, Fe, Cu, Na, Mg, K, V, Cr, Mn, Zn, Ba, Re, Ti, Cl could be found in the fine particles. Al, Si, Ca, S and Fe were the main elements. Their mass level followed Si>Al>Ca>S>Fe. Considering speciation of trace elements playing key role in their toxicological effects, speciation of copper was selected to be analyzed by XAFS. The XAFS results demonstrated speciation of Cu in fine particles ($PM_{2.5}$) is present as Cu (I), while significant amount of Cu is present as Cu (II) in the ultrafine particles ($PM_{0.1}$). Armed with the above results, celluar toxicity will be carried out to assess health risks induced by fine particles in the atmosphere of Shanghai metro system.

Anthropogenic global warming affects marine ecosystems in complex ways, but the possibility of declining oxygenation is a growing concern. Forecasting the extent, rate and intensity of future ocean deoxygenation and its effects on oceanic biota remains highly challenging because of the complex feedbacks in the earth-ocean-biota system, and the lack of sensitive proxies to reconstruct oceanic oxygen levels of the past [2]. Information from past events such as the Paleocene-Eocene Thermal Maximum (PETM, ~55.5 Ma), possibly the best geological analog for modern global warming, may help in such forecasting. During the PETM, low-oxygen conditions were widespread along continental margins, but there is no evidence that deoxygenation was global and extended into open oceans. We apply a novel paleo-redox proxy, iodine to calcium ratios, in bulk foraminiferal tests (>63μm coarse fraction). The oxidized form of iodine (iodate, IO_3^-), but not the reduced form iodide, can be incorporated in the calcite structure, thus preserving information about paleo-redox changes. Our results indicate horizontal and vertical expansion of the Oxygen Minimum Zone (OMZ) in the Pacific, Atlantic and Indian oceans following the emission of isotopically light carbon into the ocean-atmospheric system during the PETM.

Source tracing in Li–bearing brines, Salar Pozuelos, NW Argentine

F. LUCASSEN[1], L. KORTE[1], S.A. KASEMANN[1], A. MEIXNER[1] AND R.N. ALONSO[2]

[1]Universität Bremen/MARUM, Isotope Geochemistry, Bremen, Germany, Lucassen@uni-bremen.de
[2]Universidad Nacional de Salta-CONICET, Salta, Argentina

The source of the spatially restricted Li anomaly and the enrichment processes of Li in the Central Andean salt lakes (salars) are still enigmatic, even though the deposits share common features with other evaporites under arid conditions. A study on chemistry and Li and Sr isotope composition of brines and related salts in a small salar indicates heterogeneous sources of the material ($^{87}Sr/^{86}Sr$ ~0.710 – 0.720), which relates to differences between the principal magmatic, metamorphic and sedimentary rock units. Li contents in brines increases systematically with Mg, K, and Na and is highly variable within the region of NaCl – saturation, where it increases by on-going evaporation and NaCl precipitation. Li isotope variation in the brines is large (δ^7Li ~ +12 to +20‰), whereas the differences between brine and related salt are < 1‰ with the lower δ - values in the salt. In different sample areas, δ^7Li increases with the Li contents, i.e. progressive evaporation. Li concentrations of the brines vary independently of the highly systematic evaporation trend of O and H isotope fractionation, whereas δ^7Li shows a general increase with the O and H isotope variation.

A possible path for the Li enrichment in the present salar starts with the dissolution of Li from various rock sources (Sr isotope variability) with low δ^7Li (0 to +6‰ for common silicate rocks [1]). These low δ^7Li evolve to variably higher values during mineral dissolution and precipitation processes in an aqueous medium. The initially meteoric water changes its O and H isotope signature according to the extent of evaporation on its way from the Li source rock into the salar, e.g., as surface runoff or thermal spring that sample deep sources. Within the salar, the different sources do not mix thoroughly. The dominant process of Li enrichment is evaporation of the brines and halite precipitation. This is accompanied by further but potentially minor fractionation of δ^7Li, because the ^6Li prefers octahedral coordination in the halite. Complete evaporation leads to layers of high Li halite. Further enrichment of Li by reworking of such layers in dissolution – precipitation cycles, e.g. in pluvial ponds is expected.

Understanding the impact of Geochemistry: A tribute to Jean Carignan

JOHN N. LUDDEN[1]

[1]British Geological Survey, Keyworth, Nottingham, NG12 5GG, Jludden@bgs.ac.uk

Jean Carignan, a key scientist in the world of geoanalysis, passed away aged only 48 on the 12th October 2012. Jean started his scientific career as an undergraduate at the University de Quebec a Montreal. With Clement Gariepy he revisited the Pb-isotope signatures of granitoids from the Canadian Superior province. They pioneered the use of Pb-isotopes in minute quantities of separated feldspars for different suites of granitoids. This work underpinned tectonic models for source regions for these rocks, which were integrated into the Canadian Abitibi Grenville Lithoprobe project. As a tireless analyst, always searching for the next improvement that would allow the field of geochemistry to advance, Jean was hired as director of the Centre de Recherche Petrographiques and Geochimiques (CRPG) in Nancy, Service d'Analyses des roches et Mineraux (SARM) on the retirement of Kuppusami Govindaraju. It was here that he developed a mixed array of elemental and isotope analyses for the science community and is used both in France and internationally. In particular, these involved the use of the new generation of ICP-Multi collector Mass spectrometers that were being developed in the late 1990's. This led to a series of research projects in coupled trace element and isotope tracers in environmental processes ranging from Cu, Zn, Fe etc. to Hg and Pb. Jean and his team introduced a number of analytical improvements and focussed on the environmental impact of atmospheric pollutants using novel approaches with samples such as epiphytic lichens as samplers of atmospheric components of the Kola Peninsula.

In this talk I will investigate some of the impacts of his science.

The Geochemistry of London

JOHN N. LUDDEN, DENIS W. PEACH AND DEE FLIGHT

[1]British Geological Survey, Keyworth, Nottingham, NG12 5GG Jludden@bgs.ac.uk
[2]British Geological Survey, Keyworth, Nottingham NG12 5GG dwpe@bgs.ac.uk
[3]British Geological Survey, Keyworth, Nottingham NG12 5GG dmaf@bgs.ac.uk

The population of the Greater London area is expected to grow from 8.2 million in 2013 to >9 million in 2020. London sits on complicated Quaternary superficial deposits including gravels and sands of the Thames and older deposits such as the London Clay, which overlie the chalk basement, the major aquifer of SE England. The superficial deposits include a legacy of pre- and post-industrial hazardous waste and there is also local chemical contamination in groundwater.

As geochemists we must identify and provide workable solutions to removing legacy pollutants and more importantly industrial infrastructure and agricultural development of the UK and worldwide must increasingly be underpinned by solid baseline data in order to provide solutions to environmental issues.

BGS has undertaken a systematic high-density geochemical soil survey of the Greater London Area the "London Earth" project aiming to give insight into the environmental impacts of urbanisation and industrialisation as well as to characterise the geochemical baseline of the Europe's most populous city. We must communicate to councils, developers and the general public of any environmental or health risks. It is urgent that as geochemists we assess these baselines and monitor the subsurface using new sensor networks.

Experimental partitioning behavior of MORB in subduction zones at 2 and 3 GPa

STEFANIE LUGINBUEHL[1*], PETER ULMER[1] AND THOMAS PETTKE[2]

[1]Dept. Earth Sciences, ETHZ, 8092 Zurich, Switzerland (*correspondence: stefanie.luginbuehl@erdw.ethz.ch)
[2]University of Bern, Institute of Geological Sciences, 3012 Bern, Switzerland

Arc volcanic rocks show a typical geochemical signature of fluid-mobile trace element enrichments such as LILE (K, Rb, Cs, Ba). It is assumed that there is an apparent correlation between the structure and composition of the subducting oceanic lithosphere and the composition of subduction zone magmas. The slab components contributing most to the metasomatism of the wedge peridotite are the hydrated igneous oceanic crust and the sediment layer overlying it with notably high trace element concentrations. The mobility of these elements depends on both the nature and composition of the transfer agent and the phase assemblage of the residue.

To investigate the major and trace element budget within subduction zones, we conducted piston cylinder experiments at 2 and 3 GPa and 700 to 1200°C on a K-free, water-saturated and trace element-doped basaltic (pristine) MOR composition. Mobile phases are collected by the employment of diamond traps and subsequently analysed by the cryogenic LA-ICP-MS technique [1] to quantify major and trace element compositions of fluids and melts.

For K-free MORB compositions we find that the solidus lies between 800 and 850°C at 2 and 3 GPa, subsolidus phase assemblages consist mainly of the hydrous phases amphibole and epidote. Garnet, clinopyroxene and rutile, a typical eclogitic phase assemblage, is stable at higher, supersolidus temperatures. We present new results on the trace element partitioning behavior between liquids and mineral phases. In agreement with previous studies, we find that garnet is strongly controlling Heavy REE, while rutile and titanite (2 GPa, 700°C) hold back HFSE ($D^{solid/fluid} \geq 10$). Additionally we find staurolite being stable at 3 GPa and 700°C that incorporates HFSE as well as Th. Epidote is an abundant phase at PT-conditions where we suggest an aqueous fluid being released from the dehydrating slab, it strongly incorporates Light REE, Th and to a lesser extent U ($D^{solid/fluid} \geq 100$). These new experimental results are utilized in forward modelling to quantify element mobility in subduction zones.

[2]Curtin University of Technology, Perth, WA, Australia

Advanced nuclear fuel cycles offer considerable promise for improvements in safety, performance, actinide management, and provide opportunities for associated methods of energy production (e.g., hydrogen based systems). In general, the proposed reactor systems require new materials capable of performing under the extreme conditions imposed by temperature, radiation fields, and corrosive media. Here we present a comparison of the results obtained from minerals with laboratory observations using ion irradiation methods. The results generally set out the groups of potential actinide host phases in terms of those with intrinsic radiation tolerance due to recovery of damage on picosecond time scales (e.g., fluorite), those with favorable kinetics for longer term damage recovery (e.g., monazite), and many others with unfavorable kinetics. We have also conducted atomistic modelling studies of some of these minerals and other materials of interest. Together with information from the literature, the results are briefly summarized in terms of structure, bonding, and the energetics of defect formation and recovery. We briefly report on the effects of decay of Tc to Ru in rutile.

Figure 1: Atomistic simulations using empirical potentials showing the total Frenkel defect formation energies from the lanthanide, titanium, and oxygen atoms in the orthorhombic Ln_2TiO_5 compounds.

The role of Th-U minerals in assessing the performance of nuclear waste forms

G.R. LUMPKIN[1]*, R. GIERE[2], C.T. WILLIAMS[3] AND T. GEISLER-WIERWILLE[4]

[1]ANSTO, Locked Bag 2001, Kirrawee DC, 2232, NSW, Australia (*correspondence: grl@ansto.gov.au)
[2]University of Freiburg, 79104 Freiburg, Germany
[3]The Natural History Museum, Cromwell Road, London, UK
[4]University of Bonn, D-53012 Bonn, Germany

A number of alternative crystalline nuclear waste forms have been proposed for deployment in geological repositories. Materials range from general purpose polyphase waste forms for high level wastes to highly specialized waste forms designed specifically for actinides and certain fission products. Here we review the information available from natural systems relevant to the performance of candidate waste form phases. Observed mineral transformations include (approximately) constant volume chemical changes and breakdown to new phase assemblages, with or without loss of Th and U. Together with laboratory experiments, the geochemical data indicate that zirconolite is a promising host phase for actinides and certain fission products. Pyrochlore has a slightly higher dissolution rate in the laboratory and is generally more susceptible to geochemical alteration. Monazite also has low dissolution rates in laboratory experiments, favorable geochemical behavior, and minimal physical property changes due to retention of crystallinity over geological time scales. Although zircon has been studied extensively, the 17-18 % volume expansion due to alpha decay continues to be a major issue for application as an actinide host phase in nuclear waste forms.

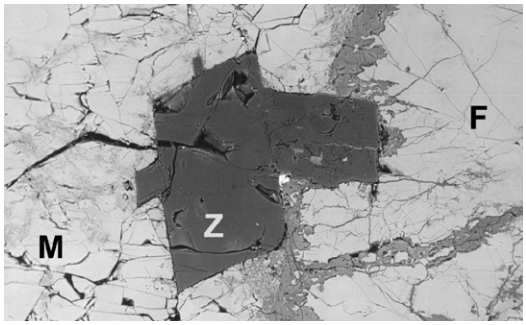

Figure 1: Monazite (M), zircon (Z), and fergusonite (F) from the Rutherford #2 pegmatite (t = 289 Ma), Amelia, Virginia. These ABO_4 minerals have reacted differently in the presence of late stage granitic pegmatite fluids. Altered areas are darker gray and most prominent in fergusonite. Image width ~ 1 mm.

Photochemistry of dissolved combined amino acids

RACHEL A. LUNDEEN, JEREMY SCHAELCHLI AND KRISTOPHER MCNEILL*

Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Universitaetstrasse 16, 8092 Zurich, Switzerland, kris.mcneill@ethz.ch, rachel.lundeen@env.ethz.ch, sjeremy@student.ethz.ch

Amino acids are an significant, identifiable portion of the dissolved organic nitrogen pool of natural waters, and are important substrates for microbes at the base of the food web. A portion of the naturally occurring amino acids are photoreactive, which means that photochemistry could play a significant role in the modulation of the microbial utilization of DON. While most research in this area has centered on dissolved free amino acids, most amino acids are present in natural waters as combined amino acids.

The purpose of the present study was to examine the differences in photoreactivity of dissolved free and combined amino acids. Specifically, this work focused on the oxidation of histidine residues in an intact protein (GAPDH) by singlet oxygen.

The results indicate that the reactivity of histidine residues is decreased when in the context of an intact protein, and that the decrease is due to decreased accessibility to the oxidant. The differential reactivity of near-surface and buried residues led to a sensitive method for tracking the intactness of the folded protein during the photolyis.

Return of Archean low sulfate levels during the earliest Mesoproterozoic Oceans

a. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan 430074, China

b. Department of Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA 02139, USA

c. State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan 430074, China

Sulfate, the second abundant anion in the modern ocean (~28mM), plays an important role in the present biogeochemical cycle of C, S and O. It has been shown that more than 50% of organic matter is remineralized through microbial sulfate reduction and as high as 80% of methane was oxidized by anaerobic methane oxidation archeae coupled with microbal sulfate reduction(Jørgensen, 1982; Valentine, 2002). Furthermore, oceanic sulfate concentration is an important proxy for oxidation state of Precambrian atmosphere and ocean.Therefore unraveling the variation pattern of oceanic sulfate concentration in geological history is very important scientific issue.

A number of studies have shown that oceanic sulfate concentration varied distinctly and periodicly in Phanerozoic (e.g., Lowenstein *et al*.., 2003). However, the details of the evolution history of the Precambrian oceanic sulfate concentration are unclear beyond the general increasing trend (Kah *et al*.., 2004). Here we analyzed sulfur isotopic composition of carbonate associated sulfate ($\delta^{34}S_{CAS}$) and corresponding disseminated pyrite ($\delta^{34}S_{py}$) at the 1.6 Ga Gaoyuzhuang Formation in the North China Craton. The results show that both the $\delta^{34}S_{CAS}$ and $\delta^{34}S_{py}$ are relatively constant, varying around 13.0‰±1.8‰ and 8.0‰±2.3‰, respectively over 200 m stratigraphic sections. Therefore the sulfur isotopic fractionation ($\Delta^{34}S$) between the sulfate and pyrite at this time was ~5‰. The relative uniformity in the $\delta^{34}S_{py}$ implicates that the pyrite was formed in the water column, and the small $\Delta^{34}S$ implicates that the sulfate concentration in the earliest Mesoproterozoic ocean would have been be extremely low, probably far less than 1 mM. Our identification of extremely low oceanic sulfate concentration in the earliest Mesoproterozoic points to a distinct perturbation in ocean chemistry, which might be related to the decline of coeval atmospheric O_2 concentration.

Petrography and geochronology of the Xianshi uranium deposit in Xiazhuang ore field of South China

JINCHENG LUO[1]*, RUIZHONG HU[1], XIANWU BI[1], YOUWEI CHEN[1] AND XIAOYAN JIANG[2]

[1]State Key Laboratory of Ore deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, 550002, China (*correspondence: luojincheng027@126.com)

[2]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China

South China is rich in numerous U deposits that provided the dominantly U source for the country in the past several decades. Xianshi U deposit is one of very particular deposit in Xiazhuang ore field, situated in southeast Guidong composite granite pluton, Guangdong province is directly associated with hosted-granite and diabase dike and the intersection part between trend and silicification zone. Additionally, the netlike diabase dikes seemingly intrude the main U mineralization of massive uraninite, based on the relatively close contacts between diabase dikes and the high-grade U mineralization. We present detailed petrography, mineral paragenesis and geochronology characteristics of the Xianshi U deposit. Four distinct types of U mineralization have been identified by cross cutting relationships and textures observed in thin sections and BSE images. Alteration is well developed, mainly including pyritization, silicification, carbonation and hematitization. The latter two types are closely related to the high-grade U mineralization. *In-situ* SIMS U-Pb dating of the different type uraninites firstly yield three group ages of 134.6 ± 4.4, 113.4 ± 2.1 and 103.7 ± 1.8 Ma, respectively. The major U mineralization event occurred at ~135 Ma, closely related to the emplacement of diabase dykes and the crust extensional tectonic regime. It appears to represent the oldest U mineralization event observed in Xiazhuang ore field. Stage 2 and stage 3 of U reconcentration generated at 113.4 ± 2.1 and 103.7 ± 1.8 Ma, respectively and appeared as veined uraninite associated with calcite vein. Two ages are consistent with hydrothermal fluid events correlated well with that of diagenetic age of diabase dykes, likely representing the age of two resetting events. Therefore, there are indications that uraninite from Xianshi U deposit has experienced at least three episodes of U concentration associated with the intrusion of local mantle-derived diabase dykes, and is likely to be interpreted to be the hydrothermal origin during Cretaceous crustal extension in South China.

Behaviors of Pb, As and Cd in the Mining Impacted Farmlands

LIQIANG LUO*, BINBIN CHU, YING LIU, XIAOFANG WANG, TAO XU, YING BO AND JIANLIN SUN

National Research Center of Geoanalysis, Beijing, China, 100037(* Correspondence, luoliqiang@cags.ac.cn)

Behaviour and correlations of Pb, As, Cd, Cr, Cu, Zn and other trace elements in farmlands near a Pb-Zn mine were investigated and evaluated. Some of the water and soil quality in the farmlands exceeded permitted standards. The highest concentration of Pb in irrigation water system was over 10 times that of the standards. The minimum, average and maximum, concentrations of Pb in farmland soils were 3.3, 14 and 35 times higher, respectively, than the environmental quality evaluation standards for farmland of edible agricultural products. The minimum concentrations of As and Cd were beyond the standards, while the average and maximum concentrations of As were 4.5 and 11 times higher than the environmental quality evaluation standards. For Cd they were 9 and 34 times higher than the standards. The concentrations of Pb, As and Cd in aerosols and dusts were extremely high and the maximum concentrations of Pb, As and Cd were 10296, 114, and 76 mg/kg, respectively.

The Pb isotope data reveals that the sources of lead in the soils around the Pb-Zn mine were a mixture of lead minerals and ores, current vehicle exhaust particles and deposits of vehicle exhaust particles before unleaded gasoline became available, and even some coal ash.

Correlations between element concentrations in water and soils in the farmlands were very strong. For example, the correlation coefficient of Pb and Cd concentrations in water was 0.944, and in vegetable farmland soils, the correlation coefficients between Pb and As, Pb and Cu, Cd and Mn and Zn concentrations, as well as between Mn and Zn exceeded 0.9. The correlation coefficients between Pb concentrations in soil and water were 0.679, and for As and Cd, they were 0.717 and 0.611, respectively. The element correlations between water and soils were rather strong and may indicate direct impacts on each other. The element concentrations in the aerosols were correlated strongly. For example, the correlation coefficients of Pb and Cd, as well as with Mn, Cu and Zn, were over 0.9 in aerosol samples.

The investigation reveals that the major sources of the pollution in the irrigation water systems and farmland soils were mining activity and vehicle exhaust particles. The contaminants from mining activities have impacts on surrounding environments and may be transported to wide ranges.

Pockmark activity inferred from pore water geochemistry in shallow sediments of the pockmark field in southwestern Xisha Uplift, northwestern South China Sea

MIN LUO[1] AND DUOFU CHEN[1]*

[1]Key Laboratory of Marginal Sea Geology, Guagzhou Institute of Geochemistry of Chinese Academy of Sciences, Guangzhou, China (*correspondence: cdf@gig.ac.cn)

Pockmarks are widespread on the seabed off southwestern Xisha Uplift, northwestern South China Sea. Some of them are enormous that are rarely observed worldwide, but their activities are poorly known up to now. We collected three gravity-piston cores from this pockmark field, one (C9) from outside but in close proximity to a giant pockmark and the other two (C14 and C19) from inside of two giant pockmarks. The sulfate concentration-depth profiles of C9 and C19 pore water are dominantly in response to organoclastic sulfate reduction (OSR), while the sulfate concentration of C14 pore water exhibits three zones of different concentration gradients resulting from various contribution of OSR and anaerobic oxidation of methane (AOM). The depth-profiles of sulfate $\delta^{34}S$ values of C9 and C14 pore water are in accordance with their sulfate concentration-depth profiles. The relatively low sulfur isotope fractionation in C14 pore water suggests a higher microbial sulfate reduction rate as a possible consequence of AOM than that in C9 pore water. The depth of sulfate-methane interface (SMI) and methane diffusive flux of C14 are estimated to be ~14.3mbsf and ~0.0144 $mol \cdot m^{-2} \cdot yr^{-1}$, respectively, based on the sulfate concentration gradient below 3.7mbsf. Pore water Mg/Ca and Sr/Ca weight ratios imply that high Mg-calcite precipitated in C14. $\delta^{13}C_{DIC}$ values of C9 and C19 pore water are inferred to derive from a binary mixing between $\delta^{13}C$ of organic matter and $\delta^{13}C_{DIC}$ of bottom water, while DIC of bottom water, organic matter, methane, and ^{13}C-enriched DIC from below SMI possibly all contribute to the DIC pool below 0.66 mbsf in C14. The integrated analysis of pore water geochemistry suggests that the pockmark where C19 was collected may be inactive while the pockmark where C14 was obtained may be presently in sluggish activity with methane-bearing fluid weakly seeping from subsurface sediments.

Study of geogas nano-particles of metal deposit in Inner Mongorlia plateau, China

SONGYING LUO[1,2], JIANJIN CAO[1,2]* AND ZHENGQUAN WU[1]

[1]Department of earth sciences, Sun Yat-sen University,Guangzhou510275,China

[2] Guangdong Provincial Key Lab of Geological Process and Mineral Resources Survey, Guangzhou510275, China

(*Corresponding:eescjj@mail.sysu.edu.cn)

Geochemistry and nano-scale science were adopt in exploration for deep and concealed mineral deposits. The nano- particles in the ascending flow from the concealed ore-bodies are closely to the deposit, and full of the ore-forming information of the type of the deposit. Also modern testing technology can provide a high sensitivity and high resolution method to observe and measure the geogas nano-particles. In our present studies, the static methods of geogas prospecting are used to capture the geogas nano-particles overlying the concealed metal deposit, that are three different types of vegetation form, climate and soil environment in Inner Mongolia plateau, China. The three concealed metal deposits are Dongshengmiao polymetallic pyrite deposit, where is located in Gobi in Hetao Plain of the Yellow River Basin, might be hydrothermal mineralization, Kaxiutata iron deposit is located on the edge of Badanjilin desert, and Bairendaba Ag polymetallic deposit is located in grassland, might be an epithermal silver deposit or a silver orogenic deposit, or of both. The samples are measured by using the TEM technique. The results showed that, the geogas nano- particles may be used as a indicators for prospecting the deep concealed ore-bodies, the characteristics and concentrations of the geogas particles is closely related to the type of the ore-bodies and bedrock, not the type of vegetation form, climate or soil environment. It is suggested that geogas prospecting is feasible and applicable to prospect many different types of metal deposit, even other minerals resources.

Water Quality Simulation in reservoirs in series on the Maotiao River, Southwest China

WENYUN LUO, JING ZHANG, MING YANG, ZHENG JIAO AND FUSHUN WANG*

School of Environmental and Chemical Engineering, Shanghai University, Shanghai 200444, China (*correspondence: fswang@shu.edu.cn)

The construction of dams in series has a great impact on the quality and structure of aquatic ecological system of river basin. In this study, we investigated six reservoirs in series on the Maotiao River, southwest China. A monthly sampling strategy was performed in these reservoirs, during year of 2006 to 2007. Nutrients concentration and other parameters, such as DO, T and pH along the river reach and water column in reservoirs were determined. The results showed that seasonal DO and thermal stratification were developed obviously in the Baihua Reservoir and the Hongfeng Reservior. In addition, we used WASP software to simulate the water quality of these six reservoirs. By comparison, simulated value fitted well with the monitoring values, especially the DO. In the Baihua Reservior, serious pollution was frequently occurred in October, and DO concentration was extremely low, due to the water overturn. Based on our monitoring and simulating results, we tried to adjust the inflow discharge, and we found that the simulated value of DO in epilimnion in the Baihua Reservior can be increased by 1.3 mg/L in October. This result indicates that the discharge regulation in upstream reservoirs is a potential method to mitigate the water pollution in downstream reservoir.

Financial supports from NSFC (Grant No. 41273128) were acknowledged.

Geoelectrochemical anomaly, mechanism and exploration of copper and nickel deposit, Hongqiling, Jilin, China

X.LUO[1], M.WEN[1*] AND F.OUYANG[1,2]

[1]Guilin University of Technology, Guilin, 541004, China (*meilanwen112@126.com)

[2] China University of Geosciences, Beijing 100083

The geo-electrochemical study of Hongqiling Cu-Ni deposit resulted in a significant understanding of the geo-electrochemical feature of this copper nickel ore deposit, such as finding the ore-forming halo mechanism of the electrochemistry, which can be used for exploring the concealed ore deposits. This exploration method, called geo-electrochemical extraction, was successfully applied in the area of the Hongqiling mining area, Jilin province, China. The geo-electrochemical result shows that there exist geochemical anomalies of Cu, Ni, Co, Pt, Cr, Sr over the ore bodies. These anomalies, with synchronous vertical feature, are characterized variable value order from high to low: Cu>Ni>Co>Pt>Cr>Sr. The study of the electrochemical dissolution of Cu- Ni ores shows that after 24-hour, $2.2x10^{-6}$ of Cu^{2+}, $1.8x10^{-6}$ of Ni^{2+}, and $1.5x10^{-6}$ of Co^{2+} dissolved from the ores appear in the solution. This experimental work proves that the Cu-Ni ores can be dissolved by using electrochemical method, and thus the geo-electrochemical extraction is feasible in searching for concealed ore deposits. The success of this exploring technique in the exploration for concealed ore deposits has been demonstrated in the subsequent exploration activities in the Hongqinling area, and resulted in discoveries of 3 areas of geo-electrochemical anomaly.

Helium isotope and C/^{3}He ratios have proven useful for differentiating between various mantle reservoirs such as mid-ocean ridges, arcs, backarcs, and mantle hotspots. True back-arc systems are similar to mid-ocean ridge (MOR) systems with ^{3}He/^{4}He of ~ 8 Ra (R = ^{3}He/^{4}He and Ra = Rair) and C/^{3}He of ~10^9. In contrast, arc volcanoes have lower ^{3}He/^{4}He and higher C/^{3}He ratios ($\geq 10^{10}$), presumably due to carbon addition by the downgoing slab. Hotspots typically have elevated ^{3}He/^{4}He (12 - 30 Ra) and C/^{3}He similar to MORBs (~10^9). We have applied this approach to the northern Lau Basin, which is host to a complicated pattern of volcanic activity, with the NE Lau Spreading Center in the west, the volcanoes of the Tofua Arc in the east, and various other volcanic centers in between. Farther west along the NW Lau Spreading Center, elevated ^{3}He/^{4}He ratios in the seafloor lavas suggest that an OIB or mantle plume component, possibly from Samoa, has influenced this extensional zone. This paper will discuss how these volcanic centers and spreading zones show varying degrees of influence from arc, MOR, and hotspot components based on their ^{3}He/^{4}He and C/^{3}He fingerprints.

Characterization of transport parameters during limestone dissolution experiments

LINDA LUQUOT[1*], TOBIAS RÖTTING[1,2] AND JESUS CARRERA[1]

[1]Institute of Environmental Assessment and Water Research (IDAEA, CSIC) Barcelona, Spain
[2]GHS, Departement of Geotechnical Engineering and Geosciences, Technical University of Catalonia (UPC-BarcelonaTech), Barcelona, Spain
(* linda:luquot@idaea.csic.es)

CO_2 sequestration in deep geological formation is considered an option to reduce CO_2 emissions in the atmosphere. After injection the CO_2 will slowly dissolve into the pore water producing low pH fluids with a high capacity for dissolving carbonates. Limestone rock dissolution induces geometrical parameters changes such as porosity, pore size distribution, or tortuosity which may consequently modify transport properties (permeability, diffusion coefficient). Characterizing these changes is essential to model flow and CO_2 transport during and after the CO_2 injection.

Here we report experimental results from the injection of acidic fluid into limestone core samples of 25.4 mm diameter, 12.5 mm length. Experiments were realized at room temperature. Before and after each acidic rock attack, we measure the sample porosity, the diffusion coefficient and the pore size distribution. During percolation experiments, the permeability changes are recorded and chemical samples taken to evaluate calcite dissolution. Several dissolution-characterization cycles are performed on each sample in order to study the evolution and relation of the different parameters.

These experiments show that far from the well injection site (i.e. intermediate pH solution (4-5)), dissolution processes are characterized by slow mass transfers. We measure a permeability decrease during the different experiments. Nevertheless, we observed a porosity increase in the sample inlet with higher pore diameters. In the opposite, we measured smaller pore sizes near the core sample outlets. These results indicate that some fine particles move from the sample inlet towards the outlet. Due to the low fluid acidity, these fine particles are not dissolved inside the samples and are transported inside. Consequently, these particles can locally clog the porous space and decrease the permeability.

Role of carboxylates released by microorganisms and roots of alpine pioneer plants in mobilising phosphorus and metal cations during early soil formation

JÖRG LUSTER*[1], HANS GÖRANSSON[2], HARRY OLDE VENTERINK[3], IVANO BRUNNER[1] AND BEAT FREY[1]

[1]Swiss Federal Research Institute WSL, CH-8903 Birmensdorf, Switzerland (*correspondence: joerg.luster@wsl.ch; ivano.brunner@wsl.ch, beat.frey@wsl.ch)
[2]Inst. of Forest Ecology, BOKU, A-1190 Vienna, Austria (hans.goeransson@boku.ac.at)
[3]Inst. of Integrative Biology, ETHZ, CH-8092 Zurich, Switzerland (harry.oldeventerink@env.ethz.ch)

In the framework of an interdisciplinary study on initial soil formation along a deglaciation chronosequence, we examined the role of carboxylates in mobilising P and metal cations, in particular at the early stages of soil development, where no or only little soil organic matter has built up.

At selected sites with 6, 70 and 128 year old soils, soil solution was collected in-situ using micro suction cups, differentiating between the rhizosphere of specific plants and bulk soil. At the youngest site, carboxylates were enhanced in all rhizospheres exhibiting plant specific patterns, while phosphate and metal concentrations were increased in rhizospheres at all soil ages. Overall and independent of soil age, soil type and sampling date, net mobilisation of P and metals correlated with the net production of carboxylates, with malate, tartrate, oxalate and citrate playing specific roles.

A comparison with laboratory experiments on P mobilisation by plants and on granite dissolution by bacterial and fungal isolates, suggests that both bacteria and fungi are important for initial nutrient mobilisation. Bacteria, releasing mainly oxalate, are efficient in mobilising metals, while fungi, releasing mainly citrate and malate, are able to mobilise both phosphate and metals [1,2]. Once first plants appear, they seem to strongly increase nutrient release from minerals in their rhizosphere with root exudation of carboxylates probably playing a two-fold role. On one hand it stimulates microbial activity, on the other hand contributes directly to weathering, in particular by means of ligands that are not produced by microorganisms such as tartrate.

Carbonate, not carbonatite, at Villamayor volcano (Calatrava Volcanic District, Central Spain)

M. LUSTRINO[1], S. AGOSTINI[2] L. S. CAPIZZI[1], M. PSARAKIS[1] AND D. PRELEVIĆ[3]

[1]Dipartimento di Scienze della Terra, Università degli Studi di Roma La Sapienza, Roma, ITALY
[2]CNR – Istituto di Geoscienze e Georisorse, Pisa, ITALY
[3]Geocycles Research Centre and Institute of Geosciences, University of Mainz, Mainz, GERMANY

The Villamayor Volcano (~9 Ma) represents the oldest volcanic activity in the Calatrava Volcanic field, Central Spain. The products of this activity have been classified in literature as leucitites despite a minor presence of modal leucite (<5 vol. %), the low K_2O content (<4.3 wt) and the low K_2O/Na_2O ratio (<1.8). The lava flows of this small volcano are strongly porphyritic with the presence of subhedral to euhedral olivine phenocrysts. A recent paper (Humphreys *et al*.., 2010) classify these rocks as leucitites and considers the olivine phenocrysts as mantle debris. The carbonate inclusion is considered to represent the relict of Ca-carbonatitic magma crystallizing calcite and, in one single case, aragonite. We challenge the Humphreys *et al*. (2010) hypothesis for several reasons:

1) The olivine crystals cannot be considered mantle xenocrysts because of their low Forsterite content (72-89 mol% Fo) and euhedral to subhedral shape..

2) The rare mica associated with carbonate within hollow olivine has relatively low Mg# (73-84 vs. 89-95).

3) The carbonate present in the Villamayor mantle sources, in equilibrium with the leucititic magma cannot be Mg-free as the Ca-carbonate (calcite and aragonite) found within the hollow olivine crystals. The calculated leucitite composition (obtained subtracting 30% olivine, considered xenocrysts by Humphreys *et al*.., 2010) is MgO-poor (0.52 wt%). This is not compatible with a mantle melt.

4) The SrO content of the carbonate inclusions is generally low (generally <0.20 wt) and never exceeding 0.54 wt%, values, compatible with sedimentary carbonates.

We propose a sedimentary source for the carbonate inclusions. In our model sedimentary carbonate is scraped off the country rocks and partially digested by the ultrabasic melt. When in contact with the carbonate xenocrysts the olivine growth is stopped, producing the typical hollow body euhedral shape of the Villamayor olivine.

Driving mineral dissolution studies in a new direction

ANDREAS LÜTTGE[1,2,*], CORNELIUS FISCHER[1,2], ROLF S. ARVIDSON[1] AND INNA KURGANSKAYA[1]

[1]Marum, Univ. Bremen, 28359 Bremen, Germany (*correspondence: c.fischer@uni-bremen.de)
[2]Rice University, Houston, TX 77005, USA

Recent studies by [1] have demonstrated that intrinsic rate variations in mineral dissolution are common and of up to 2.5 orders of magnitude. As a major consequence, we have abandoned the concept of simple closed-form rate equations. Instead, we have introduced the concept of rate spectra. Such rate spectra are the direct result of the fact that dissolution rates depend critically on surface energy distribution. This alternative avoids the highly problematic use of concepts such as reactive surface area that have proven to be mainly not quantifiable.

It is not sufficient to just critizise the existing approach that has certainly produced a sound large data base and many valuable observations. However, we are increasingly skeptic that we will gain much new insight from this approach. Instead we would like to encourage a competition for a new, more powerful approach. As a start, we suggest here one possible method that consists of experiments with analytical tools such as atomic force microscopy, RAMAN-coupled vertical scanning interferometry, among others, and comprehensive theoretical methods such as kinetic Monte Carlo (KMC) calculations. The latter tool provides the capability of predicting crystal dissolution mechanisms and rates. As an example, we will discuss a couple of two recent studies by [2,3] that have focused on phyllosilicates and quartz. In these studies, we demonstrate that complex KMC models which are parameterized with results from *ab initio* and DFT calculations can indeed successfully predict the behavior and development of dissolving crystals.

Contamination of DM-sourced magmas produced diverse flood basalts in the Karoo province?

LUTTINEN A.V.[1] AND HEINONEN J.S.[1]

[1]Finnish Museum of Natural History, P.O.Box 17, FIN-00014 University of Helsinki, Finland

Continental flood basalt (CFB) provinces represent large emplacements of mantle-derived magmas that frequently exhibit incompatible element and isotopic affinity to silicic continental crust. Whether or not this affinity stems from predominantly lithospheric mantle sources rather than crustal contamination of hotspot magmas has remained controversial.

The Middle Jurassic lavas and dikes of Vestfjella were generated during the breakup of Gondwana and represent remnants of the Karoo CFB province in Antarctica. The Vestfjella CFBs record notably diverse geochemical compositions (e.g., initial εNd from -15 to +8). The well-exposed 1-km-thick lava succession and the crosscutting dike swarm are dominated by three variably enriched geochemical types (CT1, CT2, and CT3), but the dikes also include rare lamproitic, ferropicritic, and MORB-like (initial εNd = +8) types. The Sr, Nd, Pb, and Os isotopic compositions of the MORB-like dikes overlap with those of modern Southwest Indian Ridge MORB, but the trace element compositions indicate melting at high pressures (below thick Gondwanan lithosphere).

Our calculations using the energy-constrained assimilation and fractional crystallization (EC-AFC) model demonstrate that the diverse CFB types could have been derived from a single MORB-like parental magma type by contamination. Importantly, calculations using Archean and Proterozoic granitoids and local lamproite as crustal and lithospheric mantle contaminants infer that even the most enriched CFBs of Vestfjella contain >90% of a depleted sublithospheric mantle-derived component.

These results lend support to the view that lithospheric contamination of voluminous sublithospheric mantle-derived melts may be chiefly responsible for the predominance of enriched magma types in CFB provinces.

Snow and ice algae rock - Cryo-Life habitability in an extreme environment

STEFANIE LUTZ[1], ALEXANDRE M. ANESIO[2] AND LIANE G. BENNING[1]

[1]School of Earth & Environment, University of Leeds, LS2 9JT, UK (*correspondance: s.lutz@leeds.ac.uk)
[2]Bristol Glaciology Centre, School of Geographical Sciences, University of Bristol, BS8 1TH, UK

Snow and glacial ice surfaces cover about 10% of Earth's surface and despite being extreme environments they are colonised by a plethora of organisms [1]. On an ecosystem scale, snow and ice algae are the crucial primary colonisers and producers [2]. They evolved a suite of protective biomolecules (e.g., pigments), are well adapted to cold, UV and nutrient stress [2] and dominate the organic and inorganic carbon flux on glaciers. This may also imparts them a central role in controlling the diversity and structure of other communities in glacial ecosystems, yet so far little is known about this. Microbial cryo-adaptation and preservation of life and geochemical signals also have clear implications for the life detection on other icy planets (e.g., Mars, Europa).

Here we show how assessing a variety of physico-chemical (T, melting and transition from snow to bare ice habitats, UV/PAR radiation) and biogeochemical (nutrient and trace metal scarcity, pigment and lipid compositions, and structure) parameters in varied cryogenic glacial habitats (e.g., snow, ice and cryoconites) can be used to define cryo-life habitability at a whole ecosystem scale of a glacier (~ 1 km^2 of Mittivakkat glacier, SE-Greenland). We found that by far the snow and ice algae dominate the glacial C cycle and the primary production on a glacial scale. The low nutrient (< 1 ppm) and trace metal (< 100 ppb) contents combined with slowly weathering and nutrient-scarce minerals provide an extreme setting for algae growth. Nevertheless, spectroscopic and chromatographic analyses of cells revealed a broad and, rapidly changing cryo-organic inventory during the melting season. The spatial and temporal heterogeneity in pigment composition and abundance between samples correlated well with the functional group distributions showing a clear trend among microbial communities and their adaptation strategies. These findings together with metagenomic diversity and functional gene analyses provide a first comprehensive insight into the ecology of an entire glacial surface ecosystem.

The MUSIC model over the years from a personal point of view

J. LÜTZENKIRCHEN[1]

[1]Institut für Nukleare Entsorgung, Karlsruher Institut für Technologie (KIT), Hermann-von-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen, Germany; johannes.luetzenkirchen@kit.edu

The first MUSIC papers were revolutionary: explicit consideration of distinctly different sites on a single face of a mineral based on structural considerations vs. previously used generic sites; fractional (Pauling) charges in surface chemical reactions vs. text-book integer charges; prediction of proton affinity constants vs. numerical fitting. The failure of MUSIC to describe goethite surface charge for updated particle morphology required inclusion of further details of the mineral water interface, such as the effects of H-bonds on predicted affinity constants. Fractional charges were now based on Brown-Altermatt. Up to this point basic charging was the major issue treated by MUSIC. Completion of the framework by introducing charge distribution (CD) allows modeling the adsorption of dissolved pollutants to minerals by combining macroscopic with atomistic level data. CD-MUSIC (to my mind still the most advanced model for this purpose) is heavily cited, but comparably few CD-MUSIC applications from outside Wageningen appeared, maybe related to its incompatibility with common speciation codes or due to other shortcomings of the few codes permitting fractional charges. Fortunately, popular tools like Phreeqc now include CD-MUSIC. Model calculations will exemplify recent developments and associated problems. Experimental model systems will be discussed that strongly support the MUSIC approach, but at the same time hint to limitations arising from effects that CD-MUSIC was never supposed to handle. Grateful for having met Willem van Riemsdijk early on I will surely miss discussions with him and his continued encouragement over the years.

Climate and topographic controls on soil organic carbon cycling in southern Arizona, USA

R. LYBRAND[1]*, K. HECKMAN[2] AND C. RASMUSSEN[1]

[1]Dept of Soil, Water & Environmental Science, University of Arizona, Tucson, AZ [*correspondence: rlybrand@email.arizona.edu, crasmuss@ag.arizona.edu]
[2]Northern Research Station, USDA Forest Service, Livermore, CA [kaheckman@fs.fed.us]

The objective of this research was to understand how climate and topography control soil organic carbon (SOC) sequestration across the Santa Catalina Mountain Critical Zone Observatory in southern Arizona, USA. The CZO spans significant range in mean annual temperature (>10°C) and precipitation (>50 cm yr^{-1}). SOC distribution was examined using density and aggregate separations to obtain the free, occluded, and mineral SOC pools for surface and subsurface granitic soils from divergent and convergent landscape positions. Radiocarbon analyses demonstrated that free fractions typically contained the youngest and the mineral or occluded the oldest C depending on the ecosystem. Desert scrub soils sequestered relatively little (<1%), dominantly fast-cycling SOC where the oldest C was mineral associated, indicating organo-mineral interactions as the dominant sequestration mechanism. In contrast, the conifer systems stored more SOC (>3%) and preserved the oldest C through physical occlusion mechanisms. Conifer SOC was 2x greater in the convergent site versus the adjacent divergent site. The age and chemistry of SOC in conifer convergent landscapes suggest downslope transport and burial of SOC in convergent surface soils as an important topographic control on SOC cycling. Bulk soil measurements at the mixed conifer convergent soil-weathered rock interface (~120 cm in depth) indicated a modern $\Delta^{14}C$ signal (0.0‰, -16.3‰), suggesting downward transport of dissolved organic carbon in the soil pedon. The data confirms shifts in SOC sequestration mechanisms across climatically distinct ecosystems of the southwestern U.S.

O-MIF and S-MIF effects in photolysis of CO and SO_2

J. LYONS[1], G. STARK[2], D. BLACKIE[3], H. HERDE[2] AND N. DE OLIVEIRA[4]

[1]SESE, Arizona State Univ., james.r.lyons@asu.edu
[2]Physics Dept., Wellesley College, gstark@wellesley.edu

[4]Soleil Synchrotron, nelson.de.oliveira@synchrotron-soleil.fr

CO Photolysis

O-MIF during CO photolysis in the solar nebula has been suggested as the origin of the slope-1 solar system O isotope line. Photolysis experiments have demonstrated a wavelength-dependence to the $\delta^{17}O/\delta^{18}O$ ratio of photoproduct O that seems to rule out a slope-1 trend. Simulations of the experiments using synthetic isotopic CO spectra and ALS synchrotron spectra reproduce the data well, but require an isotope dependence in the dissociation probability, ϕ, such that $\phi_{C18O} \sim 0.5*\phi_{C17O}$ for the CO E(0) band at 107 nm. Solar nebula model calculations of CO photolysis using OB stellar spectra, synthetic CO spectra, and the new values for ϕ for the E(0) band yield $\delta^{17}O/\delta^{18}O$ values close to unity, so that inclusion of the revised ϕ value improves the agreement between the nebular photolysis model and the solar system O isotope line. Direct evidence for a reduced value for ϕ_{C18O} can be made by high-resolution linewidth measurements of the E(0) band for $C^{18}O$. The cause of the isotopic differences in ϕ are the mismatch of energy levels in an indirect predicsosociation process, such as occurs in CO photolysis.

SO_2 Photolysis

Could isotopic dissociation probability effects play a role in S-MIF generation during SO_2 photolysis? Self-shielding has been shown to be important in photolysis experiments in optically-thick SO_2 columns, but a pressure effect is also seen such that the S-MIF signature in photoproduct sulfur is reduced at pressures approaching ~1 atmosphere. The pressure effect could arise from either 1) pressure broadening of the SO_2 rovibronic lines in the dissociation regions, or 2) from collisional deactivation of coupled (bound) SO_2 excited states. At the Soleil synchrotron we have measured pressure broadening in $^{32}SO_2$, and see broadening ~ 0.2 – 0.3 cm^{-1} atm^{-1} for N_2 and CO_2 gases. Such broadening appears to be insufficient to explain the pressure effect seen in photolysis experiments. We therefore consider it possible that isotopic variations in dissociation probability also occur during SO_2 photolysis. Optically-thin model simulations for the known non-unity dissociation probability region for SO_2 (~210-220 nm) show that maximum $\Delta^{33}S$ values of ~ 10‰, with $\Delta^{36}S/\Delta^{33}S \sim -1$ for elemental sulfur are possible (but far from proven) for this mechanism.

Behaviour of anthropogenic radionuclides in the proglacial environment

E. ŁOKAS[1*], P. WACHNIEW[2], M. GĄSIOREK[3] AND P. BARTMIŃSKI[4]

[1]Institute of Nuclear Physics PAS, Krakow, Poland (*correspondence: Edyta.Lokas@ifj.edu.pl)
[2]AGH University of Science and Technology, Krakow, Poland (wachniew@agh.edu.pl)
[3]University of Agriculture in Krakow, Krakow, Poland (rrgasior@cyf-kr.edu.pl)
[4]Maria Curie-Sklodowska University, Lublin, Poland (piotr.bartminski@umcs.pl)

Retreating Arctic glaciers uncover areas that are sites of intense biogeochemical and geomorphic activity. Analyses of fine-grained deposits from proglacial zones of two Spitsbergen glaciers revealed unexpectedly high concentrations of fallout radionuclides reaching 3000 Bq/kg, 1 Bq/kg and 20 Bq/kg for ^{137}Cs, ^{238}Pu and $^{239+240}$Pu, respectively. Airborne anthropogenic radionuclides are efficiently retained in cryoconites – accumulations of dust and organic matter on glacier surfaces. This highly active material is washed down as melting of glacier surface proceeds and may be redeposited in the proglacial zone. Upon entering the subglacial drainage system the cryoconite material becomes diluted with large volumes of water carrying fine-grained mineral material derived from weathering of rocks. Therefore, the extremely high activities of fallout radionuclides might be found only in those parts of the proglacial zone that receive direct runoff from glacier surface. Activities measured at other sites were similar to values reported for Arctic soils. Granulometric, mineralogical, and chemical properties showed no significant vertical variability in the collected proglacial deposits. The observed distribution of radionuclides with depth in the deposits must thus reflect changes in their delivery to particular sites. Finally, development of vegetation on these hot-spots of radioactivity will lead to introduction of fallout radionuclides into the Arctic food web.

Nanomineralogy of gemstones: From genesis to discovery

CHI MA* AND GEORGE R. ROSSMAN

Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA 91125, USA.
*Email: chi@gps.caltech.edu

Nanomineralogy is the study of Earth and planetary materials at nanoscales, focused on characterizing nanofeatures (like inclusions, exsolution, zonation, coatings, pores) in minerals and rocks, and revealing nanominerals and nanoparticles [1]. With advanced high-resolution analytical scanning electron microscope, we are now capable to characterize solid materials easier and faster down to nanometer-scales. During our nanomineralogy investigation of gemstones, nanofeatures are being discovered in many commom gems, which cause color and other optical effects, and provide clues to genesis. Presented here are a few colorful projects demonstrating how nanomineralogy works and plays a unique role in gemstone and geomaterial research.

Rose quartz contains nanofibers of a dumortierite-related phase that is pink, which is the true cause of rose color and optical star effects [2,3]. Sub-micrometer inclusions of ilmenite are the cause of color in blue quartz.

Why is obsidian black? Because most obsidians contain nanoinclusions of magnetite. 'Fire' obsidian, a variety of obsidian from Oregon, has thin layers showing varous colors. The layers, 300 to 700 nm thick, consist of concentrated nanocrystals of magnetite, giving rise to brilliant colors in reflection due to thin-film interference [4]. Whereas 'rainbow' obsidian from Mexico contains oriented nanorods of hedenbergite, which cause the rainbow effects via thin-film interference [5].

During a study of benitoite, the state gemstone of California, new mineral barioperovskite ($BaTiO_3$) and two more new barium titanate minerals $BaTi_2O_5$ and $BaTi_3O_7$ were discovered to occur in a tubular inclusion within one benitoite crystal [6].

Granite compositions: Source vs. process, revisited. An isotopic traverse across SE Australia

ROLAND MAAS[1] AND IAN NICHOLLS[2]

[1]School of Earth Sciences, University of Melbourne, Australia, maasr@unimelb.edu.au
[2]School of Geosciences, Monash University, Melbourne, Australia

Granite compositions are determined by source characteristics, by details of melting, melt extraction and transport through the crust, by magma mixing and assimilation at various scales and depths, and by magma chamber processes. The importance of each factor is often difficult to ascertain. We examine this issue using Sr-Nd-O isotope data for 430-370 Ma granites across the Paleozoic Lachlan Orogen (LO), SE Australia.

S-types granites in the eastern LO show strong isotopic links with Lower Paleozoic low-ε_{Nd} meta-turbidites which dominate the mid crust. Further west, geophysical data suggest the presence of a greenstone-dominated, lower/mid-crustal Neoproterozoic block with a thickness of 25 km above Moho, the Selwyn Block. S-type granites in this area have higher ε_{Nd}, $\delta^{18}O$ and lower $^{87}Sr/^{86}Sr$ than those in the eastern LO, and links to the meta-turbidites – present above the block – are weak. In the far western LO where the mid crust comprises thick, imbricated Cambrian metabasalts overlain by meta-turbidites, S-types show the widest isotopic range (ε_{Nd} -2 to -9), consistent with links to both metabasalts and turbidites.

I-type granites in the eastern LO show strong Sr-Nd isotope covariation; their large range in ε_{Nd} (+6 to -8) could reflect source rock heterogeneity (e.g. Cambrian greenstones underlying the meta-turbidites have a similar isotopic range), syn-magmatic mixing (crustal assimilation), or both. I-types in the western part of the orogen are isotopically diverse, with distinct trends in Sr-Nd-O isotope plots in the various structural zones, but links to known lower crustal features appear to be weaker than for the S-types.

The data from this example suggest that heterogeneity in source (isotopic) compositions is transferred to S-type granite/volcanic compositions with little disturbance by post-melting processes, at least at an orogen-wide scale. I-type petrogenesis appears to be more complex and probably involves mixing processes (mixed sources, syn-magmatic mixing).

Temporal variations of atmospheric helium isotopes

J.C. MABRY[1]*, T.F. LAN[1], P. BURNARD[1] AND B. MARTY[1]

[1]CRPG-CNRS, 54501 Nancy, France (*correspondence: jmabry@crpg.cnrs-nancy.fr)

The isotopic composition of the atmosphere ($^3He/^4He$ = 1.382±0.005 x 10^{-6}) is distinctly different from crustal helium ($^3He/^4He$ ~10^{-8}). Several authors [e.g. 1, 2, 3] have proposed that the amount of excess crustal helium entering the atmosphere due to modern fossil fuel extraction may be enough to upset the balance of the helium composition in the atmosphere on a timescale short enough to detect with modern measurement techniques. Previous attempts failed to detect variations beyond the measurement precision [3, 4]. However, recent measurements by [5] from the Cape Grim Air Archive (CGAA) found a decrease of the atmospheric $^3He/^4He$ of 0.23-0.30‰ per year over the period 1978 to 2011. We will attempt to replicate these results using a high-precision helium isotope measurement system we have devised.

Air samples are collected in copper tubes which are sealed with steel clamps. Each sample is approximately 15-20 cm^3 of air which is purified all at once and then measured in 11 standard-bracketed aliquots. The amount of helium in each sample aliquot is matched to the amount in an aliquot of the standard to minimize pressure effects. Measurements are made on a Thermo Helix Split Flight Tube (SFT) multi-collector noble gas mass spectrometer. With this system we have a long-term reproducibility of sample air of 0.05% (2σ).

Our initial measurements of the $^3He/^4He$ in CGAA samples do not reproduce the results of [5]. They are consistant with no change in the helium composition over time with an upper limit (2σ) of 0.16‰ per year decrease in $^3He/^4He$. We will make further measurements of the CGAA samples.

Sample	R_{air}/R_{std} (2σ)	# analyses
CGAA 1978	1.0402 (0.0027)	3
CGAA 1979	1.0386 (0.0010)	7
CGAA 2008	1.0387 (0.0004)	4

Application of clumped isotope thermometry to subsurface dolostone samples

J. M. MACDONALD[1]*, C. M. JOHN[1] AND J. P. GIRARD[2]

[1]Carbonate Research, Dept. Earth Science and Engineering, Imperial College London, SW7 2AZ (*correspondence: john.macdonald@imperial.ac.uk; cedric.john@imperial.ac.uk)

[2]TOTAL, CSTJF, Ave Larribau, 64018 Pau (jean-pierre.girard@total.com)

Platform carbonates are a major hydrocarbon reservoir setting, and are often dolomitized. An important parameter in characterising these reservoirs is the palaeotemperature of the various carbonate phases during burial diagenesis. Clumped isotope analysis of CO_2 from acid digestion of carbonate phases may offer the best route to accurately and precisely determining this temperature. We apply the clumped isotope palaeothermometer to natural dolostone samples from the Northern Marion Platform (NMP, offshore NE Australia) and to dolostone samples from other subsurface locations.

Initially, five dolostone samples from the NMP collected between ~100-160 metres below sea floor (mbsf) were analysed. Petrographic analysis revealed that these samples were all pervasively dolomitized: planar-s to planar-e dolomite forms 100% of the modal mineralogy. Initial clumped isotope analysis (triplicate analyses; reaction at 90°C for 45mins; acid and non-linearity corrections applied; data transferred to universal reference frame [1]) yielded temperatures of 22 °C to 31 °C using the calibration of Ghosh *et al*. [2].

As a second step, we analysed samples from subsurface wells where independent constraints using fluid inclusion thermometry exist. By testing clumped isotope thermometry on these well-constrained natural reservoir samples, we hope to show that clumped isotope thermometry is an ideal technique to determine burial temperatures in carbonate reservoir rocks, as it overcomes some of the problems inherent in fluid inclusion and conventional $\delta^{18}O$ thermometry.

Hot CD-MUSIC

M. L. MACHESKY[1]*, D. J. WESOLOWSKI[2], M. K. RIDLEY[3], M. PŘEDOTA[4], Z. ZHANG[5], P. A. FENTER[5] AND J. D. KUBICKI[6]

[6]The Pennsylvania State Univ., University Park, PA 16802, USA, (jdk7@psu.edu)

Among the many seminal contributions of Professor van Riemsdijk is the CD-MUSIC model, which was developed in collaboration with Professor Hiemstra, and has remained the state-of-the-art Surface Complexation Model since its publication in 1996[1]. Also in the mid-1990's our group began investigating ion adsorption phenomena (primarily cations) over a wide range of temperatures extending into the hydrothermal regime (10-250ºC), mostly on rutile, but also on several other metal oxides[2]. More recently, we have also complimented these macroscopic data with a variety of molecular-level information, including X-ray synchotron experiments, and static DFT as well as classical molecular dynamics (MD) simulations. CD-MUSIC has proven to be a sturdy framework within which we have been able to coherently interpret this assortment of data[3,4].

This contribution will summarize our efforts to rationalize adsorption data for rutile to 250ºC within the CD-MUSIC model framework with particular focus on Sr^{2+} and Zn^{2+}. Our classical MD simulations suggest that the enhanced adsorption observed macroscopically as temperature increases is due to adsorbed cations moving closer to the surface and shedding more bulk hydration water in the process. CD-MUSIC can mimic this behavior although the agreement is not perfect, suggesting extensions to CD-MUSIC may be warranted.

Geochemical variations of basalts from petit-spot volcanoes in the northwestern Pacific

S. MACHIDA[1,2]*, N. HIRANO[3], Y. KATO[2], A. TAMURA[4] AND S. ARAI[4]

[1] School Creative Sci. Engineer., Waseda Univ., Tokyo 169-8555, Japan (*correspondence: m-shikit@aoni.waseda.jp)
[2] School of Engineer., Univ. of Tokyo, Japan
[3] Center NE Asian Studies, Tohoku Univ., Japan
[4] Grad. School of Sci., Kanazawa Univ., Japan

Petit-spot, new type young volcanoes discovered on the old Pacific plate, originate from melting in the uppermost mantle asthenosphere, and that the magma exudes where the plate flexes and fractures before subducting [1]. Our recent studies defined that alkaline basalt lavas from petit-spot show (1) high concentrations of incompatible trace elements indicating extreme enrichment in highly incompatible elements (e.g., Rb, Ba, U, Th, and Nb) and REE, and depletion in heavy REE [1], and (2) extreme EM-1-like, Sr, Nd, and Pb isotopic compositions [2]. These results indicate that melting of small-scale recycled plate material produces petit-spot magma [2]. Thus, detailed geochemical investigation for these petit-spot volcanoes will provide key constraints on our understanding of the nature of heterogeneity of the northwestern Pacific upper mantle.

Basalts were collected from twelve petit-spot volcanoes at a site in the Japan Trench (Site A), a site approximately 600 km ESE of the Site A (Site B), and a site approximately 200 km S of the Site A (Site C). Five distinct compositional groups are identified on the basis of their major and trace element compositions. The Group 1 basalts (G1), from the Sites A and C, are enriched in LILEs and LREEs. Then, they show negative U, Th, Nb, and Ta anomalies. The Group 2 basalts (G2) from the Site A show negative U, Th, Nb, Ta, Zr, and Hf anomalies, and higher alkali contents than G1. However, on the basis of other major element characteristics, G2 are further subdivided into three groups. G2-2 have lower SiO_2 and higher FeO*/MgO than G2-1 (and G1). G2-3 show a similar major element signature to G2-2, except for lower CaO. The Group 3 basalts, obtained from Site B, show lower SiO_2 and higher FeO*/MgO than G2-2, and negative Zr and Hf anomalies. Variation of Ba/Nb of basalts from all groups correlates to Sr and Nd isotopic compositions. These observations suggest that the source heterogeneity for petit-spot magma is regulated by degree of contributions of LILEs and LREEs-enriched material.

Using noble gases for real-time tracing of oxygen turnover in aquatic systems

LARS MÄCHLER[1], MATTHIAS S. BRENNWALD AND ROLF KIPFER[12]

[1]Eawag, Dep. of Water Resources and Drinking Water, Swiss Federal Institute of Aquatic Science and Technology, Switzerland

[2]Institute for Geochemistry and Petrology, Swiss Federal Institute of Technology Zurich, Switzerland

Our recent experimental developments on membrane inlet mass spectrometric systems allow the quasi-con-tinuous measurements of dissolved gas concentrations in natural waters under field conditions. Dissolved He, Ar, Kr, N_2, O_2, and CO_2 concentrations can be quanti-fied within minutes with high precision [±1%, 1].

The method was employed in a peri-alpine river to analyze the temporal and spatial dynamics of oxygen turnover during bank infiltration.

During *low* river discharge, the measurements indicated that aeration of groundwater is dominated by direct hyporheic exchange, and that the transport of solutes and heat are decoupled. The combined Ar-O_2 analysis allowed the in-situ oxygen consumption rate and it's dependence on the water temperature to be to deter-mined. During *high* river discharge after a flood event, we found that significant amounts of excess air were produced in the vicinity of the studied groundwater wells. The formation of excess air and the correspond-ing oxygen input into the groundwater varied according to the confining conditions within the aquifer and there-fore also co-varied with different ecological process zones.

Our results show that the combined analysis of noble and biogeochemically active gases yields valuable in-formation on the dynamics and the importance of dif-ferent gas exchange mechanisms in aquatic systems with respect to biogeochemical oxygen turnover and thus groundwater quality

Attempts to unravel the history of seawater chemistry go back as far as E. Halley [1] and J. Joly [2] and more recently W. W. Rubey [3] and H. D. Holland [4] among others. We have shown previously [5] that seawater chemical changes on the multi-million year time scale through Phanerozoic time reflect the essential state of the ocean-atmosphere-sediment system with respect to major lithophile and organic component fluxes constrained by a number of observations from the sedimentary rock record.

Despite relatively rapidly changing periods like the end Permian and PETM episodes, the system appears homeostatic and self-regulating and produces two dominant chemostatic modes despite apparent time lags among various variables that suggest different biogeochemical pathways leading to the modes: (Mode I) elevated atmospheric CO_2 and depressed seawater Mg/Ca and SO_4/Ca ratios, pH and carbonate saturation states (the calcite-dolomite seas) versus (Mode II) depressed atmospheric CO_2 and elevated seawater Mg/Ca and SO_4/Ca ratios, pH and carbonate saturation states (the aragonite seas). Transitions between the two modes are S. modified and overprinted by irreversible evolutionary and ecosystem changes. One example involves the shift of the locus of biogenic carbonate sediment deposition through radiation of pelagic calcifiers and the expansion of dolomite deposition enabling development of Mode I seawater chemistry in the Mesozoic. In addition, Paleozoic deep seas might have been sites of inorganic carbonate accumulation "lost" via subduction. Without this accumulation it is difficult to account for high atmospheric CO_2 concentrations and Mode I seawater chemistry during much of Paleozoic time.

Alunite-Turquoise occurrence from Ali-Abad porphyry copper deposit, Central Iran

M. A. MACKIZADEH[1]*, B. TAGHIPOUR[2] AND L. GORGI[1]

[1]Department of Geology, Isfahan University, Isfahan, Iran (ma_mackizadeh@yahoo.com)
[2]Department of Earth Sciences, Shiraz University, Shiraz, Iran (taghipour@shirazu.ac.ir)

The Ali-Abad porphyry copper deposit is situated in Central Iranian volcano-plutonic arc belt. The oldest rocks in the area are conglomerate and sandstones of Sangestan formation (late Cretaceous). They have been intruded by Oligocene to Miocene porphyrtic granitodis.

The widespread hydrothermal alteration has been taken place in conglomerate and sandstones including: Quartz-sercite, argillic, advanced argillic, silicification and skarn formation. The following mineral assemblage has been detected:

Alunite+ turquoise + pyrite+ sercite+ garnet+ quartz+ goethite + epidote+ calcite+ jarosite

According to field and mineralogical investigations the close associate of alunite-turquoise is well established in alteration zones. Probably, the turquoise is formed in charge of alunite or other Al-rich mineral phase during latest stage of alteration process. It seems that oxidation of sulphide minerals (supergene environment) its responsible for generation of all chemical reactions necessary for alunite-turquoise formation.

[1]Taghipour, B., Moore, F., Mackizadeh, M. A., and Taghipour, S (2013) Hydrothermal garnet in porphyry copper related skarn deposits, Ali-Abad, Yazd Province, Iran, Iranian J. Scie. Tech. accepted paper.

Metal precipitation mechanisms in, "low sulfide," magmatic Cu-Ni-PGE mineralization at Sudbury, Canada: First constraints on oxygen fugacity

MATTHEW A. MACMILLAN[1], JACOB J. HANLEY[2] AND DOREEN E. AMES[3]

[1]Saint Mary's University, Halifax, NS, B3H 3C3 (*correspondence: macmillanmatt41@gmail.com)
[2]Saint Mary's University (jacob.hanley@smu.ca)
[3]Geological Survey of Canada (dames@nrcan.gc.ca)

The Sudbury Igneous Complex (SIC), Ontario, Canada, is a large (~60km x 30km), elliptical mass of layered igneous rock situated along the contact between the Superior & Southern provinces of the Canadian Shield. The SIC is widely accepted to have been produced by melting of lower crust and upper crustal veneer due to meteorite impact at ~1850 Ma [1], and is remarkably associated with world-class Cu, Ni & PGE mineral deposits. Along the North Range of the SIC, "footwall-type," deposits are subdivided into sharp-walled vein and low sulfide PGE rich Cu-Ni-PGE mineralization.

Low sulfide mineralization occurs as ≤decimetre-scale blebs, disseminations & stringers of sulfide minerals that generally comprise <3% of any sample and are mined due to their anomalously high concentrations of precious metals compared to other deposit styles at Sudbury. Sulfides in these samples are intergrown with each other, and consist of bornite, chalcopyrite & millerite, and, as a result of their textural equilibrium with a variety of hydrothermal phases (Qtz, Cal, Ep, Chl, Ttn, Grt), are inferred to have precipitated from a hydrothermal fluid.

Hydrothermal garnets, which are rare in the footwall systems, were separated from a sulfide-bearing Qtz-Cal-Ep vein (also containing a CuO phase – tenorite) within the deep 153 ore body at the Coleman Mine and allow constraints to be placed on the formation conditions of low sulfide mineralization in this area of the SIC footwall. Garnets have been studied using include fluid inclusion methods, LA-ICPMS mapping, Lu-Hf/Sm-Nd isotopes and EMP (epidote-garnet equilibria oxythermobarometer) [2]. The results address the chemistry of fluids from which low sulfide mineralization formed, and will constrain P, T & fO_2 – conditions that have not been reported for low sulfide-style mineralization within the SIC footwall.

Arc lithosphere imposes segmented, great circle volcano distribution in the central Sunda Arc, Indonesia

COLIN G MACPHERSON[1], ADAM PACEY[1,2] AND KEN JW MCCAFFREY[1]

[1]Department of Earth Sciences, Durham University, Durham, UK, DH3 1LE. colin.macpherson@durham.ac.uk

[2] Department of Earth Science & Engineering, Imperial College London, South Kensington, London SW7 2AZ, UK

The term island arc betrays the common assumption that subduction zone magmatism occurs in curved zones, which can be expressed by approximating arcs as segments of small circles on a spherical surface. Such observations are used to relate arc volcano locations to their vertical separation from seismicity in the subducted slab and to conclude that the primary control on loci of magmatism lies in the slab or mantle wedge.

The small circle approximation ignores longstanding, empirical observations that magmatic centres in many subduction systems describe linear features i.e. segments of great circles. The Sunda Arc, Indonesia, is one system that has proved difficult to accommodate in small circle models. We applied an objective line-fitting protocol; Hough Transform image analysis, to explore the distribution of central Sunda Arc volcanoes. This shows that volcano distribution in the central Sunda Arc is best described as en echelon, great circle segments each of 500 – 750km length, rather than as small circles.

Central Sunda Arc segmentation reflects weakness of the arc lithosphere resulting from tectonic forces generated close to the plate margin and/or by arc lithosphere flexure. To the east of our study area the arc has collided with Australian continental crust while highly oblique convergence to the west has produced the Great Sumatran Fault. In both cases volcano locations can be related to stress imposed upon the arc lithosphere by these specific features. Furthermore, changing locations, petrography and geochemistry of central Sunda magmatism since the late-Pliocene can also be attributed to evolving stress in the upper plate.

We conclude that the arc lithosphere stress field is the primary control on distribution of Sunda Arc volcanoes. Interplay between this stress field and the arc crust will provide a major control upon pathways of magma from the mantle wedge to the surface.

Micro-Chronology of the Earliest Solar System: Challenges for the Future

GLENN J. MACPHERSON*

*Dept. Of Mineral Sciences, Smithsonian Institution, Washington, D.C. USA 20560
(correspondence: macphers@si.edu)

During the first ~1-2 Ma of our Solar System's history, as the Sun evolved from a Class 0 to a Class II protostar, solid matter in the innermost disk was heated, evaporated and recondensed, and extensively reprocessed (including melting). Such solids are preserved in chondrites as calcium-aluminum-rich inclusions (CAIs) and amoeboid olivine aggregates (AOAs). Evidence for the original evaporation and condensation is preserved mainly in the form of characteristic chemical and isotopic signatures, but rarely in the physical properties (e.g. textures) of the objects. In contrast, evidence for repeated melting and re-heating is everywhere in the petrology of most CAIs and AOAs. Advances in the analytical precision of mass spectrometry (MS), especially secondary ionization (SIMS), thermal ionization (TIMS), and inductively-coupled plasma (ICP-MS), now permit extraordinary time resolution of early solar system events that are recorded in the petrologic properties of CAIs and AOAs. Pb-Pb ages of CAIs yield a precision of < 500 Ka. ICP-MS measurements of the ^{26}Mg-^{26}Al isotope system demonstrate that the primary fractionation (presumably via condensation) of Al from Mg took place within 20 Ka. SIMS determinations of internal ^{26}Mg-^{26}Al extinct isochrons confirm that CAI precursors formed within a very short time consistent with that determined by ICP-MS, but remelting and reprocessing of CAIs continued for at least 200 Ka and possibly as long as 600 Ka. The time resolution of such SIMS internal isochrons is now bettter than 50 Ka. The challenge now is to identify the nature of the processes that are recorded in this chronology. For example, the original fractionation event that made the CAI precursors apparently was singular and of short duration whereas remelting occurred as a result of a process that happened repeatedly over 200 Ka or more. Nor is it clear if the formation of Wark-Lovering rims was a singular event affecting all CAIs simultaneously or a repeating event over time. Finally, there is as yet no anchor that ties Solar chronology with CAI chronology. One recent suggestion is that the last (or nearly so) FU-Orionis flare in the early Sun was responsible for making the generation of CAIs we now see, but earlier generations were destroyed. Such linking of solar processes and chronology with nebular products is a major challenge for the future.

Soluble Manganese(III) and a revised Sedimentary Redox Cycle

A. S. MADISON[1,~], A. MUCCI[2], B. SUNDBY[2], B. M. TEBO[3] AND G. W. LUTHER[1,*]

[1] School of Marine Science and Policy, College of Earth, Ocean and Environment, University of Delaware, Lewes, DE 19958, USA (*correspondence: luther@udel.edu); ~present address Golder Associates Inc., 200 Century Parkway, Mt. Laurel, NJ, USA 08054 (Andrew_Madison@golder.com)

[2] Department of Earth and Planetary Sciences, McGill University, Montreal, QC, Canada H3A 2A7 (alfonso.mucci@mcgill.ca; bjorn_sundby@uqar.ca)

[3] Division of Environmental and Biomolecular Systems, Oregon Health and Science University, Beaverton, OR 97006, USA (tebo@ebs.ogi.edu)

Recent field studies have confirmed the presence of soluble manganese(III) or [Mn(III)]aq, which along with Mn(II) passes through a 0.2 μm filter, in natural waters of the Black Sea, the Baltic Sea and Chesapeake Bay. This species can account for a large fraction (up to 100%) of the dissolved Mn pool at the oxic/anoxic interface. We have applied a spectrophotometric method to determine the concentration and speciation of Mn in sediment porewaters of the St. Lawrence Estuary collected during cruises in 2009 and 2010. In all samples, [Mn(III)]aq accounts for up to 80% of the total dissolved Mn pool in the vicinity of the oxic-suboxic boundary, with concentrations ranging from the detection limit of 50 nM to 80 μM. We use flux calculations and a diagenetic model to explore the interaction of Mn(III) with other element cycles.

Data collected along the Laurentian Trough of the St. Lawrence Estuary demonstrate that the reduction-oxidation capacity of the soluble Mn pool has been underestimated since Mn(III) can act as either an electron acceptor or an electron donor during interactions with the C, N, S, O and Fe cycles. In these (hemi)pelagic sediments, our data suggest that a significant fraction of the porewater Mn(III) is produced through the oxidation of Mn(II) by O_2. Soluble Mn(III) intermediates are also produced during dissimilatory MnO_2 reduction upon organic matter mineralization and abiotic reduction of MnO_2 by reductants such as Fe(II), FeS and H_2S. Finally, our results reveal that soluble Mn(III) is likely ubiquitous in porewaters, and, as such, is a key redox species in the global sedimentary cycles of carbon, oxygen, iron and sulfur.

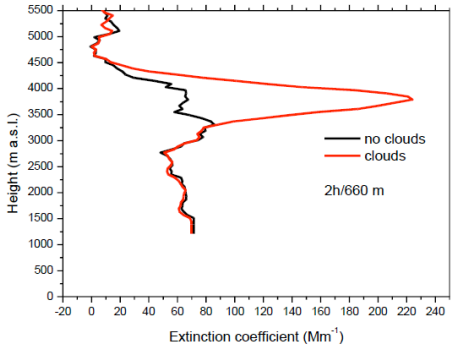
Study of droplet activation in thin broken clouds

F. MADONNA[1], M. ROSOLDI[1] AND G. PAPPALARDO[1]

[1]Consiglio Nazionale delle Ricerche - Istituto di Metodologie per l'Analisi Ambientale, Tito Scalo, Potenza, I-85010, Italy

fabio.madonna@imaa.cnr.it

The impact on climate of thin clouds is one of the most uncertain. Their importance is related to their global mean cloud fractional coverage [1]. Moreover, they provide significant information about the mechanisms leading to clouds formation. Thin clouds are difficult to observe accurately and large discrepancies exist among different observation techniques [2]. A study to assess the behaviour of macrophysical and microphysical properties of thin clouds is proposed. The study takes advantage of multi-wavelenght lidar and microwave radiometer measurements performed at CIAO (CNR-IMAA Atmospheric Observatory), in Potenza, Italy. Particular attention has been paid to optically thin broken stratocumulus where it is possible to investigate the fast change between non-saturation and saturation conditions in an aerosol layer and the droplet activation.



In the plot, it is reported the profiles of aerosol exctinction coefficient integrated over 2 hours obtained including (black) or excluding (red) clouds. The plot shows the seperation between the region where droplets are activated from that where aerosol particles seems to be not affected by nucleation processes. The results of the mentioned study over two years of data, including aerosol, water vapour and liquid water measurements, will be presented.

Geochemical and mineralogical characteristic of current roadside pollution from experimental monitoring plots located in different countries

TADEUSZ MAGIERA[1], MARIOLA JABŁOŃSKA[2], MARZENA RACHWAŁ[1] AND MAŁGORZATA WAWER[1]

[1]Institute of Environmental Engineering, Polish Academy of Sciences, 34 M. Skłodowskiej-Curie Str., 41-819 Zabrze, Poland (*correspondence: tadeusz.magiera@ipis.zabrze.pl)

[2]The Faculty of Earth Sciences, University of Silesia, 60 Będzińska Str., 41-200 Sosnowiec, Poland (Mariola.Jablonska@us.edu.pl)

The aim of the study was characterisation of current particulate pollutants emitted by traffic sources and deposited on roadside topsoil. For this purpose 7 cm of topsoil were removed and replaced by 30 plastic boxes filled with pure quartz matrix. Such experimental monitoring plots were installed in Poland, Germany, Finland, Tadjikistan, Greece and China close to arteries with high traffic volume. Geochemical analyses of some heavy metals (HM) were conducted by AAS (Fe, Mn, Zn, Pb, Cu) and ICP (Cd, Co, Mo and W) after extraction in aqua regia. Additionaly SEM and X-ray diffraction analyses were conducted in soil layer removed from monitoring place and in sand matrix after 1 and 2 years of exposition.

Chemical analyses of removed topsoils have shown that the highest contents of Fe, Mn, Zn, Pb, Cu were noted in Poland and Germany, but the highest amount of W was detected in Finland. After 1 and 2 years of exposure a big changes in HM content in quartz sand were observed. Contents of Fe, Mn, Zn and Pb in most monitoring plots were even three times higher after 2 years than after 1 year of exposure. There was significant increase of W in sand matrix after 2 years' exposure in samples from Finland.

Mineralogical analyses revealed different iron forms: metallic iron (α-Fe), Fe oxides (mostly magnetite and hematite), Fe-Zn and Fe-Cu oxides (ferrites) and other mineral components as: barite, aluminosilicates glassy phases and different kinds of spinels. In matrix from Finland plot tungsten carbide particles were also commonly observed.

Lithium isotope evidence for pervasive metasomatism of sub-continental lithospheric mantle

T. MAGNA[1], L. ACKERMAN[1,2] AND P. ŠPAČEK[3]

[1]Czech Geological Survey, Klárov 3, CZ-11821 Prague, Czech Republic; tomas.magna@geology.cz

[2]Inst. Geology, Academy of Sciences CR, Rozvojová 269, CZ-16500 Prague, Czech Republic

[3]Inst. Geophysics, Academy of Sciences CR, Boční II, CZ-14134 Prague, Czech Republic

We present Li contents and isotope compositions in a suite of spinel peridotite/harzburgite xenoliths, enclosed in Tertiary alkaline lavas from three volcanic centres in the western part of the Eger rift, Bohemian Massif, belonging to the European Cenozoic Rift System. Secondary features were observed in subset of xenoliths implying metasomatism by alkali-rich melts with carbonate affinity [1]. Whole-rock xenoliths show no to slight Li enrichment (1.4–5.8 ppm) coupled with extreme ^{7}Li depletion in some samples (δ^{7}Li from –9.7 to 2.5‰), attesting to dramatic departure from δ^{7}Li of pristine mantle (δ^{7}Li=3–4‰). More complex co-variations are observed for bulk δ^{7}Li and modal olivine, clinopyroxene and orthopyroxene for the three volcanic centres. δ^{7}Li values do not correlate with parameters of magmatic fractionation and/or fluid activity and are thus regarded as independent parameter of secondary metasomatism. However, carbonate-rich metasomatism does not impart specific Li signature to xenoliths that carry distinctive Nb–Ti enrichments in melt pockets [2]. On the contrary, relics of oceanic crust preserved as eclogites are ubiquitous in the wider area which may carry strongly negative δ^{7}Li values [3]. Their melts can metasomatize the sub-continental mantle and erase its intrinsic Li signature [4]. Therefore, we propose a scenario whereby xenoliths from the sub-continental mantle beneath central Europe were invaded by eclogitic melts formed at lower temperatures that carry distinctively light Li isotope compositions from earlier subduction of Saxothuringian lithosphere, operating in the area during the Devonian/Carboniferous although timing of the metasomatic imprint remains uncertain. Host alkaline basalts always have higher δ^{7}Li than the xenoliths, as also reported for xenoliths with mantle δ^{7}Li signature [5], implying uniform relationship of basalt–xenolith systems in continental settings.

Arsenic methylation in the bedrock aquifer of the Willamette Basin, Oregon, USA

SCOTT C. MAGUFFIN[1] AND QUSHENG JIN[1]

[1]1272 University of Oregon Eugene, OR, USA

Groundwater arsenic contamination is a significant threat to human health in many regions of the world. In aquifers, arsenic typically exists as arsenate or arsenite. Methylated arsenic, such as monomethylarsonate (MMA), dimethylarsinate (DMA), and trimethyarsenate, are less abundant and often overlooked as potentially significant species of arsenic. Identifying biogeochemical processes that control arsenic speciation is critical for developing remediation strategies and for predicting the mobility of arsenic in groundwater.

We analysed arsenic speciation in the bedrock aquifer of the Willamette Basin, Oregon, USA. Our results show that arsenite is the main species, with concentrations up to several parts per million (ppm); DMA is the main methylated species, with concentrations up to 20 ppb. Significantly, the concentrations of DMA correlate linearly with those of arsenite. Based on these observations, we hypothesize that in the aquifer 1) methylated arsenic species are produced from inorganic arsenic by prokaryotic methylation; and 2) prokaryotic methylation can be a significant process in the cycling of arsenic.

To test our hypotheses, we incubated aquifer sediments in reactors and monitored arsenic speciation over time. We also included sterlized sediments as a biological control. We observed the accumulation of MMA and DMA in all but the sterilized control. To determine the *in situ* rate of arsenic methylation, we conducted a push-pull test in the bedrock aquifer. Based on the field observations, we calculated that DMA accumulated at a rate of 1 to 3 ppb per day. Because DMA is produced and consumed simultaenously, this value represents the minimum rate of DMA production in the aquifer.

Our results demonstrate that DMA is produced *in situ* at a significant rate by indigenous aquifer prokaryotes. The results suggest that arsenic methylation is an important factor in evaluating the occurence and mobility of arsenic in groundwater. Because of the volatility of many methylated arsenic species, arsenic methylation may also constitute a significant pathway in the global cycling of arsenic.

Structure, dynamics, and spectroscopy of metalloproteins from methanogenic and hydrocarbonoclastic microbes

(*correspondence: jmagyar@barnard.edu)

The increasing scarcity of conventional, easily accessible petroleum sources leads to an increasing dependence on hard to reach petroleum in deep, cold offshore waters. These extraction processes lead to significant environmental challenges, including unprecedented spills in deep water. Here, we report progress toward an understanding of molecular adaptations for life at low temperatures, based on our study of cytochrome *c* from *Colwellia psychrerythraea*, a psychrophilic, hydrocarbonoclastic marine bacterium responsible for a large portion of the early bioremediation of the 2010 *Deepwater Horizon* oil spill in the Gulf of Mexico. Although surface oil spill bioremediation is well-established, the biogeochemistry of deep marine oil spills is not yet well understood. An understanding of psychrophilic metalloprotein dynamics and thermodynamics is essential to a full understanding of biogeochemical cycling in these environments.

Further insights into microbial metal uptake processes are gained from our parallel studies of a putative metalloregulatory protein from the methanogenic archaeon *Methanocorpusculum labreanum*. We suggest that this protein is involved in regulation of nickel uptake, which is essential for methanogenesis. In addition, we have determined that this protein is an iron-sulfur cluster-binding flavoprotein, suggesting a role in electron transfer processes as well.

For both *Colwellia* and *Methanocorpusculum*, we have used genomic information to identify specific proteins of interest. The genes are either synthesized chemically or amplified from genomic DNA by PCR and cloned into *E. coli*. The proteins have been overexpressed and purified, and we are currently characterizing them by a wide variety of spectroscopic and other techniques, including UV-vis absorption, circular dichroism, fluorescence, atomic absorption and NMR spectroscopies; X-ray crystallography; differential scanning calorimetry; electrochemistry; and analytical HPLC.

Isotopologue effects in the generation and consumption of nitrous oxide

PAUL M. MAGYAR[1]*, SEBASTIAN KOPF[1], VICTORIA J. ORPHAN[1] AND JOHN M. EILER[1]

[1]California Institute of Technology, Pasadena, CA 91125, USA (*correspondence: pmagyar@caltech.edu)

Nitrous oxide in air and natural waters is produced and consumed by chemical and biochemical reactions that fractionate isotopes by a variety of equilibrium and kinetic mechanisms. Previous measurements of $\delta^{15}N$, $\delta^{17}O$, $\delta^{18}O$, and position-specific ^{15}N incorporation ('site preference') have identified characteristic fractionations for many of these processes. In particular, site preference measurements have successfully distinguished between N_2O produced by bacterial nitrification and denitrification. But there remain too few constraints to fully characterize the sources and sinks of pools of N_2O in complex natural settings, and no existing isotopic tools distinguish among some biological sources, e.g., archaeal and bacterial nitrification. It is possible additional progress could be made by adding new constraints from the study of the multiply substituted isotopologues of N_2O [1].

We use high resolution multi-collector gas source mass spectrometry to measure the relative proportions of six singly and doubly substituted isotopologues of nitrous oxide, including $^{14}N^{15}N^{16}O$, $^{15}N^{14}N^{16}O$, $^{14}N^{15}N^{18}O$, $^{15}N^{14}N^{18}O$, $^{14}N_2{}^{17}O$, and $^{14}N_2{}^{18}O$ [2]. Each of these species has unique chemical and physical properties that potentially lead to distinctive isotope fractionations. Here, we describe the measurement of N_2O produced by diffusion through a pinhole, which produces an isotope effect dependent only on molecular mass. This tests our ability to accurately determine the 6-dimensional isotopic 'fingerprint' of a given fractionation. For the mass 47 species, $^{14}N^{15}N^{18}O$ and $^{15}N^{14}N^{18}O$, our measured result are within 0.1‰ of the expected value. In addition, we have analyzed N_2O produced by pure cultures of a denitrifying bacterium that lacks a N_2O reductase enzyme. It has a site preference consistent with the expectation for denitrifiers [3]. Measurements of site preference and of multiply-substituted isotopologues are both consistent with a kinetic isotope effect produced at the catalytic center of the nitric oxide reductase enzyme and distinct from the predicted equilibrium fractionation [4].

Coupling fluid residence times, erosion rates and weathering fluxes to evaluate the operation of a hydrologic thermostat

K. MAHER[1]* AND C.P. CHAMBERLAIN[2]

[1]Department of Geological and Enviornmental Sciences, Stanford University, Stanford, CA, 94305, kmaher@stanford.edu

[2]Department of Environmental Earth System Science, Stanford University, Stanford, CA 94305, chamb@stanford.edu

The Earth's thermostat is thought to be a negative feedback between atmospheric CO_2 levels and chemical weathering of silicate rocks that keeps temperatures relatively moderate over geologic time scales. To evaluate the operation of this thermostat, we relate the weathering flux per area of continent to the cooperation between runoff and tectonic processes. The two are linked here by the balance between the time that water spends in the weathering zone (which depends on runoff, hydraulic conductivity and the length of the flow path) and the kinetics of mineral weathering (which depend on composition, temperature and erosion rate). We use two types of equations: (1) a reactive transport equation that quantifies weathering-derived solute as a function the fluid residence time; and (2) an equation that relates erosion to the abundance of fresh minerals in the soil. We calculate the weathering-derived solute concentration (C) as a function of the Damköhler number (Da), which is modified to account for the effect of erosion on the supply of fresh minerals. This approach requires that as fluid residence time becomes shorter than the equilibrium time, solute concentrations decrease and solute fluxes plateau. This relationship is observed in modern rivers draining tectonically inactive areas wheres solute fluxes are smaller and Damköhler numbers lower, because reduced supply of fresh lengthens the equilibrium time. In contrast, in active mountain ranges, high relief and rapid supply of fresh minerals result in long fluid residence times and short equilibration times such that solute concentrations and fluxes are high. This approach allows weathering rates to increase asymmetrically between tectonically active and inactive areas in response to changes in climate, to create a bimodal hydrologic thermostat. However, to fully evaluate this model for weathering fluxes requires improved understanding of the reactive flow paths in large catchments and how they are moderated by physical/chemical erosion, the underlying causes for variations in concentration-discharge relationships and the biogeochemical factors that influence the equilibrium time.

Iron speciation and aging in organic-rich aquatic systems

P. MAHESHWARI[1,2], Y. WANG[2] AND T.D. WAITE[2]*

[1]Civil Engineering, Indian Institute of Technology Gandhinagar, Ahmedabad 382424, India
[2]Water Research Centre, School of Civil & Environmental Engineering, University of New South Wales, Sydney 2052, Australia (*correspondence: d.waite@unsw.edu.au)

Iron is ubiquitous in natural environments and used widely in engineered treatment systems as a coagulant or adsorbent. These systems typically contain dissolved organic matter which may influence both speciation and time- dependent transformation of iron species present. In an attempt to understand the speciation and transformation of iron in organic-rich systems, a ferric salt was added in a controlled way to supernatant from a bench-scale membrane bioreactor high in soluble microbial products (SMP) and the system allowed to age and the reductive reactivity of Fe examined. In particular, for each aging time, ascorbate was added to these samples in varying concentrations. The formation of Fe(II) upon reduction of Fe(III) species by ascorbate was measured using ferrozine colorimetry [1].

Following Wang and Waite [2], we assumed the Fe(III) to be present as either weakly bound Fe(III)SMP, strongly bound Fe(III)SMP and AFO. The relative distribution of iron into these forms and their rate constant for ascorbate reduction are shown in Figure 1. It was observed that despite AFO being the most stable form, dissolved Fe(III) mainly exists as strongly bound SMP complexes with weakly bound Fe(III)SMP turning negligible after extended aging.

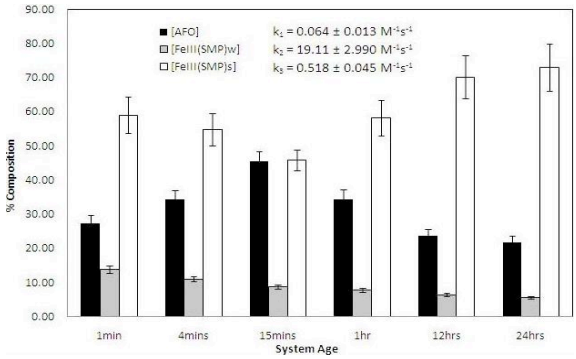

Figure 1: Relative composition of Fe(III) species and their corresponding ascorbate reduction rate constants.

Microbial communities colonising bedrock outcrops in a Swedish forest

S MAHMOOD*, A EKBLAD, D BYLUND AND RD FINLAY

Uppsala BioCenter, Department of Forest Mycology and Plant Pathology, Swedish University of Agricultural Sciences, Box 7026, SE-750 07, Uppsala, SWEDEN (*correspondence shahid.mahmood@slu.se)

We are using mor-layer covered bedrock outcrops as a model system to study patterns of microbial colonisation of rocks and biogeochemical processes that lead to mobilisation of mineral nutrients essential for plant growth and ecosystem function. The nutrients released from the bedrock are utilised by the microbial community, taken up directly by roots or transported to roots via mycelia of ectomycorrhizal fungi that form symbiotic associations with tree roots. We are testing the following hypotheses: (1) Microbial communities that have the ability to weather minerals or capture mobilised nutrients will increase in relative abundance or activity on the rocks compared to the overlying organic mor-layer. (2) Ectomycorrhizal fungal communities make a major contribution to the biological weathering of minerals/bedrocks in forest ecosystems. Bedrock outcrops colonised by ectomycorrhizal fungal mycelia/tree roots should therefore have a relatively higher concentration of organic acids than the rocks colonised by mosses or apparently bare rocks. (3) Since the organic sources of C tend to have a very low $\delta^{13}C$, we expect that the rock surfaces that exhibit varying degrees of biological weathering would also reflect differences in their $\delta^{13}C$ signatures depending on the level of biological activity (deposition of C in the form of organic acids/microbial biomass, root exudates and solubilised organic matter etc). To test hypothesis 1, we are analysing fungal and bacterial communities colonising rocks using 454- pyrosequencing. To test hypothesis 2, the rock surface minerals are being used for analysis of organic acids using LC-MS/MS. To test hypothesis 3, the rock surface minerals are being used for analysis of $\delta^{13}C$ using IRMS.

Effect of N on microbially mediated weathering of primary minerals

S. MAHMOOD[1], C. MARTINS[1], M OLOFSSON[2], D. BYLUND[2] AND RD. FINLAY[1]*

[1] Uppsala BioCenter, Dept Forest Mycology & Pathology, Swedish University of Agricultural Sciences, Box 7026, Uppsala SE-750 07, Sweden. (*roger.finlay@slu.se)
[2] Dept Natural Sciences, Technology & Mathematics, Mid Sweden University, SE-85170 Sundsvall, Sweden.

The aim of this study was to determine whether N addition affects: (a) composition of microbial communities in forest soil responsible for mobilization of nutrients from primary minerals, (b) kinetics of organic acid production, (c) rate of nutrient release from primary minerals and uptake by plants, and (d) C allocation patterns in the rhizosphere. We used microcosms with pine seedlings growing in mor layer soil from granite outcrops in a mixed pine-spruce-birch forest. Fungal mats often observed at the mor layer-rock interface harbor microbial communities that mobilize mineral nutrients from granite rocks and/or capture and transport the mobilized nutrients to tree roots via mycelial networks of ectomycorrhizal fungi. The growth substrate was amended with quartz, apatite, biotite or no minerals and two concentrations of a slow release N fertilizer in factorial combinations. Microcosms were sampled destructively after 0, 6, 12 & 60 weeks. Bacterial and fungal communities were analysed by DGGE & 454 pyrosequencing and soil solutions sampled to study kinetics of organic acid production (LC-MS) and for elemental analysis (ICP-AES) to determine weathering rates. C allocation patterns were studied using ^{13}C-RNA based stable isotope probing (SIP) of rhizosphere microbial communities. After 12 weeks there were only small changes in rhizosphere bacterial communities in response to N application and/or mineral amendments but fungal community structure exhibited larger changes. N had a negative effect on mobilization of nutrients from these minerals into the soil solution, and also reduced plant nutrient uptake. Seedlings in apatite-amended substrates had higher biomass compared to those grown in biotite-treated substrates and also higher P concentrations.

Contemporaneous crustal records in the eastern and western Dharwar craton: Evidence from U- Pb and Lu - Hf isotope sytematics

B. MAIBAM[1]*, A. GERDES[2] AND J.N. GOSWAMI[3]

[1]Department of Earth Sciences, Manipur University, Imphal, India, e-mail: bmaibam@yahoo.com (*Presenting author)
[2]Institute of Geosciences, Goethe-University Frankfurt, Germany, e-mail: gerdes@em.uni-frankfurt.de
[3]Physical Research Laboratory, Ahmedabad, India, e-mail: goswami@prl.res.in

Combined U - Pb and Lu - Hf isotope systematics of detrital (metasedimentary) and magmatic (orthogneissic) zircon grains from the eastern and western Dharwar craton provide new insight on the tectonomagmatic evolution of this ancient crust in the Indian shield. This data set establish the antiquity and nature of the source magma (juvenile or recycled) sampled by the analyzed zircon grains and provide a better understanding of the Archean curstal evolution in the Indian shield. For this study we have selected five samples (three from the western and two from the eastern block) thatyielded reasonable number of zircon grains.

U - Pb ages for detrital zircon grains suggest presence of ≥3.4 Ga crustal components in both the western block and the eastern block of the Dharwar craton. Zircon from magmatic rocks of the western block yielded ages ranging between 3.1 - 3.2 Ga, while those from the eastern block show a bi-model distribution with records of older components (3.0 - 3.2 Ga) and presence of younger events (overgrowth at 2.7 and 2.5 Ga). Magmatic and detrital zircon grains of western Dharwar block exhibit εHf(t) of +1 to +5 and Hf model ages of 3.25 - 3.45 Ga suggesting formation of juvenile crust during this epoch. A predominant phase of crustal reworking during 2.85 - 3.1 Ga could be inferred from the subchondritic εHf values (-5 to -0.9) for detrital zircon grains.

The age data for majority of the detrital and few magmatic zircon grains from the eastern Dharwar craton suggest formation of juvenile crust (εHf of +1 to +4) during 3.2 to 3.6 Ga. A crustal reworking phase during 2.5 to 3.0 Ga could be inferred from the εHf ranging from +4 to -16 in majority of the magmatic and some detrital grains. The combined U–Pb-Hf isotope data is consistent with the idea that crust formation processes took place contemporaneously in both western and eastern blocks of the Dharwar craton.

Effects of aqueous phosphate on U(VI) sorption

F. MAILLOT[1]*, V. MEHTA[2], J.G. CATALANO[1], D.E. GIAMMAR[2] AND Z. WANG[3]

[1]Earth & Planetary Sciences, Washington Univ., St. Louis, MO 63130, USA, (*correspondence: fabien.maillot@wustl.edu)
[2]Energy, Environmental and Chemical Engineering, Washington Univ., St. Louis, MO 63130, USA
[3]Pacific Northwest National Lab., Richland, WA 99352 USA

Uranium contamination of soils and groundwater has resulted from past mining, processing, and waste disposal activities. Among the in-situ remediation strategies for oxic subsurface environments, phosphate-based treatments have generated significant interest [1]. The soluble uranyl ion [$U(VI)O_2^{2+}$], stable in oxidizing environments, has a strong affinity for phosphate, which can potentially reduce its aqueous concentrations by promoting the nucleation of low-solubility U(VI)-phosphate minerals or by enhancing U(VI) sorption to subsurface minerals.

We investigated the effect of aqueous phosphate on U(VI) sorption on montmorillonite (Clay Mineral Society source clay SWy-2) and goethite. Both minerals are important components in the reactive fine fraction of soils and sediments at sites contaminated with uranium [2]. We determined U(VI) adsorption isotherms at several pH conditions and initial [PO_4^{3-}]. Uranium speciation was further investigated using U L_{III}-edge EXAFS and Time Resolved Laser Fluorescence spectroscopies.

A series of possible competing and cooperating reactions may occur in the presence of U(VI) and phosphate, including the formation of U(VI)-phosphate precipitates, U(VI)-phosphate ternary surface complexation [3], and surface site competition between U(VI) and phosphate. Formation of uranyl-phosphate minerals was observed in the presence of either goethite or montmorillonite. Before the onset of precipitation however, our results show contrasting behavior between these two systems. While phosphate does not substantially influence the extent of U adsorption on montmorillonite, it was found to enhance U sorption on goethite at pH 4 and to inhibit it at pH 8. These observed differences indicate that the specific mineralogy of a contaminated field site could greatly influence the applicability of phosphate-based uranium remediation.

The effect of Alkali-Feldspar composition on mineral-melt partitioning of Trace Elements

M. MAIMAITI[1]*, F. ARZILLI [2] AND M.R. CARROLL [3]

[1]Geology Division, University of Camerino, Via Gentile III da Varano Camerino (MC) Italy,62032 (*correspondence:maierziyaguli.maimaiti@unicam.it)
[2] Geology Division, University of Camerino (arzilli.Fabio@gmail.com)
[3] Geology Division, University of Camerino (michael.carroll@unicam.it)

The aim of this work is to better understand how variations in Alkali-Feldspar composition can influence trace elements substitution and mineral-melt partitioning. Feldspars are a group of very common and important rock-forming minerals. Moreover Trace elements are useful as they are much more sensitive to partial melting, crystal fractionation and magma mixing, contamination processes, and thus Trace elements can provide geochemical and geological information out of proportion to their abundance.

To investigate systematically the trace element partitioning between alkali feldspar and silicate melt, this study examines Ba, Rb, Sr partition coefficient variations with feldspar Or, Ab, An content by using experimental data from Arzilli (2012), Mahood and Stimac (1990) and London (1996). We have discovered that for our experimental data, exponential model fits better than simple linear regression model. We suggest that the relationship between partitioning of Ba, Rb, Sr and feldspar Or, Ab, An content is not well produced by a simple linear model and better results are obtained with an exponential model involving feldspar Or content.

We are currently working more on the effect of Alkali-Feldspar crystal growth rate on trace elements partitioning as when the growth rate is fast, the crystal can be less selective in allowing trace elements to enter their structure.

Pseudomorphic replacement of diopside during interaction with (Ni,Mg)Cl_2 aqueous solutions

A. S. MAJUMDAR*, H. E. KING, T. JOHN, C. KUSEBAUCH AND A. PUTNIS

Institut für Mineralogie, Universität Münster, Corresstraße 24, 48149 Münster, Germany
*correspondance: asmajumdar.min@uni-muenster.de

Alteration of peridotite, including serpentinization, has a special place among fluid rock interaction that not only drastically changes rock properties at the ocean floor but also leads to rich ore deposits worldwide. During peridotite serpentinization, olivine and orthopyroxene are more reactive than clinopyroxene. Hence, it may be reasonable to assume that after initial serpentinization of olivine and orthopyroxene, the hot hydrothermal solution rich in metal ions (e.g. Ni) can open further possibilities for relict clinopyroxene to react.

We present a hydrothermal experimental study of diopside-(Ni,Mg)Cl_2 solution interaction to clarify the replacement mechanism and pattern of element mobilization during alteration. Different chloride solutions were used with Ni/Mg ratios of 0, 0.5 and 1. Experiments were carried out in cold seal pressure vessels at 300-600 °C and 1 kbar pressure for 15 days in gold capsules. For 500-600°C $NiCl_2$ experiments solutions were also spiked with 50% $H_2{}^{18}O$ to study the behaviour of isotopic exchange, hence, the replacement mechanism. Raman, SEM and microprobe analyses were performed on reactive samples to identify the phases and to observe textural and compositional features.

The reactive samples show a sharp compositional and structural interface between diopside and the pseudomorph phases. A complex rim of Ni poor and Ni rich regions are present in $NiCl_2$ and (Ni,Mg)Cl_2 experiments. Here, the precipitated phases are willemseite and/or nepouite. For $MgCl_2$ experiments, only talc was detected. The experiment with ^{18}O-enriched solution documents a shift in the Si-O(bridging)-Si band of willemseite towards lower wavenumbers confirming that diopside pseudomorphism occurs via an interface coupled dissolution precipitation, where the spatial coupling between dissolution-precipitation is dependent on temperature. The study also shows evidences for Ca transport in the opposite direction to Ni and/or Mg during alteration. This may be important as a geochemical tracer for economic Ni deposits and Ca mobilization during serpentinization.

Mineralogy and thermodynamics of secondary arsenic phases

JURAJ MAJZLAN[1], PETR DRAHOTA[2] AND MICHAL FILIPPI[3]

[1] Institute of Geosciences, Friedrich-Schiller-Universität Jena, Germany, Juraj.Majzlan@uni-jena.de
[2] Institute of Geochemistry, Mineralogy and Mineral Resources, Charles University, Prague, Czech Republic, drahota@natur.cuni.cz
[3] Institute of Geology, Academy of Sciences of the Czech Republic, Prague, Czech Republic, filippi@gli.cas.cz

Arsenic is an integral part of the toxic load of many types of mining waste. The parageneses of arsenic minerals in the primary assemblages (rocks, ores) and the secondary assemblages (oxidation zones, polluted soils, waste forms) are quite variable. In this contribution, we will describe different mineral assemblages found at sites polluted by arsenic, including naturally polluted soil profiles, rocky mine dumps, tailings, underground spaces, and caves. Here, the mineralogy is not only dictated by the bulk chemical composition but also by the local conditions and shows surprising variations. For example, although mining waste is commonly dominated by arsenic-rich hydrous ferric oxide and scorodite ($FeAsO_4 \cdot 2H_2O$), polluted soils contain more commonly pharmacosiderite [$(K,Na,Ba)Fe_4(AsO_4)_3(OH)_4 \cdot 6\text{-}7H_2O$] and Ca-Fe arsenates such as arseniosiderite. This difference could arise from different availability of element due to different time scales. If so, such differences could suggest how the waste forms could react and transform in the future. In waste forms from material processed by pressure oxidation contain yet different types of ferric arsenates, not known as minerals. Little is known about their solubility and reactivity. The chemical composition of the whole system influences, of course, the nature of the secondary arsenic minerals, and the link between the two can be easily established.

In addition to the crystalline arsenate phases, As(V) can be also incorporated into the crystal structure of iron oxides, especially hematite, as epitaxially intergrown clusters with angelellite-like local structure. This mode of occurrence may be found especially in older systems with relatively low pollution loads.

Thermodynamic data suggest, not surprisingly, that scorodite is the most stable phase in the system Fe_2O_3-As_2O_5-H_2O. Kaňkite, bukovskýite, As-rich hydrous ferric oxide, $FeAsO_4$, and presumably also zýkaite are metastable. The data for more complex ferric arsenates (pharmacosiderite, arseniosiderite, yukonite) are missing; this work is in progress and could reveal interesting relationships between the simpler and more complicated ferric arsenates.

Cathodoluminescence of barytocalcite $CaBa(CO_3)_2$

M. MAKIO[1], H. NISHIDO[2], N. KUSANO[2] AND K. NINAGAWA[2]

[1] Graduate School of Social and Cultural Studies, Kyushu University, 744 Motooka, Nishid-ku, Fukuoka, 819-0395, Japan

[2] Department of Biosphere-Geosphere Science, Okayama University of Science, 1-1 Ridai-cho, Okayama 700-0005, Japan (correspondence: nishido@rins.ous.ac.jp)

Anhydrous double salts of $CaCO_3$ and $BaCO_3$ have not been investigated with respect to CL properties up to date. In this study we have characterized CL emissions in barytocalcite $CaBa(CO_3)_2$, of which structure is different from rhombohedral-calcite type.

Single crystals of three barytocalcite (Blagill, UK; Fosters, UK; Langban, Sweden) were selected for CL spectral measurements at various temperatures.

CL spectra of barytocalcite at room temperature have a pronounced emission peak at around 600 nm in red region. It can be assigned to an impurity center of divalent Mn ion (4G-6S) as an activator, which occupies Ca site in barytocalcite structure, where the centered wavelength is appreciably smaller than the value of calcite (620 nm) due to different crystal field. Barytocalcite has aragonite-like structural configuration rather than calcite-like one. Therefore, various types of Ca sites substituted with Mn ions can be suggested for this Ca-Ba series carbonates, which might modify the strength of crystal field around activated Mn ions. Temperature controlled CL measurements reveal that the CL intensity of Mn activated emission in barytocalcite decreases in an increase of sample temperature, suggesting a temperature quenching effect especially pronounced in the range of −50~25 °C. The intensity at −189 °C is twice as much as that at room temperature. Furthermore, an increasing temperature results in a shift of the emission peak to shorter wavelengths, which might be attributed to an increase in the distance between Mn ion and adjacent ligand.

Hematite scalenohedra –ancient jewelry and a problem of sedimentary mineralogy

EMIL MAKOVICKY, MATTEO PARISATTO AND FLEMMING HØJLUND[123]

[1]Institute for Geoscience and Natural Resource Management, University of Copenhagen, Østervoldgade 10, 1350 Copenhagen, Denmark, emilm@geo.ku.dk

[2]Department of Geosciences, University of Padova, Via Gradenigo 6, 35131 Padova, Italy, matteo.parisatto@unipd.it

[3]Moesgaard Museum, Moesgaard Allé 20, 8270 Højbjerg, Denmark, farkfh@hum.au.dk

In 1964 a scalenohedron of hematite was found in archaeological excavations of the bronze-age layer (1980-2020 BC) of the Tell of Qala'at al-Bahrain on the shores of the Persian Gulf, together with faience and carnelian beads. We subjected the scalenohedron to X-ray tomographic investigation using a Bruker microCT-Skyscan 1172 high resolution scanner. The system has a polychromatic microfocus X-ray source with a tungsten anode; it was run at 100 kV and 10 W. 2000 radiographs were acquired over 360°, 9 radiographs were averaged for each angular position.

Scanning revealed considerable internal porosity of the 'crystal', with a preferential concentration of small pores in the central portions and with larger, elongated pores in the subsurface portions. The internal structure reveals that it is a pseudomorph after a scalenohedral carbonate, composed of an intergrowth of hematite tablets and grains. Its geometry coincides with that of calcite {21-34} scalenohedron, with minor presence of {10-10} and {02-24}.

Mineral trade knows such 'hematite scalenohedra' from the Arzanah and Hormuz Islands in the Persian Gulf. Both are top portions of tall salt diapirs occluding fragments of Precambrian Hormuz Formation: blocks of various volcanic rocks, sediments and even iron ore, forming a jumbled mass. Specularite is reported in geological descriptions but not the hematite pseudomorphs which look very much like our specimen. Our research revealed an extensive replacement of well-crystallized carbonates by hematite (may-be in relation to the formation of large hematite masses which in this pre-iron-age society were polished into hematite weights) but it leaves open the question at which geological stage the evaporite sequence produced perfect carbonate crystals and when were they pseudomorphosed by hematite. This may have practical importance, a number of these diapirs being connected with the Gulf gas and oil occurences.

The slab-to-mantle volatile transfer is related to the fluid speciation, which in turn is a function of fO_2, in a system buffered by equilibria involving redox-sensitive elements. The redox processes taking place in the portion of mantle wedge on top of the subducting slab is poorly investigated and the oxidising power of fluids is still unknown.

A case study is represented by grt-orthopyroxenites and peridotites from Dabie-Shan (China) hosted by grt-coe gneisses which contain an association of opx + grt ± cpx ± ol, formed at the expenses of a previous grt-peridotite. Grt includes primary polyphase inclusions corresponding to a solute-rich aqueous fluid enriched in LILE and LREE. Orthopyroxenites represent metasomatic layers produced after the reaction of mantle peridotites with a Si-saturated fluid phase sourced by the associated crustal rocks. The trace element pattern of this fluid shows a peculiar LILE signature which is recorded by subduction grt-peridotites from Sulu (China). These samples show porphyroclastic grt, cpx and phl, and a younger paragenesis of fine-grained ol + cpx + opx + phl ± magnesite equilibrated with neoblastic grt.

We measured the Fe^{3+} distribution of the major phases of orthopyroxenite and peridotite with Flank Method electron probe microanalyses and EELS. Pyrope-rich metasomatic grt presents a complementary decrease in Al_2O_3, relative to the increase of Fe_2O_3. Diopsidic cpx contains $Fe^{3+}/\Sigma Fe$ up to 0.51 and high Na, requiring the incorporation of an aegirine component. The coupled Na-Fe^{3+} enrichment in cpx suggests a corresponding enrichment in the whole rock and could be favoured by the influx of alkali-rich metasomatic fluid phases. To investigate the role of deep fluids in the redox processes of the suprasubduction mantle we also measured the Fe^{3+} in the microprecipitates of polyphase inclusions using EELS on a TEM. The solute content of slab fluids may contain high Fe^{3+} concentrations and surprisingly inclusion phases such as phl may contain up to 0.70 of $Fe^{3+}/\Sigma Fe$. If net bulk rock oxidation can be demonstrated, silicate-alkali-rich C-bearing fluids could be regarded as potential carriers of oxidising components to the suprasubduction mantle.

Timing and distinct magma sources in ultramafic-mafic intrusions of the Taimyr Peninsula (Russia)

K.N. MALITCH[1], I.YU. BADANINA[1] AND A.P. ROMANOV[2]

[1]Institute of Geology and Geochemistry of the Uralian Branch of Russian Academy of Sciences, Ekaterinburg, Russia (*correspondence: dunite@yandex.ru)
[2]Krasnoyarsky Research Institute of Geology and Mineral Resources, Krasnoyarsk, 660049, Russia

It is commonly assumed that ultramafic-mafic intrusions and associated PGE-Cu-Ni sulphide deposits of Northern Siberia represent a small component of a major episode of mafic activity at ~250 Ma, which included formation of the most extensive flood-basalt province on Earth [1]. Recent studies, however, advocated protracted evolution of the ore-forming magmas parent to the Noril'sk-type intrusions [2-4].

This report presents the results of uranium-lead ages of zircons and whole-rock Nd-Sr isotope data for the same suite of lithologies from the Binyuda and Dyumtalei ultramafic-mafic intrusions located in the limits of the Taimyr Peninsula (Russian Arctic). The rocks investigated comprise sulphide-rich varieties of (1) melanotroctolite and (2) ferrogabbro (i.e. gabbro abnormally high in iron) occurring in bottom parts of the Binyuda and Dyumtalei intrusions, respectively.

Zircons are characterized by similar U-Pb ages (248.5±11 Ma at Binyuda and 244.4±2.4 Ma at Dyumtalei). In contrast, silicate material show distinct Sr-Nd isotope signatures (εNd=3.5±0.7 and $^{87}Sr/^{86}Sr_i$=0.70493±0.00021 at Dyumtalei, εNd=-3.4±0.3 and $^{87}Sr/^{86}Sr_i$=0.70585±0.00004 at Binyuda). The determined Nd-Sr variability is interpreted to represent a primary source signature of the lithological units. An important role of the juvenile component is clearly defined for the Dyumtalei intrusion, whereas a major contribution from a SCLM source is inferred for the Binyuda intrusion.

These signatures clearly manifest deviation from those typical for the ore-bearing intrusions of the Noril'sk Province, characterized by a significant time span of zircon and baddeleyite U-Pb ages (from ca. 350 to 230 Ma), relatively constant εNd values (+1.0±0.5) and heterogeneous radiogenic $^{87}Sr/^{86}Sr_i$ (from 0.70552 to 0.70798).

The study was supported by RFBR (grant 13-05-00671) and the Uralian Division of Russian Academy of Sciences (grant 12-5-9-019-Arctic).

Effect of variable CO_2 on andesite-lherzolite reaction: Implications for mantle hybridization and generation of alkalic basalts

ANANYA MALLIK *[1] AND RAJDEEP DASGUPTA[1]

[1]Rice University, Houston, TX, USA (*am33@rice.edu)

Presence of recycled oceanic crust, a major heterogeneity in the Earth's mantle, is invoked in the source of many ocean island basalts (OIBs) [1]. However, andesitic partial melts derived from oceanic crust, upon reaction with subsolidus peridotite, produce basanites [2] but cannot form strongly alkalic lavas such as nephelinites. In this study, we evaluate whether such an andesite, with dissolved CO_2, can evolve to more Si-deficient magma due to partial reactive crystallization in subsolidus peridotite.

We performed piston-cylinder experiments at 1375 °C, 3 GPa with homogenous mixtures of 25% or 33% of an andesite and lherzolite KLB-1 with 1 to 5 wt.% CO_2 in the starting melts (0.25 to 1.62 wt.% bulk CO_2). Upon reaction, with increasing CO_2 in the reacting melt: a) modes of reacted melt, opx and garnet increased while that of olivine and cpx decreased b) the andesite evolved from basanite to nephelinite c) the residual melts, on a volatile-free basis, showed variation in SiO_2 from 44-40 wt.% and 45-43 wt.%, TiO_2 from 6-5 wt.% and 7-6 wt.%, Al_2O_3 from 14-11 wt.% and 13-10 wt.%, MgO from 13-17 wt.% and 12-17 wt.%, CaO from 8-11 wt.% and 8-11 wt.% and Mg# from 68-75 and 69-73, for 25% and 33% melt-added series, respectively and d) FeO* and Na_2O did not show significant variation.

Our results show that with increasing CO_2 in the andesite, its reaction with lherzolite yields greater degree of Si-undersaturation owing to dilution of melt SiO_2 by CO_2 and lowering of melt SiO_2 by enhanced crystallization of opx at the expense of olivine. Increased precipitation of garnet lowers Al_2O_3 in the reacted melts. Increased CaO and MgO and no significant trend of FeO* and Na_2O with greater bulk CO_2 content confirm propensity of Ca^{2+} and Mg^{2+} over Fe^{2+} and Na^+ in entering silicate melt as carbonates. Residues show more opx-enrichment with greater CO_2 in the system. We have developed a model for quantitative prediction of mineral modes in hybrid residues as a function of melt-rock ratio and dissolved CO_2 in the reacting melt. At a given MgO, the CO_2-bearing reacted melts are better match for alkalic OIBs in terms of SiO_2, Al_2O_3, CaO, Na_2O and CaO/Al_2O_3 than their volatile-free analogs.

Use of uranium, thorium and carbon isotopes for thermal groundwater and travertine dating

MALOV A.I., BOLOTOV I.N., ZYKOV S.B., DRUZHININ AND S.V., POKROVSKY O.S.

Institute of the Ecologic Problems of the North, UB RAS, Naberezhnaya Severnoi Dviny, 23, Arkhangelsk, 163061, Russia
malovai@yandex.ru

The use of ^{14}C dating in groundwater in some cases, is facing serious difficulties. It first of all - reducing the specific activity of 14C in groundwater due to dissolution of carbonate host rocks, overstates age, and mixing with younger water, substantially understates it. In this regard, we propose the sharing of ^{14}C and ^{234}U-^{238}U for dating. However, ^{234}U-^{238}U method now not enjoys great popularity. This is due to the need to determine a large number parameters. It should be noted difficulty in defining SSA, and respectively, α-recoil loss factor. For practical use of the ^{234}U-^{238}U method, we offer to introduce in the calculation the generalized parameter (probability of the transfer of ^{234}U into water, or "effective α-recoil loss factor") derived empirically from geological benchmarks, hydrodynamic calculations, and paleo-hydrogeological reconstructions [1]. For hydrothermal system located within mainland European Subarctic 14C age of thermal waters is 9-12 ka, 234U/238U age - 6-11 ka. Calibrated δ13C age of travertine - to 3 ka. U-Th age of travertine -- up to 1.5 ka. Assessment calculations show that when dating groundwater isotope of uranium, 10% admixture of young water (up to 100 years) reduces the age of ancient water (11 ka) by 11%. Joint dating of the groundwater and from them formed travertine possible to estimate the velocity of the groundwater in the hydrothermal system and the speed of neotectonic uplift of the area.

Biogeochemistry of the Big Toroki sapropel lake, Western Siberia

A.E. MALTSEV*, G.A. LEONOVA, S.K. KRIVONOGOV, AND V.A. BOBROV

Institute of geology and mineralogy SB RAS, Koptyug Pr. 3, Novosibirsk 630090, Russia
(*coresspondence: maltsev@igm.nsk.ru)

We investigated a 1.8 m long sediment core of Lake Big Toroki (N 55º 24', E 80º 36'). The lake has a closed basin of 9.57 km^2 in area and a 1 m in depth and is overgrown by macrophytes [1]. Its water is low-mineralized (845 mg/l), and belongs to the hydrocarbonate Na-Mg class according to [2]. The sediments are organic-mineral sapropels (C_{org} 45.4 %) according to [3]. Water macrophytes are the main producers of the organic matter. The sediment sequence consists of a substrate, bluish-gray sandy silts (180–160 cm), blackish peat (160–120 cm), coarse peaty sapropel with abundant mollusk shells (129–122 cm), blackish peaty sapropel with random gastropod shells (120–75 cm) and greenish macrophytic sapropel with random bivalve shells (75–0 cm).

Total organics, C_{org} and carbonates vary along the core in compliance with its sediment units. Total organics is 40–50% in the sapropel, 60–61% in 120–130 cm and sharply declines below 140 cm. C_{org} is 14–18% in 0–70 and 120-135 cm intervals, 9–13% in the middle and sharply declines from 6.4 to 0.47 % in 140–180 cm interval. Carbonates are low, 3–4 %, in the upper 0–75 cm and progressively increases to 14–16 % below.

The sediment pore waters showed variations in Fe, Mn, Cu, Zn, Pb and Cd. Sharp peaks of Fe and Mn are in the lower middle (90–130 cm), Cu, Zn and Cd in the upper middle (60–80 cm) and Pb in the top (0–40 cm) parts of the core. Changes of H, N and S, which mostly compose the organic matter, match variations of C_{org}.

This research was supported by the SB RAS Integration Project no. 125.

What causes the rapid change of Cenozoic magma sources in the Pamir?

N. MALZ*[1], L. RATSCHBACHER[1], J. A. PFÄNDER[1] AND C. MÜNKER[2]

[1]Institut für Geologie, TU Bergakademie Freiberg, Germany (*correspondence: malz@geo.tu-freiberg.de)
[2]Institut für Geologie und Mineralogie, Universität zu Köln, Germany

The Pamir mountains, building the western elongation of the Tibet plateau, were formed by the India-Asia collision ~55 Ma ago. Extreme shortening resulted in extremely thickened crust making the Pamir an ideal natural laboratory to study crustal melting processes.

After the India-Asia collision, post-collisional granitoids appear at ~46 Ma and the magmatic activity in the Pamir was rather sparse until ~33 Ma. During this time, Sr- and Nd-isotope compositions (initial $^{87}Sr/^{86}Sr$: 0.7223 to 0.7067 and initial εNd: -10.3 to -2.6) indicate a gradually increasing amount of mantle components, coupled with decreasing SiO_2 contents (77 to 62 wt.%). At ~29 Ma, this trend reverses with an increasing crustal component up to ~14 Ma; initial $^{87}Sr/^{86}Sr$ compositions increase again from 0.7064 to 0.7203 and initial εNd decrease from -3.7 to -8.4. Apart from these highly evolved granitoids, basaltic magmatism occurred contemporaneously. The youngest samples at ~11 Ma from the easternmost region of the Central Pamirs are ultrapotassic tephrites to tephriphonolites, showing some of the least radiogenic Nd isotopic compositions (initial εNd: -9.6 to -12.3) together with rather radiogenic Sr isotope compositions (initial $^{87}Sr/^{86}Sr$: 0.7100-0.7104).

What triggers the variable proportions of mantle and crustal components in the the sources of Cenozoic igneous rocks over such short time intervals? The post-collisional magmatism in the Tibetan Plateau is supposed to be influenced by a slab break-off at 55-40 Ma [1], leading to the ascent of asthenospheric material, thus triggering partial melting in the ascending mantle and the lower crust. Such a scenario provides a viable explanation for the increasing amount of mantle component in the 46-33 Ma igneous suites of the Pamir. The ongoing (crustal) shortening led to an extremely thick crust, in which anatexis caused the 29-14 Ma magmatism. Moreover, the subducting cold Indian slab interrupted the asthenospheric upwelling. We will further test this genetic model by combined Lu-Hf and U-Pb measurements on igneous zircons.

The Eastern Rift Zone through time: A record of plume pulsing or magma plumbing evolution?

CHRISTINA J MANNING[1]* AND MATTHEW THIRLWALL[1]

[1]Department of Earth Science, Royal Holloway University of London, Egham, Surrey. TW20 0EX
(*correspondence: c.manning@es.rhul.ac.uk)

Lavas from Öræfajökull volcano, SE Iceland, exhibit isotopic compositions distinct from normal Icelandic enriched mantle, attributed to the presence of recycled sediment in their source [e.g.1, 2]. This distinctive source has recently been recognized in postglacial Eastern Rift Zone (ERZ) lavas [3], indicating the source is more widespread, as well as in the East Iceland Tertiary lavas (~13 Ma) [4], indicating that it is also long lived.

A comprehensive suite of lavas from the ERZ; Síða and Fljótshevrfi Groups (0.7 - 3 Ma) and Tertiary lavas from Skaftafell (3-5 Ma) have been analysed for Sr-Nd-Pb isotopic ratios along with major and trace elements. Whilst both Skaftafell and ERZ lavas lie on correlations trending towards an enriched end-member similar to the Öræfajökull source, the Skaftafell lavas trend to an end-member which has lower $^{143}Nd/^{144}Nd$ for a given $^{87}Sr/^{86}Sr$ and more positive $\Delta^{207}Pb$ and $\Delta^{208}Pb$. This suggests a temporal change in the composition of the enriched mantle source in the past 5 Ma. Further, the Síða and Fljótshevrfi lavas (0.7 - 3 Ma) show more depleted and less variable isotopic compositions suggesting the transition was not gradual, but that there was a distinct break in the supply of enriched mantle at ~3 Ma. Possible mechanisms for this could be: 1. Supply of discreet blobs of enriched mantle from the plume [4], 2. Changes to the magma plumbing regime resulting in a reduced contribution from the enriched source and greater homogenisation of melts between 3 and 0.7 Ma.

Fluids, subduction, and deep carbon

CRAIG E. MANNING[1]*, YUAN LI[2] AND JAMES EGUCHI[1]

[1]Department of Earth and Space Sciences, University of California, Los Angles, CA 90095, USA
(*correspondence: manning@ess.ucla.edu)
[2]Bayerisches GeoInstitute, Universität Bayreuth, 95440 Bayreuth, Germany

Studies of the deep carbon cycle have concluded that the mantle is gaining C because more carbon is subducted than is degassed by volcanism [1]. This relies on the assumption that all CO_2 lost from slabs is degassed at arc volcanoes, which is problematic because arc crust is permeable [2] and arc magmas may attain deep fluid saturation [3]. Support has also been drawn from models showing that slab fluids possess low X_{CO2} [4]. But new theoretical and experimental results show that C solubilities are likely higher than these models predict. Total dissolved carbon depends on the solubilities of all C species (e.g., CO_{2aq}, HCO_3^-, CO_3^{-2}, etc), which are controlled by pH, fO_2, halogens, and dissolved cations. Controls on these variables in subduction zones are likely to combine to elevate carbonate mineral solubility. For example, the calculated pH of model slab mineral assemblages of jadeite, white mica and quartz [5,6] along the top of the Costa Rica slab [7] indicate that the $CaCO_3$ solubility is higher at mineral-buffered pH than at the more alkaline pH of otherwise pure H_2O saturated only in $CaCO_3$, or than in molecular mixing models. Carbonate solubility is also enhanced by salts. At a given P-T, calcite solubility increases in proportion to the square of NaCl mole fraction [8]. Our studies in KCl, LiCl, and their mixtures have similar form and, at fixed P, T and X_{salt}, solubility decreases as LiCl > NaCl > KCl, consistent with Pearson Hard-Soft Acid-Base rules. Metal-carbonate ion pairing and reduction of carbonate or CO_2 to CH_4 during mantle-wedge serpentinization will further increase solubility. Models including the above effects yield ≥1 wt% total C in some slab fluids. C carried by subduction-zone fluids and deep degassed magmatic volatiles likely play important roles in the deep carbon cycle, and must be taken into account in assessing the gain or loss of carbon by the mantle.

A new lithospheric model for southeastern Sicily (Italy)

F.C. MANUELLA[1], A. BRANCATO [1], S. CARBONE[1], S. GRESTA[1]

[1]Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Sezione di Scienze della Terra, Università di Catania, Corso Italia 57, 95129, Italy (correspondence: abranca@unict.it), fmanuella@alice.it, carbone@unict.it, gresta@unict.it

An interdisciplinary approach for a new lithospheric model for southeastern Sicily and the Sicily Channel has been recently proposed by Manuella et al. [1], as retrieved from the integration of published petrologic and geophysical data.

The model elaborated by Manuella et al. [1] points out the existence of a Permo-Triassic oceanic lithosphere that broadens from the Hyblean Plateau to the Sicily Channel, underlying a thick Mesozoic-Cenozoic sedimentary and volcanic sequence, in continuity with the adjacent Mesozoic Ionian-Tethys ocean, thus confirming the hypothesis of Scribano et al. [2]. The Permo-Triassic basement consists of a level of peridotites, affected by different degrees of serpentinization (35–100 vol.%) ranging to a depth of 8–19 km, and a remarkable anomaly occurs at 19 km, corresponding to the Moho discontinuity, which has been considered as a serpentinization front.

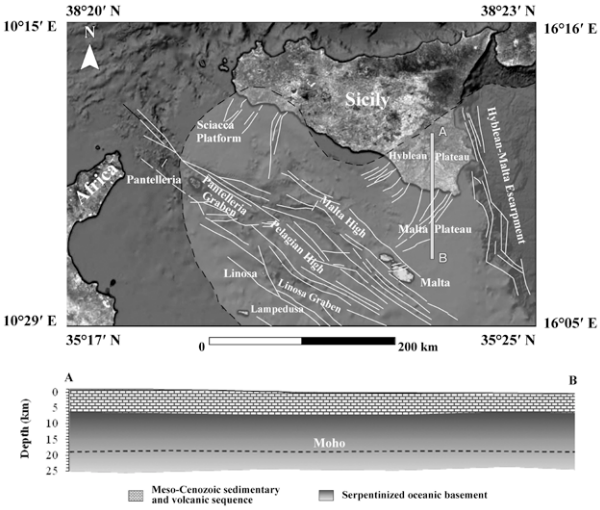

Figure 1. A schematic view of the new lithospheric model

[1] Manuella *et al.* (2013), *J. Geodyn.* 66, 92–102. [2] Scribano *et al.* (2006), *Miner. Petrol.* 86, 63–88.

Spatial and temporal variability in clay mineral and iron (oxyhdr)oxide minerals of the Changjiang (Yangtze) River suspended sediment: Monsoon controlling weathering

CHANGPING MAO[1,*], JUN CHEN[2], XUYIN YUAN[1], YINXIAN SONG[2] AND JUNFENG JI[2]

[1] Institute of Isotope Hydrology, School of Earth Sciences and Engineering, Hohai University, Nanjing 210098 China (*correspondence: maochangping@hhu.edu.cn)

[2]nstitute of Surficial Geochemistry, School of Earth Sciences and Engineering, Nanjing University, Nanjing 210093

Clay mineral assemblages and iron (oxyhdr)oxide are sensitive to bedrock geology and chemical weathering, and therefore have long been regarded as a powerful indicator of the nature of the source areas. The goal of the present work is to show quantitative spatial distribution and seasonal variability pattern of clay mineral assemblages and iron (oxyhdr)oxide in river suspended sediments for the entire Changjiang (Yangtze) basin.

The Changjiang (Yangtze) River originates on eastern periphery of the Tibetan Plateau and causes large continental masses from Tibet to the oceans. A large part of the Changjiang Basin has a subtropical monsoon climate. The suspended sediments of Changjiang River drainage basin were collected during the flood (July-August 2007) and dry (December 2007, January 2008) seasons.

In the present work, river suspended sediment was investigated by quantitative mineralogical, geochemical analyses of bulk samples and single particles.The results indicate that an increasing trend of hematite% and goethite% were observed in the main channel from the upper to middle reaches. The concentration of illite has a ranges from 60% to 80% in summer and 40% to 60% in winter, both with a decreasing trend from the upper to lower reaches. The kaolinite contents of the lower stream abruptly increased from 10% to 30% in the dry seasons (winter) relative to the flood seasons (summer). This peak is probably associated with strong inputs of suspended material from the Poyang lake and its tributaries (located between middle and lower reaches of the Changjiang River) .

Our results suggest that spatial and temporal variations in clay mineral and iron (oxyhdr)oxide minerals primarily reflect variations in the intensity of the monsoon, and which is the principal forcing factor on the mechanical and chemical weathering processes between the different sub-catchments of Changjiang River.

[4]Departamento de Mineralogía y Petrología, UGR, 18002 Granada, Spain (teresa@ugr.es)

The Cerro del Almirez massif is composed of antigorite serpentinite and chlorite harzburgite separated by a transitional zone that marks the front of prograde serpentinite-dehydration at high pressure in a paleo-subduction setting. Concentrations of Sc and V indicate that the peridotite precursor of serpentinite experienced up to 20% partial melting in the spinel stability field at $-2 < \Delta\log fO_2^{FMQ} < 0$. Peridotites underwent intense seafloor serpentinization in a fluid-dominated system. Olivine hydrolysis at ~ 200 °C and pyroxene serpentinization at > 350-400 °C remobilized Ca and REE (especially LREE and Eu) and caused the progressive enrichment of Cs, Rb, Ba, U and Pb and locally the crystallization of talc by silica fluid addition. Transformation to antigorite serpentinite upon subduction led to Sr depletion, and Ti, Tm, Yb and Lu were remobilized at the sample scale during fluid-assisted crystallization of titanian clinohumite. The high-pressure prograde breakdown of antigorite to chlorite harzburgite preserved the REE fractionations and the characteristic negative Eu anomaly of precursor serpentinites. Relative enrichment of Th-U-Nb-Ta-Pb-Sr in chlorite harzburgite cannot be balanced by closed-system dehydration of serpentinite indicating that dehydration occurred in an open system involving external fluids equilibrated with crustal sources. Open-system fluid flux in the subducted slab results in the recycling into the deep convective asthenospheric mantle of prograde harzburgite enriched in Th, U, HFSE and Pb relatively to oceanic depleted peridotite.

Isotopic composition of precipitation in Ferrara Province

MARCHINA C.[1], VACCARO C.[1]*, FAZZINI M.[1], DI ROMA A.[1] AND BIANCHINI G.[1]

[1]Dip. Fisica e Scienze della Terra, Università di Ferrara, Italy (*vcr@unife.it)

Ferrara province is located in the Po valley, a flat low-land surrounded by the Alps and the Appennines. The particularity of this area is represented by the proximity to the Comacchio Valleys and the Adriatic Sea. It is interesting to note that, in spite of the vicinity to the sea, the area is charaterized by continental climatic characteristics. Stable hydrogen and oxygen isotope ratios are dynamic tracers for the cyclying of atmospheric moisture as influenced by water vapour advection, condensation, and evaporation [1].

The stations selected for this study include various sectors of the Ferrara province and allow to characterize the isotopic fingerprint of the local meteoric water. The recorded $\delta^{18}O$ values ranging between -6.95 and -5.19, and δD values ranging between -46.21 and -31.82 are compared with Northern Meteoric water Line [2].

These data will be implemented with the investigation of further local events in the selected stations in order to create an hydro-archive, i.e. a data-set of stable isotope of meteoric water in Ferrara province. This is important considering that the stable isotopes provide a snapshot of the current climatic conditions to be compared with the literature data and with the future composition, as a proxy to evaluate on-going climatic changes.

Although ancient ferruginous environments were likely primarily anoxic, the abundant Fe^{2+} could have been oxidized to form iron oxyhydroxides by abiotic processes, iron oxidizing microbes, or free oxygen produced by oxygenic photosynthesizers within oxygen "oases". Iron oxyhydroxides are known to be strong adsorbents of phosphate. Thus, microbes in ferruginous environments would have had to contend with high Fe concentrations and low, sometimes vanishingly low, dissolved inorganic P concentrations. Lake Matano, on Sulawesi Island, Indonesia, is a stratified ferruginous lake with less than 15nM soluble inorganic phosphate. We have isolated 9 heterotrophic bacterial strains from this lake, and most are capable of solubilizing phosphate from Fe oxyhydroxide minerals. All strains grow when provided with low concentrations of soluble inorganic phosphate, but some cannot tolerate high phosphate concentrations (30 mM). When goethite with adsorbed phosphate is provided as the sole P source, all strains grow quite well, and P is released into the medium. Measurements of pH changes in unbuffered medium suggest that some isolates produce acids that contribute to P desorption, though the variability in the amount of phosphate solubilized, consumed, and released suggests that these isolates have multiple mechanisms for P acquisition from Fe particles and subsequent intracellular storage. In addition to the physiological data from these isolates, metagenomic data from Lake Matano surface water indicates that a variety of phosphorus sources can be used, including inorganic phosphates, organophosphates, and phosphonates. These data from Lake Matano use extant pelagic bacteria to characterize microbial pathways for P acquisition from sinking Fe particles, how these pathways affect rates of growth, and how different P acquisition strategies may have regulated biological activity in ancient ferruginous oceans.

The energy budget of the mantle

JEAN-CLAUDE MARESCHAL[1], CLAUDE JAUPART[2], STEPHANE LABROSSE[3] AND FRANCIS LUCAZEAU[2]

[1]GEOTOP, University of Quebec, Montreal, Canada
[2]Institut de Physique du Globe de Paris, Paris, France
[3]Ecole Normale Superieure de Lyon, Lyon, France

We have estimated the present total energy flow of the Earth to be 46 +/- 3 TW. The heat loss through the continents and their margins was obtained by integrating the available heat flux measurements which yields 14TW. For the oceans, we have used a cooling plate model for the seafloor with parameters constrained by heat flux and bathymetry data (29TW), and we used the buoyancy flux to estimate the hotspots contribution (3-4TW). After removing the radiogenic heat production in the continental crust and lithosphere (7-8TW), the total heat loss from the convecting mantle is 38+/3 TW. The mantle energy loss must be balanced by radiogenic heat production in the Earth's mantle, heat flow from the core, and secular cooling of the mantle. All the other possible sources (tidal dissipation, differentiation of the crust from the mantle, gravitational energy released by thermal contraction) account for < 1TW. Geochemical and cosmochemical estimates of the concentration in radioactive elements in bulk silicate earth (crust and mantle) yield values in the range 13-24 TW, i.e. ~5-17TW for the heat production of the Earth mantle. For our preferred estimate of 11TW, the mantle Urey ratio is 0.29. Recent measurements of the thermal conductivity of the core have led to a re-evaluation of the core heat flow with a lower bound of 9TW and a range 9-17TW. Subtracting the mantle heat production and the core heat flow from the mantle energy loss, we obtain that the present cooling rate of the mantle is ~16 TW with a very wide range (1-33TW). This represents a cooling rate of ~100 K/Gy (7-220K/Gy), much higher than long term cooling rates obtained from petrological estimates of Archean mantle temperature (~70K/Gy).

$^{206}Pb/^{238}U$ matrix induced bias in LA-ICP-MS: A multivariate study

E. MARILLO-SIALER[1], J. D. WOODHEAD[1] AND J. HERGT[1]

[1]School of Earth Sciences, The University of Melbourne, Victoria, Australia
e.marillosialer@student.unimelb.edu.au

Many studies acknowledge the occurrence of systematic discrepancies between the $^{206}Pb/^{238}U$ ratios measured by LA-ICP-MS and TIMS across different reference materials (e.g. [1, 2]). In order to investigate these effects further high-precision morphology and volume determinations of laser ablation pits, obtained in several zircon materials under varying ablation conditions, have been achieved by confocal laser scanning microscopy (CLSM 700, Carl Zeiss). These provide detailed information on subtle differences in ablation behaviour between different zircon matrices. We demonstrate that small but significant differences in pit dimensions and laser penetration rates exist between zircons. Subsequent evaluation of the $^{206}Pb/^{238}U$ values reveals an association between ablation behaviour and deviations in the $^{206}Pb/^{238}U$ downhole fractionation patterns observed during ablation - a finding that has major ramifications for studies of U-Pb geochronology employing laser ablation.

The differences in ablation behaviour between zircons, however, cannot be ascribed to a single variable. Based on our initial observations the measured laser penetration rates may also be partially dependent on the crystallographic orientation of the crystals. Multivariate analysis of all possible parameters involved in the ablation process (zircon chemistry, crystallographic orientation, accumulated radiation damage, topographical and morphological data, and ablation cell spatial variations) will be used to identify the most important causes of these artifacts, and thus hopefully provide a means of correcting the results. Our ultimate goal is to offer researchers a method for producing high-accuracy U-Pb ratio measurements by LA-ICP-MS.

Fe, S isotope systematics of the 3.24 Ga old Mendon-Mapepe Formations, Kaapvaal Craton, South Africa

JOHANNA MARIN-CARBONNE[1], ELODIE MULLER[1], VINCENT BUSIGNY[1], CLAIRE ROLLION-BARD[2] AND PASCAL PHILIPPOT[1]

[1] Institut de Physique du Globe de Paris, Sorbonne Paris Cite, Universite Paris 7 Diderot, UMR 7154 CNRS,France
mcarbonne@ipgp.fr

[2] Centre de Recherches Pétrographiques et Géochimiques, Université de Lorraine, UMR 7358, 15 rue Notre Dame des Pauvres, F-54500 Vandoeuvre-lès-Nancy, France

Variations of Fe and S isotope compositions of sedimentary pyrites have placed important constraints on the chemistry and redox evolution of the Earth's ocean and atmosphere over geological time. In order to better constrain the paleo-environmental conditions and potential biological role on these pyrite formations, we developed coupled Fe and S isotope and trace element compositions analyses in 28 samples from the Barberton Barite Drilling Project (BBDP). The BBDP intercepted the transition from deep-water black cherts and komatititic basalts of the Mendon Formation to shallow-water sulfate deposits and terrigeneous and volcanoclastic sediments of the 3.24 Ga old Mapepe Formation. In situ Fe and S isotope compositions of pyrite were measured with ims 1280 HR2 at CRPG, with a reproducibility better than 0.2 ‰ (2σ) in both $\delta^{56}Fe$ and $\delta^{34}S$. Iron and S isotopes of bulk-rocks were analysed at IPGP, with a reproducibility better than 0.1 ‰ (2σ) in $\delta^{56}Fe$, $\delta^{34}S$ and $\Delta^{33}S$.

In situ and bulk-rock analyses reveal a large range of variation from -4.3 ‰ to +3.2‰ for $\delta^{56}Fe$, from -6.6 ‰ to +3.5 ‰ for $\delta^{34}S$ and from -3.5‰ to 1.8‰ for $\Delta^{33}S$. Although mean in situ pyrite Fe and S isotope compositions are generally well correlated with bulk-rock values, there are some offset depending on the presence of other Fe and S mineralogical phases (sulfates, carbonates, clays). This is well illustrated by co-variations between Fe and S isotope compositions with some major and trace elements (SiO_2, Al, U…). Pyrites of all samples show a clear correlation between in situ $\delta^{56}Fe$ and $\Delta^{33}S$ values. Pyrite from sedimentary rocks display a rough trend between negative $\delta^{56}Fe$ and $\Delta^{33}S$ values and positive $\delta^{56}Fe$ and $\Delta^{33}S$ values (mostly in BIFs). These large Fe and S isotope variations may reflect a mixing between different sources and record pyrite formation pathways. Coupled S and Fe isotope composition at μm-scale provides new insights into the origin of isotope variations in Archaean pyrites and its link to ocean chemistry.

Mineralogical and geochemical zoning at high-temperature contacts as a fonction of CO_2 pressure: An example from Romanian skarns

STEFAN MARINCEA[1]*, DELIA-GEORGETA DUMITRAS[1], ANGELA MARIA ANASON[1], CRISTINA GHINET[1] AND AURORA MARUTA IANCU[1]

Geological Institute of Romania, 1, Caransebes Str., Bucharest, Romania, RO-012271. (*correspondence: marincea@igr.ro)

Obviously mineral zoning occurs in two high-temperature skarn deposits: Cornet Hill and Măgureaua Vaţei (Metaliferi Massif, Apuseni Mountains, Romania). In both occurrences, an extensive metasomatism affected Tithonic - Kimmeridgian reef limestones of the Căpâlnaş-Techereu unit. The magmatic Upper Cretaceous intrusions at the contact are monzodioritic to quartz-monzodioritic.

The metasomatic mineral zoning is defined by the predominance of a mineral species and is, from the outer to the inner part of the metasomatic area: (1) calcite (marble) / tilleyite / spurrite + perovskite / wollastonite + gehlenite + vesuvianite / wollastonite + grossular / quartz monzonite at Cornet Hill (CH) and (2) calcite (marble) / wollastonite + titanian andradite + vesuvianite / gehlenite + grossular at Măgureaua Vaţei (MV). Differences in mineral zoning and in crystal chemistry of mineral species are principally due to the different pressures of volatile components (i.e., CO_2, SO_3, H_2O) which are higher at MV and lower at CH. Silicate-carbonates (e.g., spurrite, tilleyite) and hydrous or hydroxyl-bearing silicate-carbonates (e.g., scawtite, fukalite) are restricted to the CH skarn area. Sulfate-bearing mineral species (i.e., ellestadite-OH, thaumasite) are more common at CH, whereas a silicate-bearing apatite occurs at MV.

The hydrothermal alteration results in a restricted association of hydroxyl-bearing minerals at MV (i.e., xonotlite, hibschite, thomsonite), whereas at CH the association also includes afwillite, gismondine, tobermorite, riversideite.

Chemical geothermometry of geothermal fluids: past, present, and future

LUIGI MARINI

Consultant in Applied Geochemistry, I-55049, Viareggio (LU), Italy (luigimarini@appliedgeochemistry.it)

Most water geothermometers, including the Na-K and silica functions were initially derived on a purely empirical basis. Long ago, geochemists observed a general decrease in Na/K ratio and a general increase in SiO_2 concentration of thermal waters with increasing temperatures. The first geothermometers were based on these empirical correlations. Studies of hydrothermal alteration mineralogy developing in high-temperature hydrothermal systems as well as modeling of both mineral-solution equilibria and irreversible mass transfer taking place during water-rock interaction suggested that geothermometers are governed by equilibrium reactions between hydrothermal minerals and the aqueous solution under reservoir conditions. A new generation of geothermometric techniques was consequently proposed and a theoretical justification for water geothermometers was found.

Moreover, a different approach to geothermometry, based on speciation-saturation calculations carried out at different temperatures, was also suggested. It was shown that the saturation indexes with respect to a number of plausible hydrothermal alteration minerals converge to 0 at the equilibrium temperature, if the geothermal water is in equilibrium with the considered minerals.

Also gas geothermometers were initially empirical or partly empirical and were later improved by introduction of vapor-liquid distribution coefficients into equilibrium relations. The importance of addition to or removal from equilibrium liquids of equilibrium vapors was thus demostrated. This approach was later extended to fumarolic gas discharges. Besides, geothermometric functions involving the H_2/Ar and H_2/N_2 ratios were proposed, based on the hypothesis that Ar and N_2 are present in hydrothermal fluids in relative contents close to those of air-saturated groundwater.

In addition to provide a condensed history of chemical geothermometry, this presentation also intends to review main geothermometers and related graphical tools, trying to emphasize advantages and limitations and to give practical hints to the user. Future developments are also briefly considered.

How to protect geochemists working on environmental issues from litigation?

LUIGI MARINI

Consultant in Applied Geochemistry, I-55049, Viareggio (LU), Italy (luigimarini@appliedgeochemistry.it)

Four researchers working on environmental geochemistry at the Dept. of Env. Sciences of Siena University are involved in litigation. In December 2002, their institution was entrusted by the Italian Ministry of Defense to perform a geochemical-environmental study of two Sardinian firing ranges, due to their experience on the environmental impact of Depleted Uranium (DU) gained through previous investigations carried out in Kosovo. The geochemical-environmental study was focused on the distribution of U and other toxic heavy elements in soils, but active stream sediments, natural waters, and wild and cultivated plants were also investigated. Unfortunately, in contrast with the expectations of several inhabitants of the area, the Siena researchers did not find any evidence on the presence of DU in the surveyed area. The study of the Siena researchers was harshly criticized by the public prosecutor of Lanusei, technically advised by a full professor in physics of Brescia University, who is also member of the CERN of Genève. The crime of aggravated intentional omission of precautions against accidents and disasters was ascribed to the Siena researchers. In particular, they have been charged with: (a) not denouncing the danger of anomalous concentrations of Th present in the firing range; (b) using the knowledge gained in Kosovo to select methods that prevented to highlight the possible presence of DU. Actually, for what concerns point (a), there is no Th anomaly as Th contents in local soils are comparable with the values found in other areas of the Sardinia Region and elsewhere. For what concerns point (b), it is totally different, in terms of adopted investigation tactics, to study a small area, in which one knows that DU-shell were used and see the explosion craters (like in Kosovo), and to investigate a large area, in which one does not know if DU-shell were used or not (like in the Sardinian firing ranges). These facts demonstrate that technical advisors must be selected among experts in geochemistry to ensure a fair trial. The international geochemical community is urged to play an active role on this crucial point.

Radionuclides (^{10}Be, ^{210}Pb, ^{137}Cs and ^{7}Be) to Determine Anthropogenic Impact on Erosion Rates

J. MARQUARD[1]*, R.E. AALTO[1] AND T.T. BARROWS[1]

[1]College of Life & Environmental Sciences, Univ. of Exeter, EX4 4RJ, UK (*correspondence: jm459@exeter.ac.uk)

Short lived radiometric isotopes (^{210}Pb, ^{137}Cs and ^{7}Be) have been used widely for determining sediment sources and deposits [1-3]. However, little research has combined short and long term radiometric isotopes for this purpose. Here we combine short lived radionuclides with the long lived meteoric ^{10}Be to evaluate anthropogenic impacts on sediment erosion and redistribution during American colonial times (late 16th century) and longer timescales (within the Pleistocene). This research is based in the Christina River Basin, Pennsylvania (USA) within the Critical Zone Observatory (CRB-CZO). Anthropogenic impacts are being evaluated on soil redistribution and river channel development by using fallout radionuclides. Pre-colonial soil profiles and erosion rates are being quantified to gain information about natural erosion in the catchment. Sediment redistribution during colonial settlement is being evaluated to see the effects of land clearing and stream damming for mill use. Floodplain development within the last century is being investigated to identify changes in the source of sediment erosion due to afforestation and mill dam breaching. In addition, suspended loads in the streams from various storm events are being analysed to determine the present main source of erosion.

Initial results show changes in the concentration of the meteoric ^{10}Be tracer in river sediment of different ages. Millpond deposits that were in the streams at colonial times have a relatively high ^{10}Be concentration. Floodplain sediment that was deposited within the last century and present suspended loads have a lower ^{10}Be concentration. This clearly indicates a response of the erosional source in the streams to the environmental changes in the watershed. Deforestation and the increase in agricultural land-use enhances sediment surface erosion with high ^{10}Be and therefore lead to high ^{10}Be sediment deposits from that time. Afforestation and the increase in urbanisation in the catchment within the last 200 yrs in turn led to a decrease in upland erosion.

Ni diffusion in small angle grain boundaries of forsterite

MARQUARDT, KATHRINA[1] AND DOHMEN, RALF[2]

[1]Deutsches GeoForschungsZentrum Potsdam
[2]Instsitut für Geologie, Mineralogie und Geophysik, Ruhr Universität Bochum

Defects such as grain boundaries and interfaces are potent pathways for the transport of elements in rocks [1]; therefore they strongly affect large-scale physical properties of rocks, e.g. viscosity, electrical conductivity and bulk diffusivity. Yet data for geo-relevant materials are rare. The dependence of diffusion on the grain boundary structure e.g. defined by the lattice misfit, in silicates is unknown [p.954, 2]. Limited experimental studies in material sciences indicate major effects of grain boundary orientation on diffusion. Lately, synthetic georelevant bicrystals became available. Thus only now, first diffusion data on single grain boundaries have been produced [e.g. 3].

The effect of grain boundary orientation on diffusion in forsterite tilt grain boundaries (misorientations of 17° and 11°) was characterized by transmission electron microscopy (TEM). The site specific TEM-foils were cut using the focused ion beam technique (FIB). To study diffusion we prepared amorphous thin-films of Ni_2SiO_4 composition perpendicular to the grain boundary using pulsed laser deposition. Annealing (800-1000°C) leads to crystallization of the thin-film and Ni-Mg inter-diffuse into the crystal volume and along the grain boundary. The interdiffusion profiles were measured using the TEMs energy dispersive x-ray spectrometer standardized using the Cliff-Lorimer equa. and EMPA measurements.

We obtain volume diffusion coefficients that are consistent with earlier studies of Ni-Mg interdiffusion in forsterite at comparable temperatures. Contrasting to [4] our volume diffusion data are about an order of magnitude slower, while having similar activation energies. Grain boundary diffusion perpendicular to the dislocation lines of the small angle grain boundaries proved to be max. an order of magnitude faster than volume diffusion. The difference deceases markedly at temperatures above 1000°C.

Magma Signatures in the Terceira Rift Azores: a melt inclusion study

A FILIPA A MARQUES [1,] ZOLTAN ZAJACZ [2], PEDRO MADUREIRA[3] AND STEVEN D SCOTT [4]

[1]CREMINER (LARSyS), University of Lisbon, Portugal
[2]ETH Zürich, Switzerland
[3]EMEPC & University of Évora, Portugal
[4]University of Toronto, Dept. Earth Sciences, Canada

The Terceira Rift (TR) is a 550km long ESE trending line of volcanic reliefs (Graciosa Island, Terceira Island, D. João de Castro Bank, S. Miguel Island) alternating with deep basins (e.g. E of Terceira, Hirondelle) that define the plate boundary between the European and African plates on the Azores plateau [1]. Seismic tomography suggests that the Azores plume is centered NE of Terceira supplying upwelling plume material SW of Terceira (e.g. Faial) [2].

Melt inclusions (MI) are small portions of melt trapped during crystal growth. Their study allows the characterization of the composition of primary melts, mantle heterogeneity, magma sources and timescales. This study presents the first geochemical dataset of olivine-hosted unexposed MI sampled from submarine and subaereal lavas along the TR. Plots of incompatible trace element ratios (Fig.1) confirm the presence of distinct mantle signatures showing a mixing trend between two end-members that represent extreme topographic domains: Terceira and Hirondelle Basin. These findings will be discussed considering recent geophysical and geochemical data obtained in the area.

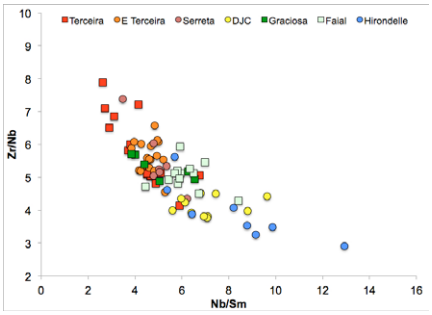

Fig. 1 Incompatible trace element plots of olivine-hosted MI from the TR. (square symbols: aereal lavas; circles: submarine lavas)

Buried lava paleosol in NW Fogo island (Cape Verde) – chemical and mineralogical evolution

R. MARQUES[1,2], M.I. PRUDÊNCIO[1,2], J. C. WAERENBORGH[1,3], J. T. COUTINHO[1], F. ROCHA[2,4], E. FERREIRA DA SILVA[2,4] AND M.I. DIAS[1,2]

[1]Campus Tecnológico e Nuclear, IST/UTL, EN10, Sacavém, Portugal (rmarques@ctn.ist.utl.pt)
[2]GeoBioTec, Univ. Aveiro, Aveiro, Portugal
[3]Centro de Física da Matéria Condensada - Univ. Lisboa, Portugal
[4]Dep. de Geociências, Univ. de Aveiro, Aveiro, Portugal

In Fogo island (Cape Verde archipelago), buried paleosoils developed between alkaline lava flows occur. Six samples (from parent rock to paleosurface) were collected from a 1 m thick profile. Weathered samples vary in colour from dark brown to yellowish. Chemical and mineralogical analyses were performed by instrumental neutron activation analysis, Mössbauer spectroscopy and X-ray diffraction.

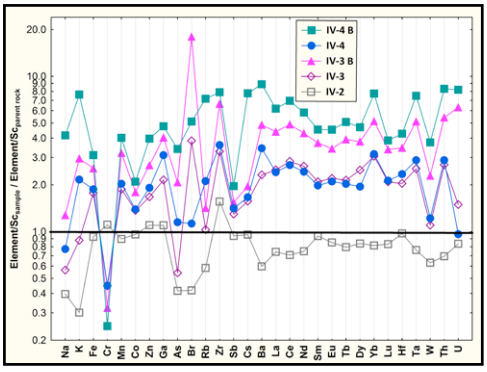

Fig. 1 – Chemical variations with depth/weathering degree (after normalization to Sc)

The main minerals of the parent rock identified by XRD are pyroxenes, olivines and phyllosilicates. In the paleosol only pyroxenes, quartz, phyllosilicates and in the most weathered/surficial samples hematite, were clearly identified.

Except for Cr a general enrichment of the studied chemical elements occurs with increasing weathering (Fig.1). The ancient surficial level has a significant enrichment in Na, K, Rb, Cs, Ba, REE, Ta, Th and U. Bromine variations may be mainly related with the presence of fluorapatite detected by XRD. Iron has a conservative behaviour. As the weathering degree increases the Fe^{3+}/Fe^{2+} ratio increases from 35% up to 85% and hematite is formed.

Bottom up approach for the predictive modelling of sorption isotherms on argillaceous rocks

M. MARQUES FERNANDES[1]*, R. DAEHN[1], N. VER[2] AND B. BAEYENS[1]

[1]Paul Scherrer Institut, CH-5232, Villigen, Switzerland (*correspondence: maria.marques@psi.ch)
[2]Hungarian Academy of Sciences, H-1525, Budapest, Hungary

Sorption in natural argillaceous rocks is inherently too complex and multi-faceted to be mechanistically predicted. The so-called “bottom up” approach for argillaceous rocks is based on the hypothesis that the uptake of sorbates in such complex systems can be quantitatively described based on the understanding of the sorption mechanisms on 2:1 type clay minerals [1]. Illite and illite/smectite mixed layers are the major clay mineral components of many argillaceous rocks, and their properties are supposed to be responsible for the radionuclide uptake in these systems.

The aim of this work is to test the capabilities of the 2SPNE SC/CE sorption model [2] and of the generalised sorption model for Cs [3] to make blind predictions of the sorption isotherms in two argillaceous rocks, Boda Clay Formation (BCF) and Opalinus Clay (OPA). As a complementary tool Extended X-ray Absorption Fine Structure (EXAFS) spectroscopy is used to verify the assumptions made in this approach.

Sorption isotherms of Cs(I), Ni(II), Co(II) and Eu(III) were measured on BCF and OPA rock samples in their respective pore-waters. The sorption prediction on these argillaceous rocks was then carried out using the mechanistic sorption models developed for illite [2, 3], and the results scaled over the illite and illite/smectite weight content in the sample. Generally a good agreement between the measured data and the predicted values was found. However, some discrepancies were observed, e.g. for Ni(II) on BCF at higher Ni(II) equilibrium concentrations. EXAFS was therefore used to verify the sorption mechanisms along the isotherm at the molecular level. In the isotherm region, where prediction and measurement coincide, sorption was in fact the only uptake-controlling mechanism. In contrast, EXAFS showed precipitation as additional uptake processes in the isotherm regions where prediction and measurement deviated.

Open-pit coal mining effects on rice paddy soil composition and metal bioavailability to *Oryza sativa* L. plants in Cam Pha, northeastern Vietnam

J. EDUARDO MARQUEZ, RAUL E. MARTINEZ HOÀNG THỊ BÍCH HÒA AND RETO GIERÉ

Institut für Geo- und Umweltnaturwissenschaften, Albert-Ludwigs-Universität, Albertstraße 23b, D-79104 Freiburg, Germany.

This study quantified Cd, Pb, and Cu content, and the soil-plant transfer factors of these elements in rice paddies within Cam Pha, Quang Ninh province, northeastern Vietnam. The rice paddies are located at a distance of 2 km from the largest Coc Sau open-pit coal mine. Electron microprobe analysis and energy-dispersive spectroscopy revealed a relatively high proportion of carbon particles rimmed by an iron sulfide mineral in the quartz-clay matrix of rice paddy soils at 20-30 cm depth. Bulk chemical analysis of these soils revealed Cd, Pb, and Cu in concentrations exceeding calculated background concentrations by 2500, 1226, and 979 %, respectively. Metals and metalloids in Cam Pha rice paddy soils, including As, Cd, Cr, Cu, Hg, Mn, Ni, Pb, and Zn, ranged from 0.2 ± 0.1 to 140 ± 3 mg/kg, in close agreement with toxic metal contents in mine tailings and Coc Sau coal. Native and model Oryza sativa L. rice plants were grown in the laboratory in presence of 1.5 mg/kg of paddy soil from Cam Pha to investigate its effects on plant growth. A decrease in growth of 60% with respect to a control was found for model plants, whereas a decrease of only 10% was observed for native rice plants. This result suggests an adaptation of native Cam Pha rice plants to toxic metals in the agricultural lands. The Cd, Cu, and Pb contents of the native rice plants from Cam Pha paddies exceeded permitted levels in foods. Cadmium was highest in the rice-grain endosperm at 0.09 ± 0.01 mg/kg, compared to the allowed content in foods of 0.05 mg/kg. Along with rice plant adaptation to contaminated soils, bioaccumulation of trace metals, such as Cd and Pb, poses a severe health risk to the population of Cam Pha. The adaptation of native rice plants, combined with bioaccumulation ratios of 1 ± 0.6 to 1.4 ± 0.7 calculated for Cd transfer to the rice-grain endosperm, strongly suggest a continuous input of toxic metals from coal-mining to agricultural lands in Cam Pha. In addition, our results imply a sustained absorption of metals by native rice plant varieties, which may lead to metal accumulation (e.g. Cd) in human organs and in turn to severe disease.

Sectoral contributions to black carbon concentrations and radiative forcing in Delhi

PALLAVI MARRAPU[1,2], YAFANG CHENG[2], GREGORY R.CARMICHAEL[1,2], GUFRAN BEIG[3], SCOTT SPAK[2], MICHAEL DECKER[4], MARTIN G SCHULTZ[4] AND SAROJ K.SAHU[3]

[2] Centre for Global and Regional Environmental Research, The University of Iowa, Iowa city, IA, United States.
[3] Indian Institute of Tropical Meteorology , Pune, Maharastra, India.
[4] Forschungszentrum Juelich GmbH,Juelich, Germany.

In this study we evaluate the air pollution levels in Delhi and their impacts on weather and climate. The two way interactions between pollution and meteorology are evaluated using the WRF-Chem model. The analysis period is focused on October 2010, the time period of the Commonwealth Games. The model is compared to BC and PM2.5 measurements at 11 sites. A sector based analysis is performed to assess the contributions to pollution and direct radiative forcing from transport, residential, power and industrial emissions. The contributions from emissions outside of Delhi are also evaluated to see the extent that regional emissions need to be controlled to meet air quality targets in Delhi. Results of simulations for emission scenarios for 2030 generated by the GAINS model that address air quality and climate strategies are also discussed.

Competitive effect of Al(III) on Eu(III) sorption to illite

R. MARSAC*[1], A. SCHNURR[1], T. KUPCIK[1], T. RABUNG[1], T. SCHÄFER[1], N.L. BANIK[1], C.M. MARQUARDT[1], M. MARQUES-FERNANDEZ[2], B. BAEYENS[2], M.H. BRADBURY[2] AND H. GECKEIS[1]

[1]Karlsruhe Institute for Technology, Institute for Nuclear Waste Disposal, D-76021 Karlsruhe, Germany. (*correspondence: remi.marsac@kit.edu)

[2]Paul Scherrer Institut, Laboratory for Waste Management, 5232 Villigen PSI, Switzerland

Clay rock formations present low permeability and strong sorption capabilities for cations, two properties that make them suitable as host rocks for nuclear waste disposal. Accurate description of radionuclide sorption onto clay rock based on geochemical sorption modelling is required to assess radionuclide migration properly. Examining published studies on trivalent actinide/lanthanide (An/Ln(III)) sorption to Illite batches (Illite du Puy) reveals data sets showing different metal ion sorption behavior [1-3] (and own experimental data). Surface complexation constants can differ by more than one order of magnitude ($\log^s K_1$=1.9 vs. 3.1).

Comparing Eu sorption data implies that in one case (stronger sorption) [3] the description of isotherms by the 2 SPNE SC/CE model requires the consideration of strong and weak sites, where binding to strong sites prevails at low $[Eu]_{tot}$ and sorption to weak sites at higher $[Eu]_{tot}$. In the other cases Eu(III) sorption appears to be linear over a wide range of $[Eu]_{tot}$, suggesting strong sites being absent or blocked. We explain this observation by slightly different Illite purification procedures notably by the effect of an acid washing step [1-3]. If Illite batches are washed at pH=3.5 with HCl during 1 week before Eu addition, we exclusively found weaker Eu sorption. A possible explanation for this observation is the incongruent Illite dissolution resulting in the release of Al(III), which in turn can compete with Eu(III) for sorption sites. In order to confirm this hypothesis we contacted Illite during 1 week with a solution containing 10^{-4} M of Al(III) (i.e. equal to [Al] due to illite dissolution at pH=3.5) at different pH. Again, we found Eu sorption behaviour similar to that of the acid treated clay. Taking the competing effect of Al(III) species into account can explain the different Eu(III) sorption data sets.

Deep ingression of meteoric water in late-metamorphic veins: a LA-ICPMS fluid inclusion study from the Rhenish Massif, Germany

A. MARSALA [1]*, T. WAGNER[2] AND M. WÄLLE [1]

[1] ETH Zurich, Department of Earth Sciences, Institute of Geochemistry and Petrology, Clausiusstrasse 25, 8092 Zurich, Switzerland (*correspondence: achille.marsala@erdw.ethz.ch)

[2] Division of Geology, Department of Geosciences and Geography, University of Helsinki, P.O.Box 64 (Gustaf Hällströmin katu 2a), FI-00014 Helsinki, Finland

The fluid evolution of late-metamorphic quartz vein systems in the fold-and-thrust belt of the Rhenish Massif has been investigated by microthermometry and LA-ICPMS microanalysis. The quartz veins are hosted in very low-grade organic-matter-rich metapelites of the Hunsrückschiefer and record two major stages of textural evolution: (1) a massive vein filling assemblage with elongate-blocky quartz, chlorite, albite and apatite, and (2) an open space filling assemblage with euhedral crystals of quartz, ankerite/dolomite and minor calcite and sulfides. The euhedral quartz crystals host well preserved fluid inclusion assemblages and permitted to reconstruct the evolution of the fluid system with time. The fluid inclusions, all aqueous two-phase with low salinity, belong to three successive generations. They show a systematic decrease in salinity from 4.7-5.3 to 3.1-3.9 and 1.4-1.7 wt.% eqv. NaCl, and a decrease in homogenization temperatures from 210-225 °C to 148-164 °C and 124-139 °C. LA-ICPMS microanalysis of individual fluid inclusions yielded reproducible concentrations of Li, Na, K, Rb, Cs, Mg, Ca, Ba, Sr, B, Al, As, Sb, S, Cl and Br. Alkali metals and boron, arsenic and antimony are correlated with the fluid salinity. Element concentrations are highest in the early fluid generation and decrease systematically in the latter two generations. Changes in salinity, homogenization temperature and elemental concentrations are explained by fluid mixing between a hot metamorphic fluid (moderate salinity and elevated concentrations of B, As and Sb) and a cooler dilute meteoric fluid during late-metamorphic exhumation and uplift. Cl/Br ratios of the fluid inclusions extend from close to seawater to values that are substantially below seawater. Because evaporitic rocks are absent in the shallow-water marine sequence of the Rhenish Massif, the elevated Br concentrations and Cl/Br ratios below seawater are best explained by fluid-rock interaction and uptake of Br from the organic matter in the metasediments.

Mélange formation, mantle-wedge diapirs and subduction zone magmatism

HORST R. MARSCHALL[1] AND JOHN C. SCHUMACHER[2]

[1] Dept Geology & Geophysics, WHOI, Woods Hole, MA, USA, hmarschall@whoi.edu
[2] Dept Earth Sci., University Bristol, Bristol, UK, j.c.schumacher@bristol.ac.uk

Components derived from the subducting slab contribute to the source region of magmas produced at convergent plate margins. The characteristic range of compositions of these magmas is commonly attributed to three-component mixing in the source regions of these magmas: hydrous fluids derived from subducted altered oceanic crust and components derived from the thin sedimentary veneer are added to the depleted peridotite in the mantle wedge, where melt is produced. We recently proposed an integrated physico-chemical model of subduction zones that includes mélange formation at the slab-mantle interface as the dominant physical mixing process, as well as low-density mantle-wedge diapirs that transport the well-mixed materials into the hot corner of the mantle wedge beneath arcs [1].

The strong petrologic and chemical contrast at the slab-mantle interface leads to the production of hybrid rock compositions by metasomatic reactions, diffusion and mechanical mixing. The rise of low-density plumes in the mantle wedge provides a mechanism to transport these buoyant hybrid rocks from the slab-mantle interface toward the source region of arc magmas. The mélange plumes may partially melt in the hot corner of the mantle wedge due to heating and decompression, or their interior parts may dehydrate and flux-melt the overlying mantle-wedge harzburgite. The combination of these processes may produce the large range of major and trace-element compositions found in modern island arc volcanic rocks.

Consequences and predictions from our model include the following: low-velocity zones at the slab-mantle interface and in the mantle wedge may represent layers and diapirs of fluid-rich mélange material instead of hot, melt-bearing mantle. The slab components are transported as solid matter into the source region of arc magmas rather than through the classically invoked fluids and melts. The temperatures and timescales for the generation of arc magmas determined from isotope and trace-element ratios need to be revisited, as these may reflect processes in the head of the mélange diapirs rather than in the subducting slab or the harzburgitic mantle wedge.

Raman hyperspectral imaging of carbonaceous materials and hematite: potential misinterpretations

CRAIG P. MARSHALL[1] AND ALISON OLCOTT MARSHALL[1]

[1]Department of Geology, University of Kansas, Lawrence, KS, 66045, USA cpmarshall@ku.edu and olcott@ku.edu

Raman hyperspectral imaging is becoming increasingly popular in geoscience applications, as geologists, paleontologists, and planetary and space scientists discover the wealth of non-destructive mineral data that Raman spectroscopy can provide. One common application of Raman hyperspectral imaging is identification of optically similar minerals within thin sections and their spatial distribution. For example, hematite, disordered sp^2 carbonaceous material, and graphite can co-occur within a sample and often appear as black opaque minerals that are challenging to distinguish optically [e.g., 1,2]. In order to distinguish between these three minerals geologists will typically collect a Raman spectrum in the carbon first-order region between 900-1800 cm^{-1}. Coincidently the hematite 2LO (which appear due to point defects of the α-Fe_2O_3 lattice) at ca. 1320 cm^{-1} is located in the same frequency region of the disordered sp^2 carbonaceous material D band (A_{1g} mode active due to disorder and decreasing crystallite size) at ca. 1350 cm^{-1}. While some geologists are cognizant of the overlap between the broad 2LO hematite mode and the broad D band of disordered sp^2 carbon, many however remain unaware [e.g., 3,4,5,6], identifying hematite by examination of the mineral fingerprint region (200-800 cm^{-1}) only [e.g., 7]. We suggest that rather than examining the mineral fingerprint region and the carbon first-order region separately for hyperspectral 2D and 3D imaging, the entire spectral region from 200-1800 cm^{-1} should be used in order to eliminate further false identification of these two minerals. Furthermore we suggest caution when interpreting the carbon first-order region as the G band (E_{2g2} mode in-plane C-C stretching LO phonon mode of an infinite crystal) from carbon is always present whatever the degree of structural order that the carbon sp^2 lattice has.

[4]Callinex Mines Inc., Vancouver, B.C., Canada (gabe@callinex.ca)

Emerald forms in a number of geological environments [1] from a wide variety of fluids, dominated by water, generally comprising a variety of salts, and compressible gases [2]. Geological environments are variable but unique in that they offer mechanisms that allow for the combination of berrylium-rich fluids to interact with chromium- and vanadium-bearing fluids or rocks. Our more recent work has concentrated on a relativey new occurrence of emerald in the Northwest Territories of Canada. Emerald from this deposit has precipitated from saline brines via inorganic sulphate reduction.

Figure 1. Zoned emerald from the Byrud deposit.

Zoned gem emerald occurs in a number of deposits worldwide. The best known occurences of zoned emerald are the Emmaville-Torrington in Australia, Erongo in Namibia, and the Byrud deposit in Norway. Recent fluid inclusion studies indicate that the zebra striping or zoned emerald (Fig. 1) is related to alternating precipitation of clear beryl and emerald in the vapour and liquid conjugates of (two-phase) boiling systems respectively.

Crustal evolution during granite emplacement: inheritance and development of heat-producing element enrichment

V. MARSHALL[1,2]*, K. KNESEL[2], S. E. BRYAN[3], C. M. ALLEN[4] AND I. T. UYSAL[1]

[1]Queensland Geothermal Energy Centre of Excellence, v.marshall@uq.edu.au (*presenting author)

[3]Earth, Environmental & Biological Sciences, Queensland University of Technology
[4]Institute of Future Environments, Queensland University of Technology

The Big Lake Suite (BLS) granite in central Australia is one of the most prospective hot-dry rock geothermal resources worldwide. We have undertaken LA-ICP-MS $^{206}Pb/^{238}U$ dating of ~500 spots in 431 zircons across two plutons to shed new insights into petrogenesis and the relationship between emplacement age and elemental enrichment; heat-producing element (HPE) enrichments vary from 144–28 ppm Th and 30–8 ppm U between plutons.

New emplacement ages were obtained for drill holes Big Lake 1 (299 ± 6 Ma, MSWD 1.6, n=33) and Moomba 1 (324 ± 5 Ma, MSWD 0.71, n=42) in the southwest pluton, and Habanero 1 (315 ± 5, MSWD 1, n=38), Jolokia 1 (319 ± 13, MSWD 0.75, n=5) and McLeod 1 (306 ± 5 Ma, MSWD 1.8, n=74) in the northeast pluton. $^{206}Pb/^{238}U$ ages suggest protracted magmatism ~325–300 Ma, reinforcing the idea of piecemeal accumulation of granitic bodies.

Inherited 427–414 Ma ages for igneous zircons were identified in all wells (except Jolokia 1) indicating a recycled Silurian magmatic component in the BLS. Although there is overlap, inherited zircons have (on average) lesser trace-element enrichment (~250 ppm U) than emplacement-aged zircons (~870 ppm U). This suggests the emplacement-aged magma had undergone a greater degree of differentiation, thereby enriching it in HPE relative to magma compositions from which the inherited zircon population crystallised.

Protracted magmatism over ~25 Myr, and differences in emplacement history, can help explain variations in U and Th enrichment across the two plutons. Samples from the southwest pluton exhibit a difference in emplacement age of ~25 Myr, yet exhibit similar maximum Th and U enrichment implying initial elemental composition and differentiation controls allowed the magma to differentiate to the same level. Comparatively, in the northeast pluton, greater variability in final Th and U enrichment suggests slight differences in source controls over the crystallisation history of the pluton.

Magmatic volatiles and mantle source lithology in the Hawaiian Plume: a view from olivine-hosted melt inclusions, glasses, and osmium isotopes

JARED MARSKE[1], ERIK HAURI[1], MICHAEL GARCIA[2] AND AARON PIETRUSZKA[3]

[1]j5241 Broad Branch Rd, Washington DC, marske@ciw.edu
[2]5241 Broad Branch Rd, Washington DC, ehauri@ciw.edu

[4]Box 25046 DFC, Denver, CO, apietrusza@usgs.gov

Variations in radiogenic isotopes (e.g. Pb,Nd) and magmatic volatiles (e.g. CO2,H2O) in Hawaiian volcanoes reveal important processes (i.e. source heterogeneity, melting, magma degassing). Shield-stage lavas likely originate from a plume source containing peridotite and ancient recycled oceanic crust (pyroxenite). The source region may also be heterogeneous with respect to volatile concentrations. However, shallow degassing makes it difficult to determine if there is a link between mantle source composition and volatile budget. Here we present Os isotopic ratios and volatile contents on olivines and glasses for 33 samples from Koolau, Mauna Kea, Mauna Loa, Hualalai, Kilauea, and Loihi to determine if volatiles in magmas correlate with geochemical tracers of source lithologies. For a given volcano, most osmium isotopic compositions of olivines are similar to the whole-rock values, yet some Mauna Loa and Loihi olivines display the significantly low 187Os/188Os values (~0.117) that may reflect partial melts of ancient recycled mantle lithosphere. SIMS analyses on Hawaiian glasses reveal a range in abundances of CO2 (10-251 ppm), H2O (0.2-1.2 wt.%), S (38-2960 ppm), and Cl (39-2960 ppm). However, most samples have low CO2 contents (<100 ppm) indicating they experienced degassing. Olivine-hosted melt inclusions may better preserve pre-eruptive concentrations and we will present new volatile contents on Hawaiian melt inclusions from the same olivines analyzed for Os isotopes.

Helium isotopes signature of mafic volcanics at Stromboli (Italy) during its magmatic evolution.

M. MARTELLI[1], A. RIZZO[1], A. RENZULLI[2], F. RIDOLFI[2], I. ARIENZO[3] AND A. ROSCIGLIONE[4]

[1]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Palermo, Palermo, Italy, m.martelli@pa.ingv.it
[2] Dipartimento di Scienze della Terra, della Vita e dell'Ambiente - University of Urbino, Italy
[3] Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Napoli Osservatorio Vesuviano, Napoli, Italy
[4] Dipartimento DiSTeM, Università di Palermo, Italy

A study on fluid inclusions of mafic minerals from selected volcanics is conducted to characterize the He and Ar isotopes of Stromboli. We also measured trace element in clinopyroxenes of selected samples and Sr-Nd isotopes. The samples belong to (i) the present-day activity of Stromboli; (ii) the extreme terms among the magmatic series erupted (calcalcaline CA and potassic KS); (iii) the ultramafic xenoliths outcropping in the island. The gas content trapped in mafic crystals is consistent with magma crystallization and fluid entrapment from mantle depths to progressively shallower conditions. All samples have $^3He/^4He$ in the range 4.0-4.9 Ra, except the KS ($^3He/^4He$ < 3.5 Ra), associated to higher Sr and lower Nd isotope ratio. Overall, He isotopes are well associated to lithophile element isotopes. The whole set of helium isotope data indicates ratios lower than those measured in the most uncontaminated Aeolian lavas (i.e., Alicudi, ~ 7 Ra) and in common volcanic arcs, due to subduction-related contamination beneath Stromboli. $^3He/^4He$ from mafic minerals are compared to those of currently geothermal fluids, with the latter ranging between 3.9 and 4.5 Ra. The maximum $^3He/^4He$ ratio measured in LP fluid inclusions (i.e., 4.6 Ra) would thus correspond to the upper limit that should be expected for surface gases during or before high-intensity eruptive events, when a deep gas component is released from the magma.

Developing the comminution age technique: Isolating the detrital minerals

A.N. MARTIN* AND A. DOSSETO[1]

[1]Wollongong Isotope Geochronology Laboratory, School of Earth and Environmental Sciences, University of Wollongong. (*correspondence: anm724@uowmail.edu.au)

The uranium-series isotopes can be used to quantify the timescales on which Earth-surface processes operate; this is essential before we can begin to try to understand how the erosion of the Earth's surface responds to climate change.

The traditional uranium-series methodology analyses the isotopic composition of the bulk sediment; however, this requires complex modelling to account for the variable isotopic composition of authigenic phases, such as carbonates and organic material [1]. The accuracy of the calculated ages can be improved by focussing on the isotopic evolution of only the detrital minerals. One such example is the emerging *comminution age* technique which calculates a radiometric age by relating the ($^{234}U/^{238}U$) of the detrital minerals to the surface area [2].

Sequential extraction procedures are currently used to remove the non-detrital fraction but these procedures are unreliable and suffer from a lack of reproducibility and completeness. To overcome this, the isolation of the detrital minerals can be monitored by analysing the ($^{234}U/^{238}U$) of the sediment throughout the procedure. This is possible as there are three domains of ($^{234}U/^{238}U$) in sediment: 1. ($^{234}U/^{238}U$) = 1 for the inner-core of detrital minerals, ($^{234}U/^{238}U$) < 1 in the outer-rind (ca. 50 nm) of sediment due to the effects of alpha-recoil, and ($^{234}U/^{238}U$) > 1 for the non-detrital fraction [3]. The minimum ($^{234}U/^{238}U$) of the sediment therefore represents the optimum isolation of the detrital minerals.

This study evaluates existing sequential extraction procedures and proposes an *optimised* procedure based on the above methodology. This will be presented in addition to the implications of the results upon ages calculated using the comminution age technique.

Fayalite oxidation processes at Obsidian Cliffs, Oregon

A.M. MARTIN[1]*, E. MÉDARD[2], B. DEVOUARD[2], L.P. KELLER[1], K. RIGHTER[1], J.-L. DEVIDAL[2] AND Z. RAHMAN[1]

[1] Johnson Space Center, 2101 NASA Parkway, Houston, TX 77058 USA (*correspondence: aud.martin23@gmail.com)

[2] Clermont Université, UBP/CNRS/IRD, Laboratoire Magmas et Volcans, 5 rue Kessler, 63038 Clermont-Ferrand, France

Fayalite $Fe_2^{2+}SiO_4$, the ferrous end-member of olivine, is present in terrestrial rocks and in primitive meteorites [1]. A ferric fayalite, laihunite $Fe^{2+}Fe^{3+}_2\square(SiO_4)_2$, has also been reported in terrestrial [2, 3, 4, 5] and martian [6] samples. In order to constrain the oxidation processes of fayalite, we have studied crystals found in lithophysae from the Obsidian Cliffs rhyolite using EMPA and SAED+EELS on a TEM, and made thermodynamic modelling.

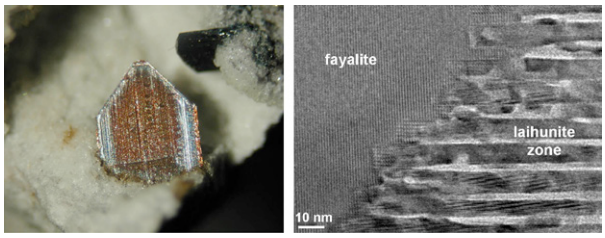

Figure 1: (a) picture of an oxidized fayalite crystal (approx. 1.6 mm tall) (©B.Lechner) (b) HRTEM image of the fayalite/laihunite interface.

Fayalite crystallized at 800-900°C and low pH_2O. Temperature decrease to 650°C induced the oxidation of fayalite into a "laihunite" zone $Fe^{2+}Fe^{3+}_2\square(SiO_4)_2$ composed of nano-lamellae of various oxidation phases (Fig.1). Further cooling, H_2O exsolution from rhyolite lava and/or infiltration of meteoric water caused the oxidation of the "laihunite" zone into an "oxyfayalite" zone $Fe^{2+}_{0.26}Fe^{3+}_{1.16}\square_{0.58}(SiO_4)$ also made of nano-lamellae.

Fayalite oxidation reactions can be used to constrain the emplacement and cooling history of the lava flow. Our data also hint at the existence of a ferric fayalite phase that is more oxidized than laihunite.

Heating from within and without, tales of contrasting long-lived crustal hots spots

M. HAND[1]

South Australian Centre for Geothermal Energy Research, University of Adelaide, S.A., 5005 Australia. (correspondence: martin.hand@adelaide.edu.au)

High thermal gradient conditions in the crust can be generated by a number of mechanisms: direct advection of heat via magmatism, high basal heat flow associated with extension/removal of lithospheric mantle, rapid exhumation of deeply buried rocks and high rates of internal heat generation. While each of these mechanisms may have characteristic time and length scales, the duration of metamorphism as perceived by geologists is generally controlled by the exhumation potential in the system which determines the thermal record of an individual rock. Therefore long-lived high-T metamorphism generally points to thermally anomalous conditions in crust with low exhumation potential where material stays within the system for an extended period of time (e.g. orogenic plateaus).

More intriguing is apparently long-lived (~ 100 Ma) high-T "hot-spot" metamorphism that appears to have operated on a sub-orogenic (~ 100km) scale length scale. This sub-orogenic scale means that rocks can potentially easily move out of the high-T region curtailing the duration of their high-T history. Such systems can be plausibly be driven by high rates of internal radiogenic crustal heat generation in chemically anomalous crust undergoing limited deformation. For example in parts of central Australia, crustal heat generation rates are regionally in excess of $8\mu Wm^{-3}$, and are spatially associated with high-T low-P granulite metamorphism.

"Long-lived crustal "hot spots" can also be generated in highly localised rift basins developed in thick continental lithosphere. Continental rift basins may accumulate in excess of 25km of sediment fill associated with voluminous mafic magmatism. This creates a logical setting for high-T, medium P metamorphism associated with on-going basin development, including high-grade intrabasinal deformation.

We discuss salient features of internally and externally driven crustal "hot spots".

Carbon budget during alteration of the oceanic crust

I. MARTINEZ*[1], S. SHILOBREEVA[2], V. BUSIGNY[1], C. LAVERNE[3], J. ALT[4] AND P. AGRINIER[1]

[1] IPGP, PRES Sorbonne Paris Cité, Paris, France (* correspondence: martinez@ipgp.fr).
[2] Vernadsky Institute, Moscow, Russia.
[3] Univ. Aix-Marseille III, Marseille, France.
[4] Univ. of Michigan, Ann Arbor MI, USA.

Although it is largely accepted that volatile elements are incorporated into the oceanic crust during alteration, the flux of carbon involved in this transfer remains poorly known. The detailed study of altered rocks is a key to better constrain the C uptake during alteration. In this work, we studied carbon concentrations and isotopic compositions in altered basaltic samples drilled from 2 different sites. We first selected a young section of altered oceanic crust (15 Ma): the ODP/IODP Hole 1256D, providing a large variety of rocks from lavas down to the gabbroic rocks. The second set of samples, which is of Jurassic age (Site 801, 150 Ma), was selected to evaluate C uptake variations during aging of the crust. All samples are enriched in carbon relative to fresh basalts. For 1256D samples, total CO_2 ranges between 564 and 2823 ppm with $\delta^{13}C$ values from -14.9‰ to -26.6‰. The carbon isotope compositions are interpreted in terms of a mixing between two components: (1) carbonate with $\delta^{13}C$ = -4.5‰ and (2) organic compound with $\delta^{13}C$ = -26.6‰ representing more than 75% of the total C in most of the samples. Jurassic samples are enriched in carbon relative to 1256D samples (with total CO_2 between 0.3 and 2wt%). Although the organic carbon concentration and isotope composition remains constant in these samples, the carbonate concentration strongly increases. A possible explanation is that higher atmospheric CO_2 in the Mesozoic [1] may have led to higher carbonate contents in the old 801 basement. Alternatively, we propose a two-step model for carbon cycling during crustal alteration: (i) organic compounds are formed close to ridge axis, either through recycling of biogenically-derived material or Fischer-Tropsch-type reactions; (ii) away from the ridge axis, the organic production decreases and carbon uptake is dominated by carbonate precipitation from seawater. The total flux of C stored in the altered oceanic crust, as carbonate and organic compounds, is estimated at $2.9\pm0.4\ 10^{12}$ molC/yr with a mean $\delta^{13}C$ of -4.7‰.

Modelling of rare earth element sorption to *Bacillus subtilis* bacteria

RAUL E. MARTINEZ[1], OLIVIER POURRET[2] AND YOSHIO TAKAHASHI[3]

[1] Insitut für Geo- und Umweltnaturwissenschaften, Albert-Ludwigs Universität, Albertstraße 23b, D-79104, Freiburg, Germany. raul.martinez@minpet.uni-freiburg.de
[2] HydrISE, Institut Polytechnique LaSalle Beauvais, 19 rue Pierre Waguet, 60026 Beauvais Cedex, France.
[3] Department of Earth and Planetary Systems Science, Hiroshima University, Higashi-Hiroshima, Hiroshima 739-8526, Japan.

In this study, rare earth element (REE) binding constants and site concentration on the Gram+ bacteria surfaces were quantified using a multi-site Langmuir isotherm model, along with a linear programming regression method (LPM). This approach found one discrete REE binding site on the Gram+ *Bacillus subtilis* surface for the pH range of 2.5 to 4.5. Average log REE binding constants from 1.08 ± 0.04 to 1.40 ± 0.04 for the light REE (LREE: La to Eu), and from 1.36 ± 0.03 to 2.18 ± 0.14 for the heavy REE (HREE: Gd to Lu) at 1.3 g/L of Bacillus subtilis bacteria. Similar values were obtained for bacteria concentrations of 0.39 and 0.67 g/L Within the experimental pH range in this study, *Bacillus subtilis* was shown to have a lower affinity for LREE (e.g. La, Ce, Pr, Nd) and a higher affinity for HREE (e.g. Tm, Yb, Lu) suggesting an enrichment of HREE on the surface of Gram+ bacteria. Total surface binding site concentrations of 6.73 ± 0.06 to 5.67 ± 0.06 and 5.53 ± 0.07 to 4.54 ± 0.03 moles/g of bacteria were observed for LREE and HREE respectively, and a log $K_{REE,j}$ of 1.46 ± 0.02 for a biomass content of 1.3 g/L. The difference in these values (e.g. a lower affinity and increased binding site concentration for LREE, and the contrary for the HREE) suggests a distinction between the LREE and HREE binding modes to the Gram+ bacteria reactive surface at low pH. A multisite Langmuir isotherm approach along with the LPM regression method, not requiring prior knowledge of the number or concentration of cell surface REE complexation sites, were able to distinguish between the sorption constant and binding site concentration patterns of LREE and HREE on the Gram+ *Bacillus subtilis* surface. This approach quantified the enrichment of Tm, Yb and Lu on the bacteria surface and it has proven to be a useful tool for the study of natural reactive sorbent materials controlling REE partitioning in the natural environment.

The conditions of formation of the Castro de Rei reduced W-skarn

I. MARTÍNEZ-ABAD[1]* AND A. CEPEDAL[1]

[1]Department of Geology, University of Oviedo, Arias de Velasco s/n, 33005, Oviedo, Spain. (*correspondence: iker@geol.uniovi.es)

The reduced W-skarn of Castro the Rei (Villalba Gold District, NW Spain) is hosted by marbles and calc-silicate hornfels of the contact aureole of a blind poskinematic Variscan granitoid [1, 2]. A hornblende-hornfels facies metamorphism is related to these granitoids, at pressures up to 2 kb [3]. Prograde skarn developed in marble is characterized by garnet (Gr_{41-77}), pyroxene (Hd_{33-100}), quartz and calcite with minor scheelite, K-feldespar and apatite. Locally, it can be formed by wollastonite, garnet (Gr_{62-82}) and piroxene (Hd_{43-70}). Prograde skarn and calc-silicate hornfels were overprinted by two stages of retroskarn. The first stage consists of ferrotremolite, epidote (Ps_{19-31}), zoisite (Ps_{0-19}), quartz, calcite, K-feldspar and sulfides and the second stage is characterized by prehnite or chlorite, quartz, calcite and sulfides. Based on mineral associations, fluid inclusion and stable isotope studies, a T-X(CO_2) isobaric (2kb) diagram with selected phase equilibria [4] was used for establishing the conditions of the skarn formation.

Fluid inclusions in garnet and quartz indicate that the prograde skarn was formed from a low-CO_2 (<0,06 mole fraction) aquocarbonic fluid. At this X(CO_2) the minimum formation temperature of the wollastonite-bearing skarn is 555ºC. For the garnet (Gr_{41-77}) and pyroxene (Hd_{33-100}) skarn, the formation temperature is above 520ºC, in agreement with the ^{18}O fractionation between quartz and garnet that yields a temperature of 534ºC. Ferrotremolite, epidote (Ps_{19-31}) and zoisite (Ps_{0-19}) from the first stage of retroskarn are formed at lower X(CO_2) (<0.04 mole fraction) and a temperature below 450ºC. For the second stage of retroskarn, fluid inclusions and occurrence of prehnite indicate near 0 X(CO_2) and temperatures below 385ºC. This is consistent with the maximum formation temperature calculated for the chlorite [5], up to 325ºC.

Surface ocean $\delta^{11}B$-pH reconstructions and insights into the ocean-atmosphere carbon exchange during the last deglaciation

M.A. MARTÍNEZ-BOTÍ[1]*, G. MARINO[2], G.L. FOSTER[1], P. ZIVERI[2], M.J. HENEHAN[1], P.G. MORTYN[2,3] AND D. VANCE[4]

There is a long-standing debate about the causes of the glacial-interglacial fluctuations in atmospheric CO_2 concentrations (pCO_2). One of the most established hypotheses involves the "storage" of CO_2 in the deep ocean during glacial periods, and the subsequent re-communication of this deep carbon reservoir with the surface ocean and atmosphere during deglaciations (mainly via upwelling in the Southern Ocean), thereby causing atmospheric pCO_2 to increase [1-3]. Yet direct evidence for carbon leakage from the ocean into the atmosphere during deglaciations is currently lacking.

Boron isotopes ($\delta^{11}B$) in planktic foraminifera are a proven proxy for past surface oceanic pH [4,5], which has provided valuable insights into past changes in the ocean carbonate system, and ultimately into past atmospheric pCO_2. Here we will present new planktic foraminifera $\delta^{11}B$ results from sediment cores retrieved from the Eastern Equatorial Pacific and Subantarctic Atlantic Ocean that yield novel insights into the causes and mechanisms of pCO_2 rise during the last deglaciation.

[4]Dept. Mineralogía y Petrología (UGR), Spain (mortega@ugr.es)

The western Mediterranean region has provided excellent marine archives for paleoclimate reconstructions. In particular, the Alboran sea basin where exceptional high sedimentation rates allowed high-resolution analyses for reconstructing past climate variability. Elemental ratios have revealed as reliable proxies for such reconstruction and have served to characterize arid/wet fluctuations, intensity of atmospheric fluxes and dust deposition, as well as bottom-water oxygen conditions. Over the past 20,000 cal yr BP, ratios mirroring eolian input (Zr/Al, Ti/Al and Si/Al) evidenced a major input of dust from the offset of the Last Glacial Maximum to the Oldest Dryas. Mg/Al, K/Al and Rb/Al ratios have provided information on fluvial contribution, and record humid conditions during the subsequent Bolling-Allerod warm period, further supported by the decrease of Zr/Al ratio. These ratios have also allowed a detailed reconstruction of paleoclimate conditions during the Younger Dryas and the Holocene. Ratios of redox sensitive elements such as U/Th, Zn/Al, Cu/Al, and V/Al ratios have also supported fluctuations in oxygen conditions at time of deposition, although these elements are particularly susceptible to diagenetic remobilization that could alter the original records. Regarding productivity fluctuations, reconstructions based on Ba proxies, including Ba/Al ratios, have shown a significant increase in the Ba/Al ratio during cold periods, i.e., H1 and Younger Dryas (derived from authigenic marine barite) evidencing enhanced marine productivity. In contrast, during the early Holocene the Ba/Al ratio indicate decreasing productivity. However, the biogeochemistry of Ba is not yet fully understood and mechanisms for barite precipitation in the water column still require further investigation.

Isotope geochemistry in waters affected by mining activities in Portman bay (Spain).

M.J. MARTÍNEZ-SÁNCHEZ[1]; M.L. GARCÍA-LORENZO[2]; C. PÉREZ-SIRVENT[1]* AND M. HERNANDEZ-CORDOBA[3].

[1]Department of Agricultural Chemistry, Geology and Pedology. Faculty of Chemistry, University of Murcia, Murcia, Spain. melita@um.es (*presenting author García-Lorenzo, M.L. mglorenzo@geo.ucm.es)

[2]Department of Petrology and Geochemistry. Faculty of Geology, Unibersity Complutense of Madrid, Madrid (Spain)

[3]Department of Analytical Chemistry. University of Murcia.

The objective of this work was to characterize processes affecting waters from Portman bay by way of isotopic analysis, particularly H and O stable isotopes from water molecule and S and O from dissolved sulfates were studied.
Portman bay is situated close to the mining region of La Unión and was subject to mining from the time of the Roman Empire to 1991, when the activity ceased. From 1957 to 1991, the Peñarroya Mining and Metallurgical Society performed ore extraction on a large scale. From Lavadero Roberto, the waste materials were discharged directly into the sea in the inner part of the bay, and later they were also discharged to sea at a distance of the shore. These wastes mainly consisted in ore materials (sulfides as galena, pyrite and sphalerite), phyllosilicates in addition to siderite, iron oxides and sometimes alteration products such as jarosite, alunite, kaolinite and greenalite.

Mining activities have produced great amount of wastes, characterized by high trace elements content, acidic pH and minerals from weathering processes. According to the isotopic analysis, the origin of waters from Portman Bay is not marine, they are meteoric waters subjected to evaporation except for two superficial samples from Portman Bay, where seawater remained stagnated in impermeable sediments. The possible marine infiltrations only take place in the deepest layers (>17 m) because below this depth materials showed low permeability. Superficial waters from Portman bay have undergone evaporation while deep waters showed no evidence of this process. The isotopic results suggested that the sulfates mainly come from sulfide oxidation and transport of produced sulfosalts. The oxygen isotopes of water and sulfates were used to indicate the mechanisms of this oxidation, being Fe^{3+} the principal oxidant of pyrite. Moreover, there is evidence showing that sulfate oxygen is derived from water under aerobic and anaerobic conditions. Isotopic data also suggested that a reduction process is taking place under anaerobic conditions, favored by the depth.

Limestone-based technosols. A remediation technique for sediments contaminated by heavy metals.

M.J. MARTÍNEZ-SÁNCHEZ[1]; M.L. GARCÍA-LORENZO[2]; C. PÉREZ-SIRVENT[1]*; E. GONZÁLEZ[1]; V. PÉREZ[1]; S. MARTÍNEZ[1]; M.D. BELANDO[1], L. MARTINEZ[1] AND C. HERNANDEZ[1].

[1]Department of Agricultural Chemistry, Geology and Pedology. Faculty of Chemistry, University of Murcia, Murcia, Spain. mjose@um.es (*presenting author)

[2]Department of Petrology and Geochemistry. Faculty of Geology, Unibersity Complutense of Madrid, Spain.

The aim of this work was to assess the suitability of limestone-based technosols for decreasing the toxicity of the leachates caused by rain in sites contaminated by heavy metals. For such a purpose, 64 technosols were prepared in containers of $0.75m^3$, filled with 4 types of sediments collected from Portman Bay and subjected to different stabilizer proportions (limestone filler), different thickness of a drainage layer and presence/absence of a topsoil cover. The technosols were then submitted to different humidity/dryness cycles simulating the usual rain conditions in the zone and percolates were analyzed using a bettery of bioassays.

Portman bay is situated close to the mining region of La Unión. The entire area around the bay was subject to mining from the time of the Roman Empire to 1991. Since 1957, the wastes from mining operations were discharged directly into the sea in the inner part of the bay, while later on, they were also discharged to sea at a distance of the shore. These wastes mainly consisted in ore materials (galena, pyrite and sphalerite), phyllosilicates, in addition to siderite, iron oxides and sometimes alteration products such as jarosite, alunite, kaolinite and greenalite. These materials have suffered a concentration process by floatation with sea water and as a result of the discharge, the whole of the bay has filled up with wastes which also extend into the Mediterranean Sea.

The obtained results suggest that selected remediation technique reduces significantly the toxicological effect of the percolate to the tested organisms. The ecotoxicological testing may be a useful approach for assessing the toxicity as a complement to chemical analysis. In addition, the use of a battery of bioassays allows diminishing problems related to false positive results. The use of limestone filler constitutes an excellent option in sediments polluted by trace elements, because of risk for human health or ecosystems does not exist after the intervention. in addition, the designed experience allow to optimize stabilizer quantities, and may suppose a big cost-saving project in areas affected by mining activities.

The composition of zircon in peraluminous Variscan granites from Northern Portugal

HELENA C.B. MARTINS[1]* AND JOANA ABREU[1]

[1] DGAOT, Centro de Geologia, Faculdade de Ciências Universidade do Porto, Portugal, hbrites@fc.up.pt (* presenting author)

A group of peraluminous Variscan plutons were selected from the study of zircon composition. The selected plutons are: the post-D_3 Vila Pouca de Aguiar and the Lavadores plutons [1, 2] and the late-D_3 Vieira do Minho pluton [3]. The zircons occur as euhedral to subhedral crystals and exhibit finely concentric oscilatory zoning in BSE imaging. Internal zoning is mainly related to variations of Hf, Y, U and Th concentrations. Compositional ranges in zircon from all granites are present in Figure 1.

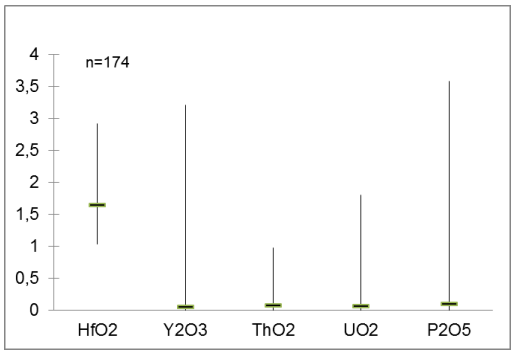

Figure 1: Compositional variation of zircons. Bar shows the complete range of zircon composition (vertical line), including the median (short horizontal line).

The zircon crystals have Zr/Hf ratio varying between 29 to 56, with no significant differences between the different granites. These values are in the same range of other peraluminous granites [5] and are in accordance with a crustal signature of zircon as suggested by several authors [4, 5].The range of Zr/Hf values in zircon crystals of the studied granite plutons overlaps with that of the potential protholits proposed in the genesis of these peraluminous granites, namely meta-igneous crustal sources at different levels [1, 3].

Sr and Pb isotopes in surface water and bottom sediments from a public water supply reservoir, São Paulo, Brazil

V.T. S. MARTINS.[1]* ; C. S. D. MURAKAMI[2] AND C. H. GROHMANN[3]

[1] Institute of Geosciences, University of São Paulo, São Paulo, SP, 05508-080, Brazil (*correspondence: veridian@usp.br)

[2] cintia.murakami@usp.br

[3] guano@usp.br

São Paulo is the biggest city of South America, with almost 20 million people living in its metropolitan area (MASP) of almost 6000 km^2. This population is mainly supplied by public surface water reservoirs, one of them being the Guarapiranga Dam, which provides water to 3,7 million people that live in the southeast of MASP. The Guarapiranga Dam surroundings are occupied by more than 800 thousand people that may compromise the quality of its waters. In order to investigate the existence of anthropogenic influences on the surface water of Gurapiranga Dam, the chemical composition of water and the surroundings rocks and sediments, as well as the Sr and Pb isotopic ratios of them, were analysed.

The results obtained from samples of water and sediment (bottom or margins), indicate that the water collected in only one point showed evidence of sewage contamination with the presence of high nitrate (>20 mg/L). In the sediments and bottom margin appeared high concentration of copper in the closest points of catchment water by the supply company. The presence of copper may be associated with the use of copper sulfate as algicide to prevent the eutrophication process of the reservoir and occurs mainly in the deepest parts of the dam.

The Sr isotope data indicated as well as the Pb isotopes, that the surface waters isotopic ratios are similar to the leachate (nitric and hydrochloric acids 3.5 M) from the bottom and margins sediments, that exhibited high content of copper (0.717) and organic matter, or with higher clay content. Furthermore, the Sr isotope ratios are also similar to those of rainwater (0.715). As for the Pb isotopes, the Sr isotopes do not clearly distinguish anthropogenic sources from natural sources, since both sources have similar ratios to surface waters in this case. Further studies should indicate that isotopes can be used as monitors of safe drinking water.

[3]Eni Donegani Env. Technologies, San Donato Milanese 20097,Italy, roberto.bagatin@eni.com

Zeolites are environmentally compatible crystalline aluminosilicates, which have well defined micropore dimensions and composition in a rigid crystal lattice. The shape of their internal pore structure can strongly affect their adsorption selectivity toward host molecules [1-3]. In the present work, organophilic synthetic zeolites which are cheap and available on the market, differing in topology, channel systems and free window apertures, and emerging organic contaminants (i.e. pharmaceuticals, fuel-based-pollutants) differing in chemical properties and molecular dimensions, were tested. A combined diffractometric, thermogravimetric, and gas chromatographic study was used to: (i) measure the sorption capacity of hydrophobic zeolite materials weighed against organic pollutants dissolved in water; (ii) quantify aspects of their removal efficiency for potential use in wastewater and groundwater remediation; (iii) understand zeolite structural features for the adsorption of emerging organic pollutants from aqueous solutions. Coupling the information gathered from these approaches can help in selecting adsorbent materials for water treatment.

Nitrogen isotopes in lunar soils: A record of contributions to planetary surfaces in the inner solar system

B MARTY[1], M. CHAUSSIDON[1], E. FÜRI[1], K. HASHIZUME[2], F. PODOSEK[3], R. WIELER[4] AND L. ZIMMERMANN[1]

[1]CRPG-CNRS, Université de Lorraine, Vandoeuvre, France, bmarty@crpg.cnrs-nancy.fr
[2]Osaka University, Japan
[3]Washington University, St Louis, USA
[4]ETH, Zürich, Switzerland

The nitrogen isotope composition of inner planets ($\delta^{15}N$ = 0 ‰ for the terrestrial atmosphere) and meteorites (between -40‰ and +40‰ for most meteorite clans) differs drastically from both Solar ($\delta^{15}N$ = -386 ‰ [1]) and Cometary ($\delta^{15}N$ ≈+800 ‰ for CN and HCN) values. On Earth, $^{15}N/^{14}N$ ratios span over less than 40 ‰. In contrast, values measured in lunar soils and rocks vary by up to 400 ‰. Since trapped lunar noble gases are exclusively sourced by the solar wind, these variations were initially interpreted as a temporal evolution of the solar wind N isotope composition [2]. Ion probe measurements and N-Ar systematics of soil grains have shown that these N isotope variations instead result from mixing between light N from the solar wind and a ^{15}N-rich component of non-solar origin [3,4]. The latter could have originated from implantation of ancient atmospheric N from the Earth, when the terrestrial magnetic field was weaker than Today [5]. However, the analysis of fluid inclusions in 3.5 Ga-old quartz is consistent with a N content and isotopic composition of the Archean atmosphere comparable to modern values [6], which suggests that the terrestrial magnetic field was strong enough to retain atmospheric N since at least 3.5 Ga. Thus escape of atmospheric N should have occurred before 3.5 Ga ago, e.g., in the Hadean, which is difficult to reconcile with the exposure ages and antiquities of lunar soils generally lower than 2-3 Ga. The secular varations of the N isotope composition of lunar soils are better accounted for by mixing solar wind N with asteroidal (IDPs, micrometeorites, meteorites) nitrogen, and temporal N isotope variations are consistent with a marked increase of the meteoritic flux in the last few hundreds of Ma. The N isotope systematics of lunar soils permit to constrain the fraction of cometary impactors to less than 13%, and the water flux to the lunar surface to about 600 tons/yr [7].

The composition of the Archean atmosphere as a tracer of volatile echange between the mantle, the surface and the outer space

B. MARTY[1], M. PUJOL[1,2], R. BURGESS[3], E. HEBRARD[1], L. ZIMMERMANN[1] AND P. PHILIPPOT[4]

[1]CRPG-CNRS, Université de Lorraine, Vandoeuvre les Nancy, France. bmarty@crpg.cnrs-nancy.fr
[2]Present address : Total E&P, Pau, France
[3]Manchester University, UK
[4]IPG Paris, France

The terrestrial atmosphere evolved through time as a result of exchanges of volatile elements with the mantle, the crust, and the outer space. Measurements of noble gases and nitrogen in Archean rocks (barite, hydrothermal quartz, cherts) give insights into the composition of the atmosphere at the time of rock formation. Trapped fluids consist of a mixture of one or several hydrothermal component(s) with an atmospheric end-member, presumably contributed as atmospheric gases dissolved in fresh- or sea-water. The isotopic compositions of Archean neon, argon and krypton appear similar to the present-day ones for radiogenic or fissiogenic isotopes. Compared to extraterrestrial precursors, Archean atmospheric xenon is enriched in its heavy isotopes by 1-2 %/amu, and intermediate between chondritic and modern atmospheric [1]. We interpret this difference as resulting from a preferential escape of Xe backwards through time [1,2], due to its increasing photoionization by hard UV light from the young Sun deep into the atmosphere and a more efficient trapping interaction with the primitive organic haze [3]. 3.5 Ga ago, the $^{40}Ar/^{36}Ar$ ratio was 143±24, which, when integrated into a 3-box (mantle, crust, atmosphere) K-Ar model, is consistent with a significant volume of felsic crust between 30% and 55% of its present-day volume at that time [4]. The partial pressure of atmospheric N_2 was similar to, or lower than, the present-day one, and the Archean N isotopic composition was similar within 2-3‰ to the modern one [5]. These results indicate efficient magnetic shielding of the atmosphere since 3.5 Ga, and, together from estimates of the density of the Archean atmosphere [6], set constraint on the P_{CO2} in the Archean atmosphere at <0.7 bar.

Ectomycorrhiza-bacterial interactions in weathering

MARUPAKULA S*, MAHMOOD S AND FINLAY RD

Uppsala BioCenter, Dept Forest Mycology & Pathology, Swedish University of Agricultural Sciences, Box 7026, Uppsala SE-750 07, Sweden. (*srisailam.marupakula@slu.se)

The role of ectomycorrhizal fungi in mobilising nutrients from organic polymers is widely accepted but the function of mycorrhizal fungal mycelia in mobilising and transferring nutrients from mineral substrates to the host trees is less well understood [1]. In addition to increasing the nutrient absorbing surface area of their host plant root systems, the extraradical mycelia of ectomycorrhizal fungi also provides a direct pathway for translocation of photosynthetically derived carbon to microenvironments in the soil. The continuous provision of energy-rich compounds, coupled with the large surface area of the mycelium, suggests that it may constitute an important niche for bacterial growth and colonization, however the role of these microbial interactions in weathering is still poorly understood. It has been shown that different soil horizons harbour different ectomycorrhzal fungi [2] and that the ectomycorrhizal fungi allocate organic acids to mineral substrates. In this study we use high-throughput sequencing to study the distribution of different bacterial and fungal taxa in O, E or B-horizon soil from a podzol collected from Jädraås, Sweden. Bacterial microbiomes from single mycorrhizal root tips colonised by different fungi were also examined to determine whether distinct bacterial communities were associated with particular mycorrhizal fungi.

Simulating magma ascent: An experimental challenge

H. MARXER*, P. BELLUCCI, S. ULMER AND M. NOWAK

University of Tuebingen, Department of Geosciences
*correspondence: holger.marxer@uni-tuebingen.de

Isothermal decompression experiments with H_2O-bearing phonolitic melt (synthetic Vesuvius AD 79 "white pumice" composition) were conducted at super-liquidus *T* (1323 K) in an internally heated argon pressure vessel. The samples were decompressed from 200 MPa at true and interpolated decompression rates (DRs) of 0.0028-4.8 MPa·s^{-1}, applying a novel continuous decompression (CD) [1] as well as former stepwise decompression (SD) techniques to investigate the effect of decompression path on melt degassing. At target *P* the samples were quenched rapidly.

The comparison of the vesiculated glass products in terms of bubble number density (BND), size distribution of bubbles and residual H_2O-content in the glass reveals a massive influence of the applied decompression path on the degassing behavior of the melt. Decompression of the H_2O-bearing melt induces supersaturation with H_2O. At a certain ΔP, bubbles will nucleate homogeneously within the melt and grow by H_2O diffusion into the bubbles to regain equilibrium. The extent of supersaturation is controlled by the actual decompression rate, because the diffusion distance of H_2O is limited within a certain time. The experiments have shown that the BND increases with decompression rate, whereas average size decreases. At low CD rates of ≤0.024 MPa·s^{-1} only few bubbles nucleate in the melt, because the decompression rates provide sufficient time for H_2O diffusion into existing bubbles. Bubble growth is the predominant degassing process. Residual H_2O-contents in the glasses indicate that an equilibrium degassing path can be simulated at low decompression rates. In comparison to CD, all corresponding SD run products feature higher BNDs and smaller bubble diameters for low decompression rates. SD results in instantaneous supersaturation due to rapid *P* drop, which can only be reduced by a massive nucleation event. The differences between the decompression techniques decrease with increasing nominal decompression rate due to the effect of a rapid *P* drop, enhancing bubble nucleation.

SD techniques are not suitable to investigate the dynamic processes during continuous magma ascent, at least at low nominal decompression rates. Ongoing experiments with CD will give new insights into the dynamic processes within ascending magma prior to eruption.

[5]Department of Geology, Cadi Ayyad University, Marrakech, Morocco; youbi@uca.ma

The eruption of continental flood basalts of the Central Atlantic Magmatic Province (CAMP) is coeval with mass extinction at the Triassic–Jurassic (Tr–J) boundary. In order to define the role of CAMP volcanism in triggering the biotic turnover, it is crucial to define whether or not onset of CAMP preceded the main end-Triassic climate disruption marked by a significant negative Carbon isotope excursion (CIE) of up to – 8 ‰. However, the temporal relationships between volcanism and CIE still remain circumstantial due to the difficulty in correlating a continental event (volcanism) with one recorded in marine sediments (CIE). Sediments underlying CAMP basalts in Morocco are characterized by high contents of MgO (10–32 wt.%) and of mafic clay minerals (11–84%). This geochemical signature must be linked to deposition of mafic clay minerals derived from early-erupted CAMP basalts. The measured C-isotope compositions of bulk organic matter show marked negative CIEs (up to -6‰) in association with the highest MgO peaks. This geochemical anomaly can be readily correlated with the initial negative CIE shortly preceding the Tr–J boundary. Our data show that the end-Triassic CIE and associated mass extinction occurred when CAMP had already been active and supports the hypothesis that the cause of the mass extinction was CAMP volcanism.

Interaction of nanoparticles with microorganisms

S. MASAKI[1] , H. SHIOTSU[1], F. SAKAMOTO[2] , T. OHNUKI[2] AND S. UTSUNOMIYA[1]

[1] Department of Chemistry, Kyushu University, Fukuoka 812-8581, Japan (utsunomiya.satoshi.998@m.kyushu-u.ac.jp)
[2] Advanced Science Research Center, Japan Atomic Energy Agency, Tokai, Ibaraki 319-1195, Japan

Due to ubiquitous and abundant occurrence of nanoparticles (NPs) and microorganisms in the surface and subsurface environments, they encounter and interact in aqueous systems. Microorganisms can also form NPs on the cell surfaces by uptaking or releasing ions from/to solutions. Despite numerous studies reported biomineralization of NPs, knowledge on the interaction between micoorganisms and NPs is still limited. Here we report the response of microorganisms to NPs using *S. cerevisiae* (yeast) and CeO_2 NPs (CeNPs).

Yeast was harvested in a YPD media prior to the experiment or a YPD media containing 250 ppm CeNPs (7 nm). The yeast was then contacted with a 1 mM NaCl solution (P-free) for 0-120 h at four pHs: 2, 3, 5 and 7. A variety of analytical techniques have been employed to investigate substances released from the cells, including inductively coupled plasma mass spectrometry (ICP-MS), ion chromatography (IC), high performance liquid chromatography (HPLC) and total organic carbon analyzer (TOC). The cytotoxicity of CeNPs was determined by the classical methylene blue straining technique and the mutated proteins were identified by peptide mass fingerprinting (PMF) analysis.

The solution analysis revealed that yeast released ortho-phosphate, organic phosphorous compound and various organic matters (<3 kDa) in all solutions. Phosphate released from the cells adsorbed on CeNPs at greater extent than inorganic phosphate by a factor of two. Although dissolved organic carbon (DOC), in general, inhibits phosphate adsorption to mineral surfaces, the released organic substances enhanced anion adsorption in the present study and possibility changed surface property of CeNPs. No cytotoxicity of CeNPs was detected; however, CeNPs induced an excess expression of two proteins: Eno2p and Rps24bp. In addition, the abundance and type of released substances were modified by CeNPs. Because Eno2p is related to the glycolytic system, CeNPs can affect the yeast's metabolism. That is, stimulating glycolytic system, which is the fastest step in the energy production process, lead to the decrease of tricarboxylic acid cycle via the electron transport chain, resulting in the modification of the released substances. The phenomena elucidated in the present study provided new insights to the fundamental process in the interaction between microorganisms and NPs in the Earth surfaces.

Characterization of woody biomass ashes and their utilization potential

CHRISTOPH MASCHOWSKI[1], RETO GIERÉ[1] AND GWENAELLE TROUVÉ[2]

[1] Albert-Ludwigs-Universität Freiburg, Germany (maschowski@minpet.uni-freiburg.de)
[2] Université de Haute-Alsace, Mulhouse, France, (gwenaelle.trouve@uha.fr)

Ash from biomass combustion is typically considered a waste product. Bottom ashes, however, are sometimes used as source of nutrients in fertilizer additives. Fly ashes may be enriched in hazardous constituents (e.g., heavy metals, dioxins, and chlorides). Therefore, they should not be distributed into the environment but rather be land-filled.

In this study, bottom and fly ashes from two different types of solid biomass fuel, wood chips and Miscanthus grass, were sampled on site at a district heating plant and a power plant, respectively. These ashes were investigated by using X-ray diffraction and subsequent pattern analysis by Rietveld refinement method to gain semi-quantitative results for crystalline phases. The results were compared with those from analogous ashes, which have been produced under controlled laboratory conditions from pellets of wood and Miscanthus. Furthermore, the samples were characterized by laser diffraction to determine their particulate size distribution.

The main focus was put on the calcium oxides (mainly lime), which are present in both types of ashes and could bear utilization potential as CO_2-neutral clinker substitution in cement production. Main sources of lime in the ashes of both fuel types are extraneous calcite (present as grains in the fuels and then decomposed during combustion) as well as biogenic Ca phosphates and oxalates, as indicated by SEM/EDX analysis and elemental maps. The Miscanthus fuel used in the power plant, however, was co-combusted with 2 wt% of limestone in order to minimize fouling and slagging and certainly contributed to the lime content of the Miscanthus ashes. Another component of the ashes is SiO_2, mainly under quartz specie. In the wood fuel, the silicon originates from extreaneous quartz grains, whereas in Miscanthus it is probably also of biogenic origin.

The second focus of this study was on alkali and alkaline earth metal species. They can help to classify the fuel type. Potassium contents were relatively low for both fuel types, indicating a diminished fouling and slagging potential on combustor walls and convection tubes.

Both ash types contain similar crystalline phases, and our data are close to literature. These results may be used to evaluate the potential of such ashes as secondary raw materials.

The influence of the elemental composition on the cubanite mineralization

A. V. MASHUKOV*, V. G. MIKHEEV AND A. E. MASHUKOVA

Siberian Federal University, Krasnoyarsk, Russia,
(*correspondence: AVMashukov@sfu-kras.ru)
(VMicheev@sfu-kras.ru)
(AMashukova@sfu-kras.ru)

Using the methods of X-ray and Mössbauer spectroscopy, scanning electron microscopy, there were studied the samples of Norilsk ore types in order to identify compounds containing cubanite. Depending on elemental composition there were singled out sample series.

The concentration of selected elements varied from sample to sample and reached maximum values in percent age: for Cu - 23.0, Fe - 41.7, S - 34.0, O - 1.1. The relative magnetization (I/I_0) of the samples at different temperatures are shown in Table 1

t°C	20	200	240	300	400	500	560
I/I_0	1 0,67	0.61 0.40	0.84 0.15	0.38 0.12	0.14 0.08	0.06 0.03	0.02 0.02

Table 1: The temperature dependence of the relative magnetization, for I/I_0 line 1 - heating, line 2 - cooling.

The samples have a complex and diverse composition of a wide range of values having the remanent magnetization and its resistance to various demagnetizing factors.

Magnetization changes irreversibly with the change of temperature. This fact, as well as the discrepancy of Curie temperature in the cycle «heating - cooling», indicates the presence of a mechanical mixture, consisting of two and more ferromagnetic phases.

The magnetic phase has the spectrum composed of two six-linear spectrums. The peaks on the spectrum borders show the iron oxide presence. The sample magnetism is caused by the presence of the minerals of sulphide and oxide groups, containing Fe^{2+} and Fe^{3+} as the main components.

Phases containing Cu, Fe, S have complex composition: cubanite I (36,1% $CuFe_2S_3$), cubanite II (54,8% $CuFe_2S_3$), chalcopyrite (5,0% $CuFeS_2$), magnetite (2,22% Fe_3O_4), magnetite (1,64% Fe_2O_3). The position of the absorption lines in the magnetically ordered areas indicates the presence of $CuFeS_2$. Some of the samples of this group have broadened lines, indicating the existence of various positions of the Fe ions in the sublattices. Intergrowths of chalcopyrite (CuFeS2) are characterized by the isomer shift of 0,058 mm/s and the absence of quadrupole splitting.

Thus, the presence of the characteristic structures of the solid solutions decomposition shows a wide temperature range of sulphide crystallization.

Long-term effects of CO_2-charged brine on caprock integrity and existing heterogeneities within the Entrada Sandstone, Green River, Utah

[7]Department of Geology, Utah State University, 4505 Old Main Hill Logan, UT 84322-4505 16

Natural CO_2 has been escaping through geysers related to fault zones at Green River, Utah for at least 400 ka [1]. A scientific drilling project in 2012 to sample the CO_2 system, showed that the uppermost formation, the Entrada Sandstone, contained zones with high CO_2 pressures, despite this unit being exposed at surface. Core revealed that The Entrada sandstone comprised bleached sandstone layers interbedded with variably bleached and carbonated thin siltstone layers which have acted as aquitards.

Results from mineralogical, petrological, and geochemical analysis of the CO_2-reservoir rocks and sealing siltstone layers from the Entrada Sandstone core are presented together with a reactive transport model of the mineralogical changes. We determine the length scales and mechanisms of CO_2 penetration of the sealing siltstone caprocks, and especially the significance of carbonate precipitation on its sealing properties.

Mineral and chemical evolution of fragmental massive sulfide ores

V.V. MASLENNIKOV[1]*, R.R. LARGE[2], S.P.MASLENNIKOVA[1] AND L.V.DANYUSHEVSKIY[2]

[1]Institute of Mineralogy UB RAS, Miass, Russia (correspondence: mas@mineralogy.ru)
[2]CODES, Tasmania University, Hobart, Australia (Ross. Large@utas.edu.au)

The styles of mineral and chemical evolution of fragmental massive sulfide ores at the Urals and Rudny Altai VMS deposits depends on the primary composition of sulfide clasts and impurity of adjacent sediments.

In the early diagenetic stage, pyrrhotite fragments are replaced by sooty pyrite with increasing grades of Au, Ag, V and U. Pseudomorphic chalcopyrite-2 and sphalerite-2 have inherited Ni, Mn, As, Pb, Tl, Au, Ag, and Te from replaced colloform pyrite fragments. In the submarine supergene zone, chalcopyrite-2 may be partly replaced by bornite or tennantite enriched in Ag and Bi. In pyrite-rich fragmental ores, sphalerite-1,2 is commonly dissolved, but in sphalerite-rich classtic sediments, sphalerite-2 is a dominant product of the sulfide evolution. In submarine supergene zones, all sulfides can be replaced by oxyhydroxides and then transformed to hematite and magnetite in later metamorphic stages. In the last stage of diagenesis, fine grained pyrite is overgrown by pyrite euhedra while chalcopyrite-2 and sphalerite-2 are recrystallized to twin crystal aggregates depleted in most of the trace elements. These mineral concequences are typical of clastic sulfides associated with jasper at the margins of the massive sulfide. In calcareous and serpentitite-rich clastic sulfide sediments, pyrite nodules are commonly the products of diagenesis. In carbonaceous clastic sulfide sediments, diagenesis results in nodular as well as framboidal pyrite. Fine grained diagenetic pyrite inherits high contents of trace elements from ore clasts. In the metamorphic stage, the diagenetic pyrites are replaced by pyrrhotite and euhedral pyrite. The range of submarine supergene and metamorphic alteration assemblages of fragmental massive sulfide ores is due to dissolution of clastic and diagenetic sulfides or their recrystallization and refining.

This mineral research was supported by Program N23 of Presidium RAS (project 12-P5-1003) and LA-ICPMS analyses of sulfides were carried out at CODES, University of Tasmania [1].

Accurate measurement of diffusion profiles in altered wellbore cement using XMCT

HARRIS E. MASON[1,*], WYATT L. DUFRANE[1], STUART D.C. WALSH[1] AND SUSAN A. CARROLL[1]

[1]Physical and Life Sciences Directorate, Lawrence Livermore National Laboratory, 7000 East Ave, Livermore, CA 94551
(*corresponding author: mason42@llnl.gov)

Recent, intense effort has been focused on characterizing and modeling the degradation of wellbore cements exposed to CO_2-rich brines due to their role in geologic carbon storage. Scanning electron microscopy (SEM) and micro X-ray computed micro-tomography (XCMT) show the development of three discrete alteration layers in the reacted wellbore cement: a portlandite depleted zone, a Ca-carbonate zone, and an amorphous zone. Alteration models have assumed discrete, sharp contacts between these layers where the chemistry and mineralogy change drastically. Despite the power of XCMT to provide detailed 3D images of these alteration zones, little has been done to refine the geometrical models of wellbore cement alteration using these data.

Interpretation of XCMT images of wellbore cement can be problematic given the large distribution in grain and pore sizes as well as similarities of the mineral compositions and densities. Application of simple grayscale thresholds to XCMT data to identify alteration zones is problematic because of the zones span a narrow range in composition and density. Instead of thresholding, we rely on an advanced user-guided segmentation method which extracts the reaction zones by looking for not only differences in greyscale, but also in texture. This method allows us to more accurately define reaction boundaries and their extent in three dimensions.

With the reaction zone extents as guides, we take the analysis a step further and build 3D maps of mineral and elemental abundances. Using the geochemical model [1] and specific mineral linear X-ray attenuation coefficients we calculate what phases are present and their relative abundances in each zone. The end result shows that the reaction regions are defined by rather diffuse regions where multiple reactions can occur simultaneously, rather than by sharp regions.

Hydrocarbon Source Appraisal in $PM_{2.5}$ in Rio de Janeiro

C. MASSONE,[1,2], A. WAGENER[1]*, A. GIODA[1] AND A. SCOFIELD[1]

[1]Chemistry Department, PUC-Rio, 22453-900 RJ, Brazil (*correspondence: angela@puc-rio.br) (agioda@puc-rio.br) (scofield@esp.puc-rio.br)

[2]IEAPM, 28930-000 RJ, Brazil (cgmassone@gmail.com)

The work aimed at characterizing hydrocarbons present in atmospheric particulate matter (2.5 μm) in urban and rural areas. For this HV sampling of $PM_{2.5}$ over 24h occurred weekly along 12 months. Determination included 45 PAHs, n-alkanes, UCM, hopanes and steranes. Amongst the 16 USEPA PAH *m/z* 252 and 276 predominated, however in urban centers alkylated homologues were as well important (Fig 1). The presence of mature hopanes (Fig 2) and homologue n-alkane series confirm the petrogenic component derived from vehicular emission of unburned fuel. The ratio B(a)Py/(B(a)Py+B(e)Py near 0.5 indicates moderate fotodegradation of B(a)Py independently of the season. Acephenanthrylene, Bz(c)phenanthrene, diBz(a,j)chrysene, pentaphene, Bz(a)chrysene, picene and indene(7,1,2,3-cd)chrysene were also found and used for source appraisal.

A physicochemical approach to the early generation of continental crust by melting of oceanic crust

H.-J. MASSONNE[1]

[1]Universität Stuttgart, Azenbergstr. 18, D-70174 Stuttgart, Germany (h-j.massonne@mineralogie.uni-stuttgart.de)

The phase relations of three rocks (basalt, Archaean greywacke, and quartz diorite) each with different H_2O contents were studied by thermodynamic calculations for the P-T range 0.5-4.5 GPa and 550-1300°C using the computer program PERPLE_X [1] and the haplogranitic melt model by Holland & Powell [2]. The obtained P-T pseudosections were contoured by the following parameters: volume, K/(Na+Ca), Na/Ca and Si/Al of melt, and density of the total rock and restite. The melt and restite formed in the three studied rocks could be reasonably well characterized with these parameters and the obtained phase relations. For instance, melts representing TTGs are generated in the basaltic protolith in the pressure range 1.2-2.0 GPa between temperatures of 600-1000°C. The restite shows densities above 3.3 g/cm^3 at pressures in excess of 1.3 GPa when more then 5 vol.% of melt has formed in a low-H_2O basaltic composition and at >1.0 GPa and with >20 vol.% melt (T > 850°C) in a more hydrated basalt. TTG melts can also form in the two other studied rocks at a slightly elevated pressure range compared to the basaltic compositions. However restite densities exceed 3.3 g/cm^3 only in the stability field of coesite.

The obtained calculation results suggest the following geotectonic scenario which is capable to form considerable volumes of continental crust in Archaen times. The formation of relatively thick plates of oceanic crust, the hydration of their surface and final collision leads first to thickened oceanic crust and the generation of a granitic protocrust by partial melting in the hydrated realm of the underthrust oceanic plate during the collisional process. Subsequently, the protocrust is, in fact, further thickened by this process, but TTG melts are predominantly formed in the underthrust oceanic plate at a later stage. The restites in this partially melted regime reach densities above those of the mantle to be delaminated. The suggested crust-forming process could have occurred until late Proterozoic times.

A multi-component model for the partial melting in presence of CO_2 and H_2O in the mantle

MALCOLM MASSUYEAU[1], YANN MORIZET[2] AND FABRICE GAILLARD[1]

[1] ISTO CNRS- Univ. Orléans, ORLEANS, France (*correspondence: malcolm.massuyeau@cnrs-orleans.fr)
[2] Université de Nantes, Nantes Atlantique Universités, Laboratoire de Planétologie et Géodynamique de Nantes (LPGN), UMR CNRS 6112, NANTES, France

The link between volatiles and mantle melting has so far been illuminated by experiments revealing punctually, at a given P-T condition and under a specific chemical system, properties such as solubility laws, redox equilibria, and phase equilibria. The aim is to establish a multi-component model describing the Gibbs free energy of melt produced by mantle melting in presence of CO_2-H_2O: Carbonatite-carbonated melt and basalts.

Near solidus melts are dominated by carbonate-rich compositions, evolving towards basaltic compositions at higher temperatures. However, this carbonate-silicate transition is complex, abrupt, and dependent on temperature, pressure and the chemical composition of the system. In order to simulate partial melting in a variety of mantle conditions, we established a parameterization of the mixing properties allowing the complex activity-composition relationships for multi-component hydrated carbonated melts to be accounted for. Using the Margules formalism, this parameterization is calibrated on crystal-liquid, redox, fluid-liquid and liquid-liquid equilibria obtained by experimental studies in the P-T range 1-10 GPa and 900-1800°C (more than 500 data points). We so far adjusted the activity of the SiO_2 and CO_2 melt components which constitutes the main part of the silicated and carbonated frameworks. The SiO_2-CO_2 interaction reveals a strong non-ideality requiring a strongly asymetric Margules formulation. We also determined the standard thermodynamic properties for the CO_2 melt component.

As applications, we define the composition of incipient melts as a function of depth underneath MORs and Hot-Spots and identify regions of CO_2 saturation for kimberlitic melts.

Multiple sulfur isotopic evaluation of porewater sulfate profiles

ANDREW L. MASTERSON[1], WILL BERELSON[2] AND DAVID T. JOHNSTON[1]

[1]Dept. of Earth and Planetary Sciences, Harvard University, Cambridge MA 02138: amasters@fas.harvard.edu
[2] Dept of Earth Sciences, USC, Los Angeles CA

Modern marine sediment porewater sulfate concentration profiles provide information about total and depth dependent rates of organic carbon remineralization. These profiles only provide net rates, however, as oxidative sulfur cycling is a challenge to uniquely quantify. Researchers have demonstrated active oxidative sulfur cycling in organic rich sediments (where sulfate reduction otherwise dominates) using the $\delta^{18}O$ of porewater sulfate. The utility of this approach, which still carries great promise, relies on a robust understanding of *in situ* sulfur oxidation processes. Furthermore, recent work targeting the oxygen isotopic consequences of the sulfate reduction network, and experimental work on oxygen isotope exchange with sulfur intermediates, demonstrates a complexity to interpreting these records that is to date not fully explored.

Aimed at improving the estimates of net and gross sulfate reduction derived from porewater sulfate profiles in organic rich sediments, we present multiple S ($^{34}S/^{32}S$ & $^{33}S/^{32}S$) and sulfate oxygen ($^{18}O/^{16}O$) isotopic profiles from 5 anoxic basins within the California Borderlands and Mexican Margin (Alfonso, Mazatlan, Soledad, Santa Monica, San Blas). All sites exhibit linear sulfate concentration profiles that are used to infer rates of methanotrophy using simple flux balance models, and thus extracting rates of sulfur recycling complements those estimates. We discuss the utility of applying coupled minor sulfur isotope ($^{33}S/^{32}S$) and $^{18}O/^{16}O$ systematics in improving estimates of sulfur reycling processes in these oxidant limited systems, and their implications for improving early diagenetic models of sulfur mediated remineralization reactions.

Groundwater chemistry in 2012 in Miyagi Prefecture including Tsunami affected area

HARUE MASUDA[1], SHINJI NAKAYA[2], REO IKAWA[3] AND NAOATSU MARUI[4]

[1]Osaka City University, harue@sci.osaka-cu.ac.jp
[2]Shinshu University, nakayas@shinshu-u.ac.jp
[34]AIST, reo-ikawa@aist.go.jp, marui.01@aist.go.jp

Geochemical characteristics of the surface and ground waters (total 238 samples) in Miyagi Prefecture, of which coastal area was damaged by Tsunami occurred in association with the giant earthquake on the 11th March, 2011, was documented to figure out the situation of aqueous environment in 2012 and assess the future risk of groundwater by the Tsunami deposits and Fukushima-Daiichi nuclear disaster.

Anthropogenic impact on the studied water was not obvious for whole studied area, and all the studied waters were free from radiogenic Cs. Salinization is prominent in the groundwaters located in the Tsunami affected area, especially the shallow well waters from <10m depths in the southern part of the prefecture. The highest Cl concentration is 14000 mg/L, while the rate of seawater is commonly less than 3 % (500 mg/ L) one year after the Tsunami. Fe and Mn are occasionally higher than the standards of drinking water (0.3 and 0.05 mg/L respectively) in the Tsunami affected groundwaters, while, minor toxic element concentrations (As, Cd, Se, Pb, Cr^{VI}, Zn, F-) are generally lower than the standard values for drinking water. Those elements were released from the host sediments probably due to the reduction of groundwater in association with seawater contamination by the Tsunami, and Tsunami deposits do not seriously cause the contamination at present. However, the groundwater chemistry must be monitored in the future to assess the groundwater as water resources since the recharging age of the studied groundwaters are generally 20 to 50 years.

A model study on the effects of polyacrylic acid added in geothermal water on the growth of silica scale at a geothermal power plant

SACHI MASUNAGA[1]*, MAYUMI ETOU[1], YOSHIHIRO OKAUE[1] AND TAKUSHI YOKOYAMA[1]

[1]Faculty of Science, Kyushu University, Fukuoka, 812-8581,Japan
masunaga@chem.kyushu-univ.jp (*presenting author)

Polyacrylic acid (PAA) has been added as an inhibitor of calcium carbonate scale at the Takigami geothermal power plant, Oita prefecture, Japan. In the geothermal power plant, since the addition of PAA, the amount of silica scale formed from geothermal water has been reported to incerase compared with that before the addition.
Alminum (Al) is extremely concentrated into the silica scales in spite of its low concentration in geothermal water. Therefore, it is considered that Al plays an important role for the formation of silica scale from geothermal water[1]. Moreover, Al forms a stable Al-PAA complex[2]. As a result, it is necessary to consider the interaction among Al, PAA and silicic acid in geothermal water.

In this study, some model experiments were carried out to elucidate wheather PAA accelerates the growth of silica scale in geothermal water containig Al, PAA and slicic acid.

At pH 8.5, which is pH value of the geothermal water, PAA didn't affect the polymerization of silicic acid, while Al and Al-PAA inhibited the polymerization between monosilicic acid and polysilicic acid (M-P reaction). From ^{27}Al NMR, we found that 4-coordinated Al in supersaturated silicic acid solution can convert into 6-coordinated Al by the addition of PAA, indicating the formation of Al-PAA complex. The Al-PAA complex adsorbed on the surface of silica gel and retarded the dissolution of the silica gel. It can be deduced that the growth of silica scales from geothermal water is accelerated due to the inhibitions of M-P reaction and of dissolution of silica by the Al-PAA complex.

Iron mobilisation from volcanic ash/glass by atmospheric processing

E. MATERS[1]*, P. AYRIS[2], C. JACQUES[1], A. GUEVARA[1], R. HENLEY[3], S. OPFERGELT[1] AND P. DELMELLE[1]

[1] Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium (*correspondence: elena.maters@uclouvain.be, caroline.jacques@student.uclouvain.be, alicia.guevara@epn.edu.ec, sophie.opfergelt@uclouvain.be, pierre.delmelle@uclouvain.be)

[3] Research School of Earth Sciences, Australian National University, Acton, Australia (r.143.henley@gmail.com)

Deposition of volcanic ash can provide a source of bioavailable Fe to remote regions of the ocean where Fe deficiency limits primary production. Understanding controls of ash Fe solubility is essential for assessing volcanogenic Fe input to the marine environment. It is well known that interaction with acids (e.g., H_2SO_4, HNO_3) and exposure to cloud condensation/evaporation cycles during transport increase Fe solubility in mineral dust. Airborne volcanic ash particles, which act as cloud condensation nuclei and are co-emitted with volcanic acids (e.g., H_2SO_4, HCl, HF), are similarly expected to undergo atmospheric processing. We investigated the influence of such processing on ash Fe solubility by i) exposing six ash samples (57-74 wt.% SiO_2) to pH 1 H_2SO_4 for 336 h to mimic contact with acid during transport, and ii) subjecting a glass sample (58 wt.% SiO_2) to three 12-h cycles of alternating pH 2 and 6 H_2SO_4 to simulate pH changes during cloud evaporation and condensation, respectively. Solution sub-samples were analysed for Si, Al, Fe, Mg, Ca, Na and K concentrations by ICP-AES. Changes in sample surface compositions were assessed by X-ray photoelectron spectroscopy, and untreated ash surfaces were examined by scanning electron microscopy. Results suggest that surficial Fe salts do not constitute a significant fraction of the soluble Fe mobilised from ash in acid. The Fe release trend is consistent with leaching/dissolution of silicate components in the ash. We propose that ash surface properties imparted by eruption plume processing, including oxidation in a water- or HCl-rich environment or interaction with HF, are key in governing ash Fe release. The preliminary findings of the pH cycling experiment suggest that Fe release over 36 h is driven by dissolution and precipitation of Fe(III) at pH 2 and 6, respectively. Acid mobilisation of Fe does not appear to increase significantly over multiple cycles.

Volcanic ash and aerosol

TAMSIN A. MATHER[1]

[1]Dept. Earth Sciences, University of Oxford, South Parks Road Oxford OX1 3AN, UK, tamsinm@earth.ox.ac.uk

Volcanoes are an important source of silicate particles (e.g., ash) and aqueous aerosol (e.g., sulphate) to the Earth's atmosphere and environment. Persistent emanations represent a key background flux to the atmosphere maintaining its characteristics and composition, while sporadic large-scale eruptions have the potential to perturb the atmosphere's chemical and radiative balance as well as having other direct effects on the Earth's environment. The recent travel chaos in Europe during the Icelandic eruptions of Eyjafjallajökull and Grimsvötn in 2010 and 2011 has also brought into sharp focus the vulnerability of highly developed societies, remote from volcanoes, to their far-flung effects.

In this talk I will explore some of the nature and impacts of volcanic ash and other volcanic particles and how volcanologists study them. I will cover topics such as the generation of particles during volcanic activity, their effects in the plume (e.g., lightning generation and the scavenging of gases), their fall out and their environmental effects (e.g., the potential of volcanic ash to fertilize the oceans). Recent work has also shown the importance of understanding the relationship between volcanic emissions and cloud properties in order to understand the perturbation that anthropogenic emissions represent in terms of the Earth's radiative budget via the indirect aerosol effect.

High Cesium Concentrations in Groundwater in a Coastal Granitoidic Fracture Network

F. MATHURIN[1]*, H. DRAKE[1], B. KALINOWSKI[2], AND M. ÅSTRÖM[1]

[1]Linnaeus University at Kalmar, Sweden, (*presenting author: frederic.mathurin@lnu.se)
[2]Swedish Nuclear Fuel and Waste Management Co, Sweden

This study aims to increase the understanding of the sources and mechanisms by which elevated Cs concentrations build up naturally in deep and low temperature (<20ºC) groundwater residing in fractured crystalline bedrock.

The hydrochemical monitoring program carried out by the Swedish Nuclear Fuel and Waste Management Co (SKB) revealed that high variability in natural Cs concentrations, with values up to several µg/L (Fig. 1), occurs in fracture groundwater at the Äspö Hard Rock Laboratory (Äspö HRL) and the nearby Laxemar area (Sweden) down to 1155m depth. Related to the various types of water residing into the bedrock [1], the highest Cs concentrations were found in both old deep-seated saline and marinogenic groundwater (Fig. 1). The SEM-EDS and XRD analyses of fracture coatings reveal that high Cs concentrations (>50 ppm) in the bulk fracture coatings correlate with a mineral enrichement in illite, together with mixed-layer clays and chlorite. Based on hydrochemical modelling, intrusion of Baltic Sea water (K and NH_4 rich water), together with cation exchange, constitute a consistent explanation for the high Cs concentrations observed in the marinogenic groundwater at the Äspö HRL.

The Cs sorption mechanism and results presented here are relevant for recognition of conditions of importance in term of bedrock disposal of toxic waste materials as fractured bedrock constitutes the last retention barrier separating radionuclides (including ^{134}Cs and ^{137}Cs) from the biosphere if the release of radionuclides in the repository occurs.

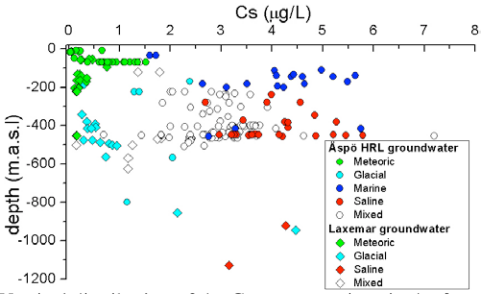

Fig. 1. Vertical distribution of the Cs concentrations in the fracture groundwater.

Control of oxygen fugacity in piston cylinder experiments

V.MATJUSCHKIN[1]*, B.TATTITCH[1] AND J.D.BLUNDY[1]

[1] University of Bristol, Wills Memorial Building, Quenn's Road, Bristol, BS8 1RJ, United Kingdom (*vladimir.matjuschkin@bristol.ac.uk)

Controlled oxygen fugacity experiments in a piston cylinder apparatus can be carried out using a double capsule technique and different solid oxygen buffers as suggested by Eugster (1957) and Jakobbson (2012). However both the capsule designs used in these studies as well as the choice of the spacer in the piston cylinder assemblage can affect the fO_2 in the experimental charge. The main goal of our study was concentrated on minimizing variability in fO_2 by testing different types of spacers, capsule materials and filling materials. In order to control and/or read the achieved fO_2 in the capsule we have examined the reaction of 3 different fO_2 sensors: NiPd, CoPd and magnetite-ilmenite. All experiments were carried out at 1GPa and 1000°C using the same piston cylinder apparatus.

The results show that use of Al_2O_3 as spacer material in combination with noble metals such as Pd and Pt can lead to oxidation of experimental charge up to ΔNNO+5 as Pd or Pt do not prevent enough hydrogen loss during experiment. Alternatively, using wet spacer materials (e.g pyrophyllite) may reduce the experimental by diffusion of hydrogen into the capsule. Applying MgO spacer with Pt and AuPd (80/20) capusles we could achieve consistent fO_2 between ΔNNO+2.5 and +3.5 for experiment durations up to 72 hours. In contrast, the use of pyrex (borosilicate glass) sleeve as spacer material in combination with AuPd capsules showed minimal loss of hydrogen (water) as well as no detectable boron diffusion through the capsule walls. As result, both NiPd and CoPd internal sensors indicated consistent fO_2 values of ΔNNO+1 (±0.2) for experiments tested up to 26 hours.

A further important factor we tested is the reaction of different solid buffers depending on the fO_2 we aspire to achieve. The metal sensors such as NiPd or CoPd are suitable for short and long time experiments (given the presence of an appropriate amount of water) and are able to register the changes of fO_2 already after first 12 hours of experiment. In contrast, magnetite-ilmenite oxide sensor needs more time for equilibration showing consistent results only after 24-72 hours runs.

Geomicrobiology of ancient polymetallic Kupferschiefer black shale - minireview

R. MATLAKOWSKA* AND A. SKŁODOWSKA

Laboratory of Environmental Pollution Analysis, Faculty of Biology, University of Warsaw, Miecznikowa 1, 02-096 Warsaw (*correspondance: rmatlakowska@biol.uw.edu.pl)

The highly mineralized upper Permian Kupferschiefer black shale located in the Fore-Sudetic Monocline (SW Poland) is a polymetallic, organic-rich sedimentary rock. It belongs to one of the largest copper and silver deposits in the world but it contains also large amounts of precious and rare elements such as nickel and platinum.

Indigenous microorganisms occurring in the black shale play a role in the biotransformation of the rock. The significant impact of heterotrophic bacteria represented by *Pseudomonas* sp. *Acinetobacter* sp. *Bacillus* sp. and *Microbacterium* sp. [1] includes such activity as: (i) degradation of sedimentary organic matter and metalloorganic compounds [2], (ii) bioweathering of rock-forming and ore minerals [3, 4], (iii) complexation of elements by bacterial extracellular metabolites such as siderophores and organic acids. All these activities strongly influence redistribution of carbon and other elements in the rock and are of environmental significance of the global biogeochemical cycle of elements in deep underground environment.

Chemical composition of chromian spinel of Podiform chromitite, Sangun Zone, southwest Japan.

ICHIRO MATSUMOTO

[1] Faculty of Education, Shimane University, Matsue, Japan. chromim@edu.shimane-u.ac.jp (corrspondence)

There are many chromitite pods in the Sangun zone belongs to inner zone of Southwest Japan. Most many chromitite pods enclosed by dunite rich ultramafic portion were discovered and outputted in this Zone, in Japan. Maximum size of chromitite-pod called “Nanago-ore body” which is 40*210*25m ($2.1*10^5 m^3$) in size from Wakamatsu chromite mine of the Tari-Misaka ultramafic complex. In this study, I summarized the relationships between chromian spinel in chemistry and size of chromitite-pods for its origin which controls a size.

Chromitite-pods are divided into two groups by Cr# (Cr/(Cr+Al)) of chromian spinel from chromitite that are relatively high-Cr# (Cr#: 0.55<) group and low-Cr# (Cr#: 0.47-0.55) group. High-Cr# groups are from “Nanago-ore body” and “10^{th} ore body” of Wakamatsu mine from Tari-Misaka ultramafic complex and chromitite pods from Takase and Ashidachi ultramafic complexes. Low-Cr# groups are from 51^{st}, 52^{nd}, 53^{rd}, 54^{th}, 55^{th}, and 56^{th} ore bodys of Wakamatsu mine from Tari-Misaka ultramafic complex and chromitite-pods from Inazumiyama, Mochimaru, Yagami, Ashidachi, and Yanomine ultramafic complexes.

Cr# of chromian spinel in dunite-harzburgite host rock of chromitite varies from 0.45 to 0.65 in “Nanago-ore body” and “10^{th} ore body” of Wakamatsu mine and 0.40 to 0.60 in the other chromititite-pods.

Relationships Cr# of chromian spinel from chromitite-pods and from dunite-harzburgite indicated that it was a relatively large-scale chromitite which shows high Cr# of chromian spinel in this area. The results of above characteristics clearly show that spinel precipitation and concentration are more intense at “Nanago-ore body” than at the other chromitite bodies of the Wakamatsu mine and the other chromitite-pods of other ultramafic complexes. That is supposing the origin of chromitite is the magma mixing which continues with melt and the reaction of a wall rock ultramafic rocks [1], the reaction ratio and reaction stage are important. Matsumoto *et al*., (2002) [2] also pointed out this importance by resarch of Wakamatsu chromitie mine. This study support the idea.

Surface morphologies of regolith particles of asteroid Itokawa recovered by the Hayabusa missions have important imformation about phenomena on the surface of an airless celestial body. In previous studies, space weathering rims were found on Itokawa particles by TEM and STEM [1, 2]. Especially, vesicles were identified in thick space weathering rims probably caused by solar wind He^+ implantation [2]. Blister structures corresponding to the vesicles were also observed on the particle surfaces by FE-SEM [3].

In this study, we carried out ion irradiation experiments to olivine particles (Fo_{70}) at the Wakasa Wan Energy Research Center and Institute of Low Temerature Science in order to understand relationship between space weathering processes and surface nano-morphological changes of Itokawa paricles. The fragments were irradiated by H^+, H_2^+ and He^+ ions at 4 to 50 keV with fluences of 1×10^{16} to 1×10^{18} ions/cm^2. Irradiated samples were observed by FE-SEM. Ultra-thin sections of the samples prepared by FIB were observed by TEM and STEM. Lunar regolith particle surfaces were also observed by FE-SEM for comparison. Blister structures and numerous bubbles, which have silimar structures to the Itokawa particles, were observed on the irradiated olivine samples. The blister structues were also observed on the lunar particles. The mean size and number density of blisters on lunar and Itokawa regolith particles are within almost the same range, suggesting that blisters formed on lunar and Itokawa particles by the same process.

Improved understanding of sources and processes of metal mobilization from sulfidic mine wastes through the application of post-transition stable isotopes

MATTHIES, R[1,2]* AND BLOWES, D W[1]

[1]Department of Earth and Environmental Sciences, University of Waterloo, 200 University Avenue West, Waterloo, ON Canada N2L 3G1 (*correspondence: romy_matthies@gmx.net)
2 School of Civil Engineering and Geosciences, Newcastle University, Newcastle upon Tyne, NE1 7RU, UK

The generation of metalliferous mine waters can result in potentially harmful impacts on environmental receptors. We conducted a 30 week lab-scale humidity cell test with sulfidic tailings from the Kidd Creek massive sulfide deposit, Canada. In 7-day cycles, the mine waste was exposed to three days of dry and moisturized air to accelerate sulfide-mineral oxidation. On day seven, metals were mobilized through flushing with deionized water. For the first time, we combined this prediction technique with a detailed study on the fractionation of stable zinc isotopes to i) identify principal metal sources and ii) improve understanding of the geochemical processes leading to metal mobilization. The dissolution of secondary and tertiary oxyhydroxisulfates at the beginning of the study led to considerable changes in zinc isotope ratios, potentially indicating kinetic fractionation of zinc isotopes. Thereafter, zinc was primarily mobilized through the oxidation of primary sulfide minerals with little or no change in $\delta^{66}Zn$ values. The limited isotope fractionation observed may assist in the use of zinc isotopes as a tracer of anthropogenic, metal mine sources in future studies.

Inter-laboratory calibration of Zn isotopic compositions for organic and inorganic reference materials

N. MATTIELLI[1]*, A. E. SHIEL[2,3], K. GORDON[2], D. WEIS[2], J. PETIT[4] AND E. COUDER[1].

[4]UMR 5805 EPOC-OASU, TGM, Université de Bordeaux1, 33405 Talence cedex, France

Significant inaccuracy in MC-ICP-MS measurements of Zn isotopic composition may be caused by inorganic and organic resin-derived components added to samples during column chemistry or/and to incomplete separation of the analyte from the sample matrix [1]. In addition, previous studies [1, 2] have shown that mass bias corrections, using sample-standard bracketing and external normalization, fail to accurately correct for these matrix effects.

The present work aims to calibrate several organic and inorganic reference materials to assess the accuracy of Zn isotopic measurements. Analyses of a broad compositional range of USGS rock reference materials, including the basalts BCR-2 and BHVO-2 and the gabbro HRM-27, and organic reference materials, including the lichen BCR-482, the rye grass BCR-281, the San Joaquin soil SRM 2709, the light sandy soil BCR-142 and the lobster hepatopancreas TORT-2, have been systematically performed on two Nu Plasma MC-ICP-MS (Nu 015 at ULB and Nu 021 at PCIGR).

Two anion exchange chromatography procedures have been compared for Zn isolation using 0.2 mL or 2 mL of AG 1-X8 resin. Elemental concentrations were determined by ICP-MS for each digested sample and Zn eluate cut to monitor both Zn recovery and the presence of potential matrix interferences. Zn isotopic ratios have been corrected both by external normalization using Cu and by sample-standard bracketing with IRMM 3702 and Lyon JMC Zn standard solutions. The lightest and heaviest δ^{66}Zn values (±2SD; relative to Lyon JMC) of the study are exhibited by the lichen BCR-482 (+0.09±0.06‰) and the lobster hepatopancreas TORT-2 (+0.49±0.07‰), respectively.

Across-arc geochemical variations in Central America subduction zone: evidences from Honduras basalts

MICHELE MATTIOLI[1], SAMUELE AGOSTINI[2] AND ALBERTO RENZULLI[1],

[1] Dipartimento di Scienze della Terra, della Vita e dell'Ambiente, Università di Urbino "Carlo Bo", Campus Scientifico "Enrico Mattei", 61029 Urbino (PU), Italy
[2] Istituto di Geoscienze e Georisorse, Consiglio Nazionale delle Ricerche, Area della Ricerca di Pisa, Via G. Moruzzi, 1, 56124 Pisa (PI), Italy

The across-arc geochemical data on the subduction zone of Central America are relatively scarce in Honduras where the active volcanic front does not occur inland but few km offshore the Pacific Ocean coast. In order to fill this gap we selected quaternary basalts from a arc to back-arc transect, enclosing (i) El Tigre, a stratovolcano in the Gulf of Fonseca, (ii) Yojoa Lake and Sula Graben back-arc volcanism, and (iii) Utila, a quaternary volcanic island near the strike-slip boundary between the North-American and Caribbean plates, about 200 km behind the front.

We found systematic variations in trace elements and isotopic compositions of basalts across this Honduras transect. Lavas from El Tigre are calc-alkaline with a significant LIL enrichment and Nb depletion, a strong slab signature and incompatible element contents similar to those in the main front of the adjacent volcanoes from El Salvador and Nicaragua (e.g. Ba/La up to 80). The back-arc quaternary volcanism of Yojoa Lake, Sula Graben and Utila is Na-alkaline, with a wide range of composition at Yojoa (basalts, hawaiites, mugearites, benmoreites, trachytes) and a more restricted, mafic composition at Sula and Utila (basalts and hawaiites). The back-arc basalts have similar major-trace element compositions to OIBs, such as relative enrichment in Nb and Ta, depletion in Pb and no pronounced peaks of fluid–mobile incompatible elements (Ba/La < 20).

The Sr and Nd isotopic data show a clear systematic variation passing from arc to back-arc, with El Tigre lavas characherized by higher $^{87}Sr/^{86}Sr$ (≈0.7038), and lower $^{143}Nd/^{144}Nd$ (≈0.51301), Utila basalts having typical values of a Depleted Mantle unaffected by any subduction imprint (≈0.7028 and 0.51310, respectively), whereas Sula and Yojoa have intermediate values.

$^{208}Pb/^{204}Pb$ and $^{206}Pb/^{204}Pb$ isotope ratios of El Tigre are very similar to arc volcanoes of El Salvador and Nicaragua (38.2 and 18.5, respectively), whereas back-arc samples have higher $^{206}Pb/^{204}Pb$ (18.6-18.7 for Sula and Yojoa, 18.7 for Utila island).

Modal metasomatism in upper mantle from Eastern part of Central European Volcanic Province (SW Poland).

MAGDALENA MATUSIAK-MAŁEK[1], JACEK PUZIEWICZ[1], THEODOROS NTAFLOS[2] AND MICHEL GRÉGOIRE[3]

[1]University of Wrocław, magdalena.matusiak@ing.uni.wroc.pl
[2]University of Vienna, Austria
[3]University Toulouse III-CNRS, France

Cenozoic volcanic rocks of mafic affinity occur aboundantly in central Europe forming the Central European Volcanic Province. The ascending magmas intentsively sampled upper mantle peridotites. Mantle xenoliths from the Eastern part of CEVP (SW Poland) are in general strongly depleted and nominaly anhydrous.

Small amounts of hydrous phases (mostly pargasitic amphibole) in xenoliths from Lutynia and Wilcza Góra were reported in literature (Blusztajn and Shimizu, 1994, Chem.Geol; Matusiak-Małek *et al*., 2010, Lithos). The first locality with significantly higher amounts of amphibole was described by Nowak *et al*. (e.g. 2010, EGU2010-9299) from Wołek Hill.

Mafic and ultramafic xenoliths from Wilcza Góra basanite form four compositional groups. Almost half of the xenoliths contain pargasitic amphibole with modal compositions up to 5%. Amphibole forms: (1) integranular grains; (2) amphibole-spinel-clinopyroxene clusters in host peridotite; (3) cores of clinopyroxene II; (3) lamellae in pyroxenes and (4) amphibole-olivine vein. Composition of amphibole follows compositional variations of host peridotite. The mg-number in amphibole occuring in peridotitic xenoliths is 0.910, the TiO_2 content is 0.262-0.413 wt.%. Amphiboles in xenoliths affected by "Fe-metasomatism" have mg-number from 0.892 to 0.852, while in cumulative xenoliths the latter is 0.854-0.734. The TiO_2 content is 0.533-2.220 and 2.915-3.508 wt.%, respectively. One xenolith contains vein formed of high mg-number 0.860-0.908 and TiO_2-rich (3.253-3.705 wt.%) amphibole. The REE pattern of the vein amphibole is LREE-enriched with negative inflection from Nd to La. It perfectly mimics REE composition of coexisting clinopyroxene.

Amphibole in Wilcza Góra xenoliths stands for local modal metasomatism in upper mantle beneath SW Poland. Composition of the amphibole suggest that it was introduced to the host peridotite together with clinopyroxene I due to reaction with hydrous mafic alkaline melt(s).

Oxidation state of iron in a primary Martian basaltic melt

A. K. MATZEN[1]*, J. R. BECKETT[2], A. B. WOODLAND[3] AND B. J. WOOD[1]

[1] Oxford Deptartment of Earth Sciences, UK, OX1 3AN (*correspondence: andrew.matzen@earth.ox.ac.uk)
[2] California Instute of Technology, Pasadena, CA 91125
[3] Goethe-Universität, D-60438, Frankfurt am Main

Olivine is an extremely important mineral in the generation and evolution of basaltic melts. Roeder and Emslie [1] concluded that the olivine (ol) silicate liquid (liq), exchange coefficient, $K_{D,Fe^{2+}\text{-}Mg} = (FeO/MgO)^{ol}/(FeO/MgO)^{liq}$ (by weight), is 0.30±0.03, independent of temperature (T) and liquid composition. An accurate $K_{D,Fe^{2+}\text{-}Mg}$ is predicated on a precise measurement, or calculation, of the abundances of Fe^{2+} and Fe^{3+} (expressed as $Fe^{3+}/\sum Fe$) in the liquid. It is well known that major-element composition can affect $Fe^{3+}/\sum Fe$ [e.g., 2], and very few measurements have been made on primitive liquid compositions relevant to Martian petrogenesis. We measured the $Fe^{3+}/\sum Fe$ ratios of a series of experimentally-produced glasses to better constrain the appropriate $K_{D,Fe^{2+}\text{-}Mg}$(s) to use for Martian systems.

One-atmosphere, super-liquidus (1450°C) experiments were performed on a synthetic basalt modeled after the primitive magmas found near Home Plate (50% SiO_2; 10% Al_2O_3; 18% FeO*; 12% MgO) [3] at log$f$$O_2$s ranging from -10 to -0.68. $Fe^{3+}/\sum Fe$ of the resulting glasses were measured using Mossbauer and XANES spectroscopy. $Fe^{3+}/\sum Fe$ vary from 0.06 to 0.68, and compare favorably with estimates based on terrestrially-relevant experiments [4]. Our results appear to contrast with much lower $Fe^{3+}/\sum Fe$ reported for similar experiments on a Zagami bulk composition [5].

One-atm experiments on model Martian compositions provide the tightest constraint on $K_{D,Fe^{2+}\text{-}Mg}$ because T and fO_2 are well known, allowing us to use [4] to predict the amount of Fe^{2+} present in each liquid. The median of 17 published 1-atm experiments yields $K_{D,Fe^{2+}\text{-}Mg}$ = 0.354±0.008 (error is one mean absolute deviation). Applying this $K_{D,Fe^{2+}\text{-}Mg}$ to the ol-phyric shergottites, leads to the possibility that Y980459, NWA 5789 and 2990 are liquid compositions (others appear to have accumulated olivine), identical to the results of [3].

Geochemistry of rare earth element (REE) in weathered crust from the granitic rocks in Sulawesi Island, Indonesia

ADI MAULANA[1]*, KOTARO YONEZU[2], AKIRA IMAI[3] AND KOICHIRO WATANABE[4]

[1] Faculty of Engineering, Kyushu University, Fukuoka 819-0395, Japan (*correspondence: adi-m@mine.kyushu-u.ac.jp)
[2] Faculty of Engineering, Kyushu University, Fukuoka 819-0395, Japan (yone@mine.kyushu-u.ac.jp)
[3] Faculty of Science, Akita University, Japan (akira@gipc.akita-u.ac.jp)
[4] Faculty of Engineering, Kyushu University, Fukuoka 819-0395, Japan (wat@mine.kyushu-u.ac.jp)

We report for the first time the geochemistry of rare earth elements (REE) in weathered crusts of I-type and calc-alkaline to high-K (shoshonitic) granitic rocks at Mamasa and Palu region, Sulawesi Island, Indonesia. The weathered crusts can be divided into horizon A (lateritic profile) and B (weathered horizon) in the Mamasa region with the present of horizon C (weathering front) in the Palu region. Quartz, K-feldspar, kaolinite, halloysite and montmorrilonite with Ca-amphibole prevail in the weathered crust. The total REE content of the weathered crust are relatively elevated (40 to 75%) compared to the parent rocks, particularly in the lower part of horizon B in Mamasa profile and in horizon C in Palu profile. This suggests that REE-bearing accessory minerals may be resistant against weathering and may remain as residual phase in the weathered crusts. The mass transfer illustration using isocon diagram shows a different transfer trend from Mamasa and Palu weathering profile. The positive Ce anomaly in the horizon A of Mamasa profile indicated that Ce is rapidly precipitated during weathering and retain at the upper soil horizon, suggesting the occurrence of redox-controlled process which leading to the CeO_2 precipitation.

Bioavailability of metals associated with aquatic natural organic matter

PATRICIA A. MAURICE[1]*, KESHIA KUHN[1], LISA NEUBAUER[2], THILO HOFMANN[2] AND FRANK VON DER KAMMER[2]

[1]Civil & Environmental Engineering & Earth Sciences, Univ. of NotreDame, Notre Dame, IN 46556 USA *corresponding: pmaurice@nd.edu
[2]Dept. of Environmental Geosciences, Univ. of Vienna, Vienna, Austria

This research focused on the bioavailability of trace metals associated with natural organic matter (NOM) to aerobic bacteria, using abiotic experiments with the siderophore desferrioxamine B (DFOB) and live-culture experiments with aerobic *Pseudomonas mendocina*. Trace metal contents and distributions in reverse osmosis, XAD-8 and XAD-4 isolates from the Suwannee River (SR), were measured prior to and following reaction with DFOB using field flow fractionation (FFF) with in-line UV/vis, fluorescence, and ICP detection. Results showed that Fe is preferentially associated with intermediate to high molecular weight (MW) components at both the native pH of the SR (3.4) and pH 7, Al is fairly uniformly distributed, and Cu is preferentially associated with lower MW components. Reaction of SR XAD-8, XAD-4 and RO samples with excess of the microbial siderophore DFOB removes ~75% of Fe within 1 hour. Al and Cu are also decreased, but not as efficiently. Upon reaction with DFOB, loss of some higher MW components and addition of more low to intermediate MW components suggests that Fe, and perhaps also Al, likely bridges organic components. Live-culture experiments showed that while siderophores are useful for Fe acquisition from NOM by *P. mendocina,* they are not required. Overall, our research shows that metals bound to NOM are likely highly bioavailable, and further emphasize that trace metals need to be considered in any study of aquatic NOM.

Linking soil chemistry, treeline shifts and climate change: a scenario

CHRISTIAN MAVRIS[1*,2,5], SUSANNE P. ANDERSON[2], MARKUS EGLI[1], ALEX E. BLUM[3], GERHARD FURRER[4] AND DENNIS DAHMS[5]

[1]Dept. of Geography, University of Zurich, CH-8057 (*correspondence: christian.mavris@geo.uzh.ch)
[2]INSTAAR, University of Colorado, Boulder, CO 80301, USA
[3]US Geological Survey, Boulder, CO 80303, USA
[4]Inst. Biogeochemistry & Pollutant Dynamics, ETH Zurich, CH-8092
[5]Dept. of Geography, University of Northern Iowa, Cedar Falls, IA, USA

Global warming can destabilize our fragile ecosystems. As cold areas become warmer, both flora and fauna must adapt to new conditions [1]. It is widely accepted that climate changes deeply influence the treeline shifts. But there is little knowledge about what happens to the soil chemistry when ecosystems tend to replace each other. Will elemental availability become a crucial factor in progressively warming conditions?

The Sinks Canyon and Stough Basin - SE flank of the Wind River Range, Wyoming, USA - offer a case study to answer these questions. Conceptually, the areas were divided into three main subsets: tundra, forest and subarid environment, all with soils developed on granitoid moraines. From each subset, a liquid topsoil extract was produced and mixed with the solid subsoil samples in batch reactors at 50 °C. The batch experiment was performed over 1800 h, and the progress of the dissolution was regularly monitored by analysing liquid aliquots with IC and ICP-OES.

The nutrients are released within the first hours of the experiment. Si and Al are continuously released into the solution, while some alkali elements – i.e. Na - show a more complex trend. Organic acids (acetic, citric) and other ligands produced during biodegradation play an active role in mineral dissolution and nutrient release. Furthermore, the mineral colloids detected in the extract (X-ray diffraction) can significantly control surface reactions (adsorption/desorption) and contribute to specific cationic concentrations. The experimental set up is then compared to a computed dissolution model using SerialSteadyQL and PHREEQC software.

Decoding the mechanisms driving mineral weathering is the key to understand the main geochemical aspects of landscape adaptation during climate changing conditions.

Mg isotope fractionation during hydrothermal carbonation of serpentine

V. MAVROMATIS[1,*], A. BEINLICH[2], H. AUSTRHEIM[3] AND E.H.OELKERS[1]

[1] GET, CNRS, UMR 5563, Toulouse, France, mavromat@get.obs-mip.fr(*), oelkers@get.obs-mip.fr. [2] MDRU, EOS, University of British Columbia, Canada, abeinlic@eos.ubc.ca. [3] PGP, University of Oslo, Norway, h.o.austrheim@geo.uio.no

As (*i*) the Mg isotope compostition of seawater is lighter than that of the mantle and (*ii*) Mg isotopic composition of the mantle is considered homogeneous [1], significant fractionation processes must be ocurring during the alteration of the continental crust [2,3]. This study has been initated to explore possible processes accounting for this fractionation.

Here we present new observations of Mg isotope fractionation during the carbonation of the Linnajavri Ultramafic Complex, N-Norway. Carbonation of the serpentinite in this complex ocurred at closed system conditions (except for the volatiles) at ~275 ºC resulting in the formation of mainly magnesite and talc [4]. Textural observations and reaction path considerations indicate that mineral replacement began with magnesite precipitation resulting in an increasing Si activity in the alteration fluid eventually saturating talc. The original serpentine has an isotopic composition of δ^{26}Mg (DSM3) =-0.11±0.05, whereas talc is enriched in ^{26}Mg with average δ^{26}Mg =0.17±0.08 and magnesite is depleted in ^{26}Mg with average δ^{26}Mg =-0.95±0.15. These observations indicate that Mg isotopes are efficiently fractionated at mid-crustal PT conditions.

The observed fractionation has significant implications for the Mg isotope distribution in natural waters due to the large difference of the dissolution rates of Mg bearing silicates relative to Mg-bearing carbonates – the dissolution rates of magnesite are ~3 orders of magnitude faster that that of talc at 25 ºC and pH=8 [5,6]. Our observations suggest that Mg isotope fractionation during carbonate formation and their faster erosion rates at Earth's surface conditions may explain the enrichment of seawater in ^{24}Mg compared to that of fresh mantle Mg and that Mg-bearing hydrous silicates may represent the missing sink for residual the ^{26}Mg.

Tracing the movement and fate of injected CO_2 in a mature oil field using geochemical, isotopic and modeling approaches

B. MAYER[1], G. JOHNSON[1,2], C. DALKHAA[1], M. SHEVALIER[1], M. NIGHTINGALE[1] AND I. HUTCHEON[1]

[1]University of Calgary, 2500 University Drive NW, Calgary, Canada, T2N 1N4.

*Correspondance: bmayer@ucalgary.ca

Carbon capture and geological storage is a potential technology to reduce CO_2 emissions into the atmosphere. Monitoring of CO_2 storage sites is required by many of the emerging regulations with specific interest in accounting of injected CO_2 in various target reservoirs. At the Pembina Cardium CO_2 Monitoring Project in central Alberta (Canada), we have used chemical data and carbon and oxygen isotope ratios of produced water and gases sampled repeatedly from various observation wells to trace the movement of injected CO_2 and assess pore space saturation with CO_2. The distinct carbon isotope ratios of injected CO_2 in association with gas compositional and flux data were used to determine the percentage of injected CO_2 produced at several observation wells using two end-member mixing calculations [1]. Changes of $\delta^{18}O$ values of produced water of up to 4 ‰ were caused by oxygen isotope exchange between CO_2 and H_2O following CO_2 injection [2]. The changes in the $\delta^{18}O$ values of water were used for a quantitative assessment of CO_2 dissolved in the fluids and of free phase CO_2 in the pore space of the reservoir. Subsequently, we combined seismic and geochemical information with reservoir modeling approaches in an attempt to determine a carbon budget for injected CO_2 in the mature oil field. Results of partitioning calculations indicate that two years after commencement of CO_2 injection the majority of the CO_2 remained in a free phase within the reservoir, while smaller amounts of injected CO_2 were dissolved in water and oil. In April 2010, CO_2 injcetion at this pilot site was stopped but geochemical monitoring commenced for an additional 2 years until June 2012. We observed continued increases of $\delta^{18}O$ values of formation water suggesting increases in CO_2 pore space saturation in the vicinity of two observation wells. The obtained results indicate that chemical and isotopic techniques can play a crucial role in monitoring the movement and the fate of CO_2 in geological reservoirs during and after CO_2 injection.

Adsorption of ^{109}Cd onto metaloxide nanoparticles

NATALIA MAYORDOMO[1]*, JUAN-LUIS LOPEZ-GOMEZ[1], URSULA ALONSO[1] AND TIZIANA MISSANA[1]

[1]CIEMAT, Avenida Complutense, 40. C.P 28040 Madrid (Spain) *natalia.mayordomo@ciemat.es

To reduce the environmental impact of hazardous pollutants, as the highly toxic metal Cd, geochemical barriers providing confinement are required. To enhance contaminant retention in geochemical barriers, different nanoparticles (NPs) are being analysed, taking into account their inherent retention properties, either single or combined with other materials.

To assess which NPs better prevent the risk of contaminant leakage, detailed experimental and theoretical sorption studies in a wide range of geochemical conditions, are demanded. The stability of the NPs, upon contaminant adsorption in different environments, is an aspect that must be also evaluated.

In this study, the retention capability of two metaloxide NPs (Al_2O_3 and CuO) as candidate sorbents for Cd immobilisation in geochemical barriers was analysed.

Sorption experiments have been carried out in different electrolytes ($NaNO_3$, $NaHCO_3$, Na_2SO_4 and $NaClO_4$) and in a wide range of pH and ionic strengths, to simulate different environmental and salinity conditions. Sorption isotherms at different Cd concentration were also performed.

In addition, particles size and surface charge were systematically measured in all experiments to assess NPs stability, essential to predict their performance.

Geochemical modelling of a wide set of experimental sorption data contributes to probe the capability of selected NPs as ^{109}Cd adsorbents in geochemical barriers and contamination risk assessment.

Acknowledment: The research leading to these results has received funding form the Spanish Government under the project NANOBAG (CTM2011-27975). N. Mayordomo acknowledges the FPI BES-2012-056603 grant from MINECO (Spain).

Paleo-methane emission events in Krishna-Godavari basin, Bay of Bengal: Geochemical signatures

ANINDA MAZUMDAR

Gas Hydrate Research Group, Geological Oceanography,National Institute of Oceanography, Goa - 403004, India

Marine cold seep associated authigenic carbonates are known from modern and past geological records. Cold seeps are characterized by expulsion of fluid enriched in methane, hydrogen sulfide, and bicarbonate from the seafloor that results in the precipitation of calcium carbonates and pyrite at or below the sediment-water interface, often associated with a proliferation of chemosynthetic communities. Cold seeps are known to be associated with methane hydrate deposits. Methane hydrate, a crystalline, ice-like form of methane and water (molar ratio 1:6) exists within the marine sediments at suitable temperature-pressure conditions [1]. In the Krishna-Godavari (K-G) Basin (Bay of Bengal), seismic data show the regional presence of gas hydrates manifested in the form of a bottom simulating reflector (BSR). BSRs represent a phase boundary where low-velocity gas-charged sediments occur below the hydrate stability zone. Recent drilling and logging activities on-board JOIDES Resolution in the Indian margin under the aegis of Indian National Gas Hydrate Program (NGHP) have confirmed the existence of massive gas hydrate deposits in the K-G Basin [2]. Extensive fault and fracture zones in K-G basin sediments are apparently responsible for the advective transportation (focussed flow) of methane rich fluid from the base of gas hydrate stability (BGHSZ) to the sediment water interface. The sharp perturbation in sulfate, sulfide and bicarbonate concentrations at the sediment -water interface is attributed to the anaerobic oxidation of methane (AOM) performed by a syntrophic consortium of CH_4-oxidizing archaea and sulfate-reducing bacteria [3]. Here we report repeated evidence of such methane expulsion events in K-G basin in the quaternary period. Highly ^{12}C enriched authigenic carbonates in the form of chimneys, massive crusts, chemosynthetic clams and other faulnal records indicate cold seep events[3]. Destabilization of deep seated methane hydrate is one possible cause for these sudden methane pulses. Shale tectonics induced fault and fracture opening and change in geothermal gradient could be one of the plaussible reson for focussed gas emission events.

Thermal structure of the Sgurr Beag thrust, NW Scotland

S.E. MAZZA[1]*, R.D. LAW[1] AND M.J. CADDICK[1]

[1] Dept. of Geosciences, Virginia Tech, Blacksburg, VA 24061, USA (*correspondence: mazza@vt.edu)

In the Caledonides of NW Scotland, well-understood *metamorphic* temperatures (*T*m) and *deformation* temperatures (*T*d) [i.e. 1, 2] progressively increase up structural section in the Moine thrust sheet at the foreland edge of the orogenic wedge. However, the thermal history of the hinterland thrust sheets is less well-constrained [3]. This study is focuses on determining *T*d and *T*m for the Sgurr Beag thrust sheet in the hinterland of the Scottish Caledonides, to test whether potentially thrust-related inversion continues into the structurally higher thrust sheets that are penetratively deformed at higher (upper amphibolite) temperatures.

Preserved microstructures imply a wide range of possible deformation temperatures, which are quantified with the quartz c-axis fabric opening angle thermometer [4]. *T*d from quartz opening angle thermometry increases up section, ranging from 395°C to 583°C ± 50°C. This indicates that if the isothermal surfaces dip towards the hinterland, thrust-related thermal inversion continues into the Sgurr Beag nappe. This study also presents new metamorphic *P-T* constraints for the Sgurr Beag nappe, based on garnet-biotite thermometry and GASP barometry, indicating *T*m of ~620°C at 5.8 to 7.4 kbar. Together, *T*d and *T*m indicate that deformation continued past peak metamorphic conditions in the Sgurr Beag thrust sheet.

New applications of dissolved gallium in the oceans: Promoting increasingly routine measurement

JASON A. MCALISTER[1]* AND KRISTIN J. ORIANS[1]

[1] University of British Columbia, Vancouver, Canada (*Correspondence: jmcalister@eos.ubc.ca)

Dissolved gallium (Ga) is present in the oceans at picomolar concentrations, consistent with more routinely measured dissolved trace metals such as iron and aluminum, yet Ga exhibits comparatively less contamination risk, therefore easing sample collection and analysis. Shown here are three applications utilizing dissolved Ga concentrations in the ocean to study carbon dynamics, climate change, and mechanisms controlling sources and sinks of trace elements and isotopes (TEIs) in the ocean. Dissolved Ga is applied to 1) development of a model utilizing dissolved Ga profiles to estimate particulate abundance, 2) utilization of dissolved Ga as a new parameter differentiating Pacific and Atlantic source waters to the western Arctic Ocean, and 3) identification of differentially sourced plume waters of the Columbia River. Particulate abundance is vital to estimates of carbon flux and drawdown of CO_2 from the atmosphere. Dissolved Ga profiles are utilized here to model relative particulate abundance of $CaCO_3$ and opal, complimenting established sediment trap and U-Th methods, and providing potential for particulate abundance to be estimated on an increasingly routine basis. Arctic inputs from the Atlantic, identified by a strong dissolved Ga gradient, represent comparatively warm waters that threaten sea ice melt and CO_2 release if able to permeate Pacific source water stratification via upwelling over the extensive shelf area of the Arctic Ocean. Finally, the Columbia River plume provides a spatially and temporally unique environment, combining the plume induced salinity gradient with dynamic winds resulting in upwelling and downwelling conditions oscillating on the order of days. A plume endmember mixing model developed here utilizes dissolved Ga to identify offshore waters associated with formation under divergent wind conditions, influencing scavenging reactions and therefore concentrations of dissolved TEIs. Oceanographic study of complex multiparameter problems such as climate change requires a broad suite of variables including trace elements and isotopes. Results of this work encourage increasingly routine measurement of dissolved Ga concentrations and application to oceanographic research, including future GEOTRACES cruises.

Experimental dissolution of $FeCO_3$ under controlled sulfidic conditions

ALISON MCANENA[1]* AND SIMON W. POULTON[2]

[1]Institute of Marine and Coastal Science. Rutgers, The State University of New Jersey, New Brunswick, 08901 NJ, USA (*correspeondence: amcanena@marine.rutgers.edu)

[2]School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, UK

In modern sedimentary environments, reduced Fe minerals (e.g. siderite; $FeCO_3$) tend only to precipitate under anoxic conditions in environments where high $Fe(II)_{aq}$ pore water concentrations are accompanied by low rates of sulfide fixation. In contrast, siderite-rich sediments are extensively observed throughout the Precambrian rock record, both in marine shales and banded iron formations. However, rising atmospheric oxygen and the gradual rise in oceanic sulfate concentrations through time ultimately led to the increased sulfidation of reactive Fe minerals, and hence less preservation of siderite in marine sediments. Nevertheless, high concentrations of siderite, particularly during the Precambrian, persist in sediments that contain pyrite, likely due to sulfate limited conditions during diagenesis. However, the reactivity of siderite towards dissolved sulfide is currently unknown.

We investigate the kinetics of siderite dissolution in the presence of sulfide under varying conditions. The rate of Fe(II) carbonate dissolution was measured experimentally on samples of synthetic and natural $FeCO_3$, under controlled initial sulfide concentrations, mineral surface area and pH. We propose a reaction mechanism where carbonate species undergo direct substitution with dissolved sulfide on the mineral surface, ultimately producing FeS as a major reaction product. The rate constant (k_{Fe}) determined by the sulfidation of siderite is similar to other highly reactive Fe minerals,such as ferrihydrite, but up to 5 orders of magnitude faster than more crystalline Fe(III) oxides; with complete siderite dissolution occurring over just tens of minutes.

Our data suggest siderite in marine sediments is highly reactive towards dissolved sulfide, even in the presence of low sulfide concentrations. FeS formation is limited by sulfide (and hence, initial sulfate) availability, with experimental results explaining the stability of co-precipitating FeS and $FeCO_3$ species observed within some sedimentary environments. We therefore conclude that the remobilization of reduced Fe(II) minerals by sulfide may have contributed greatly to Fe cycling in both modern and ancient anoxic environments.

Chromium isotope fractionation during pedogenesis: Influence of redox recycling

C.N. MCCLAIN*, K. MAHER, K.L. WEAVER AND J.L. DRUHAN

Department of Geological and Environmental Sciences, Stanford University, Stanford, CA 94305, USA (*correspondence: cynthia.mcclain@stanford.edu)

Tracking the fate of Cr and δ^{53}Cr during physical and chemical weathering of soils is central to investigating both naturally occurring Cr(VI) drinking water contamination and the use of Cr as a paleoredox proxy. Cr is a unique system to study because it is possible to monitor variations of both the fluid δ^{53}Cr(VI) as well as the solid δ^{53}Cr(III) in space and time to interpret modern and ancient (bio)geochemical cycling. However, determining fractionation factors from observed isotope patterns is difficult due to multiple transformation pathways, recycling, and inherent heterogeneity in soils. The coupling of Cr-, Fe- and Mn- cycling and the presence of secondary minerals such as Fe-Cr-oxyhydroxides and Mn-oxides in soils indicates that Cr(III) available for oxidation may have been recycled (oxidized and reduced multiple times). Here we present a theoretical study that quantitatively tracks Cr isotopes during pedogenesis by modeling oxidation, reduction, fluid flow and physical denudation. We apply the model to a corresponding field study of solid and fluid speciation, isotope composition, physical and chemical gradients occurring in a modern serpentine mollisol developed on ultramafic bedrock in the Putah Creek watershed of the northern California Coast Range. The model is parameterized using both field and published data. Results demonstrate that increased recycling changes apparent fractionation, depending on fractionation factors assumed. These simulations show that it is difficult to attribute in-situ fractionation factors to specific reactions without careful evaluation of phases, mechanisms and rates. Our modeling methods can also be applied to other elements (such as Fe) and environments (such as groundwater aquifers) to evaluate the spatial variability in isotopic composition imposed by redox recycling.

Seafloor massive sulfide exploration in SW Pacific - A commercial perspective

TIMOTHY F. MCCONACHY[1]

[1]SVP Science & Exploration, Neptune Minerals, Inc., Suite 3, Level 7, North Tower, 1-5 Railway Street, Chatswood, NSW, 2067, Australia tim.mcconachy@neptuneminerals.com

The discovery and recovery of seafloor massive sulfides near Galapagos and black smokers at 21ºN on the East Pacific Rise in the late 1970s is arguably one of the great natural science discoveries of the 20th Century. Since then, black smokers have been found in all the world's oceans. Because of the high concentrations of copper, lead, zinc, silver and gold associated with seafloor massive sulfides, they have gone, in the space of less than 30 years, from being a scientific curiosity to a potential new source of metals for commercial use, attracting significant speculative investment by private and public companies and state-owned enterprises. One commercial Mining Licence has been granted in the Bismarck Sea by the Government of Papua New Guinea and further mining licences are likley to follow in other countries' waters along the SW Pacific Ring-of-Fire.

The SW Pacific region is attractive to explorers for two main reasons: firstly, it has convergent plate boundaries with associated volcanic arcs and back arcs which host deposits of massive sulfide that generally contain superior metal grades due to complex crustal melting and fractionation processes; and secondly, countries in the region are able to grant secure title to explore within their territorial waters and Exclusive Economic Zones under existing legislation.

Land-based explorers are finding that new deposits are hard to discover and difficult to permit; and drilling, feasibility, construction and stripping typically takes 10 years or more. By contrast, on the seafloor, new deposits are relatively easier to find, they are high grade, have no or little overburden and mining does not require high levels of infrastructure or capital; and mine scheduling is flexible.

Neptune Minerals holds granted licences and licence applications in seven countries in the SW Pacific. It has completed exploration programs using a combination of hydrothermal plume survey, moderate to high-resolution acoustic seabed mapping, ROV mapping and sampling, geophysics, drilling and spot sampling, making and assessing a number of new discoveries. The company's 'baby step' approach to its exploration, environment and social licences is akin to adopting a precautionary approach.

Black carbon concentrations and fluxes during recent millennia from a developing array of Arctic ice cores

J.R. MCCONNELL[1]*, D. DAHL-JENSEN[2], D. FRITZSCHE[3], M. NOLAN[4] AND M. SIGL[1]

[1]Desert Research Insitute, Reno, NV 89509, USA (*correspondence: Joe.McConnell@dri.edu, Michael.Sigl@dri.edu)
[2]University of Copenhagen, Copenhagen Denmark (ddj@gfy.ku.dk)
[3]Alfred Wegener Institute, Potsdam, Germany (Diedrich.Fritzsche@awi.de)
[4]University of Alaska, Fairbanks, AK, USA (matt2013@drmattnolan.org)

Short-lived aerosols such as black carbon (BC) and dust are important components of climate forcing, although warming from increased carbon dioxide and other greenhouse gas concentrations is the long-term driver of climate change. With their short lifetimes in the atmosphere, aerosol concentrations and deposition rates are dominated by regional – rather than global – sources and intra- and inter-annual variability is high. Such aerosols in snow are especially important in the high latitudes because of their strong impact on albedo.

Because most BC aerosols in high latitudes originate in lower latitudes, changes in long range transport processes and pathways may dominate over changes in source strength in determining concentrations and deposition rates in these regions. However, detailed understanding of past and present concentrations, deposition rates, sources, and transport pathways of BC to and within the Arctic is lacking. Here we present and discuss detailed records of BC measured in a developing array of ice cores widely distributed around the Arctic. We use a range of elemental and chemical tracers measured in the same ice cores to identify likely sources and to investigate spatial and temporal patterns of BC deposition during recent centuries and millennia.

Transformational science with a new global volcanic gas emissions database

B. MCCORMICK[1], E. COTTRELL[1], T. FISCHER[2], G. CHIODINI[3] AND C. CARDELLINI[4]

[1]Department of Mineral Sciences, National Museum of Natural History, Smithsonian Institution, Washington, DC, USA
[2]Department of Earth and Planetary Sciences, University of New Mexico, Albuquerque, NM, USA
[3]Istituto Nazionale di Geofisica e Vulcanologia, Osservatorio Vesuvio, Napoli, Italy
[4]Dipartimento di Scienze della Terra, Università di Perugia, Perugia, Italy

Volcanic degassing is regularly monitored at many volcanoes worldwide, with direct sampling and both ground- and satellite-based remote sensing techniques. Recent years have seen a sea-change in instrument sophistication and capability. The literature contains a wealth of additional data arising from campaign measurements of degassing. However, there is currently no existing inventory of volcanic gas emission measurements in an easily accessible form, such as an online relational database.

Inspired by the Deep Carbon Observatory's DECADE initiative to estimate global volcanic CO_2 flux, we are building a new database incorporating all published degassing and volatile data for Earth's volcanoes. Appropriate metadata will be carefully defined and attention paid to data quality. Numerous factors influence the accuracy of gas emission measurements, and some categorisation or quantification of the uncertainty present in each data entry is crucial. Emissions fluxes and relevant metadata will be incorporated into the database of Smithsonian's Global Volcanism Program as we aim to directly link gas emissions to volcanic activity. Gas compositions will be incorporated into the EarthChem database with the intent to make these two databases interoperable.

Our vision is for the database to become an essential tool of the volcanological community, and we seek close collaboration with the volcanic emissions community from the onset. Close consultation with gas geochemistry and monitoring experts will ensure that the data and metadata types defined and implemented in the database are fit-for-purpose, and that the proposed database search capabilities, visualisation schemes and output standards meet the user needs of these researchers. We will build on lessons learned from the Italian volcanic gas database, GOOGAS. We are also working closely with cyber-infrastructure specialists to ensure the new database is fully inter-operable with existing online resources (e.g. EarthChem, WOVOdat, Global Volcano Model, GOOGAS, IRIS) and can be extended beyond gas emissions into other monitored parameters in the future.

HIMU lithospheric mantle in the Southwest Pacific: Tracing the roots of Zealandia

ALEX J. MCCOY-WEST[1]*, VICKIE C. BENNETT[1] AND YURI AMELIN[1]

[1]Research School of Earth Sciences, Australian National University email: alex.mccoywest@anu.edu.au

The existence of a widely sampled HIMU reservoir in the Southwest Pacific is well documented from the Pb isotopic compositions of intraplate basalts with $^{206}Pb/^{204}Pb>19.5$. The origin of this signature however, remains controversial with proposed sources including metasomatised subcontinental lithospheric mantle and ancient oceanic lithosphere stored in the deep mantle [e.g. 1-3]. Here we further investigate the origin of HIMU characteristics through a combined petrologic and Sr-Nd-Pb isotopic study of a suite of mantle xenoliths assembled from 12 localities throughout New Zealand. Prior Re-Os isotopic study of this suite [4] demonstrated that a substantial portion of the lithospheric mantle underlying southern New Zealand is Paleoproterozoic in age (c. 1.7 Ga) and thus > 1 b.y. older than the oldest overlying crustal rocks.

For this investigation Sr, Nd and Pb isotopic compositions were determined from leached clinopyroxene mineral separates of the xenoliths using ID-TIMS methods. Pb isotopic compositions were determined using a ^{202}Pb-^{205}Pb double spike. Initial results show a narrow range of measured $^{206}Pb/^{204}Pb$ between 19.5-21.1 and with no simple correlation with $^{238}U/^{204}Pb$ or with Os isotopic composition. $^{87}Sr/^{86}Sr$ isotopic compositions show a narrow range centered about 0.7025-0.7028, with $^{143}Nd/^{144}Nd$ isotopic data having more variability. The CPX leachates had lower $^{206}Pb/^{204}Pb$, showing that the HIMU signature does not result from contamination by the host basalts.

The Pb isotopic results are consistent with a widespread HIMU component residing in the lithospheric mantle beneath Zealandia. The homogeneous measured Pb isotopic compositions and lack of correlation with Os model ages imply a multi-stage history for lithosphere development in the region, with Paleoproterozoic melt extraction as reflected in Os isotopic signatures followed by an extensive, but much younger metasomatic event generating the Pb isotopic characteristics.

Abundance and ubiquity of H_2O in the martian interior

FRANCIS M. MCCUBBIN*

Institute of Meteoritics, 1 University of New Mexico, MSC03-2050, Albuquerque, NM 87131, USA (fmccubbi@unm.edu)

There is substantial evidence supporting the past existence of abundant flowing water on the martian surface, however the source for this water remains elusive. Earlier studies of martian meteorites resulted in estimates of less than about 35 ppm H_2O [1], which is incompatible with an internal source for the surface water. These earlier studies primarily relied upon bulk rock water contents of the meteorites and were likely affected by magmatic degassing [2]. Even modern efforts to estimate H_2O abundances in martian melt inclusions likely suffer from volatile loss [i.e., 3].

We have revisited the abundance and distribution of H_2O in the martian interior through studies of volatile bearing mineral phases in martian meteorites [4-5], which are more likely to retain their OH components during magmatic degassing. There are water contents available for amphibole and biotite in the Chassigny meteorite [5-7] and apatite in a number of enriched and depleted shergottites [4]. If the water in these minerals was primary to the parental melts, the magmatic source regions from which the parental melts were derived likely have 70-300 ppm H_2O. This would imply that both geochemically depleted and enriched sources on Mars have elevated H_2O abundances and Mars' ancient surface water could be internally derived.

Bio-calcification and its response to ocean acidification: new insights from boron isotopes

M.T. McCulloch[1,2], J.A. Trotter[1], M. Holcomb[1,2] and P. Montagna[3]

[1] Oceans Institute and School of Earth and Environment, The University of Western Australia, Crawley 6009, Australia.
[2] ARC Centre of Excellence in Coral Reef Studies, UWA.
[3] ISMAR-CNR, via Gobetti 101, I-40129 Bologna, Italy.

Bio-calcification is not only responsible for building the majestic coral reefs of the tropics, but is also a determinant of the oceans carbonate chemistry and ultimately the CO_2 content of the biosphere upon which life depends. By its very nature, biomineralisation occurs within a restricted, physiologically controlled environment, whose connectivity to external seawater is poorly known. Understanding these factors is thus fundamental to quantifying the response of this key group of organisms to CO_2 driven climate change and ocean acidification. Boron isotopes are an ideal tool to interrogate these processes, as its speciation is pH dependent, and biocalcifiers specifically incorporate the isotopically distinct borate species into their carbonate skeleton.

Using boron isotope systematics we show how biological up-regulation of the pH of the calcifying fluid is a characteristic of both azooxanthellate and zooxanthellate aragonitic corals. Scleractinian corals up-regulate pH at their site of calcification such that internal changes are approximately one-half of those in ambient seawater [1]. Although the absolute magnitude of the pH-buffering capacity is species-dependent, it provides a mechanism to raise the saturation state of the calcifying medium, thereby potentially increasing calcification rates at relatively little additional energy cost. This is especially evident in deep-sea corals where high degrees of pH up-regulation has facilitated calcification at, or in some cases below, the aragonite saturation horizon. Models [2] combining biologically induced pH regulation with abiotic calcification, (IpHRAC) now make it possible to unravel the effects of increased temperature and reduced seawater saturation states on bio-calcification. Up-regulation of pH is not however ubiquitous among all calcifying organisms; those lacking this ability may undergo severe declines in calcification as CO_2 increases.

[2] Dept. Of Agronomy, Kansas State Univ., Manhattan, KS USA xlin@ksu.edu
[3] Bluff Road Landfill, City of Lincoln, Lancaster County, NE USA 68517 kwelding@lincoln.ne.gov

A new laser-based open path methane analyzer (LI-7700, LI-COR Biosciences) was used to measure methane emission rates by eddy covariance from June to December 2010 at the municipal landfill in Lincoln, NE USA. The instrument provides continuous measurements at 10 Hz with minimal maintenance and can operate on solar power. High frequency corrections for effects of temperature and water vapor on methane absorption spectra, and operation in dusty environments present special challenges that will be discussed. Methane concentrations varied sharply from near background to more than 60 ppm. Methane emission rates varied as much as 35-fold from day to day and depended strongly on changes in barometric pressure (P), increasing with falling P and decreasing with increasing P. Emission rates were systematically higher in December than during the summer period. Higher rates were associated with changes in P that were larger in magnitude and longer in duration in winter than in summer, and with lower mean temperatures, which appeared to reduce methane oxidation rates. Power spectrum and ogive analysis showed that 10 days of averaging were required to capture 90% of the variance in emission rate. Implications of these results for estimating landfill emission rates will be discussed.

The Earth and its building blocks

W. F. McDonough[1]

[1] Dept of Geology, University of Maryland, College Park, MD, 20742-4211, USA.

The composition of the Earth was shaped by the chondritic building blocks that most likely populated the inner solar system. The observed isotopic composition of the *available* chondrites, which are few and only recently (<10^5 years) delivered, reveal an enstatite chondrite (EC) match, or similarity, to that of the Earth. However, and in stark contrast, the Earth does not match EC for their volatile element abundances, nor their mineralogical attributes. Based on the planetary mass fraction of Fe in the Earth's core, the planet is strongly reduce, intermediate in redox potential between ordinary (OC) and EC. Increasingly, it is observed that the niningerite and oldhamite in EC, as well as other phases, is the the alteration product of sulfidation of ferromagnesian silicates and not a primary feature[1].

The 142Nd isotope data [2] has opened up a new vista in revealing aspects of solar system history and the nature and distribution of the early building blocks. A fundamental observation from this isotope system is that the three domainant classes of chondrites, CC, OC and EC, have clear differences in their average 142Nd/144Nd compositions and the Earth is most similar to the EC class [3]. Interpretation of the 142Nd signature of the Earth include a deep hidden reservoir [4] or loss of the equivalent reservior to space by an ablation process [5]. Alternatively, the data are consistent with early solar system heterogeneity [6].

Neutrino geoscience, the detection of electron anti-neutrinos from beta-decays of Th and U series, is now providing data on the amount and distribution of U and Th inside the Earth. The latest results from the KamLand and Borexino experiments were reported earlier this year [7,8] and demonstrate that the Earth contains a considerable amount of primordial heat and favors both cosmochemical [9] and geochemical models [10]. Combined with data for the composition of the continental crust, these models will be interpreted in terms of the residual amount of heat producing power left in the mantle needed for mantle convection and driving plate tectonics.

Remarkably hot quartz in resurgent intrusions associated with the 18.8 Ma Peach Spring Tuff supereruption

S.M. McDowell[1]*, C.F. Miller[1] and J. Wooden[2]

[1]Vanderbilt University, Nashville, TN 37235, USA (*correspondence: susanne.m.mcdowell@gmail.com)

[2]Stanford University, Palo Alto, CA 94305 (jwooden@stanford.edu)

The Silver Creek caldera (southern Black Mountains, western Arizona) is the source of the 18.8 Ma, >700 km^3 Peach Spring Tuff (PST), the only supereruption deposit in the Colorado River Extensional Corridor (CREC) [1]. A 30 km^2 intrusive complex within the caldera records ~200 ka of post-PST resurgent magmatism and consists of two primary units: the intermediate to felsic Moss porphyry (62-68 wt% SiO_2; 18.81 ± 0.09 Ma [TIMS U-Pb zircon age]) and the felsic Times porphyry (>72 wt% SiO_2; 18.63 ± 0.08 Ma) [2]. Both units intrude trachytic, densely welded intracaldera PST.

To investigate epizonal magmatic processes during and immediately after the PST supereruption, and to constrain the thermal history of the PST magmatic center, we applied Ti-in-quartz thermometry [3] to two samples of Moss, one sample of Times, and one sample of a younger (18.21 ± 0.07 Ma) crosscutting quartz porphyry dike. Quartz in the Moss yields conspicuously high Ti concentrations (~60 to 340 ppm; avg. 160 ppm), corresponding with Ti-in-qtz temperatures of ~730-980ºC (avg. 840°C, a_{TiO2} = 0.7). Ti-in-qtz concentrations for the Times (~45-150 ppm; avg. 95 ppm) and quartz porphyry dike (~50-110 ppm; avg. 70 ppm) give mean Ti-in-qtz temperatures of 780°C and 745°C, respectively. Quartz temperatures are broadly consistent with trends in zircon saturation and Ti-in-zircon temperatures for the same units. Moss temperatures are higher than those for all other units in the CREC except intracaldera PST, which yields comparable Ti-in-zircon temperatures [4, 5].

Mineral thermometry suggests that the Moss records a brief period of exceptionally hot magmatism that coincides temporally and spatially with the PST eruption. Quartz data are consistent with the hypothesis that influx of anomalously warm and/or voluminous mafic magma led to rapid production and accumulation of massive, high-T PST magma [6]. Temperatures of successive post-PST intrusions fell at a rate of ~0.25ºC/k.y.

Not so hot and not so salty microbes and their role in oil recovery and corrosion

MICHAEL J. MCINERNEY[1]

[1]Department of Microbiology and Plant Biology, University of Oklahoma, Norman, OK 73019 USA; mcinerney@ou.edu

Diversifying the global energy portfolio with carbon-free or carbon-neutral fuels is critically needed. However, fossil fuels will likely be the dominant energy source for several decades. Significant amounts of oil remain entrapped in oil reservoirs, many of which are not too hot (30 to 50°C), but are salty (salinities ranging from 2 to 19%). We conducted a test of a microbial plugging process in a hypersaline oil reservoir (14-19% salinity; 35°C). The injection of molasses and nitrate stimulated in situ microbial growth and metabolism, which blocked a major water channel and corrected interwell permeability heterogeneities. The efficacy of biosurfactant-mediated oil recovery was tested in a control field trial. Two wells received an inoculum of biosurfactant-producing *Bacillus* species and 67 cubic meters of nutrients (glucose, sodium nitrate, and trace metals); two wells received just nutrients; and one well received only formation water. The lipopeptide biosurfactant was detected only in the produced fluids from the inoculated wells. A year later, the two wells that received an inoculum were treated with the same two strains and 670 cubic meters instead of 67 cubic meters of nutrients. The lipopeptide biosurfactant concentration was about 20 mg/L and about 330 barrels of additional oil were recovered. Most probable number analysis showed that heterotrophic, thiosulfate-reducing bacteria related to *Anaerobaculum* species were the most numerous sulfide producers in a corroding oil production facility (marine salinity; 55°C). Enrichments containing *Anaerobaculum* species caused significant corrosion of metal coupons when yeast extract and thiosulfate were present. Our work shows that microbial permeability profile modification and in situ biosurfactant production are possible. Fermentative thiosulfate users are important mediators of corrosion in some oil production facilities

RESOChron: ELA-ICP-He-MS instrument for *in situ* U-Th-Pb-He geothermochronology

BRENT IA MCINNES[1], NOREEN J EVANS[1], MIKE SHELLEY[2], BRAD MCDONALD[1], DAVID GIBBS[3], ASHLEY NORRIS[4], ED ROBERTS[3], CLIFF GABAY[4] AND DES PATTERSON[5]

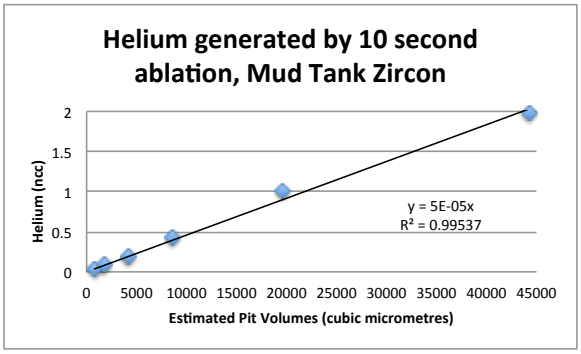
[4]Resonetics Ltd, Nashua NH, USA
[5]Patterson Instruments Ltd, USA

The development of an *in situ* microanalytical instrument capable of rapid automated U-Th-Sm-Pb-He isotope analysis of multiple grains will permit a more detailed interrogation of the time-temperature history of apatite, zircon, rutile, titanite and other accessory phases. Previous work[1-3] has demonstrated the technical feasibility of this approach, while this project advances the field via the development of a prototype system that integrates four existing commercial components: (i) a helium mass spectrometry module based on the Alphachron™ design, (ii) an ICP-MS module (Agilent 7700), (iii) an excimer laser ablation module based on the *RESOlution* design, and (iv) swappable ultra-high vacuum and flow-through analytical cells designed by Laurin Technic.



Initial *in vacuo* laser ablation testing on a large Mud Tank zircon indicate that: (i) the DL for radiogenic ^{4}He, is exceeded when ablation volumes are >780 μm^3 corresponding to a 10 μm deep ablation pit with 5μm radius; (ii) U-Th-Pb-He mapping/profiling is feasible with this new approach.

Evaluating the role of arc volcanism on Neoproterozoic to Early Paleozoic climate

N. RYAN MCKENZIE[1]*, NIGEL C. HUGHES[2], BENJAMIN C. GILL[3] AND PAUL M. MYROW[4]

Identifying the driving mechanisms for major climatic shifts deep in Earth history is challenging. Here we use a global compilation of detrital zircon age data to evaluate spatiotemporal variation in continental arc volcanism and tectonic outgassing of CO_2 to the atmosphere during the Neoproterozoic and Early Paleozoic. This data set reveals a direct link between tectonically driven CO_2 emissions and the dramatic episodes of climate change observed in this interval: the Cryogenian "Snowball Earth" and the "hothouse" world of the Cambrian. Importantly, these climatic events had profound affects on early animal evolution. Specifically, our data show the following trends: (1) a global reduction in continental arc volcanism occurred around the transition into the "Snowball Earth" whereas widespread arc systems initiated near the terminal Cryogenian and its glacial interval; (2) Continental arc systems stayed active and further expanded dramatically during the Ediacaran and into the Cambrian. This corresponding to an extreme greenhouse climate and protracted interval of global environmental stress; and (3) A global reduction in arc volcanism during the early Ordovician is associated with a period of global cooling and the onset of the Great Ordovician Biodiversification Event (GOBE). These data demonstrate that global variation in plate tectonic regimes plays a major role in steering Earth's climate and evolutionary patterns on million year time scales.

Initiation and 35 Myr duration of S-type granitic magmatism in an accretionary orogen

SEANN J. MCKIBBIN[1], BILL LANDENBERGER[2], WILLIAM J. COLLINS[3] AND C. MARK FANNING[4]

[1]Vrije Universiteit Brussel, Brussels, Belgium; seann.mckibbin@gmail.com;
[2, 3]University of Newcastle, Newcastle, Australia; bill.landenberger@newcastle.edu.au; bill.collins@newcastle.edu.au
[4]Australian National University; mark.fanning@anu.edu.au

Granites in circum-pacific igneous provinces can often be divided into 'S-' and 'I'-types on the basis of elemental and isotopic characteristics [e.g. 1]. This division reflects a dominance of sedimentary or igneous source components, and dating of granites allows tracking of the relative contributions to growing batholiths in accretionary orogens. In the Lachlan and New England Orogens of Eastern Australia, a progression from S-type through I-type to A-type granites occurs repeatedly over ~100 Myr periods. S-type intrusion occurs during the first major extensional event following major compression, while later I-type intrusion reflects a diminished sedimentary source and increasing mantle contribution. The timing of S- and I-type granites is therefore related to the tectonic evolution of orogens [2].

The S-type phase of intrusion in the New England accretionary orogen (~300-280 Ma) records an environment switching from compression to extension and back to compression as part of this process. We have undertaken U-Pb dating of zircons extracted from small (~backarc) gabbroic and dioritic bodies (Bakers Creek Supersuite), recalculated the ages of S-type granites (Hillgrove Supersuite), and compiled chronological data for the New England Orogen in order to investigate the establishment of magmatism in this area. We find a progression through: (1) diverse magmatism involving gabbroic, dioritic, S- and I-type during establishment of magmatism (305-295 Ma); (2) a major pulse of S-type magmatism (295-285 Ma), ending with; (3) I-type and HREE-depleted (deep crustal) magmatism around the time of the Hunter-Bowen orogenic event (~285-266 Ma).

Magmatism occurs over a ~35 Myr period in the region of most voluminous intrusion, but timing varies along-strike and may reflect assymetric rifting of the orogen. Together, these data time the heating, melting, depletion, and exhaustion of the S-type magma source.

Identifying the sources of iron in reservoir fluids at a CO_2 injection pilot in Alberta, Canada

BREEGE MCKIERNAN[1]* MICHAEL WIESER[1]
MICHAEL NIGHTINGALE[2A] AND BERNHARD MAYER[2]

[1]Department of Physics and Astronomy, University of Calgary, 2500 University Drive NW, Calgary, AB, T2N1N4, Canada (bmckiern@ucalgary.ca (*presenting author)

[2]Department of Geoscience, University of Calgary, 2500 University Drive, NW Calgary, AB, T2N1N4, Canada (night@earth.geo.ucalgary.ca, bmayer@ucalgary.ca)

The Pembina oil field is situated in western-central Alberta, Canada. After decades of water-flooding, a CO_2 injection pilot project was constructed to enhance tertiary oil recovery. A detailed geochemical monitoring program was conducted to study the impact on the geochemistry of reservoir fluids and rocks [1]. Increased iron concentrations, up to 144 µg/g, were measured at observation wells in the vicinity of the two CO_2 injectors after CO_2 injection commenced.

Iron isotopic compositions were measured and two possible sources of iron were investigated: leaching from the production pipes and siderite dissolution. Iron isotope data are summarized in Figure 1.

Data suggest that neither siderite dissolution nor iron leaching are the only processes occurring at the site. Either a third source of iron or BSR are responsible for the measured iron delta values.

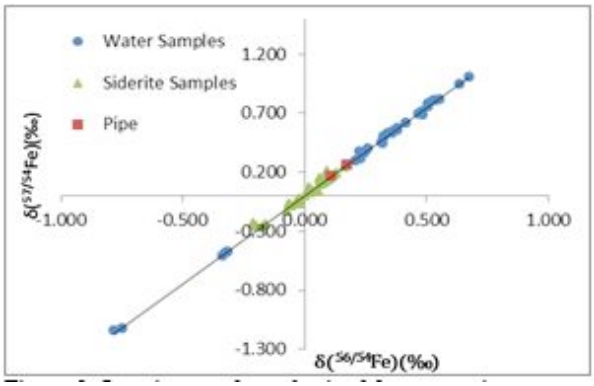

Figure 2: Iron isotope data obtained for reservoir water obtained from observation wells, siderite samples from the reservoir and production the pipe.

EARTHTIME: Past, Present, and Future

NOAH MCLEAN[1]

[1]NERC Isotope Geosciences Laboratory, Keyworth, Nottingham, UK
noahm@bgs.ac.uk

The last ten years have seen a revolution in geochronology. Recognizing that the apparent precision achievable by a new generation of mass spectrometers and laboratory techniques outstripped inter-laboratory agreement and revealed unrecognized inter-chronometer biases, the EARTHTIME initiative was formed to move science forward through community engagement and collaboration. A series of inter-related experiments in the U-Pb and Ar-Ar communities, including inter-lab comparisons, community tracer calibration and distribution, and adoption of software and data reduction norms, have been broadly successful, in large part due to international cooperation.

The success of the U-Pb and Ar-Ar experiments have since inspired the same approach from other chronometers whose increasing measurement precision and proliferation of laboratories has elicited the same questions. The U-series community is now embarking on a large international inter-laboratory comparison, in conjunction with first-principles calibration efforts; the LA-ICP-MS U-Pb community has completed an inter-laboratory comparison and is presently engaged in software package comparison and development of data reduction norms; and the EarlyTime initiative, focused on geochronology of meteorites, is organizing an inter-laboratory comparison. These efforts seek to replicate, and strive to be informed by, the progress made by EARTHTIME.

As these parallel projects advance and the accuracy of each system improves, it is worthwhile considering both the limiting uncertainties and the ultimate goals involved. Minimizing and correctly estimating inter-laboratory biases by measuring multiple 'secondary' standards across many laboratories yields a community-wide measure of the external reproducibility of each method. As measurement uncertainties and internal repeatability improve, along with our ability to estimate them, this external reproducibility and the ability to tie each system back to first principles measurements define accuracy and precision for each system.

These uncertainties also determine how well we can compare between isotopic systems, an ultimate goal of EARTHTIME and the larger geochronology community. Decay constant uncertainties dominate our ability to combine data from multiple chronometers, and active research and debate is focused on inter-relating these decay constants through geologic comparisons, for instance dating the same discrete event in time with multiple chronometers.

Did the Moon Form at 4.36 Ga?

CLAIRE L. MCLEOD[1]* AND ALAN BRANDON[1]

[1]Department of Earth and Atmospheric Sciences, University of Houston, Science and Research Building 1, Houston, TX, 77204, *clmcleod@central.uh.edu

Magma ocean crystallisation is an important stage of early planetary differentiation and evolution. Estimates for the timing of lunar magma ocean (LMO) crystallisation, and consequent formation of the lunar crust (ferroan anorthosites; FANS, and the Mg suite), is not well constrained with ages spanning from 4.57 Ga to 4.18 Ga[1,2,3,4]. More recent studies[5,6] on lunar crustal samples are consistent with a late *c*. 4.36 Ga age for the moon from Sm-Nd, Rb-Sr and Lu-Hf isotopes. The Sm-Nd isotopic systematics of KREEP samples and lunar mare basalts constrains the age of LMO crystallisation from 4.49 Ga to 4.31 Ga[7], while the Lu-Hf system suggest that the KREEP reservoir also formed *c*. 4.36 Ga[8]. The U-Pb ages of lunar zircons indicate a potentially older age for LMO solidification at *c*. 4.42 Ga[9].

To further examine LMO crystallisation and its relationship to the timing of lunar formation, a suite of mare basalts that span the range of petrologic types from the Apollo collection will be evaluated for their Sm-Nd systematics. High-precision $^{142}Nd/^{144}Nd$ to date indicate a closure age of *c*. 4.34±0.04 Ga for the Sm-Nd mare basalt source reservoirs[7,10]. With the additional new $^{142}Nd/^{144}Nd$ data presented here, we will test whether the previously obtained correlation with $^{143}Nd/^{144}Nd$ represents an isochron with an age *c*. 4.36 Ga, the implication of this being that the mantle source closure time for the basalts is consistent with a rapid LMO solidification following a late lunar formation time. Alternatively, if these new data do not lie on a coupled ^{142}Nd-^{143}Nd isochron, this would indicate multistage histories for their lunar mantle sources[11]. In the latter case, the coupled ^{142}Nd-^{143}Nd data for lunar basalts implies a more protracted differentiation history and are likely more consistent with an early formation time of the Moon.

Magma-mixing processes recorded in compositionally zoned titanite from the Ross of Mull Granite, Scotland

G. W. MCLEOD[1]* AND T. J. DEMPSTER[2]

[1]Earth & Environment, University of Leeds, Leeds, LS2 9JT, UK (*correspondance: g.w.mcleod@leeds.ac.uk)
[2]Geographical and Earth Sciences, University of Glasgow, G12 8QQ, UK (tim.dempster@ges.gla.ac.uk)

Accessory minerals play a significant role in the control of trace element behaviour and consequently may be crucial in deciphering magma genesis and crystallization histories. Titanite is characterised by slow diffusion of trace elements, and as such may preserve magmatic zoning. The incorporation of REE and HFSE within titanite makes it ideal for assessing petrogenetic processes.

In plutonic environments the detail of petrogenesis is often lost as slow rates of cooling allow minerals to chemically re-equilibrate during sub-solidus diffusion. The Ross of Mull Granite displays a variety of plutonic level magma-mixing phenomena and represents an excellent site to test the potential of titanite to preserve geochemical fingerprints of its genesis. A textural and geochemical investigation of titanite from the pluton reveals that zoning in trace elements strongly correlates with field evidence of magma-mixing processes. Diorite enclaves contain a range of textures indicative of variable states of interaction with the host granite and suggest that a number of discrete mixing events have occurred, both prior to emplacement at the present level and in situ.

Titanites from both the enclaves and the host granite show compositional zoning dominated by fine-scale oscillatory types as well as major discontinuities linked to dissolution events associated with changes in titanite, and associated ilmenite, stability. The zones reflect growth during changing melt chemistry and correlate with variations in REE and HFSE. Introduction of fresh diorite magma into the granite host, and the subsequent mixing processes, induced compositional, temperature and oxygen fugacity changes to which titanite responded. Processes recorded by titanite zoning include; (i) homogenisation of crystal free melts; (ii) crystal transfer and scavenging between partially crystallised magmas; (iii) melt segregation and transfer from crystalline enclaves; and (iv) late-stage diffusive exchange. Titanite thus records both localised and distal mixing activity and is capable of revealing many otherwise hidden events within the magma chamber.

Trace element partitioning between carbonate globules and silicate glass in volcanic carbonatites

S. C. McMahon[1]*, E. R. Humphreys-Williams[2], C. E. L. Gilder[1], R. A. Brooker[1], T. E. Jeffries[2] and M. J. Walter[1]

[1]School of Earth Sciences, University of Bristol, BS8 1RJ, UK (correspondence: sorcha.mcmahon@bristol.ac.uk)
[2]Department of Earth Sciences, Natural History Museum, Cromwell Road, London, SW7 5BD, UK (E.Williams@nhm.ac.uk)

The origin of globular-shaped carbonate in silicate glass in carbonatites is subject to much debate. Whether such 'globules' represent immiscible carbonatite melts or rounded calcite crystals has important implications for calcio-carbonatite genesis. Here we present major and trace element analyses of carbonate and silicate glass from volcanic carbonatites in the Calatrava Volcanic Province (CVP), Spain and the Auvergne, France, as well as new experiments reproducing the CVP textures.

Compelling textural evidence for liquid immiscibility includes curved menisci against silicate melt, and budding of globules (suggestive of coalescence) [1]. However, experiments have shown that similar globules can form as solid carbonate crystals in equilibrium with silicate melt [2]. Experimentally produced immiscible carbonate melts also do not reproduce the stoichiometric calcite and dolomite compositions observed in the natural volcanic carbonatites.

One way to resolve whether the globules formed as melts or solids in natural and experimental samples is to investigate the way elements are distributed between the two phases. LA-ICP-MS has been employed for *in-situ* trace element analysis of both carbonate and glass. Partitioning into a crystalline phase is controlled by the characteristics of the lattice site where the element resides, subject to strictly defined constraints related to the element size (ionic radius) and the charge. Classic Onuma parabolae are observed, suggesting a crystal control over the partitioning in some volcanic carbonatites, with calcite globules representing crystalline carbonate crystallised from carbonate-rich silicate melt. Experimentally we have reproduced these pure calcite 'globules', as well as more complex immiscible alkali-bearing carbonate melts. We report on the partitioning characteristics for both and draw comparisons with the natural samples in order to elucidate their origin as solids or melts.

[4] University of Tasmania, AU (Zanna.Chase@utas.edu.au)
[5] University of Southern California, Los Angeles, CA, 90089 (bereleson@usc.edu)

The riverine supply of fine-grained sediment to coastal regions along the Northeast Pacific margin generates a patchy "depositional" setting with sediments containing varying amounts of sands and muds. The mid-shelf adjacent to the Umpqua River, features a mud-rich sediment patch that is relatively rich in operationally defined reactive iron. Reactive iron concentrations here covary with the distribution of organic material, suggesting that there may be a coupling between their delivery and burial.

Downcore profiles of dissolved iron from a number of locations along the Oregon margin shows that sediments can range from being relatively enriched to depleted in dissolved iron concentrations. Although this pattern may point to a connection between the diagenesis of continentally derived sediment and the iron supply to coastal waters from the sediments, other factors such as rates of fluid advection, bottom water dissolved oxygen contents, and the availability of fresh organic material likely influence net iron transport across the sediment-bottom water boundary. In an effort to separate some of the factors that might influence dissolved iron input to the overlying water column, we compare iron benthic fluxes along the Oregon and California margin with fluxes from the "hypoxic" shelf region in the Gulf of Mexico. Our results do not suggest significantly greater benthic iron fluxes within the Gulf of Mexico compared to the Oregon and California margins.

Materials from geochemically inspired studies : from Titan's tholins to extremophile bacteria

PAUL F MCMILLAN[1]

[1]Dept. of Chemistry, University College London, 20 Gordon St., London WC1H 0AJ, UK

Geochemistry and experimental geology studies have long been linked to the identification and processing of new materials with great technological importance and high societal impact. Examples range from hydrothermal and sol-gel synthesis of ceramics to development of techniques for *in situ* studies of functional materials under extreme conditions. New research extending from planetary sciences to deep life geochemistry are leading to new developments in nanomaterials technology and biochemical processing with medical and forensic applications. Here we describe and discuss recent results that extend from fundamental studies and interplanetary based observations of Titan's atmosheric aerosols to new materials being developed for efficient charge storage and energy use applications on Earth, to the involvement of new studies of extremophile bacteria in the deep Earth enviroment to development of nanotechnology and biomedical applications. These examples will illustrate the continued and emerging links between geochemistry, advanced materials science and biology, with enormous benefits to society.

Secondary organic aerosol formation in aerosol water: Impact on aerosol physical properties

V. FAYE MCNEILL[1]

[1]Department of Chemical Engineering, Columbia University, New York, NY, USA 10027 vfm2103@columbia.edu

The chemistry of atmospheric aerosols influences their direct and indirect effects on climate. Inorganic aerosols may acquire an organic component via *in situ* interactions with volatile organic compounds (VOCs), a family of processes known as secondary organic aerosol (SOA) formation. SOA formation is one of the greatest sources of uncertainty in estimations of aerosol climate forcing. Pathways for aqueous-phase SOA formation have been identified in which water-soluble VOCs dissolve into cloud droplets or wet aerosols, followed by aqueous-phase reactions which lead to the formation of SOA material. Our recent laboratory studies show that particle-phase chemical reactions between organics and inorganic salts can lead to secondary organic products which absorb light in the UV and visible, thus changing the optical properties of the particle. We have also shown that aqueous-aerosol SOA products may be surface-active, therefore potentially enhancing the ability of small particles to nucleate cloud droplets (CCN activity). In addition to these bulk surfactant effects, our work demonstrates that the surface adsorption of methylglyoxal and acetaldehyde from the gas phase can depress aerosol surface tension and increase CCN activity. Finally, I will introduce a photochemical model of coupled gas and detailed aqueous aerosol chemistry that we have developed in order to study the formation of secondary organic aerosol material in aerosol water and the associated changes in aerosol physical properties. I will present results for atmospheric scenarios and highlight needs for additional experimental work.

Production of archaeal lipid biomarkers in stable isotope labeled incubations of MCG-rich sediments

T. B. MEADOR[1]*, G. KUIPPERS[1], C. LAZAR[1,2], M. KÖNNEKE[1], A. TESKE[2] AND K-U. HINRICHS[1]

[1]MARUM Center for Environmental Sciences and Department of Geochemistry, University of Bremen, 28359 Bremen, Germany (*correspondence: tmeador@marum.de)

[2]Department of Marine Sciences, Univ. North Carolina at Chapel Hill, Chapel Hill, NC 27599-3300, USA

The Miscellaneous Crenarchaeota Group (MCG) exhibit a global-distribution in anoxic, aquatic sediments and occur throughout a variety of distinct geochemical sediment regimes [1]. Several researchers have proposed that MCG live heterotrophically on organic carbon sources that are buried in the seafloor [1, 2], and Lloyd *et al*. [3] recently identified peptidases within the MCG genome; however, there is still no direct evidence of the metabolic strategy employed by these archaea. We incubated MCG-rich sediments from the White Oak River estuary anaerobically with deuterated (D) water and ^{13}C-bicarbonate [cf. 4], and determined the growth response of the MCG community in response to the addition of various organic substratres by quantifying the production of archaeal intact polar lipid (IPL) biomarkers, including compounds thought to be specific for MCG.

After a period of 145 days, evidence of D uptake into IPLs containing crenarchaeol indicated that several substrates stimulated benthic Crenarchaeota, which was supported by increases in the relative abundance of MCG clones in archaeal 16s rRNA clone libraries by up to 30%. The incubations amended with monosaccharides, peptone, or with yeast extract and acetate showed the highest label incorporations, translating into an ~ 5-fold increase in cell production rate, relative to a control incubation with no substrate ammendment. Given that only minimal ^{13}C was incorporated into archaeal lipids, our data are consistent with heterotrophic growth by MCG. Furthermore, these findings provide new evidence for the benthic production of crenarchaeol, likely by MCG, which is in conflict with the presumed planktonic source of this biomarker [e.g., 5].

Reconstructing the magma feeding system of the Cappadocian ignimbrites (Turkey) through amphibole thermobarometry

E. MEDARD[1], J.-L. LE PENNEC[1], J.E. FRANCOMME[1] A. TEMEL[2] AND F. NAURET[1]

[1]Clermont Université, UBP/CNRS/IRD, Laboratoire Magmas et Volcans, 5 rue Kessler, 63038 Clermont-Ferrand, France (E.Medard@opgc.univ-bpclermont.fr)

[2]Hacettepe University, Faculty of Engineering, Department of Geological Engineering, 06800, Beytepe-Ankara, Turkey

The Cappadocia area of Central Turkey superbly exposes a succession of Neogene dacitic to rhyolitic ignimbrites and fallout deposits, recording 10 Ma of magmatic activity. This provides an excellent example of long-lived, relatively low frequency magmatic system, with a low average magma production rate (about 10^{-3} km^3/a), but short-lived large eruptions (up to 300 km^3 for the Cemilköy ignimbrite). Most of the ignimbritic and fallout units share a very similar, low-variance, phenocryst mineralogy (plagioclase + biotite + amphibole + magnetite + quartz), which makes them perfect targets for Al-in amphibole barometry.

An accurate Al-in hornblende barometer has been recalibrated from literature data and new experiments on the Kızilkaya ignimbrite. This new barometer takes into account the effect of both edenite and Tschermack substitutions on Al concentrations. Our data, combined with existing litterature data, show a very good pressure-dependence of the Tschermack substitution (correlation coefficient of 0.95) for amphibole in equilibrium with biotite, plagioclase and quartz. Our new barometer reproduces experimental pressures with an average error of 36 MPa in the 100-400 MPa range. More experiments are underway to improve the barometer's accuracy.

Pre-eruptive temperatures are relatively stable for most units, between 700 and 760 °C. Amphiboles crystallized in the upper crust, between 9 and 14 km depth, hinting at a constant depth of magma storage beneath the Cappadocian ignimbrite field. Detailed investigation of one of the youngest unit, the Kizilkaya ignimbrite, produces a tight unimodal pressure distribution at 260 ± 20 MPa (9.8 ± 0.8 km depth), with a maximum data dispersion lower than the 2σ uncertainty of the barometer. If the erupted reservoir was homogeneous, as suggested by the absence of magma mixing, and amphibole was present in the entire reservoir, the aspect ratio of the magma chamber would be relatively low, with a minimum diameter of 7.5 km and a 1.5 km maximum height.

From small-scale chemical processes to long-term (radioactive) contaminant migration predictions

JOHANNES C.L. MEEUSSEN[1], THOMAS J. SCHRÖDER[1] AND JORIS J. DIJKSTRA[2]

[1]Nuclear Research and Consultancy Group Petten, The Netherlands. (* Correspondence: meeussen@nrg.eu)
[2]Energy Research Centre of the Netherlands, Petten The Netherlands(j.j.dijkstra@ecn.nl)

Migration rates of (radioactive) contaminants in porous materials, such as soil rock and concrete, are dominated by distribution of ions over pore solution and solid phase. Precipitation and adsorption are small-scale chemical processes that determine the distribution and in this way control migration rates at larger scales. The often multicomponent nature of such interactions results in a strong dependence of single element behaviour on chemical conditions, which complicates the translation of experimental results to field conditions. Credible contaminant migration predictions require a model that contains the major soil reactive phases / surfaces, e.g. the different oxide and organic matter surfaces, dissolved organic carbon, including their mutual chemical interactions in a thermodynamic consistent way[1]. The combined CD-MUSIC model for oxides, the NICA-DONNAN model for organic matter, and the LCD model go a long way achieving this. To accommodate these combined models an advanced numerical framework is required[2]. It is, however, important to realize that whatever the assumed sophistication of the conceptual- or numerical model, careful evaluation of model accuracy is essential for its usefulness in practice. Such an evaluation can only be done by testing the model on truly independent data [3].

The structural determinants of silicon fractionation properties of silicate minerals: a First-Principles Density Functional Study

M. MÉHEUT[1]* AND E. A. SCHAUBLE[2]

[1]GET, Université Paul Sabatier, Toulouse, France (*correspondence: meheut@get.obs-mip.fr)
[2]ESS Dept., UCLA, Los Angeles, USA

Silicon is among the new isotopic systems that are emerging due to recent analytical progress in mass spectrometry. Thorough understanding of the parameters influencing natural Si-isotope variation is therefore of great importance to assess potential geochemical applications.

Ab initio methods based on density functional theory have proven successful in predicting equilibrium fractionation factors as a function of temperature (e.g., 1). We use the PBE functional, combined with norm-conserving pseudopotentials and plane wave basis sets. We focused on phyllosilicate minerals: kaolinite, lizardite, talc and pyrophyllite, which appear to span a wide range in fractionation properties despite having the same basic silicate polymerization. In this family of silicates, calculated Si isotope fractionation appears to be correlated with chemical composition:

$$\Delta^{30}Si(min, quartz, T) = \sum a_X(T)\frac{X^{eq.}}{Si^{eq.}} \qquad (1)$$

with $X^{eq.}$ representing the cation equivalents of X=Al, Mg, Si, i.e. the number of ½(SiO_2), ⅓(Al_2O_3), (MgO) units in the mineral, and $a_X(T)$ is a parameter depending on temperature. Further analysis leads us to interpret this relationship as an electron donation effect, such that $a_X(T)$ should increase with decreasing electronegativity of X. To assess the generality of this relationship, we computed fractionations for a more diverse suite of minerals. Within the MgO-Al_2O_3-SiO_2 system, relation (1) continues to hold for quartz, pyrope and enstatite (R^2 = 0.99, n=7), but forsterite is strongly anomalous. To assess the effects of Ca^{2+}, Na^+, K^+ and tetrahedral Al^{3+} on Si fractionation, we computed the properties of albite, anorthite, microcline, diopside, wollastonite, jadeite, grossular, and the three Al_2SiO_5 polymorphs. Preliminary results suggest almost all of these minerals follow relation (1) reasonably well (excepting wollastonite), if tetrahedral Al^{3+} is assumed to have no effect on Si fractionation ($a_{Al}(T)=0$).

These results suggest that particular attention should be given to chemical compositions in Si isotope studies.

Characterising the speciation and solubility of platinum group elements (PGE) in hydrothermal fluids is useful in understanding the formation of PGE deposits, and for supporting the development of new exploration tools for high value magmatic nickel sulfide deposits, whose small footprints may be extended by hydrothermal remobilisation of PGE. A number of experimental studies have investigated Pd speciation and solubility in hydrothermal chloride solutions, with reasonable agreement over the nature and stability of Pd(II) chlorocomplexes (Barnes and Liu, 2012). In contrast, there are significant discrepancies among the available thermodynamic properties for the predominant Pd bisulfide species. This uncertainty severely hinders numerical modelling of PGE mobility in hydrothermal fluids.

Ab-initio molecular dynamics (MD) simulations were performed to investigate the stability of possible Pd-Cl and Pd-HS complexes in hydrothermal fluids. The simulations revealed the preference of four-fold square planar structures of both chloride and bisulfide complexes at high P,T (300 ˚C, 500 bar). We are building a geochemical model for Pd transport via thermodynamic integration (Mei *et al*., 2013). The species geometry and thermodynamic properties derived from the MD simulations will be compared with the existing thermodynamic properties (Boily and Seward, 2005) and with new EXAFS measurement of Pd chloride complexes in hydrothermal brines up to 340 ˚C.

Protein-silica interactions: The effect of lysozyme on the structure of amorphous silica

D.B. MEIER[1]*, D.J. TOBLER[2], C.L. PEACOCK[1] AND L.G. BENNING[1]

[1] School of Earth and Environment, University of Leeds, United Kingdom (*correspondence: eedbm@leeds.ac.uk)
[2] Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark

Amorphous silica is one of the two dominant biominerals in the world's oceans where it is precipitated by diatoms, radiolarians or siliceous sponges. Furthermore, in geothermal settings microorganisms can become quickly silicified through the precipitation of silica from under- or oversaturated geothermal waters. In both cases, the interaction between amorphous silica and cell internal or cell wall macromolecules, like proteins, are crucial for templating the siliceous structures or for enhancing microbial silicification [1, 2]. However, how and if proteins affect the structure, composition and morphology of amorphous silica at the molecular level is only poorly understood

Here, we quantified the effect a typical protein (lysozyme) has on the atomic structure and composition of amorphous silica that was precipitated from supersaturated aqueous solutions in the absence or presence of variable lysozyme concentrations (0 – 10'000 ppm).

Synchrotron-based pair distribution function (PDF) analyses showed only a minor change in the short range ordering (>15 Å) of amorphous silica precipitated in the presence of ≥ 1000 ppm lysozyme. This suggests limited structural interactions and hardly any incorporation of the lysozyme within the amorphous silica structure. Fourier Transform Infrared (FTIR) spectroscopic analyses however, indicate significant incorporation and surface interaction between lysozyme and amorphous silica at all lysozyme concentrations.

Further PDF and FTIR experiments are underway to test for artifacts and to confirm the findings reported above. Moreover, thermogravimetric analyses, X-ray diffraction, total carbon analyses and high resolution microscopy will help to quantify the ratio of incorporated to adsorbed protein contents, the water contents, and the morphology of amorphous silica as a function of protein content.

Multi-element 2D analysis of drilling cores containing mining residues using LIBS and chemometric analysis

J.A. MEIMA

Bundesanstalt für Geowissenschaften und Rohstoffe (BGR) Hannover, Germany (jeannet.meima@bgr.de)

Laser-induced breakdown spectroscopy (LIBS) is a type of atomic emission spectroscopy that uses a laser-generated plasma to ablate, atomize, and excite material from a sample surface. LIBS has potential for rapid non-destructive and in-situ geochemical analysis. However, quantitative analysis with LIBS, especially of heterogeneous materials, is very challenging; matrix effects and plasma variations influence the LIBS signal. These limitations have succesfully been overcome using multivariate chemometric methods and repetitive measurements in other applications [e.g. 1].

This study tries to estimate limits of detection and accuracy for multi-element LIBS analysis of drilling cores containing mining residues (Harz, Germany) with the LIBS system described below. The LIBS system uses a Nd:YAG 50 mJ 1064 nm laser and an Echelle spectrograph with CCD detector (285-960 nm, resolution 28-94 pm). On the drilling cores, nine meter in total and each one cut in halve, 1000 x 12.5 mm large surface strips were measured, representing 20000 individual (5 accumulated laser shots each) LIBS measurements. Over 100 alternating layers consisting of sludge, Pochsand or wall rock were found; all layers were sampled and analysed by XRF as reference samples. A calibration model was developed with Partial Least Square Regression (PLSR) analysis.

A qualitative LIBS analysis based on characteristic emission lines for heavy metals and major elements has shown, that significant chemical differences may exist between layers. Inside a layer of sludge or wall rock, the LIBS signal appears to be relatively constant. On the other hand, Pochsand layers that consist of very course sand appear to be very heterogeneous; heavy-metal enrichment is clearly related to distinct particles. Multivariate chemometric analysis on the relatively homogeneous layers is currently applied to build and test calibration models for a quantitative interpretation of the LIBS measurements.

H_2O-adsorption at the (100)-pyrite surface: Forcefield simulation studies supporting GIXRD-experiments

S. MEIS[1]*, U. MAGDANS[2], X. TORRELLES[3] AND H. GIES[1]

[1]Institute of GMG, Ruhr-University Bochum, 44780 Bochum, Germany, (*correspondance: sandrina.meis@rub.de)

[2]IA Physics, RWTH Aachen, 52056 Aachen, Germany, (magdans@physik.rwth-aachen.de)

[3]ICMAB-CSIC, Campus de la UAB, 08193 Bellaterra, Spain, xavier@icmab.es

It is of great importance to study mineral-adsorbate interfaces, because in natural processes mineral surfaces are able to function as templates for the ordering of organic molecules and water. The periodically ordered surface atoms induce an ordering of the adsorbates, so that specific chemical reactions can take place near surfaces. The (100)-pyrite (FeS_2) surface plays an important role in many environmental, biological and mineralogical processes, e.g. in acid mine drainage processes and in the Iron-Sulphur world scenario, that describes one possibility for the origin of life [1].

The structure of the (100)-FeS_2-H_2O interface was determined with grazing incidence X-ray diffraction experiments under environmental conditions, previously[2]. An adsorption model for H_2O at the (100)-FeS_2 surface was determined including three adsorption layers in a distance of 1.9(1)Å, 3.0(3)Å and 5.4(4)Å to the surface, a transitional zone of partial ordered H_2O molecules and H_2O molecules that occupy vacancies of the topmost FeS_2-layer.

Here we report about molecular dynamic (MD) simulations of the H_2O-adsorption on the (100)-FeS_2 surface, carried out with the program package Materials Studio 5.0, particularly the program "Adsorption locator", from Accelrys Inc. Using the forcefield COMPASS27 we confirmed the experimental achieved adsorption model of H_2O. Additionally we determined the orientation of H_2O-molecules within the adsorption layers, the exact positioning of the H-atoms and we get information about the influence of the H_2O-density on the ordering within the adsorption layers. The comparison of the experiment and different MD simulations is well suited to get detailed information about the atomic structure of the (100)-FeS_2-H_2O-interface and to get information about interface systems under perfect adsorption conditions compared to interface systems exposed to higher entropy.

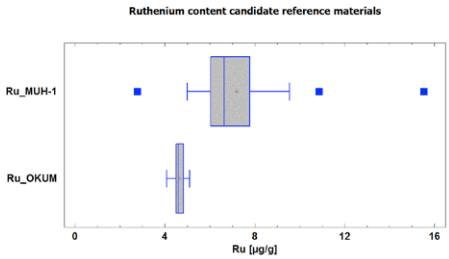
[4] University of Vienna, Austria

As for many isotope systems, certified reference materials (CRM) of *real* samples are very sparse. Solutions with known isotopic composition exist for QA/QC purposes, but for the evalution of the combined standard measurement uncertainty *matrix matched* CRM need to applied. For method validation, calibration and verification purposes of Os isotopic composition and platinum group element content (PGE) two ultramafic RM with different matrices have been prepared. OKUM, an ultramafic komatiite and MUH-1, a depleted harzburgite (Kraubath, Austria) have been prepared and are already certified for major and trace elements by an interlaboratory certification process lead by the International Association of Geoanalysts (IAG). Whereas the dominant PGE bearing phases in lherzolites are sulfides, the dominat phases in harzburgites are alloys and laurites. As a result, the homogeneity of harzburgites with respect to PGE distribution is generally much worse than for lherzolites and komatiites.

Initial homogeneity tests with 2 g and smaller test portion sizes demonstrate this significat difference.



This test already demonstrates that validated methods with lherzolitic RM such as UB-N cannot be applied to harzburgites as these are generally heterogeneous.

Both RM show PGE distributions typical for mantle restites and komatiite melts with $^{187}Os/^{188}Os$ of 0.127 and 0.27 respectively and thus ideal matrix RM for mantle studies.

Early diagenetic quartz formation at a deep iron oxidation front in the Eastern Equatorial Pacific

P. MEISTER[1]*, B. CHAPLIGIN[2], A. PICARD[3], H. MEYER[2], C. FISCHER[4], D. RETTENWANDER[5], G. AMTHAUER[5], C. VOGT[4] AND I.W. AIELLO[6]

[1]Max-Planck Institute Marine Microbiology, 28359 Bremen, Germany (*correspondence: pmeister@mpi-bremen.de)
[2]Alfred Wegener Institute, 14473 Potsdam, Germany
[3]Eberhard Karls University, 72076 Tübingen, Germany
[4]University of Bremen, 28359 Bremen, Germany
[5]University of Salzburg, 5020 Salzburg, Austria
[6]Marine Laboratories Moss Landing, CA 95039-9647, USA.

Diagenetic quartz formation at low temperature is still not well understood. Lithified chert consisting of microcrystalline quartz was recovered at ODP Site 1226 in the Eastern Equatorial Pacific [1] near the base of a 420 m thick Miocene-Holocene sequence of nanofossil and diatom ooze. Precipitation temperatures calculated from oxygen isotope values in the cherts are near to present porewater temperatures, and a sharp depletion in dissolved silica occurs at 385 m, indicating that silica precipitation is still going on.

It has been observed that quartz forms in experiments in the presence of fresh precipitated iron oxyhydroxides [2]. Indeed, a deep iron oxidation front occurs above 400 m sediment depth, which is caused by upward diffusing nitrate from an oxic seawater aquifer in the underlying basaltic crust. Sequential iron extraction and analysis of the X-ray absorption near-edge structure (XANES) revealed that iron in the cherts predominantly occurs as illite and amorphous iron oxide, whereas iron in the nanofossil and diatom ooze occurs mainly in smectites. Mössbauer spectroscopy confirmed that the amorphous iron in the cherts is largely oxidized.

Two possible mechanisms may be operative during early diagenetic chert formation at iron oxidation fronts: (1) quartz precipitation may be initiated by adsorption of silica to freshly precipitated iron oxides. (2) Iron oxidation lowers the pH, which brings the reactive surfaces of iron oxides closer to the zero point of charge, facilitating the binding of SiO_2. We suggest that the formation of early-diagenetic chert at iron oxidation fronts is an important process in suboxic zones of silica-rich sediments. The largest iron oxidation front ever occurred during the great oxidation event ca. 2.5 Ga ago, when large amounts of iron and chert beds were deposited.

B content and $\delta^{11}B$ from cultured diatoms (*Thalassiosira weissflogii* & *T. pseudonana*): Relationship to $pH_{seawater}$ and diatom C acquisition

*L.M. MEJÍA[1], J. FIETZKE[2], K. ISENSEE[1], A. MÉNDEZ[1], J. PISONERO[1], N. SHIMIZU[3], C. GONZÁLEZ[1], B. MONTELEONE[3] AND H. STOLL[1]

[1]Universidad Oviedo, C/ Arias de Velasco s/n, 33005 Oviedo, Spain. *correspondence: [luzmamera2@yahoo.com]
[2]Helmholtz Centre for Ocean Research Kiel, Wischhofstr. 1-3. 24148 Kiel, Germany
[3]WoodsHole Oceanographic Institute, Woods Hole, USA

Despite the importance of diatoms in regulating climate, most geochemical records are based on carbonates. Among them, B content and $\delta^{11}B$ has been widely used to reconstruct pH from foraminifera and coral fossils. We present preliminary results of $\delta^{11}B$ on diatom opal and compare them to $\delta^{11}B$ on inorganically precipitated opal. We measured B content in opal with the aim of determining if [B] can be used as a pH proxy or to identify physiological responses to acidifying pH.

Thalassiosira pseudonana and *Thalassiosira weissflogii* were cultured at varying pH and Si and C quotas were determined. Frustule B content was measured by LA-ICPMS and ion probe. Cells of both species grown at higher pH have higher [B] and higher Si requirements per fixed C. If this trend is representative of diatom silicification in a future more acidic ocean, it could contribute to changes in the efficiency of diatom ballasting and C export, as well as changes in the diatom abundance in the phytoplankton community in Si-limited regions. If B enters the cell through the same transporter employed for HCO_3^- uptake, an increased HCO_3^- requirement with decreasing CO_2 concentrations, and higher $B(OH)_4/HCO_3^-$ ratios would explain the observed increase in frustule B content with increasing pH.

With current analytical precision, frustule [B] is unlikely to resolve ocean pH with a precision of paleoceanographic interest. However, if B content was controlled mainly by HCO_3^- uptake, then B content measurements might reveal the varying importance of active HCO_3^- acquisition in the past. Though as occurs with B content, $\delta^{11}B$ may depend either on seawater pH and/or biomineralization processes, preliminary $\delta^{11}B$ results show very low values, which agrees with the very low pH at the site of silicification (~5). At this acidic pH, it is very unlikely that $\delta^{11}B$ provides enough sensitivity to reconstruct $pH_{seawater.}$ Conversely, $\delta^{11}B$ in diatom opal may be used to constrain $\delta^{11}B_{seawater}$, which is very important for foram-based pH reconstructions.

Investigation of the processes of organic matter diagenesis in sediments of Lake Beloye, West Siberia, by the pyrolytic methods

V.N. MELENEVSKY[1]*, G.A. LEONOVA[2], V. A. BOBROV[2], A.S. KONYSHEV[4] AND A.E. MALTSEV[5]

[1,4]A.A. Trofimuk Institute of Petroleum Geology and Geophysics, Siberian Branch of the Russian Academy of Sciences, Russia (*coresspondence: vmelenevsky@yandex.ru)
[2,3,5]Institute of Geology and Mineralogy, Siberian Branch of the Russian Academy of Sciences, Russia

During diagenesis, biopolymers (proteins, fats, carbohydrates, lignin, etc. synthesized by animals and plants) of organic matter (OM) transform into a geopolymer - the so-called kerogen composing most of the OM of ancient sediments. Starting from the sedimentation and deposition of OM of plant and animal genesis, many biochemical and chemical reactions run in it.

Study of the Holocene sediments of Lake Beloye (West Siberia) in the depth range 0 — 137 cm gave an insight into the transformation of organic matter (OM) at the early stages of diagenesis. Analysis of OM was performed by pyrolytic methods (Rock Eval (RE) and pyrolysis + gas chromatography-mass spectrometry (Pyr-GC-MS)). RE pyrolysis is intended for the identification of oil source rocks, but owing to its simplicity and reliability, this method has been widely used for the study of immature OM in soils and recent lacustrine and marine sediments [1, 2]. The Pyr-GC-MS is the main method for the study of the molecular composition of protokerogen. It consists in conducting the flash-pyrolysis at >600 ºC with a subsequent gas chromatography-mass-spectrometry analysis of the products [3]. Using RE and Pyr-GC-MS methods, 15 and 8 samples have been studied, respectively. The results of the work are presented in detail in [4].

The work has shown that the macromolecular aliphatic structure of the kerogen and the precursors of sterane and hopane geomolecules — sterenes and hopenes — form at the early stages of diagenesis. We suggest that macrophytes and bacteria are the main sources of OM for the studied lacustrine sediments.

Geochemistry of the Salma eclogites (Belomorian mobile belt, Baltic Shield)

A.E. MELNIK

Institute of Precambrian geology and geochronology RAS, St. Petersburg, Russia (meliks1@yandex.ru)

In the north-western part of the Belomorian mobile belt were found numerous bodies of an eclogitic rocks, which were named Salma eclogites [1]. Salma eclogites include two types of eclogitic rocks (after basic and after ultrabasic rocks) which occur as tectonic blocks of various size and shape in gneisses. Sm-Nd (grt-cpx-wr) and a local zircon U-Pb dating give the eclogites ages of 1.9 Ga [2]. The data have not proved previously published the Archean values of eclogite metamorphism age. The eclogites are variably affected by overprinted amphibolization. So, rims of Salma eclogite bodies are commonly strongly amphibolized and also some bodies are completely replaced by amphibolites. Geochemistry of REE and trace elements in the eclogites and garnet amphibolites (completely retrogressed eclogites) were investigated using ICP-MS. Both basic and ultrabasic less retrograded eclogitic rocks have an almost flat chondrite-normalised REE patterns (YbN/LaN – 1,15-1,96) (Fig. 1). Retrogressed Salma eclogites and garnet amphibolites after eclogites in comparison with fresh rocks are enriched in REE (especially in LREE) and trace elements (U, Th, Nb, Ti, Zr). The enrichment in REE and high field strength elements is caused by fluid affection during retrograde metamorphism.

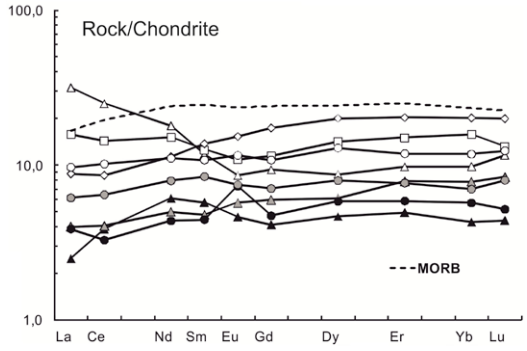

Figure 1: REE distribution in Salma eclogites (solid symbols - ultrabasic eclogites; gray symbols - basic eclogites; open symbols - retrogressed eclogites and garnet amphibolites after eclogites).

Geochemical characteristics of volcanic and plutonic rocks in the 36 Ma Organ Mountains caldera, USA: Are they telling the same story?

V. MEMETI[1]* AND J. DAVIDSON[1]

[1]Durham University, Dept. of Earth Sciences, Durham, DH1 3LE, UK, (email: valbone.memeti@durham.ac.uk)

Volcanic and plutonic rocks are often studied as separate magma systems as they naturally represent different crustal depth levels. Results from such studies have often led to inconsistent interpretations regarding the geochemical processes and the time scales responsible for the compositional variations. This has resulted in a blurred understanding of the connection between these two sub-systems and how magma plumbing systems operate over time.

We are examining the ~36 Ma Organ Moutains caldera in New Mexico, USA, where contemporaneous volcanic and plutonic rocks of the same arc magma system are juxtaposed due to extensional tectonics along the Rio Grande Rift. Detailed geologic and structural mapping [1] and high precision $^{40}Ar/^{39}Ar$ ages of both volcanic and plutonic rocks [2] provide an excellent framework to study the geochemical evolution and connection of both rock types for >2.5 myrs of active magmatism. Three caldera-forming ignimbrites erupted within 600 kyrs [2] from this system with a total erupted volume of 500-1,000 km^3 next to less voluminous pre- and postcaldera trachyte and andesite lavas. The ignimbrite sequence is zoned from a crystal-poor, high-SiO_2 rhyolite at the base to a crystal-rich, low-SiO_2 rhyolite at the top. This compositional zoning pattern of increased silica is also seen from the top downward in the main intrusion, the Organ Needle batholith, which has been interpreted to be the source for the ignimbrites [1]. The plutons are composed of granodiorite and syenite, and minor diorite and leucogranite.

We will present major oxide, trace element and Sr, Nd and Pb isotope analyses of whole rocks for all plutonic and volcanic units as well as CL images and electron microprobe analyses on individual minerals and discuss 1) the geochemical relationship at rock and mineral scales of all rocks including pre- and postcaldera forming units, 2) the magmatic process(es) responsible for the compositional variations in both rock types, and 3) the possible cause(s) for the large ignimbrite eruptions as well as the smaller sized lava flows if they were derived from the underlying intrusions.

Insights into boron volatility in magmatic systems

G. MENARD[1]*, I. VLASTELIC[1], E. F. ROSE-KOGA[1], J. L. PIRO[1] AND C. PIN[1]

[1] Laboratoire Magmas et Volcans, Université Blaise Pascal, Clermont-Ferrand, France (*correspondence : g.menard@opgc.univ-bpclermont.fr)

It is generally accepted that boron behaves as a volatile element in magmatic systems but the amount of B leaving magma (i.e. the absolute volatility) is poorly known [1]. In the aim to quantify the losses due to magmatic degassing, B concentration of recent (1977-2010) lavas from Piton de la Fournaise volcano (Réunion Island) were measured by isotope-dilution ICP-MS, using a new method avoiding sample evaporation. Twenty-three samples were selected based on three criteria: 1) samples are highly fresh and not contamined; 2) they are cogenetic (they show tiny variations in Pb-Sr-Nd isotopes); 3) samples cover a wide range of eruption and degassing conditions, with an order of magnitude variation in magma effusion rate. Samples include massive basalts with variable amounts of cumulative olivine and naturally quenched samples (including Pélé's hairs and scoria).

B content varies from 1.15 to 3.98ppm. B behaving as a highly incompatible during magmatic processes, ratios involving B and another highly incompatible elements such as B/Nb have to be constant in our suite of cogenetic lavas [2]. However, while most samples show uniform B/Nb of 0.14, few samples show anormalous high (quenched samples) or low (first lavas of April 2007) B/Nb ratios. Because the samples are fresh and unaltered and do not include exotic minerals potentially holding B, we interpret these subtle variations as related to degassing processes. The amount of B loss in each sample has then been estimated taking the composition of a primitive olivine-hosted melt inclusion as representative of the undegassed melt composition. Boron loss varies between 10% for less-degassed samples to almost 30% for the first lavas of the April 2007 eruption. Moreover, the knowledge of eruptive history allows us to distinguish B loss during 1) continuous open-system degassing in the magma chamber (10%), 2) lava emplacement and cooling (4-10%) and 3) shallow closed-system degassing due to a vapor accumulation at the top of the magma chamber prior to the April 2007 eruption (5-8%) [3].

Early diagenesis of sulfur and trace element pyritization in sediments of a tropical upwelling system: Cabo Frio, southeastern Brazil

U. MENDOZA[1]*, R. DIAZ[1], M. MOREIRA[1], N. AMORIM[1], M.E. BÖTTCHER[2], W. MACHADO[1], S.R. PATCHINEELAM[1], R. CAPILLA[3] AND A.L. ALBUQUERQUE1[1]

[1]Geoquímica Ambiental, Universidade Federal Fluminense, RJ 24020-150, Brazil (*correspondence: ursmendoza@geog.uff.br)

[2]Marine Geology, Leibniz Institute for Baltic Sea Research Warnemünde, D-18119 Warnemünde, Germany

[3]Petrobras–Cenpes, RJ 21941-915, Brazil

The early diagenesis of sulfur and the potential effects of sedimentary pyrite re-oxidative cycling on the degree of trace metals pyritization (DTMP) were assessed in short sediment cores from the continental shelf under the influence of a tropical upwelling system (Cabo Frio, Brazil). Under these depositional conditions, the degree of reactive iron pyritization was limited by both dissolved sulfide availability and pyrite oxidation events. Textural analyses of pyrite framboids provide evidence of re-oxidation processes, reflecting dynamic redox conditions in the sediments. The total sulfur, the chromium reducible sulfur (CRS), and degree of pyritization (DOP) values are relatively low, and showed an increase with depth at all stations. The isotope composition of pore-water sulfate (+18.7‰ to +23‰) remained close to the seawater value, but very light stable sulfur isotope signatures of the CRS fraction (-25.2‰ to -40.8‰) are found that reflect intense bioturbation-induced sulfur re-cycling. Relations between DTMP and stable isotope signals are found, suggesting high (Pb, As, Cd and Mn), low (Zn and Cu) or negligible (Cr and Ni) influences by iron sulfide re-oxidation. Pyrite-richer sediments provide an apparent threshold for intense pyrite re-oxidation, while CRS generally becomes more depleted in ^{34}S with increasing depth. This depletion was greatest and becomes less variable when CRS contents exceed ~0.1 wt% (with $\delta^{34}S$ values averaging − 40‰ ± 1‰), after which most trace elements (Pb, As, Cd, Mn and Zn) presented more accentuated DTMP values. Before the stabilization of the pyrite re-oxidation, the release of Mn and Fe into pore water was evidenced, indicating reduction of these elements. Sulfur isotope signatures of pyrite formed under the oxic bottom water conditions at Cabo Frio are similar to those observed in euxinic sedimentary environments, as the modern Black Sea. It is also indicated, that a superimposition of sulfate reduction and intense oxidative sulfur cycling leading to pyrite re-cycling can affect benthic trace element fixation.

Essential aqueous geochemistry of Pb(II) solid formation

A. MENDOZA-FLORES[1] AND M. VILLALOBOS[1]*

[1]Environmental Bio-Geochemistry Group, Geochemistry Department, Geology Institute, UNAM, Coyoacan, CU, Mexico 04510, D.F. (*correspondence: mariov@geologia.unam.mx)

Lead is a biologically non-essential toxic metal whose biogeochemical cycle has been affected considerably by anthropogenic activities [1]. Its mobility in aqueous environments is determined by its abillity to form soluble complexes with organic matter [2], adsorbed complexes on Fe, Mn and Al oxide surfaces [3], and most of all a great variety of solids with major anions such as O^{2-}, hydroxyl, carbonate, sulfate, and nitrate [4]. However, the essential aqueous geochemistry of lead has serious gaps of knowledge. In particular, a dubious $Pb(OH)_2$ solid phase has been proposed [4,5], but never identified, and solubility product constant values with up to four orders of magnitude differences have been reported [6] and incorporated in the databases of the different geochemical speciation codes available. The goal of this work was to test the existence of this hydroxide phase and the validity of its solubility constants.

The solids formed in perchlorate and nitrate electrolyte systems, under closed and open atmospheric CO_2 conditions, were identified by X-ray diffraction and other spectroscopies. We show that no solid phase of $Pb(OH)_2$ is formed at any pH value, and thus the concentrations of aqueous Pb(II) are controlled by the solubilities of solid oxide phases and combinations of carbonates and hydroxi-carbonates, depending on the conditions imposed on the system. Therefore, widespread geochemical databases must be corrected to exclude $Pb(OH)_2$ as an actual Pb(II) solid phase forming, to yield more accurate aqueous Pb(II) solubility behavior predictions.

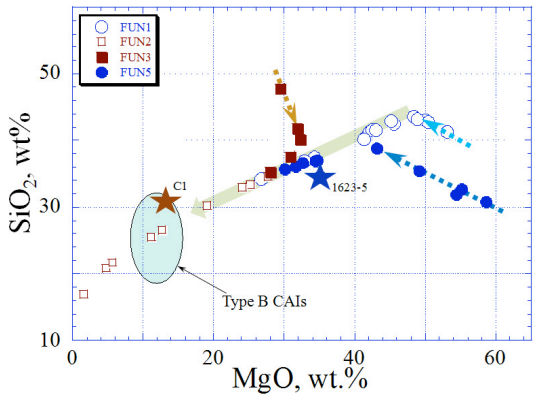
Evaporation of Mg- and Si-rich melts: evolution of chemical and isotopic compositions of FUN CAIs

R.A. MENDYBAEV[1]*, F.M. RICHTER[1], F.-Z. TENG[2], R.B. GEORG[3] AND A.V. FEDKIN[1]

[1]University of Chicago, IL, USA (* ramendyb@uchicago.edu)
[2]University of Washington, Seattle, WA, USA
[3]Trent University, Peterborough, ON, Canada

Extremely large mass-dependent fractionations of Si, Mg and O isotopes in FUN CAIs suggest that their precursors lost significant amount of matter by evaporation. Chemical and Mg, Si and O isotopic compositions of the residues produced by evaporation of forsterite-rich melts (FUN1 and FUN2) in vacuum at 1900ºC suggest that the evaporating component is Mg_2SiO_4 [1]. The evaporation trajectories of FUN1 and FUN2 pass close to the compositions of C1 and Vig1623-5 FUN CAIs, and the measured Mg and Si isotopic compositions of most natural FUN CAIs also plot close to the correlation lines established by the evaporation residues [1].

To test if evaporation of melts with compositions different from the forsteritic melts would result in residues with chemical and isotopic compositions of C1 and 1623-5, we conducted new sets of experiments in which FUN3 and FUN5 melts were evaporated at the same conditions as earlier. Starting FUN3 and FUN5 compositions were obtained by adding MgO and SiO_2 to the C1 (FUN3) and 1623-5 (FUN5) in the amounts required by enrichments in heavy Mg and Si isotopes in these CAIs.



After initial predominant loss of Si (FUN3) or Mg (FUN5), further evaporation results in loss of Si and Mg in forsteritic proportions (constant a_{MgO}/a_{SiO2} in the melt) and the evaporation trajectories are the same as established by FUN1 and FUN2 melts.

The microbial compelling attraction for hydrogarnets in the oceanic crust

B. MENEZ[1]; V. PASINI[1,2]; D. BRUNELLI[2,3]; C. PISAPIA[1], P. LE CAMPION[1], C. LAVERNE[4] AND E. GERARD[1]

Microbial life appears to develop deep in the oceanic crust, taking advantage of the redox gradients locally generated during hydrothermal alteration of the crystalline rocks. Nonetheless everything does not seem to be everywhere and habitats are proving to be highly specific, mineralogically[1] speaking. Notably, hydrogarnets were recently shown to represent microbial niches hosted in serpentinized mantle-derived rocks from the Mid-Atlantic ridge. These hydroandraditic garnets ($Ca_3Fe_2^{3+}(SiO_4)_{3-x}(OH)_{4x}$ with trace amounts of Al, Ti, Cr) serve as metabolic substrates likely providing oxidized iron and calcium to the attached microbial community[2]. Far from being anecdotic, such occurences can be found in other geographically-distant locations along the ridge system as for example in the South Western-Indian ridge, likely signing an extensive process. In addition, the extent does not appear to be limited to the peridotitic portion of the oceanic crust. We present here results obtained on hydroschorlomite, a Ti-, Ca-, Fe-rich andraditic garnet hosted in altered basalts drilled in Hole 1256D during ODP Leg 206 (Equatorial East Pacific)[2]. In situ characterizaton of the organic carbon speciation at the microscale reveals the presence of microbiologically-derived material in close association with the hydrogarnets found in the deepest cores of basalts (661–749 mbsf). The specificity of these microhabitats will be discussed and compared in terms of chemical and mineralogical characteristics, inferred hosted metabolisms along with their potential as shaping low temperature alteration processes.

Protolith and tectonic implications of the Changhai metamorphic supracrustal sequence in southeast Liaoning Province, NE China: Constraints from zircon U–Pb and Lu–Hf isotopic and whole-rock geochemical evidences

E. MENG[1], F.L. LIU[1], J. CAI[1], Y. C[2]

[1] Institute of Geology, Chinese Academy of Geological Sciences, Beijing 100037, China (mengen0416@126.com; lfl0225@sina.com; caijia91052@126.commailto:)

[2] School of Earth and Space Sciences, Peking University, Beijing 100871, China (cuiying0430@126.com)

The Changhai metamorphic supracrustal rocks, located in the eastern–central part of the Jiao–Li–Ji Belt in the North China Craton, are mainly composed of various types of garnet–mica schists, along with minor quartzites and marbles. Geochemical results indicate that the source rocks were mainly granitoids with a possible minor contribution from clastic sediments with an active continental margin signature. Detrital zircons have U–Pb age peaks at approximately 1887, 2174, 2552, 2765, and 3212 Ma, εHf values of –11.1 to +13.0, and three major time windows of average continent crustal model ages (T_{DM}) of 2.04–2.33, 2.48–2.56, and 2.72–2.93 Ga. These results suggest that sediments of the Changhai metamorphic supracrustal rocks were mainly sourced from nearby basement granitoid rocks and, to a lesser extent, from Paleoproterozoic metamorphosed strata such as the North and South Liaohe groups. Furthermore, the source rocks of the magmatic zircons analyzed in this study appear to have originated from interaction between old continental crust and juvenile material. The youngest concordant zircon age peak at 1879 Ma coincides with the timing of formation of regionally widespread granitoids, mafic igneous rocks, and metamorphism of the South Liaohe and Ji'an groups in the Jiao–Liao–Ji Belt, and requires the sedimentary protoliths of the Changhai metamorphic supracrustal rocks to have been deposited after this time. The results regarding lithostratigraphy, provenance, and depositional age indicate that the Archean Northern Liaoning–Southern Jilin Complex in the north, and the southern Liaoning–Nangrim Complex in the south were already a single continental block by 1887 Ma, and that the Changhai metamorphic supracrustal rocks was deposited at an active continental margin.

This research was financially supported by research grants from the Natural Science Foundation of China and Chinese Geological Survey Program (Grants 41202136 and 1212011120150).

Multimodal and multiscale microscopies to study biomineralization and crystallization processes

NICOLAS MENGUY[1]*, KARIM BENZERARA[1], JINHUA LI[1], LAURENT CORMIER[1], OLIVIER DARGAUD[1] AND GUILLAUME RADTKE[1]

[1]Institut de Minéralogie et de Physique des Milieux Condensés (IMPMC), UMR 7590 CNRS–UPMC–IRD, 4 place Jussieu, 75252 Paris Cedex 05, France, Nicolas.Menguy@upmc.fr (* presenting author)

For years, imaging and spectroscopic methods have been intensively used to obtain information on properties of minerals present on Earth and the processes involved in their formation. Recently, dramatic improvements have been made in terms of spatial and spectral resolutions. For instance, a resolution better than 0.1 nm may now be achieved on crystalline compounds using Z-contrast on STEM-HAADF imaging mode. It is also possible to combine both high spectral (0.1 eV) and spatial resolutions (20 nm for STXM, better than 1 nm for EELS). Moreover, owing to the FIB sample preparation method, these highly local techniques can be associated with complementary large scale analytical methods allowing a multi-scale approach.

Here, we shall present recent studies focused on the nm-scale processes involved in the formations of (i) aragonite in corals, (ii) intra-cellular magnetite in magnetotactic bacteria and (iii) crystal nucleation in glasses. For coral biomineralization, combined nano-diffraction studies, HRTEM and polarization-dependent synchrotron-based STXM imaging, have evidenced the biological control exerted by the organism leading to a hierarchically structured solid material [1]. Concerning the intracellular magnetites, we focused on asymmetric crystals formed by bacteria belonging to the *Nitrospira* phylum [2]. Atomic scale processes and crystal shape control involved during crytal growth will be discussed on the basis of ultra-high resolution observations performed on an aberration corrected STEM. In addition, we will present some results related to nanoscaled heterogeneities in glasses leading to the crystal nucleation [3]. The ability to identify directly the crystallized phase from the image will be also addressed.

Application of a novel microfluorination technique to quantify biogenic opal $\delta^{18}O$

ANTHONY J. MENICUCCI[1], HOWARD J. SPERO[2] AND JOY MATTHEWS[3]

[1]Department of Geology, University of California Davis, Davis CA USA (amenicucci@ucdavis.edu)
[2]Department of Geology, University of California Davis, Davis CA USA (*correspondence: hjspero@ucdavis.edu)
[3]Department of Plant Sciences, Stable Isotope Facility, University of California Davis, Davis CA USA (jamatthews@ucdavis.edu)

$\delta^{18}O$ data from organisms that precipitate biogenic silica, such as diatoms or grass phytoliths, are relatively rare in the literature. The paucity of opal $\delta^{18}O$ data is due to the difficulty in isolating, purifying, and analyzing the covalently bound oxygen for geochemical analysis, which typically involves dangerous fluorination reagents and/or IR laser systems. We have developed a new microfluorination technique for opal and quartz analysis that utilizes polytetrafluoroethylene powder (PTFE, C_2F_4, Teflon) as a fluorine source. Cleaned and purified samples are dehydrated-dehydroxylated at 1060ºC in vacuum prior to analysis and 0.4 mg of sample is then mixed with PTFE and graphite in silver foil capsules. Samples are analyzed at 1450ºC with a vario PYRO cube TC/EA and IRMS in continuous flow mode. All data are calibrated to VSMOW using NBS-28 quartz. Acceptable data were obtained when sample yields exceeded 88% (>80% of >300 samples analyzed), yielding replicate precision better than ± 0.4‰ (1σ).

Utilizing this method we analyzed a suite of diatom samples from a sediment trap time series collected in the Gulf of California, Guaymas Basin. Samples were collected in the late fall/early winter during three different years (1993, '94, '96). Diatom $\delta^{18}O$ ranged between 35 and 36.2‰ (VSMOW) (n=7). Five samples span a single fall through early winter period and when converted to temperature using the Labeyrie (1974) relationship, record surface water temperatures between 25-27ºC that are in good agreement with temperatures during the peak fall opal flux. These data suggest sinking diatom frustules remain suspended in the deep pycnocline through early winter and data from sediment cores are likely to be seasonally biased.

U-series isotope composition of primary minerals to determine regolith production rates on three different lithologies

D. MENOZZI[1] AND A. DOSSETO[1]

[1]Wollongong Isotope Geochemistry Laboratory; GeoQuEST Research Centre, School of Earth and Environmental Science, University of Wollongong, Wollongong, NSW, Australia. (dm791@uowmail.edu.au; tonyd@uow.edu.au)

The complex interaction between weathering, erosional and biological processes converts bedrock into regolith, namely the ensemble of soil and saprolite. Assessing rates of regolith formation is necessary to evaluating soil sustainability and investigating landscape's past history and future evolution.

Recently, uranium-series isotopes have been used to quantify independent time-integrated regolith and soil production rates [e.g. 1, 2, 3]. This is because their abundance in regolith is function of time and weathering. However, until now this method has been applied to bulk material, without distinguishing among primary minerals, secondary phases and other soil components. The overall research goal is to improve the U-series method accuracy, measuring regolith production rates on primary mineral phases in place of bulk material.

Three weathering profiles developed over basalt, granite and sandstone in NSW, Australia, have been sampled from flat-topped areas chracterized by comparable climatic regime and low erosion. Separation of primary minerals along the weathering profiles and their uranium-thorium isotopic composition will provide rates of regolith production. This will contribute to improving U-series technique and will emphasize the role of parent material in determining soil formation rates.

Superheating water to model soil "immobile" water

LIONEL MERCURY[1,*], KIRILL I. SHMULOVICH[2], AND PATRICK SIMON[3]

[1] Institut des Sciences de la Terre d'Orléans, UMR 7327 Université d'Orléans-CNRS-BRGM, 45071 Orléans Cedex, France (* lionel.mercury@univ-orleans.fr).
[2] Institute of Experimental Mineralogy, Russian Academy of Science. 142432 Chernogolovka, Russia.
[3] CEMHTI, UPR3079 CNRS-Université d'Orléans, 45071 Orléans Cedex 2, France.

Superheating

The superheated liquids are less stable than their vapour, while their criteria of internal stability are met. They can be produced when an increasing T or a decreasing internal P (including negative pressure, or liquid tension) beyond the stable values is produced in liquid in such conditions that vapor does not nucleate. This nucleation suppression can be reached in nature either during a short time by a very rapid P or/and T variation (phreatomagmatism, for instance), or by decreasing the air humidity at a liquid-air interface located in infra-micronic container (soil capillarity, for instance). The method of choice to experimentally probe superheating is the micro-thermometry of fluid inclusions [1], that can be designed in terms of composition and density of occluded liquids (in quartz). Their volumes are intermediate between macro-systems, in which superheating is restricted to low tensions with very short lifetime, and nanosystems, wherein the host matches the size of the critical vapor nucleus.

Properties and behaviours of interest

The first property available from the present experiments are the surface of the metastable PT domain available for aqueous solutions, that depends on the liquid composition and densities [2]. A second property of interest is the ability of this in-pores tensioned liquids to change the mechanical tensor in the surrounding solid, by recording the SiO_2 Raman bands in quartz during a microthermometric cycle. The third property is the transmission of the liquid tension to the dissolved solutes, again through recording characteristic Raman shifts of solutes with known liquid tension. Consequently, the solubility of gases and minerals in such superheated mixtures changes, and in general increases, with consequences on weathering and external gas cycles. At last, the superheating lifetime, the energy of the critical boiling, and the direct consequences of this return-to-equilibrium to local paragenes are explored.

[3] Dpt. of Geosciences, Univ. of Oslo, Blindern, Oslo, Norway

The Montes de Toledo batholith (MTB) is a composite Hercynian plutonic array (~ 200 km long) located within the Central Iberian Zone (CIZ). The MTB magmatism lasted from 316 to 297 Ma with prevailing monzogranitic to leucogranitic compositions and a marked S-type character. Two contrasted segments are distinguished according to their geochemical and isotopical signatures: the eastern (E-MTB) and the western (W-MTB; Villaseca *et al*. [1]). Restitic and metamorphic enclaves are commonly found, though in the E-MTB are also frequent mafic microgranular enclaves. The E-MTB granites are enriched in Ca, Fe, Na, Sr and Y-HREE, whereas the W-MTB granitoids display higher ACNK ratios and higher P, K, Rb and LREE contents. The wide whole-rock $(^{87}Sr/^{86}Sr)_{300}$ isotopic variation (0.706 – 0.723) and the abundance of inherited Neoproterozoic zircons in the granitoids imply the involvement of a heterogeneous crustal source. εHf values of the Neoproterozoic zircons from the W-MTB granites overlap those from the Schist-Greywacke Complex (εHf up to +10 and +11, respectively), suggesting a major contribution of these metasediments to the granite source. This is also supported by the similar range of their εNd whole-rock isotopic composition (from -3 to -6) and Nd model ages (1.3 – 1.4 Ga). In contrast, the Neoproterozoic zircons of the E-MTB granites show lower εHf values (< +5) suggesting a different protolith. A meta-igneous source is consistent with the common presence of inherited zircons in those granites with the same Ordovician age range as in the outcropping CIZ peraluminous augen orthogneisses (i.e., from 460 to 480 Ma).

Rates of Natural silica precipitation through time

R.MERLE[1], A.NEMCHIN[1], S. SIMONS[1], F. TOMASCHEK[2], AND T. GEISLER[2]

[1]Curtin University, Department of applied geology, Perth Australia [a.nemchin@curtin.edu.au; r.merle@curtin.edu.au]
[2] Universitat Bonn, Steinmann Institut, Bonn, Germany [tgeisler@uni-bonn.de; ftom@uni-bonn.de]

Significant deposits of amorphous and cryptocrystalline silica (opal) in the Northern Yilgarn Craton are closely associated with the formation of calcrete. Precipitation of this calcrete occurs in the areas of summer rainfall, where rapid water infiltration and high evaporation rates limit prolonged periods of dampness and plant respiration. The high U concentration accompanied by low initial Pb and Th concentrations shown by some common varieties of opal facilitates the application of the U-Pb and U-series techniques for high precision age determination of opaline silica.

We used SHRIMP (sensitive high resolution ion microprobe) U-series dating of two common opal samples found in calcretes from the weathering profile in the Yilgarn Craton (Western Australia) to determine the timing of one of the latest silicification events in the area and to investigate variations of silica precipitation rates during the late Pleistocene. All analyses indicate that ^{238}U, ^{234}U and ^{230}Th are not in secular equilibrium, allowing the calculation of $^{230}Th/^{238}U$-$^{234}U/^{238}U$ ages.

An apparent symmetrical decrease of ages from centre of the opal veins towards their contacts with the calcrete suggests that the precipitation of silica did not take place in an open space fissures, but rather as replacement of carbonate. The opal growth rate was not constant during the entire time interval between 150 and 40 kyr recorded by the two samples and the age patterns can be interpreted to represent several episodes of very fast growth of opal interrupted by periods of absence or relatively slow silica precipitation. The estimated precipitation rate variation obtained from both opal samples shows three maxima with one near 90 kyr that is visible in both samples. In addition, we found increased precipitation rates at about 135 kyr and 117 kyr in one sample, whereas in the other samples the highest precipitation rates occurred at about 70 and 45 kyr.

These rates appear to exhibit systematic variations through time that can be linked to the major orbital cycles of the Earth, suggesting that silica precipitation rates in the Yilgarn craton and perhaps in whole Australia are controlled by climate variations.

Shells of *Corbicula fluminea* mussels and the bioavailability of anthropogenic Rare Earth Elements in river water

GILA MERSCHEL[1] AND MICHAEL BAU[1,2]

[1]Earth and Space Sciences Program, Jacobs University Bremen, 28759 Bremen, Germany
[2]Integrated Environmental Studies Program, Jacobs University Bremen, 28759 Bremen, Germany

Rare Earth Elements (REE) of anthropogenic origin can be found in river water and drinking water all around the world [1]. The Rhine River and the Weser River in Germany both carry an anthropogenic Gd anomaly that results from the use of Gd in MRI contrast agents that are introduced into the rivers with the effluents from waste water treatment plants [2,3]. In addition, the Rhine River also carries an anthropogenic La anomaly (and most recently an anthropogenic Sm anomaly [4]), downstream of the Town of Worms, where industry effluents with high concentrations of La (and Sm) are discharged into the river [3]. The shells of invasive freshwater mollusk *Corbicula fluminea* were collected from both rivers to investigate the bioavailability of these anthropogenic REE. As the aragonite shell of *Corbicula* grows from the epithallial fluid of the mussel, anthropogenic metals have to be taken up by the mussel organism in order to eventually be available for incorporation in the shell. *Corbicula* shells from the Weser River and from the upper Rhine River incorporate the geogenic REE from the river water, with slight preferential incorporation of LREE over HREE. Anthropogenic La is readily incorporated into the shells, reflecting La-REE relationships in ambient river water. In contrast, anthropogenic Gd could not be detected in any of the *Corbicula* shells. These results show that anthropogenic Gd is not bioavailable, probably due to the persistence of the highly stable Gd-DTPA complex that is used as MRI contrast agent. Potential effects of high doses of REE should be investigated, because fish are known to bioaccumulate REE [5] and anthropogenic REE have been found in tap water [2].

Time resolved monitoring of Uranium contamination of oak trees

DIRK MERTEN[1]*, DIETRICH BERGER[1], ARNO MÄRTEN[1], AND MIRKO KÖHLER[2]

[1]Friedrich-Schiller-University, Institute of Geosciences, 07749 Jena, Germany (*correspondence: Dirk.Merten@uni-jena.de, Dietrich.Berger@uni-jena.de, Arno.Maerten@uni-jena.de)
[2]Wismut GmbH, 09117 Chemnitz, Germany (M.Koehler@wismut.de)

Monitoring organisms such as higher plants are used for qualitative and quantitative detection of contaminants in the environment because they take up nutrients and contaminants via air, water and soil. Since trees in temperate regions form annual rings, chronological records of environmental pollution for the near vicinity of the trees can be obtained by spatially resolved analysis of the tree rings.

In the current work a simple and minimal-destructive method for sampling and the spatially resolved (about 200 μm resolution) analysis of trees was developed. Concentration of nutrients and pollution of trees with U and other heavy metals was measured by laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) in annual rings of oak trees grown in a former uranium mining area in Thuringia. The area was contaminated with heap material during active mining and was elaborately remediated by Wismut GmbH in 2002 after termination of mining.

For quantification the standard reference material Virginia Tobacco Leaves CTA-VTL-2 was pressed and used for calibration while C was used as internal standard. Thus, it was possible to deduce a temporally resolved depiction of the element concentrations reflecting the history of uranium contamination for the last 50-60 years and also to indicate remediation success.

The U concentrations in the analyzed tree cores could be directly related to mobile U concentrations in the substrate thus verifying the applied method as a successful biomonitoring tool for U contamination in soils.

The physical and chemical characteristics of marine primary organic aerosol

MESKHIDZE, N. AND B. GANTT

North Carolina State University, Raleigh, NC, USA, nmeskhidze@ncsu.edu, bdgantt@gmail.com

Knowledge of the physical characteristics and chemical composition of marine organic aerosols is needed for the quantification of their effects on solar radiation transfer and cloud processes. This presentation examines research pertinent to the chemical composition, size distribution, mixing state, emission mechanism, photochemical oxidation, and climatic impact of marine primary organic aerosol (POA) associated with sea spray. Numerous measurements have shown that both the ambient mass concentration of marine POA and size-resolved organic mass fraction of sea spray aerosol are related to surface ocean biological activity. Recent studies have also indicated that fine mode (smaller than 200 nm in diameter) marine POA can have a size distribution independent from sea-salt, while coarse mode aerosols (larger than 1000 nm in diameter) are more likely to be internally-mixed with sea-salt. Modeling studies have estimated global submicron marine POA emission rates of ~10 ± 5 Tg yr^{-1}, with a considerable fraction of these emissions occurring over regions most susceptible to aerosol perturbations. Climate studies have found that marine POA can cause large local increases in the cloud condensation nuclei concentration and have a non-negligible influence on model assessments of the anthropogenic aerosol forcing of climate. Despite these signs of climate-relevance, the source strength, chemical composition, mixing state, hygroscopicity, cloud droplet activation potential, atmospheric aging, and removal of marine POA remain poorly quantified.

The current presentation will also summarize results from the recent marine aerosol workshop held in Raleigh, NC [1], where workshop participants identified the most critical open questions regarding sea spray aerosol and developed a list of priorities for conducting and facilitating novel research. The rankings of the most pressing science questions based on their feasibility impact on reducing the current uncertainty ranges for different processes will also be discussed. The workshop presentations are available online at: http://www4.ncsu.edu/~nmeskhi/Marine_Aerosol_Workshop/WEBSITE.html.

Effect of atmospheric organics on iron bioavailability

MESKHIDZE, N.[1], M. S. JOHNSON[2], D. HURLEY[1], AND M. D. PETTERS[1]

[1]North Carolina State University, Raleigh, NC, USA nmeskhidze@ncsu.edu, dlhurley@ncsu.edu, mdpetter@ncsu.edu

[2]NASA Ames Research Center, matthew.s.johnson@nasa.gov

Iron (Fe) delivered to the surface ocean through atmospheric pathways is of specific interest for the marine environment and plays a vital role in the earth's biogeochemical cycle. The deposition of atmospheric Fe to the ocean's surface may be an important control on primary productivity in vast areas of the global oceans. Mineral Fe at the source regions is primarily in the form of Fe-oxyhydroxides and aluminosilicate minerals. Once airborne, Fe can be mobilized from the minerals through the effect of acids, organics, and sunlight initiating a complex cycling between ferric (Fe(III)) and ferrous (Fe(II)) forms of Fe.

Here mineral dust and dissolved Fe (Fe_d) deposition rates are predicted using GEOS-Chem with a comprehensive dust-Fe dissolution scheme. The model simulates Fed production during the atmospheric transport of mineral dust taking into account inorganic and organic (oxalate)-promoted Fe dissolution processes, Fe(II)/Fe(III) photochemical redox cycling, dissolution of Fe-containing minerals (hematite, goethite, and aluminosilicates), and detailed mineralogy of wind-blown dust. Calculations suggest that during the yearlong simulation ~0.26 Tg of Fe_d was deposited to global oceanic regions[1]. Compared to simulations only taking into account proton-promoted Fe dissolution, the addition of oxalate to the dust-Fe mobilization scheme increased total annual model-predicted Fe_d deposition to global oceanic regions by ~75%. During the daytime, a large fraction of model-predicted fluxes of Fed are in the Fe(II) form, while nocturnal fluxes of Fed are largely in the Fe(III) form[1].

In addition to model simulations, laboratory experiments were also conducted to quantify the effects of atmospheric organics on Fe bioavailability after deposition to the surface ocean. Fe(II) was detected by absorbance spectrophotometry using the Ferrozine technique and total soluble iron was determined by addition of hydroxylamine to reduce Fe(III) to Fe(II). This presentation will refine the concept of what constitutes soluble Fe in atmospheric waters and bioavailable Fe in the oceans. The important role of atmospheric organics for marine biogeochemistry and carbon cycling will also be discussed.

It's getting hot on Earth - The Middle Eocene Climatic Optimum in a terrestrial sedimentary record

K. METHNER[1,2], U. WACKER[2], J. FIEBIG[1,2], A. MULCH[1,2,3] AND C. P. CHAMBERLAIN[4]

[1] Biodiversity and Climate Research Centre, Frankfurt am Main, Germany; katharina.methner@senckenberg.de
[2] Goethe Universität, Frankfurt am Main, Germany
[3] Senckenberg Research Institute and Natural History Museum, Frankfurt am Main, Germany
[4] Stanford University, Stanford, CA, USA

The Middle Eocene Climatic Optimum (MECO) is an enigmatic global warming event interrupting the protracted Cenozoic cooling. It is marked by a negative shift in marine oxygen isotope records that indicate an increase of water temperatures by up to 5 to 6 °C and thus, documents an increase in temperatures on top of the warm Eocene climate. This makes the MECO one of the hottest phases during Earth's climate history, but the questions, if and how the MECO affected continental sites are still unresolved.

Here, we present a stable isotope record ($\delta^{18}O$) and clumped isotope (Δ_{47}) temperatures from an Eocene mammal fossil locality in southwestern Montana, USA. The sampled section (Upper Dell Beds, Sage Creek Basin) comprises about 60 m of stacked paleosols that were correlated to Chron C18r by paleomagnetic and biostratigraphy. The oxygen isotopic record of pedogenic carbonates range from -12 to -18 ‰ (SMOW) and reveals prominent shifts of oxygen isotope ratios of up to 6 ‰ within 3 m of section. The associated Δ_{47}-temperatures indicate an increase in temperatures of about 5 °C, reaching peak temperatures of 31 ±2 °C, and a rapid drop in temperatures of about 9 °C. Thus, we think that this record has the potential to (1) document the MECO in a terrestrial record, (2) yield realistic temperature changes between the MECO event and the post-MECO cooling phase, and (3) help to track the isotopic evolution of precipitation during a short term climatic event in continental interiors.

Stability behaviour of silver nanoparticles in different aqueous media

G. METREVELI* AND G. E. SCHAUMANN

Universität Koblenz-Landau, Institute of Environmental Sciences, Environmental and Soil Chemistry, Landau, Germany (*correspondence: metreveli@uni-landau.de)

Due to the wide application of engineered nanoparticles (ENP) in different industrial products, in the last years, the risk potential for their release in the environment is increased as never before. Mobility and toxicological behaviour of ENP in aquatic systems is strong depending on their stability and aggregation properties [1]. Furthermore, the changes in the chemical composition of the aqueous phase can influence the aggregation reversibility [2], which can lead to the remobilisation of previously aggregated and immobilised nanoparticles. Despite the increasing amount of studies on the environmental behaviour of ENP, there is a lack of information about reversibility of the aggregation.

In this study, aggregation of citrate stabilised silver nanoparticles (Ag NP) was investigated in synthetic aqueous media and natural river water (Rhine). The influence of pH value, sodium and calcium cations and humic acid (HA) on the stability of Ag NP was characterised. The reversibility of the aggregation was studied after reducing of ionic strength (by centrifugation and washing) and applying of ultra sound at different energy levels.

Ag NP showed high aggregation at high sodium and calcium concentrations ($c(Na^+)$ > 40 mmol/L, $c(Ca^{2+})$ > 0.5 mmol/L), at low pH values (pH <3) and in river water. HA stabilised Ag NP and the stabilisation effect was much higher for pH induced aggregation than for sodium and calcium cation induced aggregation. After reducing of ionic strength, the aggregation of Ag NP was reversible especially after applying of shear forces, but the disaggregation was not fully complete. After treatment, small aggregates remained in the dispersions, which were more stable, than the big aggregates.

The results of this study show that the reduction of ionic strength and the presence of shear forces can lead to the partial disaggregation of previously aggregated nanoparticles. As a consequence, the probability of nanoparticle remobilisation can be increased.

Artificially induced migration of redox layers in Adriatic sediment

E. METZGER[1]*, D. LANGLET[1], E. VIOLLIER[2], N. KORON[3], B. RIEDEL[4], M. ZUSCHIN[4], M. STACHOWITCH[4], J. FAGANELI[3], M. THARAUD[2], E. GESLIN[1] AND F. JORISSEN[1]

[3] Marine Biology Station, National Institute of Biology, Piran, Slovenia

[4] Department of Marine Biology, University of Vienna, Vienna, Austria

Long term experimental studies suggests that, under anoxic transient conditions, redox fronts within the sediment shift upwards causing sequencial rise and fall of benthic fluxes of reduced species (Mn(II), Fe(II) than S(-II)) (e.g; Kristiansen *et al*., 2002). In order to study such processes in a more realistic system, benthic chambers were deployed on the seafloor of the Northern Adriatic and sampled after 9, 30 and 315 days of incubation. High resolution porewater profiles were sampled by DET probes and redox sensitive species were analysed (Alk, SO_4^{2-}, Mn^{2+}, Fe^{2+}).

Results show that anoxia was reached after 7 days. Mn and Fe started diffusing towards the water column giving a rusty color to the seafloor. Infaunal species appeared at the surface. After 20 days (fig. 1), all macro-organisms were dead. Porewater chemistry showed expected redox shifts. However, bottom water chemistry followed a peculiar evolution: after 1 month, sulfide had a higher concentration in the overlying water than in the porewater leading to a diffusional flux into the sediment. The source of sulfide was attributed to the decomposition of dead macroorganisms laying on the seafloor. Our results suggest that the sulfide rise in the water column in coastal waters is strongly controlled by the biomass of benthic macrofauna and can be decoupled from sedimentary geochemical processes.

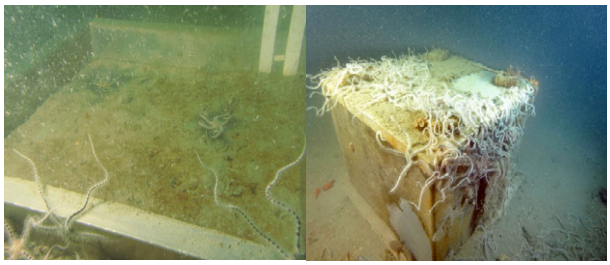

Figure 1: left: chamber after 20 days of incubation; right: chamber after 10 months of incubation.

Lateral carbon isotope homogeneity in a Late Ordovician epeiric sea

J. GARRECHT METZGER[1]* AND DAVID A. FIKE[1]

[1]Washington University, St. Louis, Missouri 63130, USA (*correspondence: gmetzger@levee.wustl.edu)

Carbon isotope ratios of marine carbonate rocks ($\delta^{13}C_{carb}$) can be used to correlate coeval ancient strata. Detailed correlation requires that the carbon isotopes of the carbon source, the oceanic dissolved inorganic carbon pool ($\delta^{13}C_{DIC}$), be homogenous on the mixing time of the ocean, (~1,000 years). Previous reports have suggested that apparent large (≥1.5‰) offsets in $\delta^{13}C_{carb}$ observed for Late Ordovician carbonate strata of North America are the result of large scale (i.e., 100s-1000s km) lateral gradients in the isotopic composition of DIC in the surface ocean (e.g., from the open Iapetus Ocean to shallow Laurentian epeiric seas [1,2]. An alternative interpretation is that apparent offsets in $\delta^{13}C_{carb}$ are in large part the result of the differential admixture of secondary carbon incorporated into the rocks resulting in variable and lower $\delta^{13}C_{carb}$ values in diagenetically altered locations [3].

Here, we present Late Ordovician $\delta^{13}C_{carb}$ data covering >1,400 km and spanning multiple depositional environments, from shallow cratonic sea to deeper foreland basins. Multiple transects through the same interval across the study area reveal no systematic $\delta^{13}C_{carb}$ gradients (maximum offsets between any coeval strata are ~0.6‰). Detailed sampling has identified discrete stratigraphic intervals with characteristic $\delta^{13}C_{carb}$ values resolvable at sub-permil levels. The work discusses the stratigraphic as well as biogeochemical implications of these findings.

The contribution of phytoliths in improving the understanding of Si cycling

J.D. MEUNIER*,AND C. KELLER

Aix-Marseille Université, CNRS, IRD, CEREGE UM34, 13545 Aix en Provence, France (*correspondance: meunier@cerege.fr)

The Si cycle is remarkably affected by biomineralisation processes through the formation of diatoms and other microorganisms in aquatic systems, and through the formation of phytoliths that constitute the main form of Si storage in terrestrial plants. After translocation from the roots to the shoots as silicic acid, the main form of Si in soil sotutions, Si is polymerized through the elimination of water by evaporation and the formation of phytoliths occurs. Phytoliths are composed of opal A (XRD-amorphous phase) particles although some authors have suggested the presence of crystalline silica. Contrary to many nutrients, Si cannot be subsequently redistributed within the plant because the phytoliths remain insoluble until the litter falls and decomposes. The beneficial effects of Si have been demonstrated by many studies using pots, hydroponic and field experiments and are particularly remarkable in plants exposed to biotic or abiotic stresses.

During litter decomposition phytoliths are either dissolved and constitute a source of recycled Si for plants or preserved from weathering and their morphoscopy may then be helpful for reconstructing the past vegetation. After presenting some evidences that phytoliths can control the biogeochemical cycle of Si at ecosystem or watershed levels, several issues concerning phytolith research are discussed. A few recent studies have provided some evidences that agriculture practices can deplete ASi pools of soil. Because phytoliths constitute one of the most rapidly bio available source of Si for crops, the consequence of soil erosion and straw exportation on crop yield should be more studied in cultivated areas In order to better integrate the phytoliths in the global models of Si cycling there is a need for a better quantification of soil phytolith pool (ASi). Extraction using gravimetric methods are time consuming and poorly correlated with extractions using alcaline dissolution protocoles such as the DeMaster's (1981), initially used for diatom test quantification in aquatic systems. We have recently shown that alkaline extraction may not be strong enough to dissolve aged phytoliths, and may underestimate ASi by a factor of 4.

Laboratory Study of Nitrate Photolysis in Antarctic Snow: Quantum Yield, Mechanism, Isotope Effects and Wavelength Dependence

CARL MEUSINGER[1#], TESFAYE A. BERHANU[2#], JOSEPH ERBLAND[2], JOEL SAVARINO[2] AND MATTHEW S. JOHNSON[1]*

Post-depositional processes alter the nitrate concentration and isotopic composition at low accumulation sites. Available nitrate ice core records can only provide input for studying past atmospheres and climate if such processes are fully understood. Reported quantum yields for the main reaction differ by orders of magnitude. The experimental system included a Xe lamp with optional UV filters, an environmental chamber with temperature control and a N_2 flow system to flush gas phase products and used natural snow from Dome C, Antarctica. Irradiated snow was sampled in 1 cm sections and analyzed for nitrate concentration and isotopic composition ($\delta^{15}N$, $\delta^{18}O$ and $\Delta^{17}O$). Observed values for the quantum yield lie in the middle of the range of previously reported values and can be explained using two types of nitrate: one easily accessible (photolabile) and one of trapped or buried nitrate. The quantum yield changes from 0.45 to 0.05 within what corresponds to weeks of UV exposure in Antarctica. An average photolytic isotopic fractionation of $^{15}\varepsilon$ = -15±0.01 ‰ was found for the experiments without a wavelength filter. These results are ascribed to excitation of the intense absorption band of nitrate around 200 nm. No fractionation was observed in the oxygen isotopes. An experiment with the 305 nm UV filter, close to the actinic flux spectrum in Dome C, showed a photolytic isotopic fractionation of $^{15}\varepsilon$ = -38±2.2 ‰ slightly more positive than the fractionation determined in the field (-40 to -74.3‰, Erbland *et al*., In review). We demonstrate that the photolytic fractionation of nitrate isotopes in snow is very sensitive to the actinic flux spectrum, leading to the reinterpretation of previous laboratory studies. In order to directly apply results from laboratory studies to ambient conditions the wavelength of irradiation has to match that in the field, as the photolytic fractionation changes significantly depending on the impinging spectrum.

The biological pump and evolution of marine animal ecosystems

K.M. MEYER[1]*, A. RIDGWELL[2] AND J.L. PAYNE[1]

[1]Department of Geological and Environmental Sciences, Stanford University, Stanford, CA 94305, USA (*correspondence: meyerk@stanford.edu)
[2]School of Geographical Sciences, University of Bristol, Bristol, BS8 1SS, UK (andy@seao2.org)

The export of organic matter from the surface ocean and its respiration at depth creates gradients in nutrient and oxygen availability that influence the structure and distribution of marine ecosystems. Today the strength of the biological pump is strongly influenced by mineral-ballasted phytoplankton. In Earth's past, however, mineralized phytoplankton were less common and, consequently, the biological pump was likely weaker. Here we use the GENIE model to explore the impact of a changing biological pump on marine chemistry and ecosystem structure. We find that under a weaker biological pump likely typical of the Paleozoic and early Mesozoic, the position of the oxygen minimum zone shallows and anoxia is more prevalent near the surface. In this scenario, less oxygen is available to benthic ecosystems on shelf environments. If so, these results imply that the mid-Mesozoic radiation of phytoplankton with mineralized tests spread oxygen demand more evenly through the oceans and reduced the spatial extent of anoxic regions. Thus, we hypothesize that the Phanerozoic trend toward greater animal abundance and metabolic demand was driven more by increased oxygen availability than by greater food availability. In fact, a reduction in productivity may have been required to generate sufficient oxygen availability in the shallow oceans to make the oceans more habitable for animals.

Preliminary U-series dating results from the GISP2 ice core

K.W. MEYER AND S.M. ACIEGO

University of Michigan, Ann Arbor, MI 48109-1005, USA (*correspondence: meyerkw@umich.edu)

Ice core climate proxy records often lack precise age constraints on the geochemical variations they record in trapped gases and/or dust inclusions. Currently, few geochronological methods exist to determine the age of the disturbed sections of deep and basal ice. Recent work on material from the Antarctic EPICA Dome C core has demonstrated advances in a radiometric dating method based on $^{234}U/^{238}U$ measurements and dust surface area [1]. Our work has focused on applying these same methods to ice samples from the Greenland Ice Sheet Project (GISP2) drill core. Given that the bottom 10% of the GISP2 core consists of disturbed deep ice argued to be 240 ka or older, external dating methods are necessary for confirming the absolute age of these samples and to further extend Northern Hemisphere climate reconstructions [2].

The U-series method depends on determining three variables: (1) the initial concentration of ^{234}U in the soluble fraction of the ice, (2) the parent concentration (^{238}U) in the dust and (3) the precise surface area of the dust grains to account for the loss of ^{234}U from the grain by α-recoil.

One of the critical assumptions of the dating method is that the the dust is of marine origin, possessing an initial $^{234}U/^{238}U$ activity ratio of 1.14 ± 0.01 [3]. Other studies have determined that there is a significant presence of soluble dust from sea salt deposition on the Greenland Ice Sheet by $^{87}Sr/^{86}Sr$, $^{234}U/^{238}U$, and ε_{Nd} measurements [4]. Our initial measurements yielded $^{87}Sr/^{86}Sr$ values ranging between 0.709439 ± 0.00002 and 0.711007 ± 0.00003. These values are in agreement with the average global $^{87}Sr/^{86}Sr$ composition of seawater, given possible interaction with the insoluble fraction. Therefore, our underlying assumption for the source of the soluble dust fraction is plausible. Initial $^{234}U/^{238}U$ activity ratios for the soluble fraction increase from 1.178 to 1.229 with depth, suggesting that the daughter excess of ^{234}U correspond to resolvable ages. Surface area and ^{238}U measurements of the insoluble fraction will be presented in the context of the uranium age equation.

(*correspondence: melanie.meyer@gzn.uni-erlangen.de)

The metamorphic belt in the southern Tianshan Mountains of NW China provides the opportunity to investigate both the metamorphic evolution of mafic rocks (upper oceanic crust with rarely preserved pillows) during subduction and the exhumation mechanisms in a subduction channel (mafic rocks as boudins enclosed in metasediments). The (U)HP-LT rocks (blueschists, eclogites and metasediments; as in many (U)HP terranes, voluminous schists enclose rare eclogite lenses and layers [1]) are interpreted to represent part of a tectonic mélange formed along a suture zone between the Yili-central Tianshan and Tarim plates ([2],[3]).

This study provides detailed information on the metamorphic evolution of both metasedimentary host rocks and mafic boudins of the (U)HP-LT metamorphic belt. Profiles across different mafic boudins and enclosing metasediments were investigated (whole rock major and trace element geochemistry by XRF and LA-ICP-MS, mineral chemistry by EMPA, thermobarometry, P-T pseudosection modeling using PerpleX) in order to constrain potential protoliths and differences in peak P-T conditions between distinct mafic boudins, and also between metasediments and mafic boudins. Furthermore, metasomatism of the subducted rocks was investigated. This study aims to increase our understanding of the metamorphic evolution of mafic rocks during subduction, the detachment from the subducted slab and the mixing of different materials and metamorphic reactions in the subduction channel during exhumation.

All eclogites investigated contain a variable amount of carbonate minerals. Thus, in addition the carbon cycle in subduction zones is addressed in the context of the P-T evolution.

The Joy of Making Planets in Disks: Dynamical and Chemical Recipes

MICHAEL R. MEYER[1]

[1]Institute for Astronomy, ETH Zurich, mmeyer@phys.ethz.ch

Cirucmstellar disks are an outcome of the star formation process, and their physical properties set the initial conditions of planet formation. Yet the total mass, orbital radius, mean density, and composition of planets formed in these disks depends critically on dynamical processes and the transmutation of the initial ingrediants (gas and dust from the interstellar medium) through chemistry. Here we review some of the key physical and chemical processes in disks that dictate the composition of forming planets. In particular we focus on new observational results that constrain theories of planet formation.

Deep fast-spread Oceanic Crust - Fluid Interactions: Petrography and Volatiles from IODP Expedition 345 Hess Deep Plutonic Crust

R. MEYER[1], R.P. WINTSCH[2], T. NOZAKA[3], K. M. GILLIS[4], J.E. SNOW[5], AND IODP EXPEDITION 345 SHIPBOARD SCIENTIFIC PARTY

[1] University of Bergen, Norway; Romain.Meyer@geo.uib.no
[2] Indiana University, Bloomington IN, USA
[3] Okayama University, Japan
[4] University of Victoria, B.C., Canada
[5] University of Houston, Houston TX, USA

IODP Expedition 345 returned to the Hess Deep Rift almost exactly 20 years after ODP Leg 147. Here we report preliminary results of the recent expedition (Dec. 2012 - Feb. 2013) in the Eastern Pacific Ocean. The Hess Deep Rift exposes a dismembered, but nearly complete lower crustal section of fast-spread East Pacific Rise (EPR) plutonic crust. Recovered core includes high Mg# (79-89) olivine gabbros, gabbros, gabbronorites and troctolites. Due to the scarcity of in-situ rocks from these depths alteration processes within such deep parts of the oceanic crust are still ambiguous. However, such data are essential to better understand global crustal mass balance, tectonics, hydrothermal processes, and cast light on deep crustal biosphere conditions. Shipboard petrography has revealed that high-temperature tremolite-chlorite replacement of olivine + plagioclase is less abundant at deeper levels, in contrast to the dominance of background greenschist/subgreenschist-facies serpentinisation of olivine in addition to prehnite +/- chlorite formation after plagioclase. Shipboard C, H and S measurements define H_2O as major volatile component (0.95 – 9.57 wt.%) in the sampled plutonic rocks. Water abundance within these rocks correlates with the degree of alteration, Ni, and modal olivine contents. The H_2O/MgO ratio of the troctolites (0.31) is consistent with that of serpentine (0.32) and indicates the importance of serpentinisation within the sampled lowest EPR oceanic crust. Localized low-temperature alteration is possibly due to Cocos-Nazca rifting associated with cataclastic deformation.

Glaciers and floodplains controls on weathering fluxes deciphered from two glacial-interglacial Nd isotopes records on both sides of New Zealand

LAURE MEYNADIER[1], ANTOINE COGEZ[1] AND CLAUDE ALLÈGRE[1]

[1]Equipe de Géochimie et Cosmochimie, Institut de Physique du Globe de Paris – Sorbonne Paris Cité, UMR 7154, Université Paris Diderot

A wide variety of climatic, tectonic or chemical factors can influence weathering intensity and/or fluxes. The interest of studying time series relies on the fact that some of these parameters varied through time and other remained constant : it is then possible to unravel informations “all other things being equal” about controls on weathering mechanisms.

We studied Nd isotopes (ε_{Nd}) in two DSDP sites (593 and 594) both in the detrital and authigenic fractions. These sites were collected on the large continental shelf, on both western and eastern side of New Zealand. The sediment covers the last 3 glacial-interglacial cycles (300 kyrs). The interest of this area is linked to the rather uniform lithology, and to the contrasts between the western and the eastern sides of NZ, introduced by the Alpin Chain topography. The Main Divide of the Alpin Chain separates the eastern side with steep slopes and high pluviometry, and the western side with small floodplains and lower pluviometry. In addition climatic forcing factors, such as the glacier extent, did vary through the glacial to interglacial periods.

Our results show ε_{Nd} variations in phase with the climatic fluctuations on both cores, but with a much lower amplitudes on the western core than on the eastern one. Given the various paleoceanographic informations available in the area we are able to demonstrate that the ε_{Nd} signal can not be explained by variations of the mixing contributions of the different ocean masses surrounding New Zealand. The ε_{Nd} signal has clearly a continental and local origin.

Using mixing calculations we show that the weathering Nd fluxes could have been up to 2 to 3 times higher during glacials than during interglacials. This result is explained by the control of glacial erosion that deliver higher amount of fine and fresh materials, easily weatherable. Moreover the lower amplitude of the variations on the western site suggests that floodplains play a key role in the chemical maturation of these fresh and fine grounded minerals delivered from the higher relief. Finally the relationship between our ε_{Nd} record and the $\delta^{18}O$ record suggest a non linear response (hysteresis like relation) of the erosion and weathering processes to climatic forcings.

Sr-Nd and Pb isotopic portray of the Crozet plume

C. M. MEYZEN[1]*, A. MARZOLI[1], G. BELLIENI[1] AND G. LEVRESSE[2]

[1] Università degli Studi di Padova, Via G. Gradenigo, 6, 35131 Padova, Italia (* correspondence: christine.meyzen@unipd.it, andrea.marzoli@unipd.it, giuliano.bellieni@unipd.it)

[2] Centro de Geociencias, Universidad Nacional Autónoma de México (UNAM), Blvd. Juriquilla No. 3001, Querétaro, 76230, México (glevresse@geociencias.unam.mx)

New Sr, Nd and Pb isotope data are presented for alkali basalts of the sub-aerial eruptive stage of East Island. This landmass is the second largest of the easternmost and oldest island group of Crozet archipelago. Its lavas are remarkably isotopically homogeneous in spanning a narrow range of isotopic variability. They occupy an intermediate position among the isotopic variability spectrum defined by Earth's oceanic island basalts. They fall in a mixing triangular shape formed by the end-member mantle components: a Depleted Mantle (DM) component, an Enriched Mantle (EM) component and a common component. The mixture domination by a large fraction of the common component suggests an isolation of the East island mantle source from homogenizing effects of convection mixing and recycling processes for Ga timescales. A possible inter-island source heterogeneity, such as those identified in the Pacific and Atlantic oceans, could exist at Crozet islands, as the younger western group is more isotopically depleted in Sr-Nd than the eastern one. Overall, lavas from Crozet islands share Pb-Sr-Nd isotopic affinities with their Reunion-Mauritius counterparts, but differ from those of Marion-Prince Edward and Kerguelen volcanoes. However, we cannot reject the seismic inference that Crozet volcanism is a secondary expression of Kerguelen hotspot, if its compositional bottom layer is heterogeneous. Finally, the Sr-Nd-Pb isotopic signatures of basalts north of the Crozet Bank along the Southwest Indian Ridge show no affinity with those of East island. The seismically ridgeward flow identified must thus be composed of isotopically distinct material from that of feeding East island volcanism.

Convergence in chemical compositions between aqueous fluid and silicate melt in the peridotite-H_2O system

KENJI MIBE[1]*, TATSUHIKO KAWAMOTO[2] AND SHIGEAKI ONO[3]

[1]Earthquake Research Institute, University of Tokyo, Tokyo 113-0032, Japan (*correspondence: mibe@eri.u-tokyo.ac.jp)

[2]Institute for Geothermal Sciences, Graduate School of Science, Kyoto University, Kyoto, 606-8502, Japan (kawamoto@bep.vgs.kyoto-u.ac.jp)

[3] Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology, Kanagawa, Japan. (sono@ sono@jamstec.go.jp)

In order to understand the magma genesis and chemical differentiation in the Earth's interior, we have been investigating the stability fields and chemical compositions of aqueous fluid, silicate melt, and supercritical fluid magma in the peridotite-H_2O system. Mibe *et al*. [1] found that the second critical endpoint occured at around 3.8 GPa in the system peridotite-H_2O. Using the quenched recovered samples obtained by Mibe *et al*. [1], we determined the chemical composition of aqueous fluid, silicate melt, and supercritical fluid in the vicinity of the second critical endpoint in the system peridotite-H_2O by EPMA analyses. A 10- to 30-um diameter electron beam was used to obtain the composition of quenched materials from aqueous fluid, silicate melt, and supercritical fluid.

In the run at 3.3 GPa, the composition of aqueous fluid was high-Mg dacitic, whereas the composition of silicate melt was peridotitic. In the run at 3.6 GPa, the composition of aqueous fluid was high-Mg andesitic, whereas the composition of silicate melt was komatiitic. At 4 GPa (i.e., above the second critical endpoint), the composition of supercritical fluid magma was basaltic. Our results clearly indicate that the compositions of aqueous fluid and silicate melt converge at around 3.8 GPa, which is consistent with the results by Mibe *et al*. [1].

Concentration and Behavior of CO_2 in MORB and OIB: a reevaluation

PETER J. MICHAEL[1]* AND DAVID W. GRAHAM[2]

[1]Dept. of Geosciences, Univ. Tulsa, 800 S. Tucker Dr., Tulsa, OK, 74104, USA (*correspondence: pjm@utulsa.edu)
[2]CEOAS, Oregon State Univ., Corvallis, OR, 97331, USA (dgraham@coas.oregonstate.edu)

Estimation of initial magmatic CO_2 contents in basalts is hindered by degassing and loss of CO_2 during magma ascent. The most widely accepted estimates of CO_2 flux are derived from ultra-depleted ([Nb]<1.5ppm) mid-ocean ridge basalts (MORB) and melt inclusions from Siqueiros region of the East Pacific Rise that did not exsolve CO_2 [1], and from highly vesicular Mid-Atlantic Ridge (MAR: 14°N) "popping rocks" that did not lose bubbles because they ascended quickly [2,3]. These data indicated that that CO_2/Nb was roughly constant at 239±46 for MORB and that CO_2 behaves incompatibly like Nb during melting and source enrichment [1]. A correct recalculation of the CO_2/Nb in popping rocks from 14°N, and new data from popping rocks at 34°N MAR, showed that their CO_2/Nb is much higher: closer to 576 [4]. These authors proposed that the low CO_2/Nb values for ultra-depleted MORB [1] are unrepresentative of the mantle. Their higher CO_2/Nb estimate [4] yields higher estimates of CO_2 flux from the mantle, in line with estimates from helium.

We have analyzed a larger set of ultra-depleted MORB glasses from the mid-ocean ridge system. Most erupted undersaturated in CO_2, have few or no vesicles, and yield extremely low CO_2 when crushed *in vacuo*. Their CO_2/Nb is 250±50, showing that this ratio [1] is widely applicable to ultra-depleted mantle. We also compiled published data for enriched submarine basalts including ridge popping rocks [4], and basalts from North Arch, Hawaii. The latter have up to 57% vesicles, suggesting two samples lost no bubbles [5]. Their CO_2/Nb is 1125 and 1216, similar to ratios for some popping rocks from 34°N. For the data set as a whole, CO_2/Nb is positively correlated with La/Sm. We propose that CO_2 is more incompatible than Nb, behaving geochemically more like Ba or Rb. CO_2/Ba is 114±43 for most ultra-depleted through highly enriched MORB. Rb and Ba should be better proxies for CO_2 because, unlike Nb, they are not retained in subduction zones during magma genesis. Thus, Rb and Ba more closely follow CO_2 during subduction and recycling into deep mantle. A Ba proxy for CO_2 suggests a MORB CO_2 flux that is ≈40% higher than [4] and ≈3x higher than [1].

'Freiberg Strategy' for obtaining matrix-matched reference materials for resource-related microanalytical methods technology

P.P. MICHALAK[1], A.D. RENNO[2], S. MERCHEL[2], F. MUNNIK[2], J. GUTZMER[2], R. UECKER[3], Z. GALAZKA[3], H-P. HELLER[1] M. RADTKE[4] AND U. REINHOLZ[4]

[1]TU Bergakademie Freiberg, DE (Przemyslaw-Piotr.Michalak@student.tu-freiberg.de)
[2]HZDR, Dresden, DE, [3]IKZ, Berlin, DE, [4]BAM, Berlin, DE,

Quality assurance of natural raw materials (e.g. ores) requires thorough studies on concentration and spatial distribution patterns of technologically relevant trace elements within the mineral matrix at the microscale. Obtaining such a goal is yet only possible with the use of beam-based microanalytical methods and a proper set of homogeneous, matrix-matched reference materials (RMs) doped with trace elements relevant to resource technology.

Natural minerals usually exhibit chemical heterogeneity at μg/g sampling masses and are unsuitable as RMs for in-situ chemical microanalysis. On the other hand, available synthetic RMs (e.g. glasses, pressed pellets) fail to satisfy matrix-match criterion.

A collaboration involving several German scientific institutions centered around TU Bergakademie Freiberg proposed a novel strategy for obtaining such RMs through the synthesis of multi trace element doped mineral matrices subsequently tested for chemical and structural homogeneity with both microscopic and spectroscopic (RMs-dependent and absolute) microanalytical methods.

Three mineral matrices vital to resource technology applications – pyrite, tantalite and feldspar – have been synthesized using flux method, Czochralski method and alkoxide-based sol-gel synthesis, respectively and doped with various sets of technologically important trace elements at the concentration range found in corresponding natural minerals. Their spatial chemical micro-homogeneity has been investigated using light and electron microscopy as well as RMs–dependent (EPMA, LA-ICP-MS) and absolute (PIXE, PIGE) analytical methods.

Quantitative and qualitative elemental spatial distribution maps have been obtained for major and trace elements for each matrix. Homogeneity of the matrices was evaluated using petrologically sensitive statistical analysis.

Established homogeneity testing protocol will be employed in the next stages of the project.

Biomass combustion – a possible source of environmental pollution?

M. MICHALIK[1]*, M. POGRZEBA[2], AND W. WILCZYŃSKA-MICHALIK[3]

[1]Jagiellonian University, Institute of Geological Sciences, ul. Oleandry 2a, 30-063 Kraków, Poland (*correspondence: marek.michalik@uj.edu.pl)
[2]Institute for Ecology of Industrial Areas, ul. Kossutha 6, 40-844 Katowice, Poland (mag@ietu.katowice.pl)
[3]Pedagogical University, Institute of Geography, ul. Podchorążych 2, Kraków, Poland (wanda.michalik@post.pl)

The content of selected elements in biomass (virginia fanpetals; cup plant; switchgrass; eastern cordgrass; miscanthus) grown on contaminated experimental field and in low-temperature ash obtained in 475ºC was studied. The soil is enriched in various elements (e.g. Zn up to 2000 ppm, Pb up to 430 ppm, Cd up to 19 ppm) and contains numerous components of anthropogenic origin (spherical dust particles from high-temperature industrial processes, fragments of various types of metallurgical slag, coal ash, etc.).

The content of potentially toxic elements determined in biomass is relatively high (e.g. Zn up to 545 ppm, Cd up to 8,5 ppm, Pb up tp 115 ppm, Hg up to 24 ppb). The content of these elements in low-temperature ash is very high (Zn from 4100 to >10 000 ppm, Cd from 30 to 207 ppm, Pb from 380 to 2870 ppm, Ag from 171 to 1048 ppb, As from 9 to 22.5 ppm, Hg below 0.5 ppb).

Detailed study of dry biomass indicates that high content of various elements is related partly to dust particles deposited on its surface (e.g. Pb, Cd and Zn sulphides, Zn containing clay minerals, Ca and Ba sulphates, particles rich in Fe, Cr, Ni, etc.) and partly to accumulation of various elements (e.g. Zn) in plant tissue.

Results indicate that in the case of biomass cultivated on the polluted sites risk of emission of elements characterized by low values of boiling point during fuel combustion or leaching of potentially toxic elements from ash to the environment is probable.

Study was supported by NCN grant No. 579/B/P01/2011/40.

Linking reactive silica with organic matter burial in Mississippi delta sediments

P. MICHALOPOULOS * AND K. PARINOS

Institute of Oceanorgaphy, Hellenic Center for Marine Research , Anavyssos, 19013, Greece

Deltaic sediments account for ~40% of organic carbon burial in the oceans. Furthermore poorly crystalline Al-Si-(Fe)-phases precipitate on biosiliceous and clastic particles as a result of reverse weathering reactions in deltaic sediments [1]. Amorphous biogenic silica and poorly crystaline Al-Si-(Fe) precipitates are quantified as reactive silica (RSi). This study examines the links between RSi and sedimentary organic matter in Mississippi delta sediments and the implications for organic matter burial and preservation. Suspended matter and sediment samples from the Mississippi river and seven delta stations were analyzed for reactive silica (RSi), total organic carbon (TOC), total nitrogen (TN) and stable isotopes ($\delta^{13}C$, $\delta^{15}N$).

Top (>50cm) and bottom sediments from delta sites close to the river mouth have identical $\delta^{13}C$, $\delta^{15}N$ values, indicating similar OM sources. In top sediments RSi is not related to TOC or TN. Below 50cm, RSi correlates with TOC,TN suggesting a diagenetic control. Correlations in mid-shelf stations show that TOC:Si, TN:Si ratios decrease from top to bottom, indicating preferential loss of TOC and TN relative to RSi. Stronger coupling between RSi and preserved residual OM is found in mid-shelf sites where sediments are more diageneticaly altered. We propose that formation of Al-Si coatings on biosiliceous particles [2-3] may also partially inhibit the decomposition of diatom-bound OM. During burial, ~34% of residual sedimentary OM appears related to RSi in nearshore and mid-shelf deposits.

Chemical and isotopic features of mafic granulites from Serre massif (Calabria-Italy)

F. MICHELETTI[1]*, A. FORNELLI[1], A. MUSCHITIELLO[1] AND G. PICCARRETA[1]

[1]Earth science and geo-environmental Dep., Bari University Italy, francesca.micheletti@uniba.it

Different types of mafic granulites characterize the lower crust of the Serre Massif (Calabria, Southern Italy). They consist of: layered metagabbros (Pl+Opx+Amph±Cpx±Bt±Qtz±Grt) and metric bodies of meta-monzogabbros (Pl+K-feld+Opx+Cpx+Bt±Qtz±Grt) at the base of the lower crust and lenses or layers of metabasites (Pl+Opx+Cpx±Bt±Amph±Qtz±Grt) interleaved with migmatitic metapelites and felsic granulites overlying the metagabbros. The magmatic protoliths are Neoproterozoic (~570 Ma), whereas the granulite-amphibolite facies metamorphism took place in Variscan times [1].

Metagabbros and metabasites are sub-alkaline (Na_2O+K_2O=1-5%) with K_2O<1%, whereas meta-monzogabbros show alkaline character (Na_2O+K_2O=5-7%) with K_2O around 3% reflecting the contents of biotite.

The meta-monzogabbros showing enrichment of incompatibile elements are interpreted as derived from small degree of partial melting of enriched mantle, probably as underplating magma in Neoproterozoic times. Subsequent or incremental mantle partial melting events produced melts with tholeiitic and calc-alkaline affinities forming the protoliths of metagabbros and metabasites.

The isotopic features (Sm-Nd, Rb-Sr) of metabasites reflect some crust contamination assisted by fluids derived from host metasediments. On the other hand, also the participation of biotite in the partial melting could account for the variation of Rb-Sr characteristics within the metagabbros and metabasites (Fig. 1).

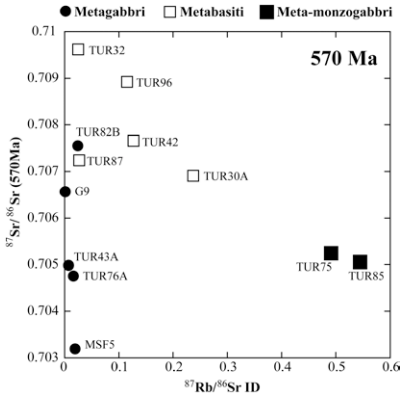

Fig. 1 Rb-Sr isotopic compositions of mafic granulites.

Crustal evolution of the intracontinental Warburton–Cooper–Eromanga Basin system, central Australia

A. W. MIDDLETON*[1], I. T. UYSAL[1] AND S. D. GOLDING[1]

[1]University of Queensland, Queensland 4072, Australia (*correspondence: alexander.middleton@uqconnect.edu.au)

The Warburton–Cooper–Eromanga basins host one of the most prospective hot dry-rock geothermal resources (Big Lake Suite granite; BLS) that stems from unusual enrichment in radiogenic elements (up to 144 ppm Th and 30 ppm U). The overlying Eromanga Basin is also endowed with substantial hydrocarbon reserves. Despite these attributes, holistic basin analysis has not been attempted leaving much of central Australia's crustal evolution poorly constrained. By conducting geochemical and geochronological analyses of primary, vein-hosted and authigenic phases, this study elaborates on its crustal evolution throughout the Palaeozoic and the influences on basin thermal and fluid flow events.

U–Pb (420 ± 6.7 Ma) and U–Th–total Pb (407 ± 16 Ma) of granite-hosted primary zircon and uraninite, respectively, provide coincident ages with Sm–Nd of carbonate veins (437 ± 17 Ma) of Warburton vein carbonates. Authigenic illite from Warburton sediments produce a Rb–Sr isochron age of 323.3 ± 9.4 Ma, consistent with previous U–Pb zircon ages estimating emplacement of the Big Lake Suite (Marshall *et al*. unpublished). Rb–Sr of granite-hosted clay fractions yield ages of 87.4 ± 4.9 Ma and 101.1 ± 6.4 Ma, in agreement with quartz encapsulated Ar–Ar total-gas ages of the same clay separates. Isotopically more robust Sm–Nd dating, however, produces older ages of 128 ± 16 Ma. Calculated $\delta^{18}O$ and δD fluid isotopic values are compatible with an influx of meteoric waters in an extensional environment.

Multifaceted analysis of primary and secondary phases produced geologically significant ages attributed to substantial thermal events throughout basinal evolution. Warburton Basin dates provide evidence of episodic magmatic activity associated with relaxation-related and back-arc extension. Dating of illite from the Cooper–Eromanga constrains intra-cratonic basin formation consistent with episodic rifting of Gondwana and opening of the Tasman Sea along the eastern margin of Australia [1]. Such consistency suggests plate-wide transmission of tensional stress to intra-continental crust weakened by abnormally high geothermal gradients, associated with the BLS, and preceding basinal tectonism [2].

Potential of uranium removal from post-uranium mining heaps by indigenous bacteria

S. MIELNICKI[1]*, L. DREWNIAK[1], M. SZYMKIEWICZ[1], B. REWERSKI[1] AND A. SKLODOWSKA[1].

Laboratory of Environmental Pollution Analysis, Faculty of Biology, University of Warsaw, Warsaw, Poland (*correspondence: smielnicki@biol.uw.edu.pl)

In Poland until 1925 there was no information about existence of uranium ore. First uranium mine was established in Kowary in 1948 and after that uranium ore exploitation in Poland had lasted to 1967. Nowadays low-grade uranium heaps exist in Southern Poland posing potential danger to surrounding environment and human beings. The traditional methods of bioremediation are well known but they are costly and inefficient, moreover they require the use of large volumes of acids which can cause irreversible environmental damages.

Alternative environmental friendly methods can be developed. Indigenous microorganisms can participate in pollution mobilisation and the resulting leak can be collected into the drainage system. Identification of indigenous microorganisms existing in the environment of piles is the first step in the assessment whether the process can take place.

Five sites containing waste with uranium concentration in the range from 112.75 to 2986 mg/L were chosen as a potential places for isolation of microorganisms, metagenomic DNA and *16S rRNA* gene analysis to define microbiological potential. Bacteria from the genus of *Halothiobacillus, Sphingomonas, Pseudomonas* and *Acidithiobacillus* were found as dominant. They are well known as microorganisms able to indirect transformation of uranium compounds.

After 14 days of incubation, indigenous bacteria in acidic conditions (starting pH 2.5) mobilized 0 - 60% of uranium (depending of the type of waste) in comparison to sterile control in which 0-50% of uranium was mobilized respectively.

These preliminary results clearly show that construction of passive bioremediation system is possible and may be efficient.

Gaussberg leicitites – new data on mineralogical and geochemical composition

N.A. MIGDISOVA[1]*, N.M. SUSHCHEVSKAYA[1], B.V. BELYATSKY[2] AND D.V. KUZMIN[3]

[1]Vernadsky Institute for Geochemistry, RAS, Moscow, Russia (*correspondence: nat-mig@yandex.ru)
[2]IPGG, St.Petersburg, Russia
[3]Max-Plank Institute fur Chemie, Mainz, Germany

New geochemical data on Quaternary magmatism of the Gaussberg volcano (Antarctica) confirms the unique features of ultra-potassium alkaline magmatism developed under exclusively continental conditions. Volcanic cone is located on the within Gaussberg rift zone possibly being a part of Lambert fracture zone. The crystallization sequence of Gaussberg volcano lavas is Ol → Ol + Cpx → Ol + Cpx + Lc. Two different types of clinopyroxene phenocrysts were detected: high TiO_2, low Al_2O_3 group (1) and high Al_2O_3 and low TiO_2 group (2). Rare element patterns for whole-rocks are similar to [1]. Rare element distribution for Cpx 1 demonstrates specific signature showing higher LILE values and appreciably lower $D^{Cpx/Lq}$ (two orders of magnitude) then in [2]. These features can be a result of fluid impact on magmatic system. Gaussberg volcano mantle source is enriched in $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ while it has low $^{206}Pb/^{204}Pb$ (≈17.5) value. High $^{87}Sr/^{86}Sr$ (≈0.707-0710) taken together with low $^{143}Nd/^{144}Nd$ (≈0.5119) ratios suggest LOMU-type of primary mantle source.

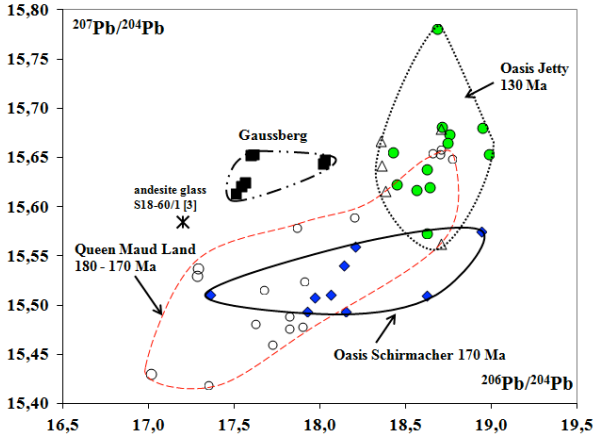

Figure 1: Isotopic data reveal that Gaussberg volcano melts source was the ancient Gondwana lithosphere but not the Antarctic mantle source (Mesozoic plumes)

Kinetics of arsenic sorption on aquifer sediment from Bangladesh imaged by XRF microprobe in flowing columns

I. MIHAJLOV[1]*, B.C. BOSTICK[1], M. STUTE[1,2], I. CHOUDHURY[3], K.M. AHMED[3] AND A. VAN GEEN[1]

[1]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY, USA
(*correspondence: mihajlov@ldeo.columbia.edu)
[2]Barnard College, New York, NY, USA
[3]Dhaka University, Dhaka, Bangladesh

To avoid groundwater arsenic (As) contamination, much of the population of Bangladesh depends on deeper wells that are low in As. Pumping these wells could draw high-As groundwater into currently As-safe aquifers. This research examines the mechanisms of As adsorption on natural aquifer sediments that can help retard the migration of As.

Freshly collected sediment from a low-As aquifer in Bangladesh was used for sorption kinetics studies in low-O_2 batch reactors set up in the field with *in situ* (unoxidized) groundwater, as well as in two small columns run under a synchrotron beam for ~20 hrs. Sorption of As onto column sediments was monitored by continuous X-ray fluorescence (XRF) imagery at 2 or 3 μm resolution, and Fe mineralogy was assessed by XANES at several representative points.

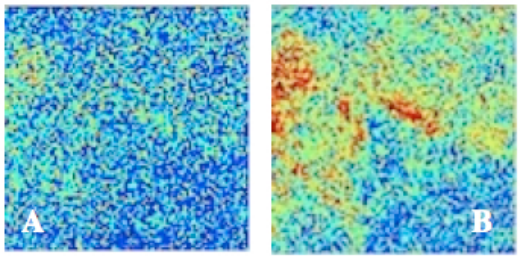

Figure 1: Same-scale and co-located XRF images of As on column sediment at time 0 (A) and after 16 hrs of continuous flow (B). Warmer colors indicate higher concentrations.

Results from both batch and beam column experiments consistently indicated that As adsorption proceeded at a high initial rate (k~0.5 hr^{-1}) over the first 1-3 hrs, after which it progressively slowed down by 1-2 orders of magnitude. Sites responsible for rapid initial adsorption varied widely in mineralogy and reactivity, while later adsorption rate was more uniform and focused on sites correlated to Fe concentrations. Microscale measurements supplement the macroscopic data and indicate that As transport is kinetically limited by diffusive processes on the grain scale or smaller.

Copper and lead isotope ratios as tracers of soils pollution from the Kombat mining area, Namibia

MARTIN MIHALJEVIC[1]*, VOJTECH ETTLER[1], BOHDAN KRIBEK[2], VLADISLAV CHRASTNY, ALES VANEK[3] AND VIT PENÍZEK[3]

[1]Institute of Geochemistry, Mineralogy and Mineral Resources, Charles University in Prague, Albertov 6, 128 43 Prague 2, Czech Republic
(*correspondence: mihal@natur.cuni.cz)
[2]Czech Geological Survey, Geologicka 6, 152 00 Prague 5, Czech Republic
[3]Department of Soil Science and Soil Protection, Czech University of Life Sciences Prague, Kamycka 129, 165 21, Prague 6 – Suchdol, Czech Republic

Copper (Cu) and lead (Pb) concentration, isotopic composition (65Cu/63Cu, 206Pb/207Pb) were studied in contaminated and non contaminated luvisols and mollisols from the Kombat mining area, Namibia. The Cu and Pb concentrations in the studied soils ranged between 21 mg/kg – 757 mg/kg, and 19 mg/kg – 815 mg/kg respectively. Concentration of both metals increased with increasing soil depth. The Pb isotopic signatures ($^{206}Pb/^{207}Pb$) in soils ranged between 1.15 – 1.21. In most of soil samples, surface horizons exhibited lower $^{206}Pb/^{207}Pb$ ratio, which originates from the slime dust pollution ($^{206}Pb/^{207}Pb$ ~ 1.15) compared to deeper soil horizons, with lithogenic Pb signatures. Isotopic composition of Cu differs on contaminated and uncontaminated sites and cultivated and non-cultivated sites. The $\delta^{65}Cu$ in the studied soil horizon ranged between –0.373 ‰ and 0.561 ‰. The most pronounced variations occurred in contaminated non cultivated soils (0.529 ‰). The contaminated surface horizons are enriched in isotopically heavier Cu (tailing materials), and $\delta^{65}Cu$ decreased with depth. Fractionation of Cu isotopes in soils is attributed to mobilization of lighter isotope, and preferential binding of heavy isotopes on secondary soil components. This study was supported by the Czech Science Foundation (projectP210/12/1413) and IGCP project no. 594.

Ar-Ar and U-Pb isotopic ages of Early Caledonian granulites from the Svyatoy Nos Peninsula (Transbaikalia)

E.I. MIKHEEV[1], A.G. VLADIMIROV[1,2*,3], A.V. TRAVIN[1], T.B. BAYANOVA[4] AND N.I. VOLKOVA[1]

[1]IGM SB RAS, Novosibirsk 630090, Russia (mikheev@igm.nsc.ru, travin@igm.nsc.ru)
[2]Novosibirsk State University, Novosibirsk 630090, Russia (*correspondence: vladimir@igm.nsc.ru)
[3]Tomsk State University,Tomsk 634050, Russia
[4]GIN KSC RAS, Apatity 184209, Russia (tamara@geoksc.apatity.ru)

Metamorphic rocks of Svyatoy Nos Peninsula (Transbaikalia) are basic granulites, graphitic marbles, diopside plagioschists and quartzites. The P-T metamorphic conditions are estimated to be 815-860°C and 7.9 to 8.3 kbar. The granulites are intruded by abundant veins of syntectonic granites and granitic pegmatites attributing to Barguzin Complex of the Angara-Vitim batholith (280-298 Ma) [1]. The U-Pb zircon dating of single grains indicates age of granulite metamorphism at 495 ± 5 Ma.

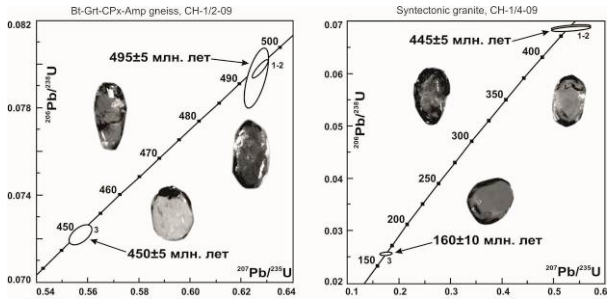

Figure: U-Pb dating of single zircon grains from Svyatoy Nos Peninsula granulites.

Syntectonic granosyenite-granites connecting with intense strike-slip deformations gave ages of 450 ± 5 and 445 ± 5 Ma. Ar-Ar ages on amphibole (256 - 245 Ma) probably date a thermal effect from the Angara-Vitim Batholith.

The sponsorships are the the Earth Sciences Department of SB RAS (IP ONZ-10.3, IP №77) and Federal Grant Programme of Russia (project № 2012-1.2.1-12-000-2008-8340).

Multiphase inclusions with kokchetavite and K-cymrite in UHP calc-silicate rocks from Kokchetav massif

ANASTASIA O. MIKHNO[1]* AND ANDREY V. KORSAKOV[1]

[1]V.S. Sobolev Insitute of Geology and Mineralogy SB RAS, Novosibirsk 630090, Russia (*correspondence:mao14@list.ru)

Ultrahigh pressure (UHP) rocks of the Kokchetav massif are of particular interest as they were exhumed from at least 120 km depth [1] and experienced peak metamorphic conditions of approximately T = 1000-1100 °C and P = 6-7 GPa [2].

Here we present findings of K-cymrite ($KAlSi_3O_8 \cdot H_2O$) and kokchetavite ($KAlSi_3O_8$) in association with muscovite/phengite, lollingite, calcite and α-cristobalite in multiphase mineral inclusions in ultrapottasic clinopyroxene (K-Cpx) porphyroblasts of calc-silicate rocks (Kokchetav massif, Northern Kazakhstan). These inclusions were interpreted to be melt at peak metamorphic conditions [3]. Findings of K-cymrite and kokchetavite in polyphase inclusion along with experimental data on K-cymrite calcination [4] proves model of kokchetavite formation through the dehydration of K-cymrite. Presence of K-cymrite in multiphase inclusions in K-Cpx porphyroblasts testifies for high K_2O-content which should be nearly equimolar to H_2O-content in melt [5]. Korsakov *et al*. [6] supposed that gneisses underwent melting to form K_2O-rich melt which migration and further reaction with the carbonate interlayers caused the formation of the calc-silicate rocks with K-Cpx. Neither kokchetavite, nor K-cymrite were reported in gneisses. This fact could imply that melt in gneisses should contain less amount of K_2O, than that in calc-silicate rocks. Therefore we assume that K-rich melt was formed during the prograde metamorphic stage at low melting degrees and than migrated to calc-silicate rocks protholith to form K-Cpx. During peak metamorphic conditions gneisses underwent extent melting which decreased K_2O-content in melt.

Transmission electron microscopy of iron metal in Almahata Sitta ureilite

T. MIKOUCHI[1]*, K. YUBUTA[2], K. SUGIYAMA[2], Y. AOYAGI[1], A. YASUHARA[3], T. MIHIRA[3], M.E. ZOLENSKY[4] AND C.A. GOODRICH[5]

[1]Dept. Earth & Planet. Sci., Univ. of Tokyo, Tokyo 113-0033, Japan (*correspondence: mikouchi@eps.s.u-tokyo.ac.jp)

[4]ARES, NASA-JSC, Houston, TX 77058, USA
[5]Planet. Sci. Inst., Tucson, AZ 85719, USA

Almahata Sitta (AS) is a polymict breccia mainly composed of various ureilite lithologies with lesser chondritic lithologies [1]. Fe metal is a common accessory phase in ureilites, but our earlier studies on Fe metals in one of AS fragments (#44) revealed unique features never seen in other ureilites [2,3]. In this abstract we report detailed transmission electron microscopy (TEM) on these metal grains to better understand the thermal history of ureilites.

We prepared FIB sections of AS#44 by JEOL JIB-4000 from the PTS that was well characterized by SEM-EBSD in our earlier studies [2,3]. The sections were then observed by STEM (JEOL JEM-2100F).

One of the FIB sections shows a submicron-sized intergrown texture composed of Fe metal (kamacite), Fe carbide (cohenite), Fe phosphide (schreibersite), and Fe sulfide (troilite). Probably, this eutectic-looking texture was formed by shock re-melting of pre-existing metal + graphite + phosphates (phosphide?) + sulfides with various amounts.

The other FIB section is mostly composed of homogeneous Fe metal (93 wt% Fe, 5 wt% Ni, and 2 wt% Si), but BF-STEM images exhibited the presence of elongated lathy grains (~2 μm long) embedded in an interstitial matrix. The SAED patterns from these lath grains could be indexed by α-Fe (*bcc*) while interstitial areas are γ-Fe (*fcc*). The elongated α-Fe grains show tweed-like structures suggesting martensite transformation. Such a texture can be formed by rapid cooling from high temperature where γ-Fe was stable. Subsequently α-Fe crystallized, but γ-Fe remained in the interstitial matrix due to quenching from high temperature. Presence of C may have enhanced its stability. This scenario is consistent with very rapid cooling history of ureilites suggested by silicate mineralogy.

Structure of Amorphous Ferric Arsenate from EXAFS Spectroscopy and Total X-ray Scattering

CHRISTIAN MIKUTTA[1]*, F. MARC MICHEL[2], PETAR MANDALIEV[1] AND RUBEN KRETZSCHMAR[1]

[1]Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland (*christian.mikutta@env.ethz.ch)
[2]Virginia Tech, Blacksburg, USA

Amorphous ferric arsenate ('AFA', $FeAsO_4 \times nH_2O$) is a secondary As precipitate frequently encountered in acid mine-waste environments. Its structure has been proposed to resemble that of scorodite ($FeAsO_4 \times 2H_2O$) in which isolated FeO_6 octahedra share corners with four adjacent arsenate (AsO_4) tetrahedra in a three-dimensional framework (framework model). Conversely, AFA was postulated to consist of single chains of corner-sharing FeO_6 octahedra being bridged by arsenate (chain model). In order to test the accuracy of both structural models, we synthesized AFAs and analyzed their structure by As and Fe *K*-edge extended X-ray absorption fine structure (EXAFS) spectroscopy and total X-ray scattering. We found that both As and Fe *K*-edge EXAFS spectra were most compatible with isolated FeO_6 octahedra being bridged by AsO_4 tetrahedra ($R_{Fe\text{-}As}$ = 3.33 ± 0.01 Å). Wavelet-transform analyses of the Fe *K*-edge EXAFS spectra of AFA complemented by shell fitting confirmed Fe atoms at an average distance of 5.3 Å, consistent with crystallographic data of scorodite and in disagreement with the chain model. Reduced pair distribution functions, $G(r)$, provided unequivocal evidence for the absence of single corner-sharing FeO_6 linkages in AFA. Analyses of radial distribution functions, $R(r)$, additionally indicated that in AFA each As atom has on average about four nearest Fe neighbors, in accordance with the framework model. In summary, our findings imply that scorodite formation from AFA in mining environments proceeds via growth of small clusters with a scorodite-type local structure.

Unconventional generation of hydrocarbons in petroleum basin: the role of siderite/water interface

V. MILESI[1]*, A. PRINZHOFER[2], F. GUYOT[1,3], F. BRUNET[4], LAURENT RICHARD[5], J.DAIROU[6] AND M. BENEDETTI[1]

Hydrocarbons in the petroleum basin of Solimões in Northern Brazil show isotopic trends similar to those of abiotic hydrocarbons observed in oceanic hydrothermal systems.

High concentrations of ferrous iron in the brines indicate a highly reduced environment. Such redox conditions are consistent with the large amount of siderite $FeCO_3$ in the sediments. The capacity of siderite-water interactions to generate unconventional hydrocarbons has been tested experimentally.

Synthetic $FeCO_3$ and water were reacted in gold containers at 500 bars, 200°C and 300°C. Siderite dissolution led to reducing conditions due to magnetite formation. In addition, at 200°C, TEM showed the precipitation of a nanometric layer of amorphous carbon covering magnetite grains. At 300°C, H_2 was produced and reacted with CO_2 to generate organic compounds such as methane and carboxylic acids [1]. The dissolved organic compounds concentrations are consistent with a cascade of reduction from CO_2 to CH_4 [2].

Alternatively, CH_4 could form through the hydrogenation of the amorphous carbon coating observed on magnetite grains. This latter mechanism is more consistent with the isotopic data from the Solimões basin where, in addition, senile kerogen and H_2-rich fluids coexist. Experimental validation is currently underway.

A new calibration of the carbonate clumped isotope thermometer based on synthetic calcites

I. MILLÁN*, S. BREITENACH, N. MECKLER, M. ZIEGLER AND S. M. BERNASCONI

ETH Zürich, Geologisches Institut, Sonneggstrasse 5, 8092 Zürich, Switzerland.
(*correspondence: isabel.millan@erdw.ethz.ch)

Previous calibrations of the clumped isotope thermometer based on synthetic calcites differ in the inferred relationship between isotopic ordering in the carbonate and temperature [1, 2]. The "absolute reference frame" proprosed by Dennis *et al.* [3] improved the interlaboratory comparison but did not eliminate the discrepancies between the laboratories. It is clear that especially for inorganically precipitated carbonates more experimental data are needed. Here we present a new calibration on synthetic calcites and compile all published calibration data available to date.

Our new calibration is based on 11 synthetic calcites precipitated at known temperatures between 4°C and 80ºC. $CaCO_3$ was precipitated inorganically by mixing solutions of $NaHCO_3$ (0.1M) and $CaCl_2$ (0.1M) at the desired temperatures. The solutions were kept at known temperatures in incubators for 5 days before starting the experiments. Analyses were conducted at ETH on small carbonate samples (ca. 170-220 μg) using a Kiel IV Carbonate Device coupled to a Thermo Finnigan MAT 253 Mass Spectrometer [4]. The samples were measured multiple times on different days, with each measurement consisting of 9-15 analyses of separate aliquots. Data are presented relative to the "absolute reference frame" [3].

We find a robust linear relationship between Δ_{47} and temperature of precipitation. We discuss several issues related to the slope of the linear regression through Δ_{47} plotted against solution temperatures and the compilation of previous calibrations in the absolute reference frame.

Hot/cold, wet/dry, big/small, erupt/stall, juvenile/anatectic? – Multiple personalities of felsic magmatism

C.F. MILLER[1]*, S.M. MCDOWELL[1], T.L. CARLEY[1], W.O. FRAZIER[1], A.S. PAMUKCU[1], A.DEJ. PADILLA[1], L.L. CLAIBORNE[1], D.M. FLANAGAN[1], G.A.R. GUALDA[1], J.S. MILLER[2], J.L. WOODEN[3] AND R.W. MAPES[4]

[1]Vanderbilt Univ, Earth & Environmental Sciences, Nashville USA, calvin.miller@vanderbilt.edu (* presenting author)

[2]San Jose State U, Geology, San Jose USA, jonathan.miller@sjsu.edu
[4]ExxonMobil, Houston TX USA, russmapes@gmail.com

Felsic magmas are linked by qtz-feldspar-melt equilibria that limit their range of major element compositions. Crustal processing is thus clearly a common factor in production of all such magmas, but this does little to resolve – and in fact obscures – longstanding and recent controversies concerning sources, generation and emplacement processes, evolution, and relationships between felsic plutonism and volcanism.

Field, geochemical, and geochronological characteristics of similarly silicic rocks from a variety of environments we have investigated* reveal remarkable diversity:

- Scales: small (~10^{-3} km^3 - increments in some plutons, small eruptions) to giant (10^3 km^3 supereruptions)
- Initial temperatures: ~700 C to near 1000 C
- Zircon inheritance: negligible to dominant
- Entrained crystal fractions: negligible to near lock-up
- Initial water contents: ~dry to wet (≤3 to near 10 wt%)
- Clear volcano-pluton connections, as well as plutons unlikely to have erupted counterparts and eruptions unlikely to have left appreciable plutonic residue
- Isotopically juvenile to ancient crust-dominated
- Involvement of mafic magma: obvious in some, apparently limited in others, absent or occult in yet others

Characteristics generally correlate and suggest that (1) cool, wet, crystal-rich magmas, largely anatectic, are doomed to stall without eruption; (2) very large magma volumes ('big tanks') may reflect unusual thermal input, either initially producing huge volumes or mobilizing stagnant mushes. Intriguing departures from simple relationships warrant further consideration – e.g. large variations in T and magma volumes in closely associated magma systems, isotopically primitive granitoids with abundant ancient zircon inheritance, very hot felsic magmas with no obvious mafic input.

Chalcopyrite in the R chondrite PRE 95411

K.E. MILLER[1]*, M.S. THOMPSON[1], T.J. ZEGA[1] AND D.S. LAURETTA[1]

[1]Lunar and Planetary Laboratory, Dept. of Planetary Sciences, University of Arizona, Tucson, AZ 85721 (*correspondence: kemiller@lpl.arizona.edu)

The R chondrites record petrologic grades from 3 to 6, suggesting parent-body histories from unaltered to nearly equilibrated. However, a growing body of evidence suggests the group may have experienced hydrothermal alteration. Reports of amphibole, biotite, and chalcopyrite in the R chondrites all support aqueous processes [1-3]. Recent observations of hydrous minerals in a second R chondrite and other indications of aqueous alteration appear to corroborate the earlier results [4, 5]. Here we expand on these efforts and report an investigation of chalcopyrite in a sulfide assemblage in the R3 chondrite PRE 95411.

Electron microprobe analysis indicates the assemblage is primarily composed of pyrrhotite with minor pentlandite, troilite, and chalcopyrite. Based on previously described methods [6], we used focused ion beam scanning electron microscopy (FIB-SEM) to prepare an electron-transparent cross section of the assemblage for transmission electron microscope (TEM) analysis [7]. Selected-area electron-diffraction confirms the presence of chalcopyrite and troilite. Energy-dispersive X-ray spectrometry shows that the chalcopyrite and troilite grains are bifurcated by an Fe-Ni-O-rich vein. The vein center contains a linear domain of Fe-rich, Ni-poor nanocrystalline material. In comparison, the material around the domain is amorphous and relatively Ni-rich and Fe-poor. Chemical mapping also reveals that the grain boundary between troilite and the chalcopyrite is enriched in Cu. These microstructural features are reminiscent of those associated with a cubanite grain in the Orgueil CI chondrite [8], suggesting hydrothermal alteration.

These results indicate that the R chondrites experienced volatile-rich conditions. Improved understanding of the distribution of volatiles provides important constraints on the formation and evolution of the solar system.

Significant observed copper isotopic abundance variations in biological materials.

KERRI MILLER[1]*, TYLER COPLEN[2] AND MICHAEL WIESER[1]

[1]Department of Physics and Astronomy, University of Calgary, 2500 University Drive NW, Calgary, AB, T2N 1N4, Canada, kamiller@ucalgary.ca (*presenting author)
[2]US Geological Survey, 12201 Sunrise Valley Drive, Reston, VA, 20192, USA

Copper is an essential nutrient in both flora and fauna and has proven to be critical in maintaining homeostatic balance by participating in many metabolic processes. Copper has two naturally occuring stable isotopes, ^{63}Cu and ^{65}Cu. The ratio between the amounts of these two isotopes can be used to indicate the source of copper to an organism, give insight to cycling processes as well as metabolic pathways. Natural variations in copper isotopic composition have a measured range of 9 ‰ in geological materials and 3 ‰ in water samples [1, 2]. Recent evidence has shown that the assimilation and subsequent use of copper in an organism may cause further fractionation. This has been demonstrated in mice where it was shown that modified gene expression caused a shift in isotopic composition of copper in the brain [3]. In a recent study, participants with Parkinson's disease demonstrated differences in the metabolism of copper isotopes [4].

In order to explore the copper isotope variability in living systems, select samples were analyzed: exotic wood samples, wild animal hair, and hair and fingernails samples from local Calgary residents. Wood samples were analyzed as part of an ongoing project to determine if isotopic systems can be used to identify the geographic origins of the wood in an effort to prevent illegal trading. Hair samples from wildlife in Alberta were analyzed to determine if copper isotopes can be used to identify the dominant source of food. Hair and nail samples from local Calgary residents were also analyzed and compared to the local drinking water. A range in δ^{65}Cu of over 20 ‰ was observed.

Construction of high-resolution trace element time-series in slow growth speleothems by ELA-ICP-MS: Challenges, new approaches and validation strategies

NATHAN R. MILLER*AND JAY L.BANNER[1]

[1]Department of Geological Sciences, The University of Texas at Austin, Austin, TX 78712-1722, USA (*correspondence: nrmiller@jsg.utexas.edu)

Speleothems hold important potential to record terrestrial paleoclimate variations over millennial scales, as increasingly supported by monitoring studies of modern karst systems. Trace element variations in drip waters and corresponding plate calcite samples demonstrate the potential for subannual resolution in settings having well-expressed seasonality (rainfall, temperature). The high sensitivity and rapid peak-hopping capabilities of quadrupole ICP-MS, integrated with the superior coupling capacity and high spatial accuracy of modern excimer 193 nm laser ablation systems (ELA-ICP-MS line scans), offers an efficient means for constructing high-resolution chemical time-series in growth-banded speleothem calcite. However, application of the technique becomes increasingly challenged with decreasing speleothem growth rates, a factor that has relegated most high-resolution trace element studies to growth rates exceeding 100 μm/yr. Slow-growth speleothem records (< 50 μm/yr) present three significant challenges to ELA-ICP-MS, namely: (1) growth banding is often not visible by standard petrographic techniques, let alone via imaging of the laser ablation system; (2) the crystallographic fabric comprising growth bands develops as successions of rhombohedral overgrowths, the scale and geometry of which can compromise the goal of obtaining unaliased stratigraphic sampling; and (3) achieving counting statistics capable of resolving subannual chemical signals is more difficult due to the need for small apertures (lower signal-to-noise) and because of more limited "dwelling" time within growth band intervals associated with rapid chemical gradients. Parallel-offset line traverses, a well-established approach for evaluating reproducibility of chemical signals, often do not show high correspondence due to such localized sample aliasing – raising the question "We know what we are targeting, but do we know what we are hitting? We reiterate the importance of locating laser ablation line scans from the informed perspective of oriented growth band fabric imagery, and developing analytical validation strategies that demonstrate the capacity to resolve slow-growth chemical waveforms.

Geochemical stratigraphy and correlation within the Faroe Islands Basalt Group: Temporal and Spatial Evolution of Mantle Sources during Continental Rupture

MILLETT, J. M[1]*., HOLE, M. J[1]., JOLLEY, D. W[1]. AND PASSEY, S. R.[2]

[1]Department of Geology & Petroleum Geology, Meston Building, Kings College, University of Aberdeen, Aberdeen, AB24 3UE UK (*correspondence: j.millett@abdn.ac.uk)

[2]*CASP, West Building, 181A Huntingdon Road, Cambridge CB3 0DH, UK*

The geochemical signatures recorded during periods of Large Igneous Province (LIP) volcanism provide important evidence as to mantle sources and magmatic evolution through time. Our understanding of the temporal development of these provinces relies on both accurate stratigraphical sampling constraints of flood basalt sequences along with the integration of available age-dating methods. In this contribution we present new major, trace and mineralogical element data for the Faroe Islands Basalt Group (FIBG), NE Atlantic. The FIBG records a near continuous ~6.6km composite eruptive succession of the Palaeogene aged North Atlantic Igneous Province. All the data is stratigraphically constrained within a GIS database and has been compared to biostratigraphic and sedimentary inter-bed geochemical data which allows high resolution inference into the timing of eruption events during continental rupture. Distinct mantle source variations occur at a number of intervals through the stratigraphy including N-MORB-like and enriched 'Icelandic' sources. The integration of the new flow by flow data for the lower Beinisvørð and upper Enni Formations helps constrain the timing and the nature of these transitions. A distinct transition from Nb-depleted N-MORB-like to a Nb-enriched 'Icelandic' source is recorded in the last few flows of the first major phase of FIBG volcanism. This transition immediately precedes the regional hiatus recorded by the Prestfjall Formation before renewed N-MORB-like source volcanism. The timing of this hiatus, directly after the short lived onset of 'Icelandic' source volcanism implies a potential link between magma plumbing and tectonic reorganisation at the time. The Enni Formation at the top of the FIBG encompasses at least two inter-digitating flow fields sourcing separate high-TiO2 enriched sources and a low-TiO2 MORB-like source. The distribution of distinct geochemical lava groups on the Faroe Islands are demonstrated to overlap both in space and time. The present results have important implications to correlation attempts involving lava geochemistry on both the local and regional scale.

Lithium isotopes in surficial waters: examples from rivers and peatlands

ROMAIN MILLOT[1]*, PHILIPPE NÉGREL[1], ANNE-MARIE DESAULTY[1] AND AGNÈS BRENOT[2]

[1] BRGM, Laboratory Division, Orléans, France (* correspondence : r.millot@brgm.fr)

[2] BRGM, Territorial Activities Division, Lyon, France

In the present work, we report data for lithium and its isotopes in two different hydrosystems in France: the Loire River basin and the Sauvetat peatland system within the Massif Central (part of the Loire catchment).

Assessing the behaviour of lithium and the distribution of Li isotopes during weathering is of major importance for studying water/rock interactions at the surface of the Earth. This is because lithium (^{6}Li ~ 7.5% and ^{7}Li ~ 92.5%) is a fluid-mobile element and, due to the large relative mass difference between its two stable isotopes, it is subject to significant low temperature mass fractionation which provides key information on the nature of weathering processes.

The Loire River in central France is approximately 1010 km long and drains an area of 117 800 km^2. Lithium concentrations in river waters of the Loire River main stream and the main tributaries span a wide range from 3.4 to 46.5 μg/L, whereas δ^7Li are between +5.0 and +13.3‰. There is a clear contrast between the headwaters upstream and rivers located downstream in the lowlands, with a siginificant decrease of the δ^7Li with the distance from the source. In addition, one of the major tributaries in the Massif Central (the Allier River) is clearly influenced by inputs from mineralized waters resulting of hydrothermal activities having lower δ^7Li values.

Concerning the peatland system in the Sauvetat area, we explore the use of Li and its isotopes as a proxy of ground-to-surface water exchanges in a peatland from a mire-lake complex in the French Massif Central, with the aim to investigate the capability of Li isotopes as hydrogeological tracers. Variations in δ^7Li values can be used to distinguish between precipitation, groundwater and anthropogenic inputs (significantly enriched in ^{7}Li) in peat lands, providing a unique perspective on the hydrologic dynamics of the system.

These two examples reveal important information about lithium and its isotopes but, considered together, provide a more integrated understanding of the factors controling lithium isotopic distribution in surficial waters.

Global silicate weathering: not always in control of climate, and not required to balance global degassing

BENJAMIN MILLS[1], ANDREW J. WATSON[1] AND TIMOTHY M. LENTON[2]

[1]School of Environmental Sciences, University of East Anglia, Norwich, NR4 7TJ, U.K.

[2]College of Life and Environmental Sciences, University of Exeter, Exeter EX4 4PS, UK.

Silicate weathering and carbonate deposition allows for net transfer of CO_2 from the atmosphere to the crust, and dependence of the rate on local temperature and CO_2 concentration stabilizes long term climate [1].

However, the operation of this process is considerably more complex than the simple kinetic relationships employed in current models. Limitation at the global scale via transport of cations is possible either under very high temperature/CO_2, such as following a snowball Earth event [2], or under very low erosion rates, such as during the Mezozoic. In both of these cases, climate stability may have been unattainable for long periods.

In the Precambrian, smaller continental area and lack of biotic soils likely provided harsh limitation of the silicate weathering flux, requiring the operation of an additional stabilizing mechanism to counter the higher degassing rates expected. Seafloor carbonatization appears to be a likely candidate [3], and additional climate regulation via this process decouples the the global silicate flux from CO_2 degassing rates.

The action of two independent stabilizing mechanisms allows for the global silicate weathering rate to increase permanently in response to biological or tectonic enhancements. We suggest that increasing rates of organic carbon burial over time (leading to planetary oxygenation), as well as changes in CO_2 dynamics, may be linked to a progressive increase in terrestrial chemical weathering rates.

A rise of oxygen in the atmosphere and oceans is one of the most popular explanations for the relatively late and abrupt appearance of animal life on Earth [1, 2]. Multiple lines of geochemical evidence support an oxygenation and ventilation of the Ediacaran ocean (635–542 Ma), corresponding with the diversification of complex life, and supporting oxygen's role as the driving environmental factor behind the rise of metazoans [3, 4, 5, 6]. However, the critical concentration of oxygen required for primitive animals remains ambiguous. Therefore, in order to evaluate the oxygen-trigger hypothesis for animal origins, the minimum oxygen concentration supportive of animal life, in general, needs to be experimentally determined.

Our experiments show that modern demosponges, serving as analogs for early animals, can survive under low-oxygen conditions of 0.5-4.0% present atmospheric levels. Given that the last common ancestor of metazoans likely exhibited a physiology and morphology very similar to those of modern sponges [7, 8], its oxygen demands may have been met well before the marine redox shifts of the Ediacaran Period. Therefore, while animals certainly require oxygen, their origination did not necessarily require a contemporaneous rise in the oxygen content of the atmosphere and oceans. Our results, overall, suggest that the relatively late origination of animal life on Earth was not due to restrictively low levels of environmental oxygen that were finally lifted during the Neoproterozoic Era.

Fluid flow and redox metal cycling in Cayman Trough hydrothermal sediments

RACHEL A. MILLS[1]*, WILLIAM B. HOMOKY[1]
AND THE DEEPESTVENTS SHIPBOARD SCIENTIFIC TEAM

[1]Ocean and Earth Science, University of Southampton, National Oceanography Centre Southampton, SO14 3ZH, UK (*correspondence: rachel.mills@soton.ac.uk, w.homoky@soton.ac.uk)

Metalliferous sediments accumulate adjacent to active hydrothermal vent sites via mass wasting of mound debris and fall-out of particles from hydrothermal plumes. Continued redox reactions at the limit of oxygen penetration lead to 'zone refining' of the sediment pile and metal enrichment around the active redox front [1]. Diffusive processes and active circulation of dilute hydrothermal fluids through the sediments may lead to significant fluxes of some elements into and out of the seafloor, though this is poorly constrained and not included in evaluations of ocean budgets for these elements.

We present dissolved micro-nutrient trace metal pore-fluid data for representative sediments from the Beebe Vent Field [2]. The Beebe Vent Field fluids are extremely deep (5000 m), high temperature (>400°C) and metal-rich. Fragile sulfide chimneys topple readily to form metalliferous sediments which are oxygen depleted within 3-7 mm of the seawater interface. The deep sedimentary setting precludes significant carbonate accumulation at the seafloor and pelagic sedimentation is minimal leaving weathered sulfide exposed to seawater. Primary chimney mineral phases which dominate the sediment, break down during seafloor weathering and there is a flux of reduced metals to the overlying water column associated with this sedimentary reprocessing. Therefore, secondary processing of hydrothermal material during active weathering of seafloor deposits can lead to enhanced fluxes of trace metals to the ocean which are then transported out of the benthic boundary layer via plume entrainment and dispersal over signficant distances.

Biomass residues from different classes of soil microorganisms are a significant source of soil organic matter

A. MILTNER*, J. ACHTENHAGEN, C. HOFFMANN-JÄNICHE, M. SCHWEIGERT, M. BRAECKEVELT, F.-A. HERBST, J. SEIFERT, T. FESTER AND M. KÄSTNER

UFZ - Helmholtz Centre for Environmental Research, Leipzig, Germany (*correspondence: anja.miltner@ufz.de)

Introduction

Cell envelope fragments originating from soil microorganisms were demonstrated to contribute significantly to the formation of soil organic matter (SOM) [1]. This hypothesis was supported by chemical and microscopic analyses [1] as well as by NMR spectroscopy [2]. Different classes of soil microorganisms have different chemical compositions of their cell envelopes and thus may contribute to SOM formation to a different extent. We compared the fate of *Escherichia coli* (Gram-negative bacterium), *Bacillus subtilis* (Gram-positive bacterium) and *Laccaria bicolor* (ectomycorrhizal fungus) in soil to estimate their relative contributions to SOM formation.

Material and Methods

^{13}C-labeled organisms produced by culturing them on labeled glucose were mixed with soil and incubated for up to 224 days. Isotopic data of soil and CO_2 released by respiration were used to set up mass balances. Additional information about the fate of the biomass C was derived from quantitative and isotopic analyses of fatty acids and amino acids. Selected samples were also analysed by scanning electron microscopy.

Results and Discussion

For all classes of microorganisms, substantial amounts of the label remained in the soil. Fungal biomass was mineralised slower than bacterial biomass, with Gram-negative bacteria being mineralised slightly slower than Gram-positive ones. The amount and isotopic composition of the biomolecules showed that substantial amounts of the bacterial biomass-derived C were incorporated into non-living SOM. Proteins seemed to be particularly prone to stabilision in soil: Highly labeled *B. subtilis* proteins were detected until the end of the experiment. Biomass residues of all types of soil organisms thus contribute to SOM formation, and proteins seem to be involved significantly in this process.

Role of zero-valent sulfur in marine methane oxidation

J. MILUCKA[1]*

[1]Max Planck Institute for Marine Microbiology, 28359 Bremen, Germany (*correspondence: jmilucka@mpi-bremen.de)

Sulfate is the main oxidant for seafloor methane, and the transition zones of methane and sulfate thus play a key role in the biogeochemical carbon cycling in methane-bearing marine sediments. Our recent results[1] suggest that the impact of anaerobic oxidation of methane (AOM) on the marine sulfur cycle might be just as important.

Using a suite of microbiological and experimental biogeochemical approaches, such as cultivation, stable- and radio-isotope labelling experiments and single-cell-based techniques, we have investigated microbial sulfur cycling associated with marine methane oxidation in microbial enrichment cultures. We could show that during AOM sulfate is only partially reduced to zero-valent sulfur, which is stored intracellularly as a mixture of cyclo-octasulfur and soluble polysulfides. The release of the produced sulfur from the cells provides a local source of zero-valent sulfur in sulphidic marine sediments. Furthermore, we could show that the produced zero-valent sulfur in a form of disulfide can be further disproportionated to sulfate and sulfide by bacteria associated with the methane-oxidizing archaea.

Our observations show an unexpectedly diverse metabolic potential of the AOM microorganisms and expand the physiological diversity of known microbial sulfur metabolisms. Moreover, our results suggest a solution to the long-standing mystery of a missing intermediate in AOM by suggesting a key role of zero-valent sulfur in this process. These new insights have important implications for the biogeochemical carbon and sulfur cycling in marine sediments.

Record of bacterial sulfate reduction during 50~210 kyr ago in the submarine hypersaline Meedee Lake, off Crete Island, Eastern Mediterranean Sea.

H. MINAMI[1]*, K. E. YAMAGUCHI[1,2], H. NARAOKA[3], M. MURAYAMA[4], M. IKEHARA[4] AND H. TOKUYAMA[4]

[1]Dept. Chem., Toho Univ. (6113023m@nc.toho-u.ac.jp); [2]NASA Astrobiology Inst. (NAI); [3]Dept. Earth & Planet. Sci, Kyushu Univ. [4]Ctr for Adv. Marine Core Res. (CMCR), Kochi Univ.

Meedee Lake (2920m deep) is a submarine, hypersaline lake with its salinity >10 times higher than that of normal seawater, due to elution of submarine evaporites formed during Messinian Salinity Crisis 5.33 to 6 Ma ago. The density-stratified lake water has been kept anoxic due to consumption of dissolved O_2 by decomposition of organic matter sinking from the overlying water.

In order to understand changing redox state and microbial activity in the submarine extreme lake environment, sediment core was collected from the margin of the lake. The core shows alternation of pyrite-bearing light- and Fe-oxide-bearing dark-colored layers reflecting fluctuating redox during deposition [1].. The sulfate-rich lake hosted sulfate-reducing bacteria.

To obtain insight into biogeochemical S cycling in the lake, we measured abundance of S-bearing species by sequential extraction method. Five phases were separately quantified: (1) AVS (acid volatile sulfide), (2) pyrite, (3) sulfate, (4) organic-S, and (5) elemental S, by using a method of [2], a combination of [3, 4, 5]. Isotopic compositions of these phases were measured by EA-IRMS at Kyushu University.

Sulfate was found to be the most abundant species, accounting for 90% in both light and dark layers. The isotopic compositions ($\delta^{34}S_{SO4}$ vs. VCDT) vary greatly from +16‰ to +32‰. Such large fluctuations are most likely due to variable (a) degrees of sulfate utilization by sulfate-reducing bacteria (SRB) and/or (b) sulfate concentration. When activity of SRB was not enhanced, sulfate utilization by SRB was not complete, and/or sulfate concentration is reasonably high, then the $\delta^{34}S_{SO4}$ values would not have much changed from their original seawater value (+21‰). Contrary, when activity of SRB was enhanced and sulfate utilization was near complete, then the $\delta^{34}S_{SO4}$ values would have progressively increased from ~21‰ (i.e., Rayleigh fractionation).

Bacteriogenic pyrite would have gone by oxidation due to lowering of lake water level and invasion of oxic seawater, while sulfate minerals would have been preserved. This study demonstrates utility of sulfur isotope compositions of sulfate minerals in sediments to uncover past activity of SRB, even if bacteriogenic pyrite was not well preserved.

Geochemical map of $^{87}Sr/^{86}Sr$ ratios using stream sediments is useful for detection of food-producing areas and human migration?

M. MINAMI [1]*, Y. JOMORI [2] AND A. OHTA[3]

[1]Center for Chronological Research, Nagoya University, Nagoya 464-8602, Japan (*correspondence: minami@nendai.nagoya-u.ac.jp)
[2]Graduate School of Environmental Studies, Nagoya University, Nagoya 464-8601, Japan
[3]Geological Survey of Japan, AIST, Ibaraki 305-8567, Japan

Geochemical map of $^{87}Sr/^{86}Sr$ ratios is needed for multiple purposes of detection of food-producing areas, tracing of patterns of ancient human migration, and culture change in earlier times, as well as environmental applications. We have started a nationwide geochemical mapping of $^{87}Sr/^{86}Sr$ ratios using catchment outlet stream sediments (<180 μm) in Japan. The $^{87}Sr/^{86}Sr$ spatial distribution in Shikoku Island and the Kii Peninsula in Japan largely reflected underlying $^{87}Sr/^{86}Sr$ bedrock distribution [1]. The result shows that $^{87}Sr/^{86}Sr$ map using stream sediments is useful for investigating the geochemical and geological features of bedrocks. Meanswhile, $^{87}Sr/^{86}Sr$ values of stream sediments might not be indicative of biological $^{87}Sr/^{86}Sr$ values of vegetation and fauna. In this study, therefore, we investigated relationship between $^{87}Sr/^{86}Sr$ ratios in biological samples and in stream sediments collected around the sampling points. The samples used are rice-plants, animal bones, paddy water and soil, and stream water and sediments collected from an area distributing of granite bedrocks in Toyota, Japan. For soil and stream sediments, bulk Sr and ammonium acetate extractable Sr (exchangeable Sr) fractions were both analyzed. $^{87}Sr/^{86}Sr$ ratios were measured with thermal ionization mass spectrometer (TIMS; VG Sector 54) at Nagoya University.

The bulk Sr fractions in soil and stream sediments showed larger $^{87}Sr/^{86}Sr$ ratios than the exchangeable Sr fractions and biological samples. The $^{87}Sr/^{86}Sr$ ratios of exchangeable Sr fractions were in agreement with the $^{87}Sr/^{86}Sr$ ratios in biological samples within analytical errors. The results suggest that the $^{87}Sr/^{86}Sr$ ratio of biological samples is constrained by the $^{87}Sr/^{86}Sr$ ratio of catchment outlet stream sediments, that is, underlying bedrocks upstream of the sampling points, and that the $^{87}Sr/^{86}Sr$ map using stream sediments can be an important database for identifying food-producing areas and ancient human migration in archaeology.

Rough morphology, thick (>5km) buried, trusted sequences of Mesozoic platform limestone and active faulting, in a very dynamic context at the boundary between the African and Eurasia plates, make Sicily a perfect place for the emergence of deep circulating waters as thermal springs. Most of them are located in its western sector (west Sicily springs=WSS); a few are related to the presence of the Etna and Iblei Mts Quaternary volcanics in eastern Sicily (ESS). Most of WSS are located along the seashore, or anyhow near the coast; others emerge inland at relatively higher elevations, but always at the edges of outcrops of the limestone sequences. The chemistry of springs suggests that the main circuit of WSS is inside the Mesozoic limestone, and the relative composition is: i) Ca-$SO_4(HCO_3)$ for those located inland, ii) markedly Na-Cl for those emerging along the sea, respectively. The $\delta^{18}O$ and δD composition of most of them suggests meteoric origin, with average recharge elevations at 700 m. Among WSS, the springs from Sciacca are the most promising for geothermal prospecting, since they seem to be a mixing between meteoric water and high temperature oxygen-shifted Mediterranean seawater. Moreover, they also have a CO_2 dominated associated gas phase suggesting the presence of a degassing hydrothermal system in the deep reservoir. Excluding the Sciacca springs in southern Sicily and some mud volcanoes at the foot of the Etna Mt., strongly CO_2-dominated and high in $^3He/^4He$ ratio, suggesting the presence of a mantle gas component, the gas phase associated to the carbonate WSS is N_2-dominated, reflecting the atmospheric recharge areas more than any deep hydrothermal systems.

Interaction of ions at the surface of soil components

BABAK MINOFAR[1,2]

[1]Institute of Nanobiology and Structural Biology of Academy of Sciences of the Czech Republic
[2]Faculty of Science, University of South Bohemia Branisovska 31Ceske Budejovice, minofar@nh.cas.cz

Complex structure of soil makes it interesting for both experimental and theoretical studies. One of most important components of soil, which has strong effect and play important role in the process of adsorption of different elements to the plants and complex formation process of many metal ions in the environment is natural organic matter (NOM).

Solvation structure and dynamics of building blocks of NOMs in aqueous solution studied and surface propensity to the air/aqueous interface observed and decrease of surface tension measured[1] which is supported by surface sensitive (VSFG) spectroscopy[2].

Also we have used the Temple-Northeastern- Birmingham (TNB)[3] model of humic acid which was proposed by Sein *et al*. for complex formation with different ions such as carbonate and iodate ions. We have observed that strong interactions between carboxylate groups of model humic acid take place both in protonated and not protonated hucmic acids. Moreover, hydrogen bonding and complex formation are two main factors which influencing the aggregation of model humic acid in aqueous solutions. Moreover, we studied the surface propensity and interaction of TNB with different organic contaminants such pesticides by classical molecular dynamics (MD) simulations and revealed that the hydrophbic interaction between organic contaminants and hydrophobic parts of humic acid is one of the most important factor for interactions and surface propensity to the air/aqueous solution interface.

[5]Univ. Denis Diderot, Sorbonne Paris Cité, IPGP/CNRS, 9Paris, France

The capacity of biominerals, in particular Fe-bearing minerals, to conduct electrons is increasingly studied with the aim of understanding the mechanisms by which bacteria can retrieve electrons from minerals [1,2] and designing electricity providing [3] or energy-storing devices [4]. Here, we present a two-step biomineralization pathway using the anaerobic Fe-oxidizing bacteria *Acidovorax sp*. strain BoFeN1 leading to the formation of α-Fe_2O_3 that was used in Li-ion batteries. Biomineralization of γ-FeOOH within the 40-nm thick cell wall of the bacteria [5], followed by a short heat treatment provided an alveolar material consisting of hollow rod-type shells made of an assemblage of nanometric and oriented α-Fe_2O_3 particles (Fig. 1A, B). This material exhibited enhanced electrochemical properties compared to abiotic controls, which relies on its specific texture at the μm- and nm-scales allowing increased electronic transfer and sustained reaction with Li^+ ions. These results have implications for energy storage and for understanding the mechanisms of electron/ion transfer through biominerals.

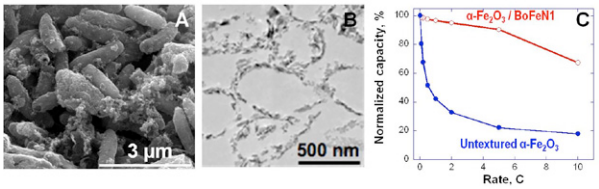

Figure 1: Texture of α-Fe_2O_3 bacteriomorphs biomineralized by BoFeN1 observed by SEM (A) and TEM in thin section (B). Electrochemical capacity-power (vs. Li^0) for textured and untextured materials (C).

The effect of light elements on metal/silicate partitioning

FRANCESCA MIROLO[1], EKATERINA S. KISEEVA[1], JON WADE[1]*AND BERNARD J. WOOD[1]

[1]University of Oxford (*correspondence: Jon.Wade@earth.ox.ac.uk, francesm@earth.ox.ac.uk, Kate.Kiseeva@earth.ox.ac.uk, berniew@earth.ox.ac.uk)

The accretion of the Earth was marked by the high-pressure segregation of most of its core, accompanied by dissolution of about 10% of one or more "light" elements into the metallic phase. Various light elements have been proposed including S, Si, C and O, with each having an effect on the partitioning behaviour of the trace elements. Metallurgical data indicate that dissolution of even small amounts of light elements in liquid Fe can have profound effects on the activities of some trace components. For instance, significant partitioning of Si into the core of the growing Earth should have affected the observed Mo[1] content of the mantle.

Here, we use the epsilion model of non-ideal interactions in Fe liquids (ε)[2]. We present interaction parameters (ε), derived from 1.5GPa, 1650ºC metal-silicate equilibration experiments, for W, Ni, Co and Mo in liquid Fe alloyed with C, S and Si.

At oxygen fugacities above IW-3, we can safely assume a 6+ valence for W and 4+ for Mo[3]. In the system Fe-S we can then derive Ni, Co, W and Mo interaction parameters. For example, our W interaction parameter (ε^{S}_{W}) is 8.4(±1), as opposed to the literature value of 6.1[4]. This means that at fixed oxygen fugacity, W becomes less siderophile with increasing metallic S content. However, for Mo in the same system we derive ε^{S}_{Mo} to be 0.5 (±1.7); the partitioning behaviour of Mo is therefore significantly less sensitive to the S content of the metallic phase. In contrast to W, the metal-silicate partitioning of Ni and Co are relatively insensitive to both S and C contents of the metal. Mars is proposed to posses a sulphur rich core, which would imply the primitive martian mantle possesses a higher W/Mo ratio than Earth's if the core's S content is taken into account.

Reconstruction of Holocene climate variability using stalagmites from the Herbstlabyrinth, central Germany

SIMON MISCHEL[1]*, DENIS SCHOLZ[1], CHRISTOPH SPÖTL[2] AND KLAUS PETER JOCHUM[3]

[1]Institute for Geosciences, University of Mainz, J.-J.-Becherweg 21, 55099 Mainz, (*correspondence: simon.mischel@uni-mainz.de)

[2]Quaternary Research Group, Innrain 52a, A-6020 Innsbruck, Christoph.Spoetl@uibk.ac.at

[3]Max Planck Institute for Chemistry, Hahn-Meitner-Weg 1, 55128 Mainz, k.jochum@mpic.de

The Herbstlaybrinth cave system lies at an elevation of 435 m asl in a small limestone area in Central Germany. The cave has a length of about 7 km and is well decorated with speleothems.

The chronology of two Holocene stalagmites is established by precise ^{230}Th/U dating using a NU Plasma MC-ICPMS at the Max Planck Institute for Chemistry, Mainz. The age model is constructed using StalAge [1]. Trace element concentrations and stable isotope ratios have been analysed at a temporal resolution of ~50 years.

In order to support the interpretation of the proxies in terms of past climate variability, we set up an extensive cave monitoring program to understand the processes occurring in the cave system.

In both stalagmites, P, Ba and U are positively correlated with each other and negatively correlated with δ^{13}C. This suggests that these proxies reflect the productivity of the vegetation above the cave. In contrast, Mg, which is interpreted as a proxy for effective precipitation above the cave [2], is negatively correlated with P, Ba and U. This indicates that the vegetation is more productive during more humid phases.

The δ^{18}O values of precipitation in the research area show a strong positive correlation to the winter North Atlantic Oscillation (NAO) index [3]. Due to strong evapotranspiration during summer months, summer precipitation does not contribute to the recharge of the cave system. Thus, the δ^{18}O values of the dripwater and speleothem calcite reflect winter precipitation. Therefore, the δ^{18}O values recorded in the speleothems from Herbstlabyrinth may give us the opportunity to reconstruct the NAO, with more positive values reflecting NAO+-conditions and vice versa.

Multiple sulfur isotope geochemistry of Dharwar Supergroup, Southern India: Late Archean record of changing atmosphere

KAORU MISHIMA[1]*, RIE YAMAZAKI[2], M. SATISH-KUMAR[3], TOMOKAZU HOKADA[4], AND YUICHIRO UENO[1,5]

[1]Department of Earth & Planetary Sciences, Tokyo Institute of Technology, Tokyo, Japan. mishima.k.ab@m.titech.ac.jp

[3]Department of Geology, Faculty of Science, Niigata University, Niigata, Japan
[4]National Institute of Polar Research, Tachikawa, Tokyo, Japan
[5]Earth-Life Science Institute, Tokyo Institute of Technology, Meguro, Tokyo, 152-8551, Japan

Sulfur isotope mass-independent fractionations (S-MIF) in sedimentary sulfides and sulfate provide strong constraints on the evolution of the early Earth's atmosphere. In the late Archean, the S-MIF signature changed dramatically: minimum $\Delta^{33}S$ at around 2.9 Ga, subsequent large $\Delta^{33}S$ variation culminated at 2.5 Ga and its sudden drop at the end of Archean. Moreover, $\Delta^{33}S$-$\Delta^{36}S$ relation shows characteristic slope of around -0.9 in the Archean period [1]. The change of $\Delta^{33}S/\Delta^{36}S$ slope may reflect perturbation of atmospheric chemistry, though the mechanisms of the large $\Delta^{33}S$ variations and the $\Delta^{33}S$-$\Delta^{36}S$ relation is still a matter of debate. We report multiple sulfur isotope data for sedimentary pyrite derived from the Dharwar Supergroup in the Western Dharwar craton, southern India. The lower unit (post-3.0 Ga) of the Dharwar Supergroup consists of basal conglomerate, stromatolitic carbonate, silici-clastics with diamictite, chert/BIF and pillow basalt in assending order. The upper unit unconformably overlies the pillow lava, and consists of conglomerate/sandstone with ~ 2.6 Ga detrital zircons, komatiite lava, BIF and silici-clastic sequence with mafic volcanics. Sulfur isotope analysis of extracted sulfide of these sedimentary rocks display clear MIF record of high $\Delta^{33}S$ values up to +3.9‰. The $\Delta^{33}S/\Delta^{36}S$ slope changes from -1.52 to -0.96 in accending stratigraphic order. The lowest slope value of -1.52 from Bababudan Group is stratigraphically just below the Talya diamictite, implying the link between shift of atmospheric chemistry and climatic system. On the other hand, carbonate rocks from Bababudan Group show very large variation $\delta^{34}S$ values up to +19.4‰ with negative $\Delta^{33}S$, whereas other sedimentary rocks show near 0‰ $\delta^{34}S$ value. The observed lithologic control possibly reflect geographical heterogeniety of S-MIF and sulfate reducing activity in the late Archean ocean.

Determination of U, Cs and Sr isotopes and their distribution coefficients in soil affected by Fukushima daiichi nuclear power plant accident

S. MISHRA[1,2], A. TAKAMASA[1], H. ARAE[1], W. MIETELSKI[3], Y. WATANABE[1], S. YOSHIDA[1] AND S.K.SAHOO[1]

[1]National Institute of Radiological Sciences, 4-9-1 Anagawa, Inage-ku, Chiba 263-8555, Japan
[2]Bhabha Atomic Research Centre, Mumbai – 400 085, India
[3]The Henryk Niewodniczanski Institute of Nuclear Physics, Polish Academy of Sciences, Krakow, Radzikowskiego 152, Poland (sahoo@nirs.go.jp)

Isotopic determination of U (^{238}U, ^{235}U and ^{234}U), Cs (^{137}Cs and ^{134}Cs) and Sr (^{90}Sr) were carried out in soil samples around Fukushima daiichi nuclear power plant (FDNPP) to find out source and extent of contamination due to fallout activity resulted as a consequense of the nuclear accident caused due to a severe earthquake followed by tsunami. ^{137}Cs activity was found to vary from 930±20 Bq/Kg to 62,200±900 Bq/Kg which is much higher than the global fallout in Japan. $^{134}Cs/^{137}Cs$ activity ratio was found to vary from 0.84-0.87, comparable with other reported values. ^{90}Sr activity found to vary from 8.4 ± 1.5 Bq/Kg to 21.2 ± 2.6 Bq/Kg. Distribution coefficients (K_d) were measured using laboratory batch method to establish transfer of radionuclides. K_d values for U, Cs and Sr were found to be log$U$-K_d≈3 > logCs-K_d≈2 > logSr-K_d≈1-2 (Fig.1). Chemical characterization with respect to different soil parameters like particle size distribution, pH, organic content, cation exchange capacity, $CaCO_3$, elemental and oxide composition of soil has been carried out to understand the geochemical behavior of these radionuclides. A good correlation was observed for U-K_d with Fe and organic content of soil. Similarly Cs-K_d and Sr-K_d show good correlation with cation exchange capacity and fine particle concentration respectively.

Site specific K_d values can be used for contaminant transport model to predict the radionuclide migration and also the relationship between soil parameters and sorption behavior of radionuclides will be helpful for soil remediation and dose assessment.

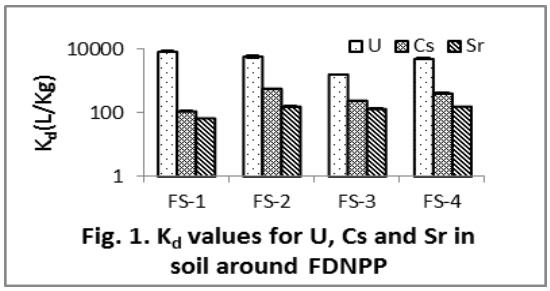

Fig. 1. K_d values for U, Cs and Sr in soil around FDNPP

Glass forming ability of sub-alkaline silicate melts

VALERIA MISITI[1], FRANCESCO VETERE[2-3], GIANLUCA IEZZI[1-2], HARALD BEHRENS[3], FRANCOIS HOLTZ[3], GUIDO VENTURA[1], ANDREA CAVALLO[1], MARCEL DIETRICH[3] AND SILVIO MOLLO[1].

[1]Istituto Nazionale di Geofisica e Vulcanologia, Via di Vigna Murata 605 00143 Rome, Italy
[2]Dipartimento di Ingegneria & Geologia, Università G. d'Annunzio, Via dei vestini 30, 66100 Chieti, Italy
[3]Institute for Mineralogy, Leibniz University of Hannover, Callinstr. 3, Hannover, D-30167, Germany

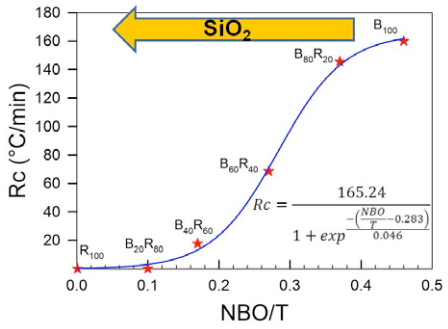
The glass forming ability (GFA) of six sub-alkaline silicate melts is quantified *via* the experimental determination of their critical cooling rate *Rc* (the minimum rate at which a liquid can be frozen to a solid with crystals < 2 vol.%). The selected compositions vary from basalt (B) to rhyolite (R) (B_{100}, $B_{80}R_{20}$, $B_{60}R_{40}$, $B_{40}R_{60}$, $B_{20}R_{80}$ and R_{100}).

For each composition, six cooling rates (150, 30, 3, 1, 0.116 and 0.0167 °C/min) are investigated between 1300 °C (liquidus region) and 800 °C (quenching temperature).

The crystallized phases and their contents are determined by image analysis on backscattered SEM pictures and include glass, pyroxene, spinel, plagioclase and, occasionally, olivine and melilite.

The estimated *Rc* values are 0.02, 0.12, 10, 50 130 and 160 °C/min for R_{100}, $B_{20}R_{80}$, $B_{40}R_{60}$, $B_{60}R_{40}$ $B_{80}R_{20}$, and B_{100} respectively.

Rc increases by 4 order of magnitude from R_{100} to B_{100} and can be related to the NBO/T (non bridging oxygen per tetrahedron) parameter as shown by the following figure:



Our results on the crystallization kinetics of the most abundant and common silicate melts in nature can be applied to retrieve solidification conditions of volcanic rocks as well as to design glass-ceramics with inexpensive starting materials.

Lithium Isotope History of Cenozoic Seawater: Changes in Silicate Weathering and Reverse Weathering

SAMBUDDHA MISRA[1,*] AND PHILIP N. FROELICH[2]

[1]Department of Earth Sciences, University of Cambridge, CB2 3EQ, UK, *correspondence: sm929@cam.ac.uk
[2]Froelich Education Services, 3402 Cameron Chase Dr., Tallahassee, FL, 32309. USA.

Weathering of uplifted continental rocks plays a central role in controlling both climate and seawater chemistry by consuming CO_2 and releasing cations to the ocean. Lithium isotopes provide a unique record of these changes because Li, unlike other tracers of ocean chemistry change, is hosted entirely in silicates. The isotopic composition of dissolved Li in seawater (δ^7Li_{SW} ~31.0‰) reflects a balance between river dissolved Li inputs (δ^7Li_{Riv} ~23‰), hydrothermal Li input (δ^7Li_{HT} ~8.4‰) and large fractionation (Δ_{SW-SED} ~15‰) during seawater-Li removal into marine authigenic clays via reverse weathering (δ^7Li_{SED} ~16‰). A geologic record of δ^7Li_{SW} change is sensitive to the very large Li-isotope fractionation factors and to changes in silicate sources and sinks on time scales of the Li residence time in seawater (τ_{Li} ~1.5 Ma). From the Paleocene (60 Ma) to the Present δ^7Li_{SW} rose 9‰, requiring large changes in continental forward weathering and seafloor reverse weathering consistent with pulsed tectonic uplift, more rapid continental denudation, increasingly incongruent continental weathering and more rapid CO_2 drawdown.

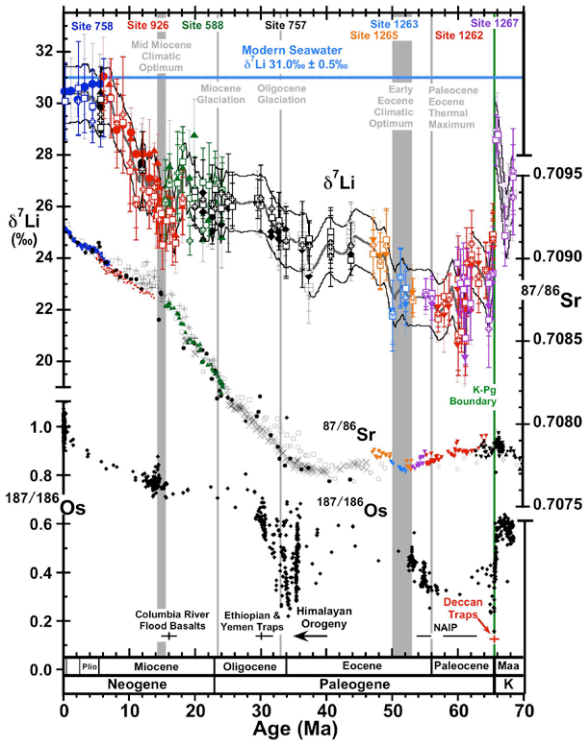


Figure: Li-, Sr-, and Os-isotope records over the past 68 Ma [1]. **[1]** Misra and Froelich, *Science*, 2012

Analysis of anion adsorption and its effects on alumina nanoparticles stability

TIZIANA MISSANA, ANA BENEDICTO, NATALIA MAYORDOMO AND URSULA ALONSO

[1]CIEMAT, Avenida Complutense, 40. C.P 28040 Madrid (Spain)

Nanoparticles may enhance contaminant transport in groundwater provided the contaminant is irreversibly adsorbed onto their surface and they are stable and mobile. Colloid-driven contaminant transport is an issue of concern associated to hazardous waste repositories, because many uncertainties still exists.

The chemistry of the groundwater mainly determines the size and charge of the particles and has a large impact on particles stability and mobility but the colloidal properties can also be affected by the contaminant adsorption itself. This is a point potentially very relevant on the overall colloid-driven transport, but scarcely considered.

The stability of colloidal systems is generally evaluated by studying the aggregation kinetic after the change of a specific chemical condition, generally pH or ionic strength of the aqueous solution. Often, the effects of divalent cations, especially Ca^{2+}, are evaluated. On the other hand, the effect of anion adsorption on colloid stability is mostly neglected.

In this work, the effects of Se(IV) (selenite) adsorption on alumina (Al_2O_3) nanoparticles were analysed. Selenite adsorption was studied in a wide range of pH (2-12) and ionic strengths ($5{\cdot}10^{-4}$ - $1{\cdot}10^{-1}$ M in $NaClO_4$) and the effect of the adsorption on the main properties of the colloids (size and charge) were analysed. Similarly, the effects of SO_4^{2-} competitive adsorption were studied.

Adsorption on Al_2O_3 was almost independent of the ionic strength and decreased with increasing pH, as expected for anions. The set of adsorption data was successfully fit by surface complexation modeling.

It was clearly shown that the anion adsorption (at medium-high surface occupancies) affected alumina nanoparticle stability. A clear shift of the isoelectric point towards more acid pH and enhancement of colloid aggregation, even at low ionic strength, were observed.

The presence of anions in the chemical composition of natural water, frequently not accounted for in stability studies, will be discussed, as well as the implications on possible colloid-driven contaminant transport in the environment.

ACKNOWLEDGMENT: The work has been partially supported by the project NANOBAG (CTM2011-27975).

Coupled μ-XAFS-FISH technique for direct observation of the microbe-metal-mineral interaction

S. MITSUNOBU[1]* AND F. SHIRAISHI[2]

[1]Institute for Environmental Sciences, University of Shizuoka, Shizuoka 422-8526, Japan (*corrspondence: mitunobu@u-shizuoka-ken.ac.jp)

[2]Department of Earth and Planetary Systems Science, Hiroshima University, Hiroshima 739-8526, Japan (fshirai@hiroshima-u.ac.jp)

Many geochemical important redox reactions are largely associated with microbial activity and are energy sources for microorganisms. For instance, recent studies suggest a significant relationship between Fe(II)-oxidizing bacteria and ancient Banded Iron Formation, one of the large geochemical events [1]. However, the detailed mechanisms of environmental biogenic reactions are largely unknown, because there are few adequate analytical techniques to observe it in high spatial resolution.

Here, we directly coupled synchrotron microprobe (μ-XAFS) with *in situ* phylogenetic analysis, fluorescence *in situ* hybridization (FISH), to determine simultaniously the chemical species and distributions of microbial community at micrometer scale (Fig. 1), which leads to better understanding the microbial reaction in the environment. We applied the coupled μ-XAFS-FISH to one of the most ubiquitous environmental biomineralizations, Fe mineral deposition by Fe(II)-oxidizing bacteria (FeOB).

In situ visualization of microbes by FISH revealed that *Betaproteobacteria* (presumably revealed to FeOB, *Gallionella spp*.) were localized within 10 μm of the Fe mat surface. Furthermore, *in situ* mineralogical characterization by μ-XAFS suggested that Fe local structure at the FeOB accumulating parts was dominantly composed of secondary short-ordered Fe-O_6 linkage, which is normally not observed in synthetic Fe oxyhydroxides [2]. The present study indicates that the coupled XAFS-FISH technique could be a potential technique to provide direct information on specific biogenic reaction mediated by specific microbe.

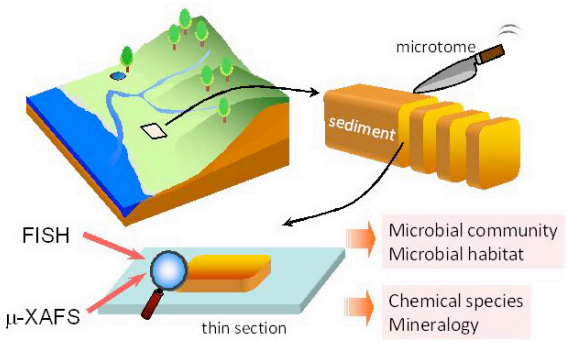

Fig. 1 Schematic figure showing coupled μ-XAFS-FISH technique.

Similarities between discordant chromitites from northern Oman ophiolite and chromitite xenoliths from Takashima alkali basalt, southwest Japan arc

MAKOTO MIURA[1], SHOJI ARAI[1], MARIE PYTHON[2] AND AKIHIRO TAMURA[1]

[1]Dept. Earth Sci., Kanazawa Univ., Kanazawa 920-1192, Japan (*correspondence: mimk1214@stu.kanazawa-u.ac.jp)
[2]Dept. Natural History Sci., Hokkaido Univ., N10W8, Sapporo 060-0810, Japan

We examined some discordant podiform chromitites in the mantle section of northern Oman ophiolite along Wadi Hilti, Fizh and Rajmi, to consider their origin. They are clearly discordant to the foliation of the surrounding mantle harzburgite. In outcrops, they show various texture (layered, massive, schlieren, anti-nodular and rarely nodular texture). Chromian spinels from all chromitites examined are full of minute orbicular inclusions of hydrous (pargasite and Na-phlogopite) and anhydrous (pyroxenes) silicates. They usually show a concentric distribution indicating a primary origin.

Their chromian spinels in all discordant chromitites show a relatively high Cr# (=Cr/(Cr+Al) atomic ratio), 0.7 to 0.8, and a low TiO_2 content, 0.15 to 0.2 wt%. The Oman discordant chromitites are comparable in chemical characteristics of chromian spinel with some arc-related plutonic rocks [1].

Their chromitite xenoliths from Takashima alkali basalt, southwest Japan arc, are similar to the Oman chromitites in spinel chemistry and texture [2]. In addition, we found laurite, one of platinum-group minerals, in the Takashima chromitite. The Takashima laurite is included in the compositional range of laurites in Oman chromitite [3]. Chondrite-normalized PGE pattern of the Takashima chromitite shows a slightly negative slope from Ru to Pt, which is also analogous to that of some chromitites from Oman.

These similarities between the Oman discordant chromitite and Takashima chromitite xenoliths, strongly suggest that some ophiolitic podiform chromitites are of sub-arc origin.

The existence of a high-pressure polymorph in a meteorite is a critical evidence for a dynamic event occurred on its parent-body. It is expected that HEDs meteorites originate from an asteroid, 4 Vesta. Although recent Dawn mission clarified that 4 Vesta suffered from heavy meteorite bombardments, a high-pressure polymorph has not been found in HEDs meteorites so far. We got one of eucrite samples, Béréba. Béréba sample studied here has several shock-melt veins, implying that it was heavily shocked. We investigated Béréba using a laser micro-Raman spectroscopy, FEG-SEM and FIB-TEM techniques to clarify a record of a dynamic event and its possible parent-body.

We focused our interests on a silica phase of Béréba in this study. Raman spectroscopy analyses showed that silica grains in the host-rock of Béréba are quartz and minor cristobalite. Most quartz grains entrained in the shock-melt veins transform to coesite. Some silica grains entrained in or adjacent to the shock-melt veins have network-like and/or lamellae-like textures. Raman spectroscopy and TEM observation indicate that such silica grains include coesite, stishovite and silica glass along with quartz. This is the first report of a high-pressure polymorph in HEDs meteorites.

The existence of stishovite indicates that pressure condition recoded in Béréba should be ~8 GPa at least based on a phase diagram obtained from static high-pressure and high-temperature synthetic experiments. U-Pb radio-isotope age of apatite entrainned in the shock-melt vein is ca 4.2 Ga [1], which is relatively younger than bulk-rock Pb-Pb radio-isotope age (ca 4.5 Ga) [2]. The young U-Pb radio-isotope age of apatite would be due to disturbance by a thermal event such as a dynamic event. When a high-pressure polymorph is heated under ambient condition, it vitrifies easily. Accordinglly, a dynamic event formed coesite and stishovite in Béréba occurred at least after ca 4.2 Ga ago.

Evaluation on reactivities of metal ions with hard ligands having oxygen donor

A. MIYAJI* AND Y. TAKAHASHI

Hiroshima University, Higashi-Hiroshima 739-8526, Japan
(*correspondence: asa-miyaji@hiroshima-u.ac.jp)

Complexation of metal cations by ligands such as hydroxide ion, carbonate ion, carboxylate ion, and phosphate ion is one of the most important factors to control behavior of metal ions in natural environment. Previous study showed that these ligands were classified as intermediate hard ligands having oxygen donor, which favors to form the ionic bond [1]. However, it was found that the reactivity of each ligand greatly depends on ionic radius and that there is a great difference of the reactivity between hydroxide ion and other ligand such as carbonate and carboxylate. For example, among the divalent alkaline earth metal ions, Mg^{2+} mainly precipitates as hydroxide (brucite), while Ca^{2+} prefer to form carbonate (calcite) or phosphate (apatite) minerals than hydroxide. However, quantitative discussion on the selectivity of metal cations is not quantitatively performed.

In this study, we evaluated the standard Gibbs free energy (ΔG_R^0), enthalpies (ΔH_R^0) and entropy (ΔS_R^0) for the complex formation of hydrated metal cations with these ligands based on a critical thermodynamic database including ΔG_R^0, ΔH_R^0, and ΔS_R^0. As a result, we found that the entropic contribution to the free energy was large in the case of hydroxide complex of small radius cation. In contrast, the entropic contribution to the free energy was small in the case of hydroxide complex of large radius cation and other complex. In addition, the enthalpy contribution was not significant in the reaction. In the aqueous complexation reaction, ΔS_R^0 was controlled by the number of water molecules replaced by the ligand, suggesting that hydroxide complex for large cation was not stable due to the small effect of dehydration.

Progress of serpentinization reactions triggered by silica addition: Petrological evidence from Iwanai-dake ultramafic body, Hokkaido, Japan

A. MIYOSHI AND T. KOGISO[1]

[1]Graduate School of Human and Environmental Studies, Kyoto University, Kyoto 606-8501, Japan.
kogiso@gaia.h.kyoto-u.ac.jp

Transformation of peridotite into serpentinite in the mantle wedge is one of the key processes that influence geodynamic regimes of subduction zones, because serpentinization changes the physical properties of peridotite, such as density, magnetic susceptibility, electric conductivity and rheology. Recent petrologic studies have proposed that serpentinization reactions proceed via a two-stage process involving the early formation of serpentine + brucite and subsequent magnetite formation. Magnetite, which is the key mineral controlling magnetic properties, electrical conductivity and density of peridotite as well as the efficiency of hydrogen generation, is thought to be formed by the second-stage reaction, but there has been little consensus among researchers regarding what factor promotes the formation of magnetite during serpentinization. We investigated successive changes in mineralogical textures associated with the progress of serpentinization observed in serpentinized harzburgite and dunite samples from Iwanai-dake ultramafic body (Hokkaido, Japan), which probably derived from a mantle wedge. Two kinds of mesh rim types were observed in the serpentine mesh texture of serpentinized harzburgite: a rim consisting of both serpentine and brucite (type-A rim) and a rim consisting solely of serpentine (type-B rim), which are always accompanied by brucite-magnetite veins. The formation of type-B rims and brucite-magnetite veins appears to have occurred concurrently with the serpentinization of orthopyroxene, suggesting that serpentinization reactions of harzburgite took place in two stages, with magnetite being formed by the second-stage reactions, which were triggered by a supply of silica component from serpentinization of orthopyroxene. In the case of serpentinized dunite, type-A rim was predominant and the fraction of magnetite does not increase with the progress of serpentinization. These observations suggest that silica supply is the trigger for the second-stage serpentinization reactions, in which magnetite and hydrogen are generated.

Effect of grid resolution and permeability anisotropy on mineral trapping for CO_2 disposal in the saline aquifer of Subei Basin, China

S.X. MO[1], F. ZHENG[1], S.M. JIANG[2], X.Q. SHI[1,*], L. ZHAO[1] AND Y. CHEN[1]

[1]School of Earth Sciences and Engineering, Nanjing University, China
[2] Department of Hydraulic Engineering, Tongji University, Shanghai 200092, China
(*correspondence: shixq@nju.edu.cn)

A vertical 2-D numerical model is built to study the interactions between water and minerals after supercritical CO_2 is injected into the saline aquifer of Yancheng Formation in Subei Basin, China using the parallel reactive transport modelling code TOUGHREACT-MP. The result shows that the carbonate minerals (e.g., calcite, siderite and dawsonite) significantly precipitated due to the dissolution of epidote, chlorite and albite. The total amount of CO_2 mineral trapping was as high as 34.0% after 5000a. The results of sensitivity analysis show that the volume of epidote significantly affects the CO_2 storage capacity. Three scenarios for the same conceptual model with different grid resolution are carried on to analysis the effects of numerical resolution. The results show that grid resolution has little impact on the reaction path of minerals dissolution and precipitation, however, the total amount of CO_2 mineral trapping using coarser grid is overestimated comparing to that with finer grid. The influence of the ratio of permeability anisotropy is also compared using another three scenarios corresponding to large, moderate and small vertical permeability, respectively. The results indicate that reduction of the vertical permeability results in more solubility and mineral trapping for a short period of time (e.g., 1000 a). However, more CO_2 is stored in minerals for the model with a moderate vertical permeability after 1000a, which implies that convective mixing process may significantly enhance mineral trapping.

Reconstructing past organic matter fluxes from $\delta^{15}N$ records

J. MÖBIUS*, B. GAYE, N. LAHAJNAR AND K.-C. EMEIS

Center for Earth System Research and Sustainability (CEN), University of Hamburg, Bundesstrasse 55, D-20146 Hamburg, Germany
(*correspondence: juergen.moebius@zmaw.de)

Organic matter fluxes from mixed layer to sea floor are hard to quantify from sediment records. Remineralization in the water column and in the sediment extinguishes the primarily produced signal to different degrees. As the reliability of biogenic barium as a proxy for primary production turned out questionable during the past decade, the quantification of organic matter fluxes is open again. In a recent study, we demonstrate that in certain settings stable isotopes of nitrogen (δ15N) may provide a tool to reconstruct past organic matter fluxes.

Stable isotope ratios of nitrogen are indicative for N sources, availability and cycling in the water column. The δ15N signal can be transferred to the sea floor by sinking particulate organic matter and further archived in the sediments. Interpretation of sedimentary δ15N records is usually complicated by an early diagenetic isotopic enrichment that mainly occurs during particle sinking and at the sediment water interface. However, we discovered that isotopic enrichment proceeds systematically due to organic matter remineralization and follows Rayleigh type fractionation logics. Accordingly, if isotopic enrichment is known, we can recalculate the amount of organic N that has been remineralized.

Our study has been carried out on Eastern Mediterranean Sea sediments from Holocene to Pleistocene sapropels and their remnants after post-depositional remineralization. The data set further comprises recent to subrecent sediments as well as sediment trap samples. Reconstructed N fluxes from recent and past sediment samples match fluxes reported in sediment traps and seem to validate our approach. Similar coincidence has been obtained for Arabian Sea core record and sediment traps. Hence, the new application of δ15N possibly is appropriable in a wider range of marine settings.

[3] Institute of archaeometry, Mannheim, Germany
* deceased

New ^{190}Pt-^{4}He method of isotope geochronology for the native minerals of platinum is based on the α-decay of ^{190}Pt isotope. Radiogenic helium in crystal structures of native metals tends to form atomic clusters that appear as nanoscale "bubbles". Therefore the stability of ^{190}Pt-^{4}He isotope system in native minerals of platinum is rather high [1].

By the novel ^{190}Pt-^{4}He method we have determinated age of Pt>Ir fluid-metamorphogenic, Pt>Os magmatogenic-fluid-metasomatic, and Pt magmatogenic-fluid-metasomatic types of platinum mineralization of alkaline-ultramafic massifs Kondyor (Aldanian Shield, Russia) and gabbro-dunite-pyroxenite Galmoenan massif (Koryak-Kamchatka belt, Russia).

Obtained age of isoferroplatinum for Pt>Ir fluid-metamorphogenic, and Pt>Os magmatogenic-fluid-metasomatic types of platinum mineralization of Galmoenan massif is 63 ± 3 Ma (average from 10 samples). The data are in good agreement with relevant geological observations. Obtained age of isoferroplatinum for Pt>Ir fluid-metamorphogenic, and Pt magmatogenic-fluid-metasomatic types of platinum mineralization of Kondyor massif is 123 ± 6 Ma (average from 20 samples). The data are also in excellent agreement with relevant geological observations and other existing geochronological determinations. Noteworthy that the age of Pt>Ir fluid-metamorphogenic and Pt>Os magmatogenic-fluid-metasomatic types of platinum mineralization doesn't have any significant discrepancy.

Conducted ^{190}Pt-^{4}He dating experiments also let us to separate a new young type of Pt mineralization on the Kondyor massif. ^{190}Pt-^{4}He ages for fine cubic crystals of isoferroplatinum turned out to be around 8 Ma. The same young age for these crystals was also obtained by the independent ^{190}Pt-^{186}Os method. These data may indicate formation of these Pt minerals under surface conditions.

Barium stable isotope fractionation during diffusion through silica hydrogel: Experimental determination of kinetic isotope effects at low temperatures

K. MOELLER[1]*, T.F. NÄGLER[1], M. DIETZEL[2] AND M.E. BÖTTCHER[3]

[1]Institute of Geological Sciences, University of Bern, Bern, Switzerland (*correspondence: kirsten.moeller@geo.unibe.ch)
[2]Institute of Applied Geosciences, Graz University of Technology, Graz, Austria
[3]Leibniz-Institute for Baltic Sea Research, Warnemünde, Germany

Only very few studies have so far focussed on barium (Ba) stable isotope fractionation in nature. Many questions thus still remain regarding the direction and extent of isotope fractionation in physical and (bio)geochemical reactions. To date, experimental studies of Ba isotope fractionation are limited to precipitation of Ba-carbonates and -sulphates [1,2] and adsorption of Ba onto Mn-oxides and clay minerals [3].

Here, we investigated Ba isotope fractionation during diffusion of Ba through a silica hydrogel. The gel was prepared in 15 cm long glass U-tubes. A concentration gradient was established by applying a $BaCl_2$ solution (0.1 and 1.0 mol/l, respectively) on one side of the gel and deionised water on the other side. Diffusion experiments were run at two different temperatures (10 and 25°C) over 2, 6, 12, 20 and 27 days, respectively.

The rates of Ba diffusion through the silica hydrogel correlate positively with initial $BaCl_2$ concentration and temperature. Ba isotope fractionation, however, appears to be independent from both boundary conditions. Initially, diffused Ba was found to be fractionated by as much as -2.2 ‰ in $\delta^{137/134}$Ba relative to the $BaCl_2$ stock solution. With continuing duration of the experiments, the $\delta^{137/134}$Ba values increased rapidly to about -0.6 ‰ after 27 days. We hypothesise that initial kinetic isotope fractionation caused by Ba diffusion switched to a later control via adsorption of Ba onto the silica hydrogel. Our experiments thus show that fractionation of Ba isotopes of more than 2 ‰ in $\delta^{137/134}$Ba (~0.7 ‰/amu) are possible under experimental conditions and that the light Ba isotopes are favoured substantially during Ba diffusion through an aqueous medium.

Geochemistry and petrogenesis of Hassan Salaran granitoid complex in SE Saqqez, western Iran

FAKHRADDIN MOHAMMAD ABDULLAH[1]*, ALI A. SEPAHI[2] AND SHELER. S. AHMAD[1]

[1] University of Garmian, Kalar, Kurdistan Region, Iraq, (*correspondence: fakhraddin.mohammad@gmail.com)
[2] Bu Ali Sina University, Hamadan, Iran (sepahi@basu.ac.ir)

The Hassan Salarn granitoid complex is located 20km to southeast of Saqqez city in Kurdistan Province, western Iran. It is composed of two distinct granitic rock suites that have various petological and geochemical characteristics. They also have different origins and petrogenesis. G_1 granitoids comprise alkali feldspar granite, syenogranite and quartz alkali feldspar syenite, whereas G_2 granitoids are composed of monzogranite, granodiorite and tonalite. Geochemically, G_1 granitoids are peralkaline, A-type and acmite-normative but G_2 granitoids are subalkaline (calc-alkaline), metaluminous, I-type and diopside-normative. G_1 granitoids are also ferroan alkali and ferroan alkali-calcic whereas G_2 granitoids are magnesian and calcic.

According to tectonic discrimination diagrams [1], G_1 granitoids plot in the field of the within plate granites whereas G_2 granitoids plot in the field of volcanic arc granites. Considering the method for classification of granites setting [2], G_1 granitoids plot in the post-orogenic field but G_2 granitoids plot in the field of mantle fractionated rocks. G_1 granitoids contain higher concentrations of alkalies, Zr, Rb, Nb, Y, Th, Ce, high FeO/MgO ratios and lower concentrations of Mg, Ca and Sr, resembling post-orogenic A-type granites. It is possible that heat from a mantle-derived magma which intruded into the lower crust, and/or rapid crustal extension have been essential generation of approriate melts producing G_1 granitoids. Thus we can conclude that G_1 granitoids were generated from a mixed mantle-crust source. Negative Nb anomalies and low contents of Ti and P probably indicate a subduction-related origin for protolith of G_2 granitoids. Negative Nb anomalies and enrichment in Ce relative to its adjacent elements can be related to involvement of continental crust in magmatic processes. G_2 granitoids are also enriched in Rb, Ba, K, Th, Ce and depleted in Nb, Zr and Y, indicating that they have had interacted with crust. G_2 granitoids may result from contamination of mantle-derived magmas by continental crust during an subduction event.

Comparing MSW landfill sites of Ottawa (capital of Canada) and Mashhad (the 2nd biggest city of Iran)

HOSSEIN MOHAMMADZADEH

Groundwater research center (GRC), Faculty of science, Ferdowsi University of Mashhad, Iran, P.O.B, 91775-1436 (mohammadzaddeh@um.ac.ir)

Waste disposal is an important issue in almost all cities and landfilling of municipal solid waste (MSW) is the most widely used disposal method in all over the world. In big cities like Mashhad (cultural capital of Iran) and Ottawa (capital of Canada), in spite of waste composting and recycling, considerable amount of MSW is disposed in landfill sites. In this study, the Mashhad municipal landfill (ML) and Ottawa municipal landfill (OL) sites which are owned and operated by the Cities of Mashhad (Iran) and Ottawa (Canada), respectively, have been investigated. The ML and OL sites were compared by looking at 1) site characterization of ML and OL; 2) waste composition and the geochemical composition of leachate in both ML and OL sites; and 3) the environmental impacts of both sites.

Landfilling in OL and ML sites began in 1960s and 1975, respectively. Both sites accept residential, industrial, commercial/institutional, and construction/demolition MSW material. However, ML is receiving about 584000 tons MSW annually (with dial average of 1600 tons), which is much more than that of OL landfill (355070 tons annually). At Ottawa landfill site, both the shallow and deep aquifers have been impacted by the landfill leachate infiltrating from the unlined portions of the landfill site. The presence of methane, DIC and the enriched d13C-DIC values at some monitoring wells, in comparison with pristine groundwater, provide evidence for leachate impact on groundwater at OL site [1, 2]. The detailed description of sampling procedures, analytical techniques, leachate composition, and leachate impact on the environment is given by Mohammadzadeh and Clark [3]. The ML site, with an elevation of 1080 a.s.l., is located on an igneous bedrock covered with alluvial deposit. Since the covered soil is not that much thick and there is fractured network in granitoeid bedrock, it is suspected that ML leachate have had an impact on groundwater resources.

Evolution of neodymium isotopic signature of seawater during the Late Cretaceous: new insights on oceanic circulation changes

M. MOIROUD[1]*, E. PUCÉAT[1], Y. DONNADIEU[2], G. BAYON[3] AND J.-F. DECONINCK[1]

[1]UMR CNRS, Université de Bourgogne, 21000, Dijon, France (*correspondence: mathieu.moiroud@u-bourgogne.fr)
[2]UMR CEA/CNRS, Laboratoire des Sciences du Climat et de l'Environnement , 91191, Gif sur Yvette Cedex, France (yannick.donnadieu@lsce.ipsl.fr)
[3]Département Géosciences Marines, Ifremer, 29280 Plouzané, France (germain.bayon@ifremer.fr)

Changes in oceanic circulation during the Late Cretaceous have been inferred from the neodymium isotopic composition (ε_{Nd}) of fish remains, which reflects the signature of past seawater [1, 2]. However the nature of these changes remains controversial, mainly due to insufficient temporal and spatial coverage of Nd isotope data. Data from continental margins in particular remain scarce for the Cretaceous [3, 4].

This work aims at reconstructing the signature of neritic and oceanic water ε_{Nd} during the Late Cretaceous/Early Paleogene in potential areas of deep water sinking and seaways linking different oceans. For this purpose, samples of fish remains, foraminifera and detrital fraction have been recovered in Late Cretaceous to Paleocene sediments from both oceanic (DSDP/ODP sites 152, 258, 323, 690 and 700) and neritic (Wyoming, Texas, New Jersey, Chile, Seymour Island, Egypt and Hokkaidō) sites.

The results primarily point out a decreasing trend after the Cenomanian-Turonian interval, previously observed in the Atlantic and the Indian sector of the Southern Ocean [5, 6] and a general increasing trend during the Maastrichtian and the Paleocene, but also document the first Cretaceous ε_{Nd} data for the Southern Pacific, the continental margins of North America and Japan, and the Panama and Drake passages. Nevertheless, further comparisons with ε_{Nd} data available in the literature and climate modelling are required to tentatively explain the oceanic circulation during the Late Cretaceous.

Water quality and human helth in relation to aquatic environment polutiom by metals

T.I. MOISEENKO[1], N.A. GASHKINA[1] AND V.V. MIGORSKY[2]

[1] V.I.Vernadsky Institute of Geochemistry and Analytical Chemistry, RAS, Kosygin 19, Moscow 119991, Russia (*correspondence: moiseenko.ti@gmail.com)
[2] Institute of the North Eco-Industrail Problems, Kola Science Center of RAS, Fersman 14, Apatity 184200, Russia

The assessment of the ecological consequences of element geochemical cycle changes due to the impact of mining and the metallurgical industry is of great importance for the health of the environment. This study collates published data concerning surface water contamination by metals, bioaccumulation and health of humans and fish within the Euro-arctic region of Russia (Murmansk region), in order to investigate their relationship. The results of metal concentration analysis of water from the sites of surface water intake for five cities and towns, as well as from pipe systems supplying drinking water to the public, show that industrial water treatment fails to remove toxic metals from the water. Fish were used as a biological indicator to show the impact of the pollution on living organisms. Renal disorders prevailed among the observed diseases within human populations. Statistical analysis demonstrated that human populations in those cities which are located in close proximity to smelters show the highest incidence of disease. The highest accumulation of metals within the kidney and liver were recorded in inhabitants of Monchegorsk, where the concentrations of many metals, especially, nickel, copper, chromium, cadmium, and lead, are 2–10-fold higher compared the normal. The highest concentrations within the kidney tissue were recorded for chromium and cadmium. Kidney pathologies are abundant within the population using the contaminated water supply for drinking water. The correlation between the content of this chemical element in water and pathology of kidney and liver of those patients who were examined postmortem was significant. Statistical analysis demonstrated that human populations in those cities which are located in close proximity to smelters show the highest incidence of disease. The highest content of toxic metals, especially cadmium, was found in the liver and kidney organs. The burden of evidence of the disorders observed in fish and in human populations indicates that there is a high probability of prolonged water contamination having a negative influence on the health of human populations.

New U-Pb ages for syn-orogenic magmatism in the SW sector of the Ossa Morena Zone (Portugal)

P. MOITA[1]*, J.F. SANTOS[2], M.M. COSTA[2] AND F. CORFU[3]

[1]Centro de Geofísica de Évora, Universidade de Évora, Portugal, pmoita@uevora.pt
[2]Geobiotec, Dep. Geociências, Universidade de Aveiro, Portugal
[3]Geology Department, Oslo University, Norway

The Ossa-Morena Zone (OMZ) is a major geotectonic unit within the Iberian Massif (which constitutes an important segment of the European Variscan Belt) and one of its distinguishing features is the presence of a noteworthy compositional diversity of plutonic rocks. In the SW sector of the OMZ, the tonalitic Hospitais intrusion (located to the W of Montemor-o-Novo) is considered a typical example of syn-orogenic magmatism, taking into account that both the long axis of the plutonic body and its mesoscopic foliation are oriented parallel to the Variscan WNW-ESE orientation. Another relevant feature of the Hospitais intrusion is the occurrence of mafic microgranular enclaves within the main tonalite. In previous works (Moita *et al*., 2005; Moita, 2007), it was proposed that: (1) the Hospitais intrusion is part of a calc-alkaline suite, represented by a large number of intrusions in this sector of the OMZ, ranging from gabbros to granites; (2) the enclaves are co-genetic to the host tonalite in the Hospitais pluton.

In this study, zircon populations from one sample of the main tonalite (MM-17) and one sample of the associated enclave (MM-17E) were analysed by ID-TIMS for U-Pb geochronology. In each sample, three fractions of nice glassy, euhedral, long prismatic and inclusion free crystals were analysed. The results from the three fractions of MM-17 yielded a weighted average $^{206}Pb/^{238}U$ age of 337.0 ± 2.0 Ma. Similarly, for the enclave MM-17E a weighted average $^{206}Pb/^{238}U$ zircon age of 336.5 ± 0.47 Ma was obtained. These identical ages, within error, are in agreement with a common parental magma for the tonalite and mafic granular enclaves.

Similar U-Pb ages have been reported in previous works for plutonic and metamorphic events in this region (e.g.: Pereira *et al*., 2009; Antunes *et al*., 2011). Furthermore, also in the SW sector of the OMZ, palaeontological studies (Pereira *et al*., 2006; Machado & Hladil, 2010) carried out in Carboniferous sedimentary basins containing intercalated calc-alkaline volcanics (Santos *et al*., 1987; Chichorro, 2006) have shown that they are mainly of Visean age. Therefore, magmatism displaying features typical of continental arc setting seems to have been active in this part of the OMZ during the Lower Carboniferous times.

Water on the primordial Earth

S.J. MOJZSIS[1]*, A. MORBIDELLI[2], K. PAHLEVAN[3] AND E.A. FRANK[1]

[1] Geological Sciences, CLOE, University of Colorado, USA
[2] Observatoire de la Cote d'Azur, CNRS, Nice, France
[3] Geology and Geophysics, Yale University, USA (*mojzsis@colorado.edu)

Water is the medium for life; it facilitates the long-term carbon cycle and aids in plate tectonics by modulating key geophysical parameters such as the mechanical strength of crust. Earth's surface hydrosphere totals 2.8×10^{-4} $M_\oplus$, and the mantle may contain $2.7(\pm1.3)\times10^{-3}$ $M_\oplus$ of water [1], approximately its storage capacity [2]. Ancient rocks show the hydrosphere existed in the first 700 Myr, and Hadean zircons extend this to about 180 Myr after solar system formation [3]. Earth has retained its volatiles since primary accretion [4], but H- and N-isotopic compositions are chondritic rather than cometary [5]. As such, water may have arrived late in the accretion epoch *viz*. the *Grand Tack* model [GT; 6] or even later via a *Late Veneer* [LV; 7]. The *Late Heavy Bombardment* [LHB] was not significant: it delivered too little (0.1% of the LV's mass), too late. Whether the LV mass ($\sim5\times10^{-3}$ $M_\oplus$) was brought in by many small undifferentiated planetesimals or a small number of large differentiated bodies is still an open issue, and we discuss advantages and disadvantages of both options. Such a mass was insufficient to deliver all the water even assuming CI composition. Earth-Moon O-isotopes exclude a CM, CI, or OC composition for the LV; EC composition would be possible but they are so water poor that they cannot explain Earth's water abundance whatever the LV mass. Volatiles were delivered towards the end of Earth accretion rather than via an LHB, LV, or Moon-forming event. This view is consistent with the latest dynamical models provided that Moon formation was fortuitously late [8].

The geochemical evolution of clinopyroxene in the Roman Province: A window on decarbonation from wall-rocks to magma

S. MOLLO[1,] AND A. VONA[2]

[1]Istituto Nazionale di Geofisica e Vulcanologia, Via di Vigna Murata 605 00143 Rome, Italy (*correspondance: mollo@ingv.it)

[2]Dipartimento di Scienze, Universita` degli Studi Roma Tre, L.go San leonardo Murialdo 1 00146 Rome, Italy

We present results from atmospheric pressure experiments conducted at 1140, 1160 and 1180 °C under the buffering conditions of air, MH and NNO. The starting materials were a shoshonite and a phonotephrite from the Roman Province. These natural samples were doped with variable amounts of CaO and CaO+MgO whose stoichiometric proportions reproduced the assimilation by magmas of calcite and dolomite, respectively.

Results underline that, during magma-carbonate interaction, the oxygen fugacity exerts a primary control on clinopyroxene composition. With increasing fO_2, the content of Tschermak molecules, i.e., $CaAlAlSiO_6$, $CaFeAlSiO_6$, and $CaTiAlSiO_6$, in clinopyroxene significantly increases at the expenses of hedenbergite and enstatite components.

The compositional variation of clinopyroxene described by our experiments is compared with the chemical analyses of natural crystals found in skarns and lavas at the Roman Province. This comparison provides that the simple ingestion of carbonate by magmas cannot explain the geochemical evolution of clinopyroxene in the Roman Province. At the periphery of magma chamber, the decarbonation reaction proceeds with the highest efficiency producing high CO_2 emissions. This causes extreme oxidizing conditions that, in turn, control the geochemical evolution of clinopyroxene in skarns. However, the oxidative capacity of CO_2 fluxing progressively decreases from the skarn shell to the interior of the magma. Consequently, the chemical analyses of clinopyroxenes found in lavas testify to laterally variable lower redox conditions in the magma chamber.

Lithospheric mantle connection of clinopyroxene inclusions in chromites from the Archean Nuasahi ultramafic-mafic complex (India)

SISIR K. MONDAL[1]*, SHOJI ARAI[2], BETCHAIDA D. PAYOT[2] AND AKIHIRO TAMURA[2]

[1]Department of Geological Sciences, Jadavpur University, Kolkata-700032, India (*correspondence: sisir.mondal@gmail.com)

[2]Department of Earth Sciences, Kanazawa University, Kanazawa 920-1192, Japan

The 3.1Ga Nuasahi igneous complex in India is a sill-like layered intrusion within the early Archean greenstone belt of the Singhbhum craton. The igneous complex consists of a lower ultramafic unit (~ 400m thick) containing three chromitite ore bodies and an upper gabbroic unit containing magnetite bands. In between the lower ultramafic unit and the upper gabbro a PGE-rich discordant breccia zone is present. The main rocks of the lower ultramafic unit are orthopyroxenite, harzburgite, dunite and chromitite. Chromites from the massive chromitites contain numerous independent clinopyroxene (cpx) inclusions (> 95% of total inclusion populations) along with tiny phlogopite (<1%). The cpx inclusions are of variable sizes and shapes (rounded, elliptical and euhedral crystals), and in places they mimic the shape of the host chromite grain, and appear as the seed and negative crystals. In addition, few opx and olivine grains are identified in net-textured chromitites. Major element analysis by EPMA confirms that the cpx inclusions are Cr-diopside in composition which suggest a lithospheric mantle origin of the inclusions. Phlogopites are K-rich and compositionally similar to mantle phlogopite. *In situ* trace element analyses by laser ablation ICP-MS show that the chondrite-normalized REE patterns for the cumulus cpx in the upper gabbro and the cpx inclusions in chromites from the massive chromitites from the Nuasahi complex are different. Previous studies showed that the chromitite-bearing sill-like ultramafic-mafic complex in Nuasahi was formed from a boninitic parental magma in a supra-subduction setting. Previous Os isotopic study of the unaltered chromites indicated melt extraction as early as 3.7Ga from a subchondritic Os isotopic source implying derivation from a subcontinental lithospheric mantle. The high-Mg parental magma of the Nuasahi igneous complex may have originated in the deeper parts of the metasomatized lithospheric mantle wedge from where the cpx xenocrysts (along with phlogopite) were collected and transported to the crustal magma chamber where it had been entrapped by the growing chromite crystals.

[5]IRSN, SERIS, L2BT, Saint-Paul-lez-Durance, France.
[6]LEMIRE, UMR 7265/CEA/CNRS/Aix –Marseille Univ., Saint-Paul-lez-Durance, France.
[7]SEPA, AREVA NC, Bessines-sur-Gartempe, France.

We investigated the influence of uranium on the indigenous bacterial communities in natural uranium ores by conducting an in-depth analysis of soil samples collected in the region of Bessines, one of the most important natural uranium deposits in France. Soil samples exhibiting 1.5 to 25.5% U in mass were compared with nearby control soils containing trace uranium. EXAFS and XRD analyses of soils revealed the presence of U(VI) and uranium-phosphate mineral phases, identified as sabugalite and meta-autunite.

A comparative analysis of bacterial diversity using DGGE [1] and high throughput pyrosequencing of 16S rRNA genes revealed the presence of complex populations in both control and uranium-rich samples. Among the 232.000 reads analyzed by pyrosequencing, 23 bacterial phyla were detected with *Proteobacteria*, *Acidobacteria* and *Chloroflexi* being predominant. Statistical analyses of the DGGE fingerprints and pyrosequencing data showed that bacterial communities of uranium-rich samples differ from that of controls. An enrichment of sequences related to iron- and uranium-reducing bacteria as well as iron-oxidizing species in uranium-rich samples was evidenced by both methods. Several iron-reducing anaerobic isolates related to *Pelosinus, Clostridium* and *Enterobacter* were cultured from the uranium-rich soil samples and characterized.

Taken together, these results demonstrate that uranium shapes bacterial diversity and suggest the existence of an iron and/or uranium redox cycle mediated by bacteria in the soil.

Towards Understanding Magnetite Biomineralisation: The Effect of Short Chain Peptides on the {100} and {111} Magnetite Surfaces

AMY E. MONNINGTON* AND DAVID J. COOKE

Department of Chemical & Biological Sciences, University of Huddersfield, Queensgate, Huddersfield, HD1 3DH, (*correspondence: amy.monnington@hud.ac.uk, d.j.cooke@hud.ac.uk)

Biomineralisation is the process by which living organisms form minerals. The earliest known example of biomineralisation is that of the biosynthesis of magnetite [1]. A major step forward in understanding the principles of magnetite biomineralisation occurred with the discovery of Magnetotactic bacteria (MTB) [2]. Despite this, much of the detailed atomistic mechanism by which the process occurs is unknown.

Numerous commercial applications for bacterial MNPs have been suggested, including the removal of radionuclides and heavy metals from waste water, MRI contrast agents, magnetic antibodies and drug and gene delivery. However, such applications are not commercially viable at present. In order to produce MNPs more economically the biomineralisation processes need to be further understood. Therefore, we are developing an atomistic model for the system, in an attempt to understand the processes involved.

Magnetite formation within Magnetospirillum magneticum AMB-1 occurs under the influence of the Mms6 protein. It was previously discovered that the Mms6 protein was linked to the control of the morphology and size of the magnetite crystals within the M.magneticum AMB-1 [3]. The acidic C-terminal region of this sequence is of particular interest due to its potential linkage to iron binding. It is hypothesised that if key iron binding sites within the C-terminus of the Mms6 protein are substituted for alanine, the protein's overall iron binding ability is diminished.

In this study, an atomistic model of Mms6-driven magnetite formation was developed, using molecular dynamics (based on classical atomistic potentials), to study the attachment of a series amino acid repeats (alanine-alanine, alanine-glutamic acid & glutamic acid-glutamic acid) to the {100} & {111} magnetite surfaces and investigate the effect on iron binding ability.

Time scales of mingling in shallow reservoirs.

C. P. MONTAGNA[1], P. PAPALE[2] AND A. LONGO[3]

[1]Istituto Nazionale di Geofisica e Vulcanologia, via della Faggiola 32, 56127 Pisa, Italy; montagna@pi.ingv.it
[2]Istituto Nazionale di Geofisica e Vulcanologia, via della Faggiola 32, 56127 Pisa, Italy; papale@pi.ingv.it
[3]Istituto Nazionale di Geofisica e Vulcanologia, via della Faggiola 32, 56127 Pisa, Italy; longo@pi.ingv.it

Arrival of magma from depth into shallow reservoirs has been documented as one of the possible processes leading to eruption, e.g. for the recent eruption of Eyjafjallajökull [1], or for most eruptions at Campi Flegrei [2]. Magma intruding and rising to the surface interacts with the already emplaced, degassed magmas residing at shallower depths, rejuvenating them and causing intense mixing and mingling. These processes can cause pressure variations in the reservoirs and eventually lead to eruptions. The chemical signatures of such processes are often identifiable in eruptive products.

We performed two-dimensional numerical simulations of the arrival of gas-rich magmas into shallow reservoirs. We solve the fluid dynamics for the two interacting magmas evaluating the space-time dependent evolution of the physical properties of the mixture, including density and viscosity. Volatile exsolution is computed self-consistently as well.

Our results show that patterns of convection and mingling develop quickly into the chamber and feeding conduit/dike, leading on longer time scales to a density stratification whereas the lighter, gas-richer magma, mixed with different proportions of the resident magma, rises to the top of the chamber due to buoyancy. Over time scales of hours, the magmas in the reservoir appear to have mingled throughout, and convective patterns become harder to identify.

Our simulations have been performed changing the geometry of the shallow reservoir, and the gas contents of the initial end-member magmas. Both parameters play an important role in determining the efficiency of the mixing processes. Horizontally elongated magma chambers favour mixing, while vertically elongate, dike-like reservoirs inhibit efficient convection. Higher density contrasts between the two magmas cause faster ascent velocities and increase mixing efficiency as well.

Petrological evidence suggests for Campi Flegrei residence and mixing times of few days, from the arrival of fresh magmas to eruption, supporting our findings [3].

Do amino acids inhibit calcite growth?

G. MONTANARI*, N. BOVET, AND S. L. S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*giulia.montanari@nano.ku.dk)

The organic matrix that regulates growth of biogenic calcium carbonate contains high concentrations of acidic amino acids. They can form long macromolecules, which bind to surface sites and inhibit growth of the mineral. In this study, we investigated the effect of single amino acid units on calcite crystal growth, to determine how their structure is related to inhibition. We tested glycine (Gly), the smallest amino acid, and aspartic acid (Asp), with concentration range from $8*10^{-6}$ to $4*10^{-4}$ M. Both have an amino group but they differ in the number of carboxylic groups. To quantify their impact on crystal growth rates, we undertook calcite precipitation experiments, using the constant composition method [1]. XPS (X-ray photoelectron spectroscopy) of calcite exposed to amino acid bearing solutions revealed that both molecules adsorbed. Calcite morphology was observed with SEM (scanning electron microscopy); rough corners and step edges indicate blocking of surface sites (Figure 1).

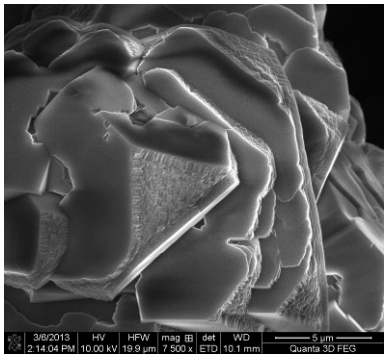

Figure 1: SEM image of calcite crystal exposed to Aspartic acid. Rounded and roughened corners and serrated edges are clearly visible.

Asp is a better inhibiting agent than Gly, which is active only for the highest concentrations investigated. The extra carboxylic group and the particular conformation of Asp can be the main factors promoting the interaction with surface sites. These results shed light on the parameters to take into account to predict or design a good scale inhibiting molecule.

Highly siderophile and chalcophile element systematics of crust-derived Ligurian garnet pyroxenites

ALESSANDRA MONTANINI[1]*, AMBRE LUGUET[2], STEPHAN KÖNIG[2] AND RICCARDO TRIBUZIO[3]

[11] Dip. Fisica e Scienza della Terra, Università di Parma, Italy (alessandra.montanini@unipr.it).
[2] Steinmann Institut, Universität Bonn, Poppelsdorfer Schloss, 53115 Bonn, Germany
[3] Dip. Scienze della Terra e dell'Ambiente, Università di Pavia, Italy

There is growing evidence from major, trace elements and isotopic systematics (e.g. Nd, 187Os, 186Os) that pyroxenites are significant constituents of OIB and MORB sources. Although pyroxenites probably play an important role in the recycling of crustal 187Os and 186Os signatures within the mantle, their highly siderophile and chalcophile element signatures are not well contrained. Here, we present platinum group elements (PGE: Os, Ir, Ru, Pt, Pd), Re, Se, Te and 187Os compositions of nine garnet pyroxenites and two peridotites from the External Ligurian ophiolites (Italy). On the basis of their mineralogical, geochemical and Nd-Hf isotopic features, the pyroxenites (HREE-depleted Type A, HREE-enriched Type-B and retrogressed) were correlated with partial melting of an eclogite source derived from gabbroic protoliths [1]. Whereas the host peridotites exhibit typical mantle-like concentrations and a relatively flat CI-chondrite-normalised HSE patterns, the pyroxenites show large concentration ranges, reaching up to 46 ppb Pd, 538 ppb Se and 81 ppb Te. Their HSE patterns display a positive slope from Os to Re, but with significant differences between the pyroxenites. Type-A pyroxenites show lower Os, Ir, higher Pt, Pd concentrations and flatter Pd-Re segments than Type-B pyroxenites. The retrogressed pyroxenites show mixed signatures with Os-Ir contents similar to Type-B pyroxenites but Pt, Pd concentrations as well as Pd-Re segments similar to Type-A. Selenium and Te are significantly enriched in all the pyroxenites but independently of the pyroxenite groups. The $^{187}Os/^{188}Os$ ratios vary from unradiogenic in the peridotites (0.1257) to highly radiogenic in the pyroxenites (0.2649-2.4748). Here we show that crust-derived mantle pyroxenites show a large range of highly siderophile and chalcophile elements signatures, which could likely contribute to geochemical and isotopic heterogeneities of the Earth's mantle.

New insights on the nucleation and growth of chrysotile, magnesite, goethite and calcite

G. MONTES-HERNANDEZ[1]

[1]ISTERRE, University of Grenoble I and CNRS, BP 53, 38041 Grenoble Cedex 9, France
german.montes-hernandez@ujf-grenoble.fr

Chrysotile, magnesite, goethite and calcite are widespread minerals in Earth systems and other telluric planets. These minerals play an important role on the fate and transport of several trace elements (including the so-called strategic elements or rare-Earth elements of economic interest) and organic molecules at the mineral-fluid interfaces. Particularly, carbonate minerals plays also a crucial role on the global carbon cycle. In general, their formation and textural properties have already been investigated in the past. However, various questions still remain unanswered concerning their formation in natural systems as well as their production at laboratory and industrial scales. In this way, various new results on the nucleation and growth processes of these minerals from macroscopic to nanoscopic scales are summarized in this meeting contribution. In last six years, independent semi-continuous or batch experiments under specific physicochemical conditions were carried out to precipitate chrysotile nanotubes via dissolution of so-called proto-serpentine precursor [1], micro-crystals of magnesite via simultaneous dehydration and carbonation of brucitic layer of dypingite precursor [2], acicular nanocrystals (in width) of goethite from ferric hydroxide gel [3] and nanosized calcite via aqueous or gas-solid carbonation of portlandite [4-5]. I note that the nucleation and growth mechanism routes of these common minerals are still debated, for example, the role of so-called precursor formation and/or pre-nucleation existence addressed in the recent years are not clear at the present time, opening a broad spectrum of experimental and modeling possibilities to decipher this fundamental scientific obstacle.

Peering into the Cradle of Life: Multiple sulfur isotopes reveal insights into environmental conditions and early sulfur metabolism some 3.5 Ga

A. MONTINARO1*, H. STRAUSS1, P. MASON2 AND A. GALIĆ2

[1]Westfälische Wilhelms-Universität Münster, Münster, Germany (*correspondance:amont_01@uni-muenster.de)
[2]Utrecht University, Utrecht, The Netherlands

Multiple sulfur isotopes have been used successfully for constraining Earth's early sulfur cycle, prevailing overall environmental and redox conditions in particular, as well as for tracing life on Earth. ICDP project "Peering into the Cradle of Life" aims at investigating the environmental conditions that existed when life emerged and evolved on our planet. Samples stem from the Barberton Greenstone Belt in South Africa (3.55–3.23 Ga), one of the oldest well preserved rock successions from the earliest part of Earth history. This study centers on core BARB5, comprising carbonaceous shale, interbedded sandstone and conglomerate and volcanoclastic rocks from the middle Mapepe Formation of the Fig Tree Group. Total sulfur abundance ranges between 0.01 and 3.03 wt.% and total carbon abundances between 0.15 and 10.29 wt.%. The carbonaceous shale displays $\delta^{34}S$ values between -0.99 and 3.33‰; volcanoclastic rocks between -6.57 and 2.32‰; sandstone and conglomerate between 0.37 and 3.44‰. Similar to the $\delta^{34}S$ values, $\Delta^{33}S$ values are different for each lithofacies. Samples from the carbonaceous shale yielded a range between 0.41 and 2.33‰; volcanoclastic rocks between -0.32 and 0.20‰; sandstone and conglomerate between 0.14 and 0.61‰. Some preliminary conclusions can be drawn. Each lithofacies is characterized by a different isotopic composition. Clearly, $\Delta^{33}S$ values in carbonaceous shale reflect mass-independent isotope fractionation, hence an atmospheric signature. In contrast, volcanoclastic rocks display rather small $\Delta^{33}S$ values but substantial variability in $\delta^{34}S$, that could reflect solely mass-dependent isotopic fractionation, hence a terrestrial signature. However, alternatives have been proposed.

THEREDA – Thermodynamic Reference Database

HELGE C. MOOG[1] AND FRANK BOK[2]

[1]Gesellschaft für Anlagen- und Reaktorsicherheit (GRS) mbH, Theodor-Heuss-Straße 4, 38122 Braunschweig, Germany, helge.moog@grs.de
[2]Helmholtz-Zentrum Dresden-Rossendorf e.V., Institute of Resource Ecology, Surface Processes Division (FWOG), Bautzner Landstraße 400, 01328 Dresden (Germany), f.bok@hzdr.de

THEREDA was founded by five institutions in Germany and Switzerland. Our main ojectives are

- To ensure that equilibrium calculations for nuclear disposal issues are consistent among different institutions
- To save basic thermodynamic data in a way which renders them usable on a long term
- To have a technical platform which facilitates the decentralized editing of data
- To provide users with ready-to-use parameter files for the most widely used geochemical codes
- To make sure that each datum can be traced back to its original source
- To classify the entered day in order to inform the user about the quality of the data and hence his calculations

Following these objectives THEREDA has evolved into a web-based platform for a common thermodynamic database. The main focus lies on providing a database for high-saline systems. However, some efforts have been made to design THEREDA as flexible as possible for future demands, as necessity arises, namely: other models for the aqueous solution, non ideal gas and solid phases, etc.

Backbone of the whole database is a Pitzer-consistent set of phase constituents along with equilibrium constants and Pitzer coefficients for the basic hexary system Na-K-Mg-Ca-Cl-SO_4-H_2O. The set is at present being extended to be valid for temperatures between 120 and 200°C, depending on the particular system. At the same time data are added to extend the database for polythermal, in parts even polybaric equilibria with $HCO_3^-/CO_2(g)$.

Consistently to the above mentioned backbone, other joint members of THEREDA collaborate to extend the database for actinides, activation- and fission products, and heavy metals. Another string of endeavour is targed towards geothermal applications.

The THEREDA team welcomes colleagues from other database projects to discuss or collaborate on specific subjects of common interest.

Reactive transport of common hydrological tracers in porous media – an experimental study

PRATHAP MOOLA[1], BERGUR SIGFÚSSON[2] AND A. STEFÁNSSON[1]

[1]Institute of Earth Sciences, University of Iceland, Sturlugata 7, 101 Reykjavík, Iceland (snp3@hi.is)
[2]Reykjavík Energy, Baejarhálsi 1, 110 Reykjavík, Iceland

Groundwater flow is commonly studied by means of tracer tests. The tracers commonly used involve inorganic salts and organic compounds. The results of such tests in porous rocks are based on the assumption that the tracers are inert, i.e. do not react with the solutions and/or minerals of the groundwater system.

In this study the chemistry of commonly used organic hydrological tracers were studied experimentally upon flow in porous rocks. The tracers studied included Fluorescein, Rhodamine B, Sodium Naphthionate, Pyranine, Amino Rhodamine G and Amino G in solutions of pH 3, 6 and 9 with three types of porous sand, quartz, rhyolitic and basaltic sand. The experiments were conducted using a Teflon flow-through reactor packed with the sand of interest. Experimental solutions with and without the tracers were alternatively pumped at fixed flow rates through the reactor and the tracer concentration at the outlet of the reactor continuously monitored spectrophotometrically. The major chemistry of the outflow solution was further studied. The experimental results were supported by 1-D reactive transport simulations conducted with the aid of the PHREEQC program. In the simulations, dissolution of the solids and formation of secondary minerals was taken into account as well as possible sorption processes. According to the experimental results and the reactive transport simulations the primary rocks alter to form secondary minerals and solutes that are partially transported out of them column (system). Some of the hydrological tracers studied were observed to be non-reactive, however, others seem to be affected by processes like adsorption and desorption. The results imply that simulation of groundwater flow in porous rocks based on tracer tests may not be valid in some cases without considering reactive transport and incorporating sorption reactions of the tracer used.

Melt inclusion constraints on the origin of the Peridote Mesa phonotephrite, San Carlos, Arizona

G. MOORE

Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI, 48107, USA (*correspondence: gmmoore@umich.edu)

The Peridote Mesa vent in San Carlos, Arizona, USA, is known for its striking array of upper mantle xenoliths, and the gem quality peridot that is mined from them. While many studies have been conducted on the xenoliths, suprisingly little is known regarding their host magma. Our previous petrographic, analytical, and experimental work [1, 2] showed that the Peridot Mesa lava is not a basanite as previously thought [3], but an evolved phonotephrite, and that the phenocrysts are consistent with crystallization of anhydrous magma during rapid ascent. Phase equilibrium experiments on the lava composition failed to reproduce the observed phenocryst assemblage however, regardless of a variety of pressures, temperatures, and volatile contents [2].

Given the energetic magmatic environment required to entrain and erupt such large (up to 50 cm dia) mantle xenoliths on the surface, one hypothesis for the inability of phase equilibrium experiments to crystallize the observed assemblage is that the erupted lava is the final product of mixing of two or more magmas that had different crystallization paths. This possibility is supported by the observation that there are several older occurences of eruptions with similar characteristics in the area [4], indicating a well-developed pathway for such magmas.

As this mixing hypothesis must be ruled out before further phase equilbrium experiments are considered, an effort has been undertaken to identify and measure the composition of melt inclusions in the phenocrystic phases found in rapidly quenched scoria. Preliminary results from the electron microprobe on the bulk composition of the melt inclusions show that, similar to the residual glass, there is not significant variation in the liquid composition, suggesting that magma mixing and/or assimilation of xenolithic material is not an important process, or is extremely rapid and efficient, resulting in a homogeneous magma.

Detection of non-stoichiometric silicate mineral dissolution in rivers draining alpine glaciers using $\delta^{44/40}Ca$

J. MOORE[1,2], A. D. JACOBSON[2], C. HOLMDEN[2] AND D. CRAW[3]

[1] Department of Physics, Astronomy, & Geosciences, Towson University, Towson, MD 21252 USA (*correspondence: moore@towson.edu)

[2] Department of Earth and Planetary Sciences, Northwestern University, Evanston, IL 60208 USA (adj@earth.northwestern.edu)

[3] Saskatchewan Isotope Laboratory, Department of Geological Sciences, University of Saskatchewan, Saskatoon, Canada SK S7N 5E2 (ceh933@mail.usask.ca)

[4] Geology Department, University of Otago, Dunedin, New Zealand (dave.craw@stonebow.otago.ac.nz)

Rivers draining glaciers frequently have high Ca concentrations, which have been attributed to the dissolution of carbonate minerals, even in predominantly silicate watersheds. Apportioning riverine Ca between silicate and carbonate weathering is typically done with the "Ca/Na method," which assumes that plagioclase is the dominant source of silicate Ca and that Ca and Na are released in stoichiometric proportions. Here, we tested whether high-precision Ca isotope measurements ($\delta^{44/40}Ca$ by MC-TIMS, $2\sigma_{SD}$=±0.07‰) could track Ca sources to non-glacial and glacial rivers draining the Southern Alps of New Zealand. The mountain range consists of schist and greywacke containing trace hydrothermal calcite (1-3%). Hydrothermal calcite and silicate rocks are isotopically distinct. The Ca isotope composition of rivers is consistent with mixing between calcite and silicate sources. Glacial rivers are statistically different than non-glacial rivers ($p < 0.001$) and have more negative $\delta^{44/40}Ca$ values. The glacial rivers plot closer to the silicate end-member. We observe no evidence for isotopic fractionation as a factor controlling the variability in stream water $\delta^{44/40}Ca$ values. For non-glacial rivers, carbonate weathering provides ~50 – 90% of the riverine Ca, and more importantly, the Ca/Na and Ca-isotope source apportionment methods yield the same results within 2%. However, for glacial rivers, the Ca-isotope method yields 25% more Ca from silicate weathering compared to the Ca/Na method. Taken together, the data point to the enhanced release of silicate Ca in glacial watersheds. We attribute the effect to non-stoichiometric release of Ca from silicate mineral surfaces damaged by glacial grinding. One implication is that alpine glacial watersheds may consume atmospheric CO_2 at higher rates than previously realized.

Recent Changes in Coastal Aquifers: Local effects expressed globally

WILLARD S. MOORE[1]

[1]Department of Earth and Ocean Sciences, University of South Carolina, Columbia, SC USA, moore@geol.sc.edu

Coastal populations are increasing rapidly, while potable water supplies are decreasing due to over-pumping and sea water intrusion into coastal aquifers. This problem has affected almost all coastlines during the past century. Here I focus on biogeochemical consequences of sea water intrusion into coastal aquifers, systems we call subterranean estuaries.

Oxygen is the most powerful oxidizing agent in most waters. However, its oxidizing capacity is limited by solubility (maximum ~0.28 mmol/L). Once dissolved oxygen is depleted, sulfate ion (~29 mmol/L in seawater) becomes the electron acceptor of choice to facilitate carbon oxidation. Thus seawater has a great deal more oxidizing capacity than fresh water. The reaction products of sulfate oxidation of organic matter include both inorganic and organic forms of dissolved N, P, and C as well as sulfide. Additionally, reducing conditions in the aquifer lead to reduction of iron and manganese oxides. This increases concentrations of Fe^{2+} and Mn^{2+} as well as other metals, plus ions that were absorbed onto the oxides. As this chemically-altered seawater exchanges into coastal waters as submarine groundwater discharge, it carries high nutrient, carbon, metal, and sulfide concentrations.

Continued seawater intrusion will lead to greater inland expansions of subterranean estuaries. This expansion may produce greater total SGD fluxes of nutrients, carbon, and metals because the biogeochemical reactions that affect their concentrations will operate over larger spatial scales and affect portions of aquifers that have not been in contact with seawater for thousands of years.

Insights into glacial weathering from a new hydrochemical database from 95 glaciated catchments

NILS MOOSDORF[1], JENS HARTMANN[1] AND JOSHUA A. WEST[2]

[1] University of Hamburg, KlimaCampus, Bundesstraße 55, 20146 Hamburg, Germany (nils@moosdorf.de)
[2] University of Southern California, Department of Earth Sciences, Los Angeles, CA 90089, USA

Chemical rock weathering in glaciated areas is involved in several feedback loops in the earth system. The fluxes and geochemical characteristics of glacial weathering have been assessed at many single locations, but only a few studies have compared multiple sites [e.g. 1] to draw broader conclusions.

Here we present a new database compiled from 95 glaciated catchments, published by 46 sources. This database allows to analyze general patterns associated with the effect of glaciers on chemical weathering.

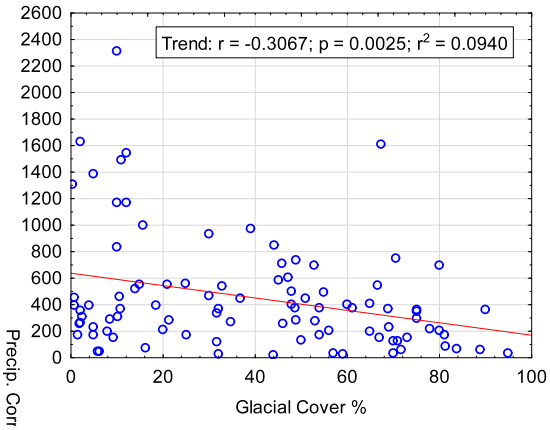

Figure 1: Precipitation corrected cation concentrations against glacial cover. Each point represents one catchment.

The first analysis of the database shows that cation concentrations decrease with increasing glacial cover (Figure 1). Mean concentrations are below the global average of 875 μMol/L [2], but cation denudation rates are on average 21.4 t km^{-2} a^{-1}, above the global average of 10 t km^{-2} a^{-1} [3].

The database will be analyzed in depth to identify relations between ion concentrations, weathering rates, stochiometry and seasonality with potential influencing factors (e.g. dominating lithology).

Dust direct radiative forcing and the complex refractive index of hematite

H. MOOSMÜLLER* AND J. P. ENGELBRECHT

Desert Research Institute, Nevada System of Higher Education (NSHE), Reno, NV 89512, USA (*correspondence: Hans.Moosmuller@dri.edu)

Ambient light absorption of entrained mineral dust in the visible and near-visible spectral region is generally dominated by iron oxides, in particular by hematite (α-Fe_2O_3) [1, 2]. Therefore, sign and magnitude of mineral dust direct radiative forcing are critically dependent on the complex refractive index spectrum of hematite, especially its imaginary part. Here, we discuss the sensitivity of mineral dust shortwave radiative forcing on the imaginary part of the hematite refractive index.

Spectra of the imaginary part of the hematite refractive index have been reported in more than 15 publications. Unfortunately, these literature values vary greatly, between one and nearly five orders of magnitude for different parts of the spectrum (Fig. 1). In addition, virtually all of these publications fail to give an error estimate for their results.

Here, we review these published values together with the respective methods of determination. attempting to give a recommendation for values and errors that should be used. Furthermore, we estimate the error in dust radiative forcing originating from the uncertainty in hematite refractive index.

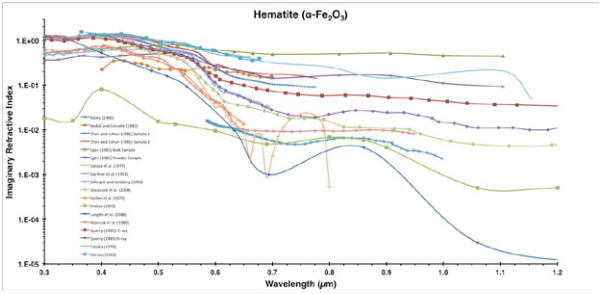

Figure 2: Imaginary part of the hematite refractive index as function of wavelength as obtained from 15 different publications.

Composition of the Earth's core from density measurements of liquid iron alloys at megabar pressure

G.MORARD[1,*], D.ANTONANGELI[1], J.SIEBERT[1], D. ANDRAULT[2], N.GUIGNOT[3], F.GUYOT[1,5] AND G.GARBARINO[4]

[1]Institut de Minéralogie et de Physique des Milieux Condensés, Univ. Pierre et Marie Curie, Paris, France *correspondence: guillaume.morard@impmc.jussieu.fr
[2]Laboratoire Magmas et Volcans, Clermont-Ferrand, France
[3]Synchrotron SOLEIL, Gif-sur-Yvette, France
[4]European Synchrotron Radiation Facility, Grenoble, France
[5] Institut de Physique du Globe de Paris, France

The liquid core of the Earth extends between 2900 km and 5150 km depth accounting for 18% of the total planetary volume. Although mostly composed of iron, it contains impurities that lower its density and its melting temperature with respect to pure Fe. Knowledge of the nature and content in light elements (O, S, Si, C) in the core has major implications for establishing the bulk composition of the Earth and for building models of Earth's differentiation.

Angle dispersive X-ray diffraction experiments in double-sided laser heated diamond anvil cell (LH-DAC) were performed at ID27 beamline at the European Synchrotron Radiation Facility (ESRF) in Grenoble. *In situ* investigations enable determination of melting temperature and structural and density properties of the Fe-based alloys. Experiments were performed on an Fe-Ni-S alloy up to 94 GPa and 2800 K and on an Fe-Ni-Si alloy up to 91 GPa and 3200 K. New results on Fe-O and Fe-C liquid alloys will be also presented.

The appearance of a diffuse X-ray scattering signal at wavevectors of about 30 nm^{-1} was used to determine the onset of melting. Extrapolations of measured melting curve up to the core–mantle boundary pressure yielded values of 3,600–3,750 K for the freezing temperature of plausible outer core compositions. We extracted densities and compressibilities from the diffuse X-ray signal scattered by the liquid up to megabar conditions, using a method developed for diamond anvil cells by Eggert and collaborators [1]. The obtained equations of state parameters indicate that sulfur, and not silicon, can more easily account for the differences in density and bulk modulus between pure iron and a reference Earth seismic model. This challenges traditional Earth's accretion and differentiation models, that do not foresee S as major light element in the core. These results thus rather argue for strong disequilibrium Earth formation mechanisms.

Origin of noble gases on Earth: a mixture of Solar, solar wind implantation and phase Q

MOREIRA MANUEL[1] AND CLAIRE ROUBINET[2]

[1]moreira@ipgp.fr
[2]roubinet@ipgp.Fr

The origin of noble gases on Earth is debated since more than 70 years and the observation that the noble gas elemental relative abundances are not solar [1]. Mantle and atmospheric noble gas isotopic compositions are neither chondritic nor solar, at the exception of the neon isotopic ratio that shows a value intermediate between the chondritic components and the solar value, wlode to the neon B value. Since the works of Cafee *et al*. [2] and Holland *et al*. [3], the question of the terrestrial primordial isotopic composition of the Kr and Xe is discussed. They show that the primordial mantle might have been chondritic instead of atmospheric. In addition to that, Pujol *et al*. [4] have shown that the archean atmosphere might have been chondritic, suggesting a xenon loss fractionation accompanied with mass fractionation. A major implication of these observations is the massive subduction of atmospheric xenon in the whole mantle.

We show in this study that the Ne and Ar were added to the parent bodies of the Earth by solar wind implantation. Atmospheric Kr isotopes, on contrary, suggest a late veneer of cometary material with a solar composition added to the chondritic krypton degassed from the mantle. The primordial noble gas compositions on Earth are therefore a mixture between the chondritic, solar, and implanted solar wind. An unknown isotopic fractionation has modified the isotopic composition of the xenon of the atmosphere, without affecting the other noble gases. Subduction of atmospheric Kr and Xe into the whole mantle is required in such a model.

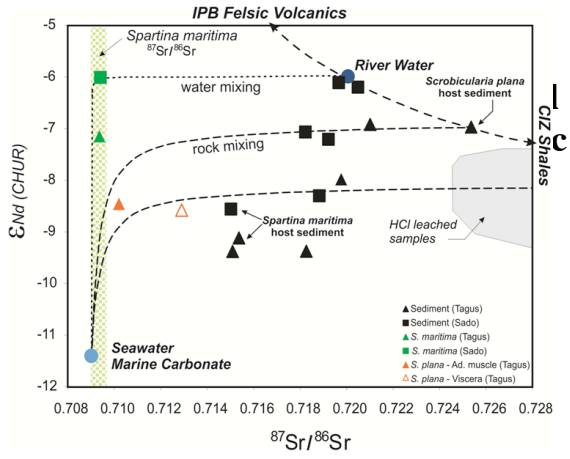
Nd and Sr isotope geochemistry of sediments and associated biota from Tagus and Sado estuaries (Portugal)

S. MOREIRA[1]*, M.C. FREITAS[1], J. MUNHÁ[1], C. ANDRADE[1] AND C. TASSINARI[2]

[1]Universidade de Lisboa, Fac. Ciências, Departamento de Geologia, Centro de Geologia. 1749-016 Lisboa, Portugal. (*correspondence: scmoreira@fc.ul.pt)
[2]Universidade de São Paulo, Centro de Pesquisas Geocronológicas. CEP 05508-080 - São Paulo, Brasil.

This study reports on Nd and Sr isotopes and elemental geochemistry of sediments and associated biota (*Spartina maritima*; *Scrobicularia plana*) collected in the intertidal domain of Sado and Tagus estuaries. Sediments display UCC type REE patterns, but variable $^{143}Nd/^{144}Nd$ (0.512171–0.512325) and $^{87}Sr/^{86}Sr$ (0.715367–0.725351) isotopic ratios, which tend to decrease with increasing Ca/Al and Si/Al values. The observed variations of isotopic ratios suggest that Nd and Sr in the Tagus and Sado estuarine sediments were mainly derived from an heterogeneous UCC source (e.g., old recycled CIZ shales + juvenile IPB volcanics) with variable inputs from relatively unradiogenic, Ca, Si – rich, marine components. *S.maritima* and *S.plana* tissues have $^{143}Nd/^{144}Nd$ isotopic ratios (0.512272–0.512330 and 0.512197–0.512204, respectively), which are similar to those of their host sediments; however, $^{87}Sr/^{86}Sr$ values (0.709193–0.709408 and 0.709321–0.710204, respectively; excepting visceras of *S.plana* bearing lithic particles = 0.712855) are much lower then those of their sedimentary substrate. These results indicate that Sr and REE in *S.maritima* and *S.plana* tissues had distinct sources; metabolic Sr was mostly derived from seawater, whereas REE were bio-processed from sources identical to those of the estuarine sediments.



Speciation study in the sulfamethoxazole-copper-pH-soil system: Implications for antibiotic retention prediction in soils

M.-C. MOREL, L. SPADINI*, K. BRIMO AND J.M.F. MARTINS

LTHE Laboratory., UMR5564 CNRS, University of Grenoble 1, BP 53, 38041 Grenoble Cedex 09, France (*correspondence lorenzo.spadini@ujf-grenoble.fr) (marie-christine.morel@ujf-grenoble.fr, jean.martins@ujf-grenoble.fr)

Most antibiotic substances are acid-base reactive and metal complexing. These characteristics determine specific chemical relationships for the prediction of their retention in soils, aquifers, and suspended matters. The results for Sulfamethoxazole (SMX), a persistent sulfonamide antibiotic commonly found in natural waters, is presented. The speciation of the SMX - Cu(II) - H^+ system in solution and the combined sorption of these components on a natural vineyard whole soil were investigated by acid base titrimetry and Infrared Spectroscopy. Cu(II) is considered to represent a strongly complexing trace element cation (such as Cd^{2+}, Zn^{+2}, Pb^{+2}, Ni^{+2}, etc.) in comparison to major but more weakly binding cations (such as Ca^{++} and Mg^{++}). The analysis showed that SMX is a medium to weak copper complexing agent and it also qualifies as a weak to medium soil sorbate at pH 6. However, the sorption of SMX in soil increases strongly in the presence of copper. This strongly supports the hypothetical formation of ternary SMX-Cu-soil complexes, especially when considering the almost quantitative sorption of the strongly sorbing copper. The data were successfully modelled with the assumption of the existence of binary and ternary surface complexes in equilibrium with aqueous Cu, SMX and Cu-SMX complexes. It is thought that other strongly complexing cations such as Cd(II), Ni(II), Zn(II), Pb(II), Fe(II/III), Mn(II/IV) and Al(III) present on the surface of reactive organic and mineral soil phases affect the solid/solution partitioning of SMX, and that the sorption strength may be estimated from existing sorption constant relationships. This study thus suggests that the state of surface-adsorbed cations significantly affects the sorption strength of SMX, and that the interactions may be predicted by combining equilibrium analysis and modeling studies.

Arsenic-chloride exchange in the Pecora River Valley (Southern Tuscany, Italy)

G. MORELLI[1]*, M.GASPARON[1,2] P.COSTAGLIOLA[3], V. RIMONDI[3], M.BENVENUTI[3], F.DI BENEDETTO[3], P.LATTANZI[3], AND M.PAOLIERI[3]

[1]School of Earth Sciences, The University of Queensland, Brisbane, Qld, 4072, Australia (*g.morelli@uq.edu.au)
[2]National Centre for Groundwater Research and Training, Australia
[2]Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Florence, Italy

High concentrations of As have been documented in large aquifers (e.g. Bangladesh, China, India -West Bengal [1]) and coastal Holocene/Quaternary alluvial plains where fresh groundwater mixes with intruding seawater [2]. Very high As concentrations have been measured in the alluvial sediments (As>500mg/kg) of the Pecora River (Southern Tuscany, Italy; [3]). As concentrations exceeding 10 μgL^{-1} [4] have been recorded in some of the groundwaters potentially exposed to seawater intrusion caused by aquifer overexploitation. To quantify how the ionic exchange between As oxianions (adsorbed on minerals' surfaces) and seawater Cl^- may contribute to the release of As in groundwater, desorption kinetic experiments were carried out on three samples from this alluvial deposit. After 24 hours, desorption experiments using four aqueous solution with different salinity extracted between 20 and 80 μgL^{-1} of As, with the highest levels extracted by seawater. For longer desorption periods (~20 days), the samples were saturated with the same solutions to constrain the timing of the As-Cl reaction. The solutions with Cl^-<2000 mgL^{-1} extracted <20 μgL^{-1} of As after at least 8 days, while the extracted As using seawater varied between 20 and 60 μgL^{-1} Compared to other experimental studies [5], the percentage of extracted As is much lower (< 0.04% of the total) because the mobile (and thus potentially bioavailable) As is only 9-11% of the total As, which is mainly associated with relatively stable Fe-oxides and sulphides. This study deomostrates the importance of a rigorous mineralogical characterization for a prediction of potential As release from coastal aquifers following seawater intrusion.

Cyclic subduction of the Aeolian Arc: Evidence from Salina.

MORETTI, H.C.[1]*GOTTSMANN, J.C.,[1]BLUNDY, J.M. [1] AND SULPIZIO, R.[2]

[1]*Department of Earth Sciences, University of Bristol, BS8 1RJ, hm12523@bristol.ac.uk
(j.blundy@bristol.ac.uk), (j.gottsmann@bristol.ac.uk)
[2]Universitá di Bari A. M., 70125, (roberto.sulpizio@uniba.it)

The island of Salina is part of the Aeolian Arc of Italy, located in the southern Tyrrhenian Sea. It occupies a central position at the junction of a sub-arcuate chain of seamounts and volcanic islands with a linear belt of volcanic islands defined by the Tindari-Letojanni fault and is related to a steeply dipping Beniof zone. Volcanic activity on Salina has stretched from 430ka to 13ka, initially consisting of mafic lavas and concluding with more evolved, mingled, basaltic andesite and rhyolite explosive eruptions.

Geochemical evidence from basalts across the Aeolian Arc suggests that whilst Panarea, Salina and Lipari have a strong signature of fluid metasomatism from a subducting slab, the outlying islands of Alicudi and Stromboli have a more complex genesis with evidence of slab sediment melting, inflowing mantle and crustal assimilation [1].

A temporal trace element analysis for Salina shows the amount of Barium, for example, varies across eruptions; some more evolved eruptions have significantly higher barium for similar levels of silca and suggest a marked cyclicity that may not be driven by fractionation alone. The variations are examined to determine the degree to which they are driven by changes in subduction fluid metasomatism as opposed to increased assimilation of crustal materials or changes in the style of fractionation.

Pathways of redox state and sulfur release track the shift from low-energy to highly-explosive basaltic eruptions at Mt. Etna

MORETTI R.[1,2], MÉTRICH N.[3], ALLARD P.[3], AIUPPA A.[6], ARIENZO I.[2] AND DI RENZO V.[1]

[1] DICDEA, Seconda Università degli Studi di Napoli, Aversa (CE), Italy

[3] IPGP, Sorbonne-Paris Cité, Univ. Paris Diderot, UMR 7154 CNRS, Paris France
[4] DiSTeM, Università di Palermo, Palermo, Italy

Basaltic magmas can transport and release large amounts of volatiles into the atmosphere, especially in subduction zones, where slab-derived fluids enrich the mantle wedge. Mt. Etna in Sicily, is one typical basaltic volcano where the volatile control on variable activity (effusive to Plinian) can be investigated. Based on a melt inclusion study of sulfur in products from Strombolian or lava-fountain activity to Plinian eruptions, here we show that different eruptive styles correspond to distinct sulfur degassing paths. Depending on their initial water content, oxidation state, and extent of CO_2-fluxing, Etnean magma batches can soon reach the limit of sulfide saturation or get rid of sulfur on degassing only. Melt inclusion data indicate that the magma involved in the powerful 122 BC Plinian eruption is richer in sulfate (S^{6+}/S_{tot} > 0.65) than the magmas erupted during less energetic explosive February 1999 and Strombolian effusive 1997-98 eruptions. We propose a direct relationship between the high sulfate (SO_4^{2-}) content in melts and hence high oxidation state of the melts and the magnitude of an eruption. Highly oxidized conditions ($[S^{6+}/S_{tot}]$melt and $SO_{2,gas}/[H_2S+SO_2]_{gas}$ > 0.6) in Etnean magma batches enhance the probability of violent explosive eruptions, such as the 122 BC Plinian event. The different patterns of sulfur release (oxidized vs reduced) of Etnean magmas are discussed and modeled.

Bend-Faulting, Serpentinization, and Mantle Recarbonation at Trenches

JASON P. MORGAN[1]

[1]Earth Science Department, Royal Holloway Univ. London, Runnymede, Surrey, TW20 0EX (jason.morgan@rhul.ac.uk)

It is well known that mid-ocean ridges are a key site for chemical interactions between oceanic crust and the hydrosphere, and that these interactions modulate the chemistry of the oceans. Subduction forearcs are also key sites of chemical fluid-rock exchanges. These fields are likely to still have many surprises to reveal, but are relatively mature. However, it is becoming increasingly evident that the oceanic lithosphere may also strongly interact with the hydrosphere during plate subduction, as it bends — by bend-faulting — when it enters a trench. I briefly review recent seismic evidence collected by the SFB574 and others that suggests that bend-faulting is associated with ~10-20% serpentinization in a layer extending at least 5km below the Moho. If this serpentine forms with a 1% carbonate fraction (note that at least this degree of carbonitization occurs during mid-ocean-ridge serpentinization processes), then bend-faulting-linked serpentinization will consume an atmosphere's worth of CO_2 every 40,000 years, and it is likely that the carbonate storage in serpentinized subducting lithosphere exceeds that in overlying oceanic crust and sediments. This poorly-understood geological process clearly merits further study, with significant potential implications for the global carbon cycle, for the geochemical evolution of the mantle, and for human exploitation for potential carbon sequestration at oceanic trenches. CO_2-rich fluids released by deserpentinization reactions may even play a role in 'lubricating' the subduction channel, and in the volatilization of the forearc. While bend-faulted Moho lies within the potential drilling window for the Chikyu marine drilling platform, it may prove to be much easier to gain constraints on bend-fault-related serpentinization from observations on Alpine serpentinites. Another critical observation to begin to document this interaction would be to find and study an active site of bend-fault fluid venting at the seafloor — with candidate sites evident in swath-mapping and deep-bottom photos offshore Central America.

Potassium stable isotopic compositions measured by high-resolution MC-ICP-MS

L.E. MORGAN[1], N. LLOYD[2], R. ELLAM[1], J. I. SIMON[3], AND M. TAPPA[4]

[1]Scottish Universities Environmental Research Centre, Rankine Ave., East Kilbride, G75 0QF, UK (*correspondence: leah.morgan@glasgow.ac.uk)
[2]ThermoFisher Scientific, Hanna-Kunath Str. 11, 28199 Bremen, Germany
[3]Center for Isotope Cosmochemistry and Geochronology, ARES, NASA JSC, Houston, TX 77058, USA
[4]JE-23 ESCG/Jacobs Technology, Houston, TX 77258, USA

Potassium stable isotopic ($^{41}K/^{39}K$) compositions are notoriously difficult to measure. TIMS measurements are hindered by variable fractionation patterns and too few isotopes to apply an internal spike method for instrumental mass fractionation corrections. Internal corrections via the $^{40}K/^{39}K$ ratio can provide precise values and are appropriate in some cases (e.g. identifying excess ^{41}K [1]) but not others (e.g., determining fractionation effects and metrologically-traceable isotopic abundances). SIMS analyses have yielded results with 0.25‰ precisions [2]. Previous studies have not resolved isotopic variation in terrestrial materials.

We measured $^{41}K/^{39}K$ ratios on NIST K standards with < 0.07‰ precisions (1σ) on the Thermo Scientific NEPTUNE *Plus* MC-ICP-MS. ^{39}K and ^{41}K were sufficiently resolved from the interfering $^{38}ArH^+$ and $^{40}ArH^+$ peaks in wet cold plasma and high-resolution mode. Measurements were made on narrow but flat, interference-free, plateaus (ca. 50 ppm by mass width for ^{41}K). Although ICP-MS does not yield accurate $^{41}K/^{39}K$ values due to significant instrumental mass fractionation (ca. 6%), this bias is sufficiently stable that relative $^{41}K/^{39}K$ values can be precisely determined via sample-standard bracketing. Measurement tolerances on matrix effects that are amplified by the cold plasma were tested; the use of clean samples and standards is critical.

On the Thermo Scientific TRITON TIMS, using a co-loaded Rb standard to normalize for fractionation, accurate but less precise $^{41}K/^{39}K$ ratios have been measured. Differences in $^{41}K/^{39}K$ between NIST K standards identified via MC-ICP-MS are also apparent in the TIMS data. Combined, these approaches yield more reliable K isotopic measurements than were previously possible and may allow for the identification for the first time of sub-permil terrestrial variations in $^{41}K/^{39}K$.

Diffusion of Helium in the mantle: an explanation for MORB-OIB patterns of 3He/4He ratios

W. JASON MORGAN[1], AND JASON P. MORGAN[2]

[1]Earth Science Department, Harvard Univ., Cambridge, MA, USA (wjmorgan@princeton.edu)
[1]Earth Science Department, Royal Holloway Univ. London, Runnymede, Surrey, UK (jason.morgan@rhul.ac.uk)

OIBs have a wide range of 3He/4He ratios, MORBs have a much narrower range peaked at 3He/4He ≈ 8 Ra. In addition, the ratio of 3He/20Ne (both stable isotopes) is significantly higher in MORB than in OIB, likewise the ratio of 4He/21Ne (both daughter isotopes produced by U and Th decay) are similarly higher in MORB than OIB. (Stable 3He/36Ar and radiogenic 4He/40Ar have the same pattern as the He/Ne plots, only with more scatter.) [See Honda and Patterson, GCA 63, 1999.] To explain this, we assume that rising mantle plumes are ‘lumpy’; a mixture that includes lumps of primordial mantle (which will be rich in 3He, 20Ne, 22Ne, 36Ar, etc.) as well as lumps containing the EM1, EM2, HIMU components, all in a general matrix of relatively-barren, previously-melted 'harzburgite'. When the rising lumps (plums) melt, the He, Ne, Ar, and most of the other incompatible elements will go into the melts that are known as OIB. But not all of the lumps melt (near the cooler edge, some don't rise shallow enough to pressure-release melt); those that don’t melt go into the asthenosphere, flowing horizontally away from the rising column. At a spreading center, this asthenosphere contributes the ‘plums’ left over from OIB partial melt-extraction but also some of the more barren matrix that the plums are embedded in becomes part of the melt because of the higher extents of partial melting that occur when making MORB. What is the effect of diffusion? If the helium, because of its small size, can diffuse a distance of 100 m or 1000 m in a billion-plus years (the ‘age’ of a lump) whereas neon or argon diffuse only decimeters or centimeters in this time because of their larger radii (i.e., not much more than non-noble incompatible elements like K, Rb, or U can diffuse), then the 3He and 4He (and H) can diffuse far out into the 'barren harzburgite' matrix. Thus when the lumps in a plume melt there will be a shortage of 3He and 4He relative to the 20Ne, 21Ne, or argon. With the extensive melting that occurs to make MORB, fluxing causes some of the barren matrix to contribute its 3He and 4He to the MORB melt which results in an excess of helium relative to neon and argon. This extraction of helium from the longtime-diffused-into barren matrix also can explain the uniformity of the 3/4 ratio in MORB as opposed to the variability of 3/4 in OIB.

Iron (oxyhydr)oxides are widespread minerals in Earth's surface environments. They exhibit a large variety of polymorphic structures that can be used as tracers of physicochemical conditions of formation, especially redox and pH. Moreover, structural defects and inorganic and organic impurities are also potential indicators of formation pathways, either biotic or abiotic. When formed at ambient temperature, iron oxide minerals usually have sub-micron size, which enhances their surface reactivity. Although the properties and occurences of iron oxide minerals have been studied for several decades, recent advances have been made in understanding the structures of nanocrystalline iron oxyhydroxides as well as their surface reactivity.

In the present communication, we will review recent spectroscopic investigations of ferrihydrite [1], schwertmannite [2], and nanomagnetite [3] that play a key role in iron and trace element cycling in the environment and in water treatment technologies. Local structures of these mineral phases, including the status of sorbed or coprecipitated impurities, will be discussed based on Extended X-ray Absorption Fine Structure (EXAFS) analyses. Implications for the remediation of arsenic contaminated waters in mining environments will be especially adressed. In addition, we will present specific properties of nanomagnetites for scavenging pollutants such as arsenic via precipitation, sorption, and redox reactions. Spectroscopic results will be interpreted in light of theoretical calculation for arsenic sorption onto the surface of the reference mineral, hematite.

Recent field studies identified a new source of natural gas in Quebec: shale gas. These gases are mainly found in the Utica Shale and result from kerogen cracking. Gases formed from kerogen cracking are referred to as thermogenic gases and are mainly composed of methane, ethane and propane. Due to the presence of natural faults in the bedrock above the Utica Shale, these gases can migrate and contaminate the shallow aquifers that are exploited for human consumption. Contamination of the aquifers can also be caused by the migration of biogenic gases formed by methanogenic bacteria in surface wetlands and lake sediments. As part of an effort initiated by the Québec *Commission d'étude environnementale stratégique* on shale gases, the project consists in the development and implementation of the methods and the analysis of the concentration and the isotopic signature of these light hydrocarbons and dissolved organic carbon (DOC) in groundwater samples. The stable isotope analyses will help determine the origin of the gas and DOC in these samples, including the discrimination between Utica shale gas and conventional gas. Water samples have been collected from >100 wells in the St. Lawrence Lowlands (Québec, Canada).

[5] National Res. Inst. of Fisheries and Environ. of Inland Sea, Fisheries Research Agency, Japan.
[6] Inst. Lowland and Marine Rese., Saga Univ., Japan.

While a large number of studies have documented rapid increase in the annual sea surface temperature (SST) and global mean sea level rising, global warming effect on enclosed coastal seas, such as Seto Inland Sea or Chesapeake Bay, is less understood. For understanding historical SST records in these shallow basins, we need to utilize a certain SST proxy preserved in sediments. However, paleo-thermometry in the shallow coastal basin is rather difficult because carbonate microfossils typically used for paleotemperature proxies are practically absent in the shallow ocean. On the hand, it is expected that organic compound based paleo-temperature proxies, such as TEX_{86}, can be utilized even in the shallow coastal sea. However, since TEX_{86} thermometry has rarely been used for such shallow marine sediments, applicability of TEX_{86} in the coastal ocean is still uncertain.

Here we test potential ability of TEX_{86} paleothermometry in shallow coastal anoxic basin. We collected particulate organic matters from the water column of Beppu Bay (Seto Inland Sea) (~70m deep) at every 10 m. The vertical depth profile of glycerol dialkyl glycerol tetraethers (GTGTs) distribution within the anoxic and oxygen-enriched water columns was determined. We also calculated TEX_{86} values, TEX_{86}^{H} and TEX_{86}^{L} temperatures which were compared with the in situ measurements of water temperatures.

Comparing total GDGTs in the anoxic water mass to those of the oxygen-eiriched water mass, those are significantly abundant in the anoxic bottom water. $TEX_{86}^{H/L}$ derived temperatures correlate with the in situ measurements of water temperatures. Therefore it is expected that temperatures delived from $TEX_{86}^{H/L}$ represent in situ water temperatures in Beppu Bay.

Technological challenges for the advanced study of subseafloor life

YUKI MORONO[1]*, TAKESHI TERADA[2], MOTOO ITO[1] TATSUHIKO HOSHINO[1] AND FUMIO INAGAKI[1]

[1]Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Monobe B200, Kochi 783-8502, Japan. (*correspondence: morono@jamstec.go.jp)
[2] Marine Works Japan Ltd., Oppamahigashi 3-54-1, Yokosuka 237-0063, Japan.

During the past decades, scientific ocean drilling has explored the subseafloor biosphere at some representative drilling sites: on the ocean margins, organic-rich anaerobic sedimentary habitats (e.g., Shimokita coalbeds) harbor sizable numbers of microbial cells over 1,000 meters below the seafloor whereas microbial populations in ultra-oligotrophic aerobic sedimentary habitats of the oceanic gyre (e.g., South Pacific Gyre) are several orders of magnitude lower. Molecular analysis at the community level demonstrates the occurrence of subseafloor microbial ecosystems that consist of phylogenetically diverse microbes; however, metabolic functions of individual microbial components and strategies for long-term survival under the energetically and geophysically severe condition have remained largely unknown. To address these issues, analytical developments customized for subseafloor life are of our essential challenges for the advanced microbiological and biogeochemical analyses.

One of the most fundamentally significant techniques is the precise detection and enumeration of indigenous subseafloor life. Recently, we have standardized an improved cell separation method, which effectively detached the cells from mineral grains of the sedimentary habitat, by applying multiple density gradient layers. Based on the cell-derived fluorescent wavelength pattern [1], the detached cells can be precisely enumerated using an automated fluorescent microscopic system [2] and/or a flow cytometry. The combined use of this technique with a cell sorter allows us to separate the cells for single cell genomics and mass spectrometry (e.g., NanoSIMS) analyses. The systematic analytical scheme currently applies to some representative deep-biosphere samples such as the South Pacific Gyre and Shimokita coalbeds (i.e., IODP Expedition 329 and 329, respectively), from which results may open a new window to the study of subseafloor life.

Characterization of the deep microbial life at different CCS sites

DARIA MOROZOVA[1]*, DOMINIK NEUMANN[1], MICHAEL ZETTLITZER[2] AND HILKE WÜRDEMANN[1]

[1] Helmholtz Centre Potsdam GFZ, International Centre for Geothermal Research, Hermannswerder 15, 14473 Potsdam, Germany. *Correspondence: Hilke.Wuerdemann@gfz-potsdam.de

[2] RWE Dea AG, Laboratory Wietze, Industriestraße 2, 29323 Wietze, Germany

Deep subsurface formations like subsurface saline aquifers or depleted gas reservoirs are candidate sites for the carbon capture and storage (CCS) technology. Since the Earth subsurface is known to be a major habitat for a high number of different groups of microorganisms, our working group aims at microbial monitoring at different CCS-sites in Germany (a 650m-deep saline aquifer and a 3.5km-deep depleted gas reservoir). Both sites are characterized by high salinity (325 g/l and up to 420 g/l) and relatively high TOC content (up to 150 mg/l and up to 300 mg/l). In order to characterize the microbial life in extreme habitats we aim to localize and identify microbes including their metabolism influencing mineral creation and dissolution. The ability of microorganisms to speed up dissolution and formation of minerals might result in changes of the local permeability and the long-term safety of CO_2 storage. Genetic fingerprinting (PCR SSCP, DGGE), qPCR and FISH are applied for identification and quantification of changes in deep microbial community caused by the injection of supercritical CO_2.

Although saline aquifers could be characterized as an extreme habitat for microorganisms due to high pressure and salinity, a high number of diverse groups of microorganisms were observed with molecular biological methods in downhole samples from the injection and observation wells at a depth of about 650m depth. Of great importance was the identification of the sulfate reducing bacteria, which are known to be involved in corrosion processes. Microbial monitoring during CO_2 injection has shown that both quantity and diversity of microbial communities were strongly influenced by the CO_2 injection.

First results of the sequence analyses from a 3,5km-deep, 120-130°C hot reservoir indicate the presence of several H_2-oxidizing bacteria, thiosulfate-oxidizing bacteria and biocorrosive thermophilic microorganisms. Due to the hypersaline and hyperthermophilic reservoir conditions, and therefore low cell numbers, the quantification of those microorganisms was not yet possible.

Crystal-chemical analyses of soil and drilled rock in Gale crater, Mars

The CheMin instrument on the Mars Science Laboratory Rover *Curiosity* performed X-ray diffraction analyses in Gale crater on both martian soil at Rocknest [1] and drilled rock at John Klein. Crystalline phases were identified and their abundances and unit-cell parameters were refined with the Rietveld method [2]. Crystal-chemical systematics, using data from the literature, were developed for the observed phases and were used to estimate the chemical compositions of the martian minerals.

Estimated Rocknest soil mineral compositions:

olivine: $(Mg_{0.63(3)}Fe_{0.37})_2SiO_4$

plagioclase: $(Ca_{0.57(13)}Na_{0.43})(Al_{1.57}Si_{2.43})O_8$

augite: $[Mg_{0.87(10)}Fe_{0.40}Ca_{0.73(4)}]Si_2O_6$

pigeonite: $[Mg_{1.13(9)}Fe_{0.70(10)}Ca_{0.17}]Si_2O_6$

In addition to the crystalline component, there is also an amorphous component. Subtracting the weighted chemistry of the crystalline component from the bulk composition, determined by APXS [3], provides an estimate of the amount and chemical composition of the amorphous component.

Currently, the analysis of the John Klein drilled rock sample continues. Preliminary data indicate the presence of smectite(s), sulfates, and igneous minerals similar to those found in Rocknest soil, representing the mineralogy of a potentially habitable environment. These data facilitate determination of comparable crystal–chemical systematics and comparisons with Rocknest soil.

The extremely sluggish volume diffusion rates of U and Pb in minerals such as baddeleyite and zircon, together with their resistance to breakdown during shock metamorphism, make them ideal recorders of inner Solar System evolution. In the case of highly shocked basaltic shergottite NWA5298, our discovery of igneous (187±33 Ma) micro-baddeleyite, with micron-wide reaction rims of much younger launch-generated zircon, promises further information on young Mars evolution if afforded high spatial resolution techniques.

Here we present the first atomic resolution STEM (HAADF detector) imaging of baddeleyite and zircon microstructure, and our progress toward their combination with atom probe tomography (CAMECA LEAP®) results for extraterrestrial phases. Conventional EBSD analysis indicates that euhedral baddeleyite CL zones are now amorphous at 50 nm length-scales, whereas high resolution STEM results reveal a mosaic of slightly misoriented nanocrystalline domains overgrown by unshocked zircon in single orientation. Rare dislocation trains in zircon are perhaps due to thermal stress on transit to outer space and Earth. Atom probe results for terrestrial reference zircon BR266 reveal a generally homogeneous distribution of radiogenic Pb^{2+}. The goal of LEAP analyses is to map Pb and trace element distribution in martian ejectic zircon rims, the age of which is constrained to lie between the youngest shocked baddeleyite date of 22±2 Ma [1] and the cosmic ray exposure ages of ~3 Ma for similar shergottites [2]. These techniques open the door to direct analysis of atom-scale mineral records of the evolution of Mars and the interplanetary travel of martian crust.

Effect of the isotopic composition of nitrite on the enrichment factor during benthic denitrification

AURELIE MOTHET[1]*, MATHIEU SEBILO[1], ANNIET M. LAVERMAN[2], VERONIQUE VAURY[1] AND ANDRE MARIOTTI[1]

[1] UPMC Univ Paris 06, UMR Bioemco, 4 place Jussieu, 75252 Paris Cedex 05, France, aurelie.mothet@upmc.fr (*presenting author)

[2] UPMC Univ Paris 06, UMR Sisyphe, 4 place Jussieu, 75252 Paris Cedex 05, France

Mediated by denitrifying bacteria under anoxic conditions, denitrification plays an important role reducing nitrate pollution in surface and groundwater. Denitrification can be traced by isotopic biogeochemistry; the isotopic enrichment factor associated with denitrification may vary significantly (i.e. for nitrogen, ε vary from -30 to 0‰). This large range might be due to the presence of nitrite, an intermediate during denitrification, not accounted for in the enrichment factor. The presence of nitrite, either transient or continuous, during denitrification is regularly observed. Variations in nitrite concentrations (production and/or reduction), depleted in ^{15}N and ^{18}O could modify the enrichment factor for nitrate, when the isotopic composition of nitrite and nitrate are measured together.

Therefore, the objective of this study was to determine the nitrogen and oxygen isotopic fractionation ($\varepsilon^{15}N$, $\varepsilon^{18}O$) associated with both nitrate and nitrite during denitrification by environmental benthic denitrifying communities. Denitrification rates were determined in sediments from four different locations in the Seine bassin (France). Nitrate reduction rates as well as nitrite production and reduction rates were determined and the ^{15}N and ^{18}O of both compounds were analysed. As expected, our results show that the isotopic composition of nitrite (^{15}N and ^{18}O) is depleted. With a maximum nitrite concentration of about 1% of the initial nitrate concentration, the isotopic enrichment factor shows a significant isotopic shift (-2‰ for nitrogen and oxygen). This indicates the importance of considering a correction of the enrichment factor for denitrification taking into account nitrite.

Calculating rates of ductile thrusting

MOTTRAM, C.M[1]*, PARRISH, R.R[2], WARREN, C.J[1], HARRIS, N.B.W[1] AND ARGLES, T.W[1]

[1] Dept. of Environment, Earth and Ecosystems, The Open University, Walton Hall, Milton Keynes, MK76AA, U.K.
[2] NERC Isotope Geosciences Laboratory, British Geological Survey, Keyworth, Nottingham NG12 5GG, United Kingdom
*correspondence: catherine.mottram@open.ac.uk

The ductile interiors of mountain belts, key to our understanding of orogenic processes, are often exhumed from mid-crustal levels by ductile shearing. The Sikkim Himalaya presents some of the best exposures of a ductile shear zone in the world. The Main Central Thrust (MCT) is a major Himalayan structure that has accommodated a large amount of movement during India-Asia convergence. In Sikkim, a duplex beneath the thrust has folded the MCT into a dome. This structural configuration allows a novel method for determining rates of processes by exploiting the late-stage folding of the MCT (figure 1).

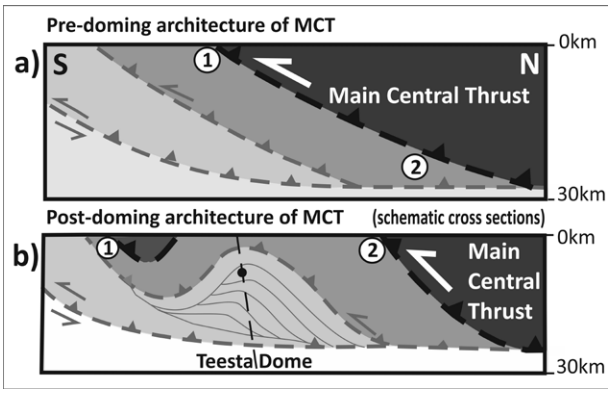

Figure 1. Illustrates a schematic cross-section before (a) and after (b) folding of the MCT. Both the two marker locations (1 and 2) are currently at the surface (b), prior to folding location 2 lay at depth (a). Therefore the age of peak metamorphism at 2 is likely to be younger than at 1, assuming metamorphism is contemporaneous with thrusting. The age difference between samples taken from locations 1 and 2 can be used to calculate a rate of thrusting.

The timing of metamorphism of rocks formed at equivalent metamorphic grades across the MCT (1 and 2 on figure 1) has been determined from U-Th-Pb monazite geochronology. The data show significant differences in the timing of metamorphism in the northern and southern exposures of the MCT in Sikkim, consistent with the figure 1 model. Rates of thrusting from initial calculations (~1cm/yr) appear slower than reported in earlier studies. This approach is the first to exploit folding of a major fault to calculate rates of ductile thrusting at a mid-crustal level.

Geochemistry of Nowdouz potassic volcanic rocks, the sample for early cenozoic potassic magmatism in NW Iran

SEYED ZAHED MOUSAVI[1]

[1]Basic science department, Meshkinshahr branch, Islamic Azad University, Meshkinshahr, Iran, (zahedmousavi@gmail.com)

The studied area is situated at 47°16´– 47°23´East and 38°20´– 38°23´North between Meshkinshahr and Ahar cities, NW Iran. Despite the importance of the potassic volcanic in geology of Iran and good studies done on it, yet there is no clear information from the history of the this volcano rocks. In this article we will attempt a review of past research results, new data (field, petrography and geochemical). In addition by using the geo-chemical data, we discuss the origin and tectonic position. This area is part of Azarbaijan structural zone. High intensity alteration systems have effected on this rocks that argilice and silica zones are importance of them. Geochemical characterization and magma series show that composition on Nowdouz volcanic rocks are basalt, leucitite, tephrites and phonolitic tephrites. Many samples are in alkalic range. A general trend are observed toward increasing alkalinity with decreasing of SiO_2.Main oxides and rare earth element characterization confirm the fractionation of assemblage of olivine, pyroxin, plagioclases based on the decreasing of MgO,CaO, FeO_t and MnO with decreasing of SiO_2 and increasing of Rb/K , Sr and also decline of Sc with increasing of SiO_2. Fairly regular linear trends in major and trace elements in SiO_2 represent the same magma reservoir for rocks of this area. Although there is a enrichment of Large Ion Lithophile Elements and depletion in High Field Strength Elements. However with survey of geodynamical models for potassic magmatism , it seems that this area, based on idea of Arabian plate sub ducting under Iranian plat in late cretaceous and geochemical feature, are comparable with postcollosion related magmatism patterns.

Archaean granites: classification, origin and tectonic implications

JEAN-FRANÇOIS MOYEN[12]

[1]Université Jean-Monnet, Saint-Etienne, France. Jean.francois.moyen@gmail.com
[2]CNRS UMR6524

The Archaean continental crust is dominated by granitoids, covering a large range of compositions and rock types. While several classification schemes exist for modern granitoids, there is relatively little application to Archaean rocks and a comprehensive terminology is lacking.

Similar to modern granitoids, Archaean rocks fall under three main groups: peralkaline granites; metaluminous granites and related rocks (granite to diorite); and metaluminous to peraluminous granites. Archaean peralkaline granites, although superficially similar to their modern counterparts, are mostly magnesian and lack the enrichments in trace elements that reflect, in the modern Earth, an origin related to fractionation of mafic melts derived from enriched mantle sources. Metaluminous granites (including sanukitoids) are, in some respect, similar to modern arc granites; but are no exact match to modern rocks, most likely pointing to different mantle enrichment processes in Archaean "subduction" environments. Metaluminous to peraluminous granites are formed by dehydration melting of mafic hydrous silicates and include potassic rocks, very similar to modern rocks and similarly generated by biotite dehydration melting; as well as sodic rocks (TTGs and low-pressure sodic granitoids), related to breakdown of amphibole (or of an equivalent eclogitic assemblage). Sodic granitoids can further be subdivided in low-pressure rocks (similar to rare, oceanic-plateau related granites, with the same apparent "arc" signature); medium-pressure TTGs; and high-pressure TTGs, that do not have a modern counterpart, suggesting some uniquely Archaean petrogenetic process, involving deep (> 15—20 kbar) melting of metamafic rocks.

The differences between Archaean and modern granitoids reflects similar differences observed in mafic rocks: Archaean mafics lack the clear dichotomy observed in the modern record between arc and non-arc samples; and do not show any evidence for strongly depleted or enriched mantle sources. Likewise, Archaean granites reveal a tectonic system with a near-primitive mantle; more common melting of oceanic plateaus; some continental collision; deep melting of mafic rocks, with no modern equivalent; and lacking modern-style subductions (with water fluxed melting of the mantle wedge), although some rocks record melting of a mantle enriched by buried surface matter.

Applications of Absorption Spectroscopy for Water Isotopic Measurements in Cold Clouds

ELISABETH MOYER[1]*, LASZLO SARKOZY[1], KARA LAMB[1]*, BEN CLOUSER[1], ERIC STUTZ[1], BENJAMIN KÜHNREICH[2], JANEK LANDSBERG[3], JAN HABIG[4], NARUKI HIRANUMA[4], STEVEN WAGNER[2], VOLKER EBERT[5], ERIK KERSTEL[3], OTTMAR MÖHLER[4] AND HARALD SAATHOFF[4]

[4]Institute for Meterology and Climate Research, KIT, Karlsruhe, Germany
[5]Physikalisch-Technische Bundesanstalt, Braunschweig, Germany

While mass spectrometry has been the measurement technique of choice for environmental water isotopic studies, absorption spectroscopy is becoming increasingly competitive for many applications. Advances in instrument sensitivity allow extending the use of isotopic measurements beyond tracing large-scale water transport, an application with relatively loose measurement requirements, to microphysics studies in cirrus and convective clouds in the dry upper troposphere. We outline measurement requirements for science applications in cold cirrus clouds, describe the development of isotopic instrumentation for microphysics studies at the AIDA aerosol and cloud chamber, and present isotopic measurements from the 2012-2013 ISOCLOUD campaign. ISOCLOUD adiabatic expansion experiments from 233-190 K produced the first direct measurements of isotopic fractionation factors at temperatures applicable to cirrus clouds and suggest the feasibility of field studies using water isotopologues as microphysical tracers.

Zinc is required for the function of more than 300 enzymes involved in many metabolic pathways, and is a vital micronutrient for living organisms. To investigate if Zn isotopes could be used to better understand metal homeostasis, as well as a biomarker for diseases, we assessed the distribution of natural Zn isotopes in various mouse tissues. We found that, with respect to Zn isotopes, most mouse organs are isotopically distinct and that the total range of variation within one mouse encompasses the variations observed in the Earth's crust. Therefore, biological activity must have a major impact on the distribution of Zn isotopes in inorganic materials. The most striking aspect of the data is that red blood cells and bones are enriched by ~0.5 per mil in ^{66}Zn relative to ^{64}Zn when compared to serum, and up to ~1 per mil when compared to the brain and liver. This fractionation is well explained by the equilibrium distribution of isotopes between different bonding environments of Zn in different organs. Differences in gender and genetic background did not appear to affect the isotopic distribution of Zn. Together, these results suggest that potential use of Zn isotopes as a tracer for dietary Zn, and for detecting disturbances in Zn metabolism due to pathological conditions.

Cd mobility in anoxic Fe-mineral-rich environments – potential use of Fe(III)-reducing bacteria for soil remediation

E. MARIE MUEHE[1]*, IRINI J. ADAKTYLOU[1], MARTIN OBST[2], CHRISTIAN SCHRÖDER[1], SEBASTIAN BEHRENS[1], ADAM P. HITCHCOCK[3], TOLEK TYLSIZCZAK[4], UTE KRÄMER[5] AND ANDREAS KAPPLER[1]

Agricultural soils worldwide are increasingly burdened with heavy metals such as Cd from industrial sources and impure fertilizers. Metal contaminants potentially enter the food chain via plant uptake from soil and may affect human and environmental health negatively. New remediation approaches are needed to diminish soil metal contents, but in order to apply them it is necessary to understand how soil microbes and minerals interact with these toxic metals.

Here, we show that microbial Fe(III) reduction leads to Cd immobilization in Cd-bearing anoxic soils. To understand how microbial Fe(III) reduction influences Cd mobility, we isolated a new Cd-tolerant, Fe(III)-reducing *Geobacter sp*. strain Cd1 from a heavily Cd-contaminated soil in Germany. In lab experiments, this *Geobacter* strain first mobilized Cd from Cd-loaded Fe(III) (oxyhydr)oxides followed by precipitation of Cd-bearing mineral phases. Using Mössbauer spectroscopy and Scanning Electron Microscopy, the original and newly formed Cd-containing Fe(II) and Fe(III) mineral phases, including Cd-Fe-carbonates, Fe-phosphates and Fe-(oxyhydr)oxides, were identified and characterized. Using Energy Dispersive X-ray spectroscopy and Synchrotron-based Scanning Transmission X-ray Microscopy, Cd was mapped in the Fe(II) mineral aggregates formed during microbial Fe(III) reduction.

Microbial Fe(III) reduction mobilizes Cd prior to precipitation of the Cd as Cd-bearing mineral phases. On the one hand, the mobilized Cd could potentially be taken up by phytoremediating plants, resulting in a net removal of Cd from contaminated sites. On the other hand, Cd precipitation could immobilize Cd more strongly and reduce Cd bioavailability in the environment, causing less toxic effects to crops and soil microbiota. However, the stability and therefore bioavailability of these newly-formed Fe-Cd mineral phases needs to be assessed thoroughly. Whether phytoremediation or immobilization of Cd in a mineral with reduced Cd bioavailability are feasible mechanisms to reduce the toxic effects of Cd in the environment still remains to be determined.

Permafrost affected soils of the Northern circumpolar region represent 50% of the terrestrial soil organic carbon (SOC) reservoir and are most strongly affected by climatic change. Although a large number of studies revealed the overall C cycles in this region, there is only scarce knowledge about the quantitative and qualitative properties of organic matter compartments and their potential stability. To unravel chemical and physical properties of SOC in permafrost soils we combined the physical soil fractionation with the evaluation of the chemical composition using nuclear magnetic resonance spectroscopy (NMR) and microscopic techniques as nano-scale secondary ion mass spectrometry (NanoSIMS).

Approximately 50-75% of Alaska's Arctic Coastal Plain is covered with thaw lakes and drained thaw lakes that follow a 5,000 yr cycle of development (between creation and final drainage), thus forming a natural soil chronosequence. The drained thaw lakes offer the possibility to study SOM dynamics affected by permafrost processes over millennial timescales. In April 2010 we sampled 16 soil cores reaching from young drained lakes (0-50 years since drainage) to ancient drained lakes (3000-5500 years since drainage).

We can show that up to over 25 kg SOC per square meter were stored as mostly labile organic matter particles rich in carbohydrates. In contrast only 9.7 ± 2.3 kg OC per square meter were sequestered as presumably more stable mineral associated OC dominated by aliphatic compounds. The formation of soil aggregates, comparable to soil aggregation in temperate soils, was proved by physical fractionation and microscopic evidence. Here we show that significant amounts of labile SOC are stored in permafrost soil layers which soon could be degraded due to the deepening of the active layer resulting from climatic change.

Unraveling cooling histories using Fe-Mg zoning of exsolution lamellae in a garnet pyroxenite from the Granulitgebirge, Saxony, Germany

THOMAS MUELLER[1], HANS-JOACHIM MASSONNE[2] AND ARNE P. WILLNER[2]

[1]Institut für Geologie, Mineralogie und Geophysik; Ruhr-Universität Bochum; D-44801 Bochum; Germany; thomas.mueller-1@rub.de
[2]Institut für Mineralogie und Kristallchemie; Universität Stuttgart; D-70174 Stuttgart, Germany

The exchange of elements such as Fe-Mg between co-existing ferromagnesian minerals is a consequence of changing external (intensive) variables, such as temperature and/or pressure and proceeds via a series of kinetically controlled processes. Compositional zoning patterns of co-existing mineral pairs can thus be used to model the incomplete diffusive equilibration process if diffusive parameters and the partition coefficient are known as a function of P and T. Unraveling such zoning patterns is the key tool to decipher the nature of measured temperatures using geothermobarometry and are thus potential recorders of cooling and exhumation processes on various timescales.

The studied sample is a garnet pyroxenite from the Granulitgebirge, Germany. The rock contains remarkable exsolution textures from former megacrysts that produced up to mm-wide, alternating lamellae of garnet (grt) and clinopyroxene (cpx). Compositional profiles of Fe and Mg measured with the electron microprobe perpendicular to the grt-cpx interfaces reveal almost flat, but often slightly zoned patterns with increasing Fe from the grt center towards the interface and decreasing Fe (from core to rim) in the adjacent cpx.

We present data from a numerical finite difference scheme that simulates diffusive exchange between grt and cpx along a virtual cooling path. The model assumes local equilibrium at the interface and diffusive fluxes are constraint by mass balance. Preliminary modeling results suggest very efficient compositonal resetting even for very fast cooling rates at temperatures above 1000 °C, so that no record of the growth of the lamellae is preserved. Nevertheless, the presence of slight chemial zoning can successfully be used to estimate P-T conditions of lamellae formation as well as cooling / exhumation rates in the temperature range between 700 – 1000 °C. Finally, modeling results indicate fast cooling rates of >> 100 °C/Ma in agreement with published estimates for the crystalline complex of the Granulitgebirge based on geochronology.

Dating deposition and low-grade metamorphism by in situ U-Pb geochronology of titanite

J.R. MUHLING[1,2]*, B. RASMUSSEN[2] AND I.R. FLETCHER[2]

[1]CMCA, The University of Western Australia, Stirling Highway, Crawley, WA 6009, Australia (*correspondence: janet.muhling@uwa.edu.au)
[2]Dept of Applied Geology, Curtin University, Kent Street, Bentley, WA 6102, Australia

Titanite ($CaTiSiO_5$) is a widespread accessory mineral, composed of major rock-forming elements, that incorporates sufficient U into its structure for U–Pb geochronology. It occurs in felsic to imtermediate igneous rocks, in very low to high-grade metamorphic rocks, in sedimentary rocks and in hydrothermal ore deposits. Because titanite can form at temperatures below 700°C, its closure temperature for the diffusion of Pb, it can provide ages for a wide range of low- to moderate temperature geological processes. Although titanite forms detrital and authigenic grains in sedimentary rocks, it has rarely been used to date deposition, diagenesis or low-grade metamorphism.

Two generations of titanite are preserved in tuffaceous rocks of the Paleoproterozoic Timeball Hill Formation, southern Africa: euhedral, brown crystals with apatite inclusions, and colorless, pore-filling cement. The brown titanite has elevated U, Th and Fe and low Al, consistent with a magmatic origin, whereas the colorless titanite has high Al and F and low Fe contents, suggestive of a diagenetitc or metamorphic paragenesis. In situ SHRIMP geochronology of brown titanite from a tuff bed gives a weighted mean $^{207}Pb/^{206}Pb$ age of ~2275 Ma and is interpreted to provide a reliable estimate for depositional age.

Authigenic titanite has been reported as pore-filling cement in a number of sandstone units worldwide but has not previously been dated. Fe contents vary widely, and some examples have elevated amounts of high-field-strength elements. The compositions may reflect local metamorphic or hydrothermal fluid compositions. In situ U–Pb dating of intergranular titanite from a tuffaceous sandstone in the Timeball Hill Formation yields an age of ~2145 Ma, which corresponds with previous estimates for a low-grade tectonothermal event in southern Africa.

Our results demonstrate that titanite is a versatile chronometer that can be used to constrain depositional ages, and those of diagenesis and low-grade metamorphism. It has the potential to increase the number of sedimentary rock units that can be dated, and to elucidate the histories of low-temperature geological processes in depositional basins.

An EBSD study of textural evolution across a shear zone in the Bergen Arcs, Western Norway

HIROKI MUKAI[1]*, HÅKON AUSTRHEIM[2] AND ANDREW PUTNIS[1]

[1] Institute for Mineralogy, University of Münster, Münster, Germany (*correspondence: hmukai001@uni-muenster.de)
[2] Physics of Geological Processes, University of Oslo, 0316 Oslo, Norway

The interaction between fluid infiltration, mineral reactions and rock deformation has been the subject of much debate and raises fundamental issues such as the mechanism of fluid transport in nominally impermeable rocks. Localisation of deformation in shear zones provides an opportunity to study the textural and mineralogical evolution from relatively undeformed wall rocks through to the highly strained shear zone and to evaluate the various mechanical and chemical processes which result in rock weakening. Rock strength or rheology is a critical parameter in geodynamic models for collision and subduction zones.

The present study was carried out from cross sections through an amphibolite facies shear zone associated with the Caledonian Orogeny (~420Ma) that transects older anorthositic granulite facies rocks (~930Ma) in the Bergen Arcs, western Norway. In this region, it is possible to study the textural and chemical changes from the relatively unaltered granulites which retain the high grade mineralogy and texture, through to highly strained and hydrated minerals within the shear zones.

Our SEM observations of the cross sections showed that the granulite facies rock is composed of plagioclase (An_{50}), garnet and an Al-rich clinopyroxene, with minor scapolite. Closer to the shear zone, the original granulitic plagioclase is replaced by a 2-phase feldspar intergrowth composed of an Na-rich and Ca-rich network where the Na-rich domains (composition ~An_{24}) are surrounded by thinner "veins" of Ca-rich plagioclase (An_{64}). At the same time the garnet grains develop Fe-richer rims of variable width and involve the production of amphibole crystals at the boundary with the plagioclase. Lastly, in the shear zone, polygonal plagioclase retaining the 2-phase structure and foliated amphibole crystals were observed.

In the present study, we investigated in detail the evolution of the microtextures by electron back scattered diffraction (EBSD). Especially, we focused on their crystal preferred orientations (CPOs) which can be related to the deformation mechanisms.

Relationship Between Volatiles and Noble Gases in Icelandic Lavas: Evidence for Crustal Recycling

S. B. MUKASA[1], L. C. LOUDIN[1], M. PETERSON[2] AND E. T. DIXON[3]

[1]Department of Earth Sciences, University of New Hampshire, Durham, NH 03824, USA
[2]Department of Geological Sciences, Brown University, Providence, RI 02912, USA
[3]US Department of Energy, 1000 Independence Ave, SW, Washington, DC 20585-0420, USA

The anomalously high volume of magma erupted on Iceland relative to elsewhere along the Mid-Atlantic Ridge historically has been attributed to an unusually hot mantle. More recently, compositional gradients in the underlying mantle, established during much earlier melting events, have also been invoked. We propose a third alternative, namely, significant quantities of volatiles in the melt source.

Olivine-hosted melt inclusions from Miðfell in Iceland's Western Volcanic Zone have major oxide compositions that place them among the most primitive lavas (highest MgO and lowest SiO_2) on the island. Trace-element-abundance patterns for these inclusions define two end-member compositions – depleted and enriched mantle sources –suggesting intimate spatial association between the two. These end-member compositions are observed even between melt inclusions from the same individual hand sample, indicative of the survival of mantle heterogeneity within an incompletely mixed magma chamber.

Although degassing is common among the inclusions, some have exceptionally high H_2O concentrations of up to 3.0 wt. %, by far the highest water concentrations ever reported in basalts from an ocean island. A subset of the olivine separates from Miðfell and Eldborg, previously analysed for Ne and He isotopic compositions, have melt inclusions which show that when $^{20}Ne/^{22}Ne$ and $^{3}He/^{4}He$ R/R_a in the host olivine are relatively low (10.39 and 18 R/R_a, respectively), the H_2O, CO_2 F, S and Cl concentrations are all elevated. In contrast, when $^{20}Ne/^{22}Ne$ and $^{3}He/^{4}He$ are high – 11.10 and 29 R/R_a, respectively – the concentrations of the five volatiles are low. This suggests that crustal recycling was an important process in mantle melting beneath Iceland.

Exceptionally high-water concentrations in some of the melt inclusions suggest that part of the uniqueness of Iceland's geochemistry and eruptive nature is due to a hydrated source rather than solely the presence of a large thermal anomaly. This has important implications for the concentration of water in mantle materials, and thus the geophysical properties that govern the nature of flow in the mantle and the magma generation that produces ocean islands.

The results of metal mercury solubility in water study

RENATA V. MUKHAMADIYAROVA [1]* AND YURY V. ALEKHIN [1]

[1] Geochemistry Department, Faculty of Geology, Lomonosov Moscow State University, 119991 Moscow, Russia (*correspondence: rinutiya@mail.ru)

Correctly determine of the metal mercury solubility in the form of $Hg^o(aq)$ results [1,2] have set us the task to adjust the Henry's constants for a wide range of temperatures and in accordance with our published data. It is well known that the process of dissolution for inert and unhydratable gases in water temperature dependence of the Henry's coefficients has an extreme [3].

For Hg^o temperature dependence of the Henry's constant has a distinct, but little extreme at the temperature range 120-130 ºC, which is close to the position of extrema in systems with inert gases (Ar, Kr). We considered our new results, data of Sorokin *et al.* [4] for Hg^o and to compare - data for such hydratable gases like CO_2 and H_2S [3].

Thus, we see that the dissolution of elemental mercury vapor in water has an extreme by temperature, and, obviously, their interaction with water is very similar to that of the inert gases, but at lower equilibrium partial pressure of the vapor. This fact provides a virtually constant value of Henry's law constant in the range log K_H = -2,40 ÷ -2,43 in a wide temperature range.

The obtained values of the Henry's constants for Hg^o show that these values are close to the values characteristic of weak hydratable gases as Ar, CH_4, CO, H_2, N_2, O_2, etc. [3]. Obviously, the data presented in [4] characterize Henry's Law constant, calculated based on the total concentrations of mercury, including the dominant to 100-150 ºC oxidized forms.

Trace-element fingerprints of chromites and sulfides from the Archean Nuggihalli greenstone belt, western Dharwar craton, India

RIA MUKHERJEE[1,2]*, SISIR K. MONDAL[1], JOSÉ M. GONZÁLEZ-JIMÉNEZ[2], WILLIAM L. GRIFFIN[2], NORMAN J. PEARSON[2] AND SUZANNE Y. O'REILLY[2]

[1]Department of Geological Sciences, Jadavpur University, India (*correspondence: ria.mkrj@gmail.com)
[2]ARC Centre of Excellence for Core to Crust Fluid Systems (CCFS) and GEMOC, Macquarie University, Australia

The Nuggihalli greenstone belt hosts discontinuous lens-shaped bodies of 3.1Ga plutonic ultramafic-mafic rocks (chromitite-bearing serpentinite and tremolite-chlorite-actinolite schist, pyroxenite, anorthosite, magnetite-bearing gabbro), that are conformably surrounded by a contemporaneous unit of metavolcanic schists (komatiite-komatiitic basalt), encompassed within the tonalite-trondhjemite-granodiorite suite of rocks. Trace-element compositions analyzed by laser ablation ICP-MS on unaltered chromites (Cr# [100Cr /(Cr+Al)] = 79-87, Mg# [100Mg /(Mg+Fe^{2+}) = 45-55) show enriched values for Ti (1766-3277 ppm), Mn (2037-2615 ppm), Zn (382-763 ppm), Co (197-257 ppm) and lower values of Ga (21-27 ppm), Ni (660-1202 ppm), V (475-682 ppm) and Sc (3.99-7.14 ppm) relative to MORB. In chromite/MORB multi-element plots the trace-element patterns of the unaltered chromites resemble Archean chromites from Ni-sulfide unmineralized komatiitic rocks. Compositionally zoned chromites have modified core (Cr# = 65-73, Mg# = 7-15, Fe^{3+}# [100Fe^{3+} /(Cr+Al+Fe^{3+})] = 5-12, Ga = 10-29 ppm, Ti = 839-1680 ppm, Zn = 7098-9188 ppm, Sc = 2-7 ppm, Mn = 1701-5554 ppm, Ni = 113-570 ppm, V = 538-893 ppm, Co = 520-866 ppm) with rims of ferritchromit and rare magnetite (Cr# = 72-99, Mg# = 2-32, Fe^{3+}# = 23-77, Ga = 1.5-43 ppm, Ti = 544-8929 ppm, Zn = 578-13039 ppm, Sc = 0.62-30.69 ppm, Mn = 1284-25176 ppm, Ni = 200-3584 ppm, V = 157-2837 ppm, Co = 112-2255 ppm). The altered chromites show inter-sample, intra-sample, and intra-grain heterogeneity in trace-element distribution owing to hydrothermal alteration. Minor sulfides represented by millerite and niccolite (~2 modal%, 20-40 μm) occur in the interstitial spaces within massive chromitites. Disseminations (5-8 modal%, 20-50 μm) of chalcopyrite, pyrite and Ni-Co bearing sulfides occur in magnetite in the interstices and as inclusions. The platinum group elements are below the detection limits of laser ablation ICP-MS for all the sulfide occurrences in the Nuggihalli greenstone belt.

A Mesoarchean Paleosol from eastern India—the second oldest paleosol on Earth

JOYDIP MUKHOPADHYAY[1#], QUENTIN CROWLEY[2], GAUTAM GHOSH[1], SAMPA GHOSH[1], KALYAN CHAKRABARTI[1], B. MISRA[1] AND SANKAR BOSE[1]

[1]Department Of Geology, Presidency University, Kolkata, India, E-Mail: Joydip17@Gmail.Com
[2]Department Of Geology, School Of Natural Sciences, Trinity College, Dublin, Ireland

The Keonjhar paleosol, in the southern part of the Singhbhum craton has long been identified [1] but its age has not previously been well constrained. The paleosol occurs between the Singhbhum Granite and supracrustal siliciclastics unconformably overlying the granite, along the western margin of the pluton. The paleosol is locally mined for pyrophyllite. Recently, the paleosol has been classified as a vertisol [2]. The Singhbhum Granite on which the paleosol has been developed has been dated at ca. 3.33 Ga (U-Pb zircon LA-ICPMS) [3]. Here we report detrital zircon U-Pb LA-ICPMS ages from overlying sandstones covering a wide geographic locality from Pal Lahara in the west to Mahagiri hills in the east. U-Pb detrital zircon ages from four samples and more than 120 concordant or near concordant analyses indicate that the youngest grains cluster between 3.0 and 3.3 Ga, and none of the zircons are younger than 3.0 Ga. Our data suggest that the depositional age of the sandstones is ca. 3.0 Ga and thus constrain the age of formation of the paleosol between 3.0 Ga and 3.3 Ga. The Keonjhar paleosol is therefore the second oldest known paleosol on Earth, after the Pilbara paleosol (ca. 3.4 Ga) [4] and provides an excellent opportunity to study the Earth's Mesoarchean atmosphere directly from the rock record.

Probing the Hadean world with noble gases

SUJOY MUKHOPADHYAY[1]

[1]Dept. of Earth and Planetary Sciences, Harvard University, Cambridge, MA 02138, USA; sujoy@eps.harvard.edu

Earth's violent accretion likely generated multiple magma oceans. In particular, the Moon-forming giant impact is often thought to have produced a whole mantle magma ocean, which would have homogenized any pre-existing chemical heterogeneity within the mantle. The ratio of primordial ^{3}He to primordial ^{22}Ne in the mantle preserves a record of magma oceans on the early Earth. Importantly, the ^{3}He/^{22}Ne ratio of the Earth's shallow depleted mantle is significantly higher than the deep mantle. To explain this observation, I propose that at least two giant impact-induced atmospheric blow-off and magma ocean degassing episodes are required and that the last giant impact did not generate a whole mantle magma ocean. Accordingly, if plumes are derived from Large Low Shear Wave Velocity Provinces (LLSVPs) at the base of the mantle, then LLSVPs (i) are not remnants of crystallization of a global magma ocean associated with the last giant impact; and (ii) are not dense cumulate piles that crystallized from the last magma ocean at shallow depths and were subsequently gravitationally overturned to the core-mantle boundary, as shallow cumulates would be the most degassed (with the highest ^{3}He/^{22}Ne ratios). LLSVPs either correspond to crystallization products from an earlier magma ocean or are produced through a mechanism not associated with magma oceans.

Mantle Xe isotopic constraints indicate that the final mantle outgassing and atmospheric blow-off events inferred from ^{3}He/^{22}Ne ratios were accomplished between ~30 to 65 Myrs after the start of the Solar System. Therefore, catastrophic outgassing associated with giant impacts, including the Moon-forming impact, must have occurred within this time window. Previous calculations of impact-induced atmospheric erosion have, however, found that it is difficult to completely remove the atmosphere from a body as large as Earth by a giant impact. The need for atmospheric loss inferred from the noble gas data can be reconciled with the dynamics of giant impacts by considering the new high-spin Moon formation hypothesis. I will discuss the origin of Earth's early atmosphere in light of the new high-spin model for Moon formation and new noble gas data from mantle-derived rocks. I propose that major differences in the noble gas signatures of terrestrial planetary atmospheres reflect the diverse outcomes of late impact events on each planet.

Of ancient reservoirs and recycled noble gases

S. MUKHOPADHYAY, R. PARAI, J. M. TUCKER AND M. K PETŐ[1]

[1]Dept. of Earth & Planetary Sciences, Harvard University, Cambridge, MA 02138, USA; sujoy@eps.harvard.edu

The noble gases provide important constraints on planetary volatile cycling and our understanding of mantle structure and dynamics. For example, OIBs have ^{129}Xe/^{130}Xe ratios closer to the atmospheric ratio than MORBs, which could either reflect a higher proportion of recycled Xe in the OIB source or the sampling of an ancient, less-degassed reservoir (>4.45 Ga, since ^{129}I, which produces ^{129}Xe, is extinct after ~100 Ma). However, measurements of mantle-derived noble gases indicate that OIB sources do not have a higher proportion of recycled atmospheric Xe relative to MORB sources. The observation that the differences in the Xe isotopic composition of MORBs and OIBs cannot be attributed solely to recycling requires that OIBs sample a reservoir that evolved with a lower I/Xe ratio than the MORB source. Thus, differences in the degree of outgassing between the MORB and OIB sources must have been established by 4.45 Ga and subsequent mixing between the two reservoirs must have been limited. As a result, if OIBs are derived from the large low shear wave velocity provinces (LLSVPs) at the base of the mantle, then the Xe data require these features to be at least as old as 4.45 Ga.

Although the differences in MORB and OIB Xe isotopic composition cannot be solely due to recycling, new high-precision Xe measurements in MORBs and OIBs indicate that ~80-90% of the Xe in the MORB and OIB sources could be attributed to recycled atmospheric Xe. Thus, recycling of atmospheric noble gases is a process important to mantle volatile budgets. Our ability to constrain mantle source ^{129}Xe/^{130}Xe and ^{40}Ar/^{36}Ar ratios through multiple step crushing experiments now reveals significant heterogeneities in these ratios among mantle sources. For example, along 500 km of the Southwest Indian Ridge, in a region removed from any known plume influence, we observe ~50% and ~80% of the total mantle variation in ^{40}Ar/^{36}Ar and ^{129}Xe/^{130}Xe, respectively. Such large variations indicate a MORB source that has experienced heterogeneous recycling and mixing of material metasomatized by subduction zone fluids carrying recycled atmospheric Ar and Xe. Thus, a more complex picture emerges from new high-precision noble gas data, of a planetary interior that has both retained broad ancient degassing features and developed fine-scale heterogeneity from a chaotic, integrated history of volatile cycling.

Nitrogen and oxygen isotopic composition of atmospheric nitrate near the highways

ARATA MUKOTAKA*, SAKAE TOYODA AND NAOHIRO YOSHIDA

Tokyo Institute of Technology, Japan
(*correspondence: mukotaka.a.aa@m.titech.ac.jp)

Nitrogen isotope ratio ($\delta^{15}N$) and conventional oxygen isotope ratio ($\delta^{18}O$) in atmospheric nitrate has been used to estimate the NO_X sources and its oxidation pathways. Recently, ^{17}O-excess ($\Delta^{17}O \approx \delta^{17}O - 0.52 \times \delta^{18}O$) is known to be more robust indicator of atmosperic nitrate formation pathways than $\delta^{18}O$ value. Although the $\delta^{15}N$, $\delta^{18}O$ and $\Delta^{17}O$ values in atmospheric nitrate have been studied in various regions [e.g. ref.1 and references therein], only a few observations of the oxygen isotope ratios in urban area have been reported. In this study, we collected precipitation and atmospheric particles near the highways located in Yokohama, Japan from Janualy 2012 to December 2012, and measured $\delta^{15}N$, $\delta^{18}O$ and $\Delta^{17}O$ values in nitrate.

Precipitation samples were collected using a funnel and plastic bottle. The atmospheric particle samples were collected on quartz filters using high-volume air sampler. The filters were replaced every week. The stable isotope ratios of nitrate were measuerd by GC-IRMS after converting nitrate to N_2O.

The $\delta^{15}N$ and $\delta^{18}O$ values in precipitation, and the $\delta^{15}N$ values in particle showed a temporal variation similar to the previously reported values (-2.2‰ < $\delta^{15}N$ < 13.6‰ and 52.6‰ < $\delta^{18}O$ < 83.4‰) [2, 3]. The variation of $\delta^{18}O$ values in particulate nitrate was similar to that of precipitation, but extremely low values (26.2‰ to 39.7‰) were observed from the end of August to the end of November. The low $\delta^{18}O$ values cannot be explained by typical nitrate formation processes that involve ozone, and imply that isotopically light oxygen, such as O_2 ($\delta^{18}O$ = 23.5‰) played a key role in NO_X oxidation prosess in the period [4, 5]. Implication from $\Delta^{17}O$ data will be also discussed.

Anoxic geothermal fields and the early life

ARMEN Y. MULKIDJANIAN[1,2], ANDREW YU. BYCHKOV[3], DARIA V. DIBROVA[1,2], MICHAEL Y. GALPERIN[4] AND EUGENE V. KOONIN[4]

[1]University of Osnabrück, Germany (amulkid@uos.de), [2]School of Bioengineering and Bioinformatics, and [3]School of Geology, Moscow State University, Russia
[4]National Center for Biotechnology Information, NLM, NIH, Bethesda, Maryland 20894, USA

We have reconstructed the 'hatcheries' of the first cells by combining geochemical analysis with phylogenomic scrutiny of the inorganic ion requirements of universal components of modern cells [1]. These ubiquitous, and by inference primordial, proteins and functional systems show affinity to and functional requirement for K^+, Zn^{2+}, Mn^{2+}, and phosphate. Thus, protocells must have evolved in habitats with a high K^+/Na^+ ratio and relatively high concentrations of Zn, Mn and phosphorous compounds. Geochemical reconstruction shows that the ionic composition conducive to the origin of cells could not have existed in marine settings but is compatible with emissions of vapor-dominated zones of inland geothermal systems. Under anoxic, CO_2-dominated atmosphere, the elementary composition of pools of condensed vapor at anoxic geothermal fields would resemble the internal milieu of modern cells.

The scientists who address the origin of life problem from a purely chemical viewpoint argue that specific formation of activated, cyclic ribonucleotides with a potential for polymerization could take place in formamide-rich solutions, particularly under the action of UV light and in the presence of borate and phosphorous compounds [2, 3].

The exhalations of even modern geothermal fields contain high amounts of ammonia, phosphate, borate and hydrocarbons, so that the anoxic geothermal fields should have been conducive for formation of simple amides and nitrogen-containing organic molecules, including activated nucleotides.

Hence, the anoxic geothermal fields, which we identified as tentative cradles of life by using the top-down approach and phylogenomic analysis, could provide exactly those geochemical conditions that were suggested as most conducive for the emergence of life by the chemists who pursued the complementary bottom-up strategy.

Mantle compositional gradients in a hot subduction setting, the Garibaldi Volcanic Belt, northern Cascade Arc

EMILY K. MULLEN* AND D. WEIS

PCIGR, University of British Columbia, Vancouver, Canada
(*correspondence: emullen@eos.ubc.ca)

Hot subduction zones challenge the dehydration melting model for primary arc basalt generation, as hot slabs may liberate water at depths too shallow to trigger mantle melting. The Garibaldi Volcanic Belt (GVB), the northernmost segment of the Cascade Arc, extends from Glacier Peak in the south to Bridge River Cones in the north and is one of the hottest subduction zones globally [1, 2]. The age of the subducting plate decreases from ~10 Ma in the south to ~5 Ma in the north at the trench [3], resulting in a northerly increase in slab temperature beneath the arc axis [1]. Together with a decrease in magmatic productivity, basalts grade progressively from typical calc-alkaline arc basalts in the south to alkalic basalts in the north, reflecting reduced melt fractions due to low slab input [4]. Both basalt varieties occur at Mt. Garibaldi. Gradual northerly decreases in La/Nb, $^{87}Sr/^{86}Sr$ (0.70318 to 0.70298) and Pb isotope ratios are consistent with the hypothesis of decreasing slab input. In addition, decoupling of ε_{Hf} from ε_{Nd} indicates sediment input as a fluid. The most alkaline basalts record minimal slab input, with Pb isotope ratios lower than in other Cascade Arc basalts and similar to Explorer MORB. However, Zr/Nb, $^{208}Pb^*/^{206}Pb^*$, ε_{Nd} (+8.9 to +7.1) and ε_{Hf} (+13.3 to +8.5) decrease to the north, indicating an arc-parallel gradient in mantle source enrichment that is unrelated to slab input. The alkaline basalts tap a mantle source more incompatible element enriched and isotopically distinct from the depleted mantle that produces calc-alkaline basalts. The enriched mantle is also hotter (~1500°C) than the sub-arc mantle wedge (max ~1350°C) [2], consistent with upwelling asthenosphere, possibly at the slab edge [5]. Arc-parallel mantle flow may draw the upwelling mantle into the arc, generating a compositional gradient upon which slab input is superimposed. The influx of this upwelling mantle may have far-reaching effects, as the $^{208}Pb^*/^{206}Pb^*$ trend begins as far south as Mt. Adams and continues to the end of the GVB.

Multiple sulphur isotope analyses of sulphate deposits from the Sargur Group, Dharwar Craton, India.

E. MULLER[1], P. PHILIPPOT[1], C. ROLLION-BARD[2] AND D. S. SARMA[3]

[1]Institut de Physique du Globe, Paris, France, emuller@ipgp.fr
[2]CRPG-CNRS, Vandoeuvre-les-Nancy, France
[3]CSIR-NGRI, Hyderabad - 500 007, India

Sulphides from sedimentary rocks older than 2.45 Gyr old define a positive $\delta^{34}S$-$\Delta^{33}S$ correlation called the "Archean Array". In contrast, Archean sulphates were deposited during short periods of times between 3.5 and 3.2 Gyr ago and define a narrow isotopic range that is not correlated with the Archaean Array. Sulphide associated with the sulphate deposits form a specific isotopic domains characterized by ^{34}S-depleted values with both positive and negative $\Delta^{33}S$. These sulphides were interpreted to reflect a combination of UV-photochemical processes in optically-thick volcanic plumes combined with terrestrial processes of biologic and/or non biologic origin. Here we present S isotope systematics of the 3.2 Ga sulfate deposit of the Sargur Group near Ghattihosahalli (Dharwar Craton, India).

The rocks investigated consist of a meter-scale layer of barite interbedded within different types of quartzites and micaschists grading towards the west into Cr-micaschists, ultramafic volcanics and felsic gneiss. Bulk and in situ S-isotope analyses were measured with IRMS in dual-inlet mode at IPGP and ims 1280 HR2 at CRPG, respectively, both with a reproductibility better than 0.2 ‰ (2σ) in $\delta^{34}S$ and 0.1 ‰ in $\Delta^{33}S$.

S-isotope compositions of barites ($\delta^{34}S$ = 3.19 to 4.35 ‰ and $\Delta^{33}S$ = -0.49 to -0.47 ‰) fall within the range of other Archaean sulphates. Pyrites in sulphates and other rock types show a narrow range of $\Delta^{33}S$ values between -0.70 and +0.37 ‰ but a larger range of $\delta^{34}S$ values between -12.21 and +0.27 ‰ in barite, -4.12 and +0.63 ‰ in micashists and quartzites, -6.96 and -2.43 ‰ in Cr-micaschists, and 1.83 and 5.99 ‰ in surrounding gneisses. These results are consistent with previous data obtained in other Archaean sulphate deposits from the Pilbara Craton and Barberton Greenstone Belt, thus arguing for a common origin. Different from other deposits, however, is the relative small range of both $\delta^{34}S$ and $\Delta^{33}S$ values, which suggests that the isotopic imprint inherited from atmospheric and microbial/hydrothermal processes have been reequilibrated in part during greenschist/amphibolite facies metamorphism and pervasive ductile deformation.

Vibrational spectroscopic study of Np(V) sorption on mineral oxides

KATHARINA MÜLLER, JULIA BERGER, MAXENCE CORDIEZ, ANNETT GRÖSCHEL, AND HARALD FOERSTENDORF

Helmholtz-Zentrum Dresden-Rossendorf, Institute of Resource Ecology, Dresden, Germany
(*correspondence: k.mueller@hzdr.de)

Mineral oxides play a decisive role in regulating the mobility of contaminants in the environment because of their widespread occurrence in rocks and soils, their tendency to form coatings on mineral surfaces and their wide-ranging technical applications [1].

Due to its long half-life and its toxicity, Np-237 is considered as a major contaminant of the ecosystem in the long-term safety assessment of nuclear waste repositories. The pentavalent state is environmentally most relevant [2].

For the first time, in-situ Np(V) sorption is comparatively studied on the oxyhydroxides of Fe, Mn, Si and Ti by ATR FT-IR spectroscopy under a variety of environmentally relevant sorption conditions. From the results, the formation of binary inner-sphere complexes on oxides of Si, Mn, Fe and Ti can be derived [3]. In case of ferrihydrite, the formation of an additional ternary Np-carbonato surface species is assumed. In addition, time resolved spectra provide kinetic information on the surface reactions.

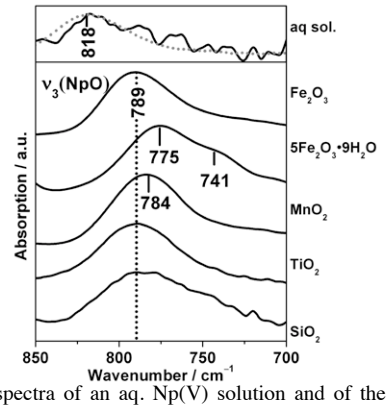

Fig. 1: IR spectra of an aq. Np(V) solution and of the sorption complexes formed onto several mineral oxides (50 μM Np(V), 0.1 M NaCl, pH 7, 60 min sorption, 0.1 mg mineral oxide/cm^2, N_2).

Nano-particulate pressed powder tablets for LA-ICP-MS

S. MÜLLER[1] AND D. GARBE-SCHÖNBERG[1]*

[1]CAU Kiel, Institut für Geowissenschaften, 24098 Kiel, (*correspondence: dgs@gpi.uni-kiel.de)

The accurate determination of ultra-trace elements in geological samples containing refractory minerals - e.g., zircon in plutonic rocks and sediments, spinel in ultramafic rocks and eclogites - is a challenge. While standard table-top or microwave-assisted digestion protocols fail in completely dissolving these minerals, alternative procedures also show shortcomings: (i) pressurized bomb digestion yields accurate results but is time-consuming; (ii) preparation of fused glasses with, and without, addition of a flux for subsequent analysis by either LA-ICP-MS or after re-dissolution with ICP-MS suffers from contamination from heterogeneously distributed impurities in lithiummetaborate, and strong memory for Li, B; (iii) shock melting using a strip-heater produces glasses contaminated with strip material. Ultrabasic or evolved rocks cannot be melted without matrix modification. All fusion techniques bear the risk of volatile losses, and glass beads typically show significant inhomogeneity of trace elements if not thoroughly homogenized during melting.

Pressed powder tablets have repeatedly reported as a means for the direct analysis of solids by laser ablation. Analytical results, however, were not convincing in terms of detection limits, accuracy, and precision if compared to results obtainable with solution analysis or homogeneous glasses. Here we show that undiluted pressed powder tablets can be successfully used for ultra-trace element analysis of granitoid, gabbroic, and ultrabasic rocks from the Oman ophiolite (Wadi Gideah reference profile) after pulverisation to nano-particle grain size. More than 40 trace elements have been analysed in a series of rock CRMs with average RSDs of 1-3% and excellent accuracy for most elements incl. HFSE. Detection limits are in the low ppb range.

Downhole Fluid Analysis coupled with Asphaltene Nanoscience for Reservoir Evaluation

OLIVER C. MULLINS

Mullins1@slb.com

For condensates, the most important compositional variation is GOR, and the cubic equation of state (EoS) treatment of GOR variations is well developed and successful. Consequently, key reservoir attributes such as vertical and lateral connectivity, extrapolating gradients to obtain contacts for reserves estimation, and properties of the produced fluids are addressed by Downhole Fluid Analysis (DFA) on the MDT measuring GOR and light end compositional variations. In contrast, black oils are generally defined as having low GOR; while black oils can exhibit GOR variations, the most important compositional variation of black oil and heavy is the asphaltene concentration. However, there had been no predictive equation of state for asphaltene gradients because the (colloidal) size of asphaltene particles in crude oils had been unknown. Consequently, the gravity term was unknown. Without knowing the gravity term, modeling of reservoir fluids is precluded.

In recent years, the molecular and colloidal size of asphaltenes in crude oils – from condensates to mobile heavy oil – has been resolved and codified in the Yen-Mullins model. These scientific advances have led to the first predictive equation of state (EoS) for asphaltene gradients, the Flory-Huggins-Zuo EoS. By coupling this new science of the FHZ EoS with the new technology of DFA, a powerful new method of reservoir evaluation has been developed leading to myriad applications. Establishing thermodynamic equilibration of asphaltenes strongly implies reservoir connectivity as proven in published case studies involving light condensates to mobile heavy oil. Huge asphaltene and viscosity gradients are obtained in mobile heavy oil columns around the world in agreement with simple application of the FHZ EoS, and where conventional modeling fails miserably. Two mechanisms of tar mat formation are seen to be a natural process readily accounted for by the FHZ EoS and resolving a long standing enigma in the oil industry. Disequilibrium has become much easier to identify using DFA & the FHZ EoS in conjunction with the cubic EoS. Methods for production optimization and risk management are identified.

The confluence of advanced asphaltene science with the third generation of DFA tools, the IFA, enables a powerful new approach to address many complexities in reservoir dynamics.

A secular solution to a diabolical problem: Porphyry vs. iron oxide-copper-gold deposits

A. HAMID MUMIN[1] AND JEREMY P. RICHARDS[2]

[1]Dept. Geology, Brandon University, Brandon, Manitoba, Canada, R7A 6A9, mumin@brandonu.ca

[2]Dept. EAS, University of Alberta, Edmonton, Alberta, Canada, T6G 2E3 Jeremy.Richards@ualberta.ca

Porphyry Cu±Mo±Au (porphyry) and magmatic-hydrothermal iron oxide-copper-gold deposits (IOCG) are distinct in being dominated by Fe±Cu-sulfide minerals in the former and Fe-oxides in the latter. Most of the largest IOCG deposits formed in the Precambrian, whereas porphyry deposits occur most commonly in late Phanerozoic rocks and are rare in the Precambrian. Despite these major differences, they share many similarities: associated magma composition (calc-alkaline to mildly alkaline); tectonic setting (orogenic to post-orogenic), depth of formation (≤5 km from surface), major metal inventory (Cu, Au), and hydrothermal alteration styles (albeit with wider development of high-T near-neutral alteration, and more restricted development of low-T hydrolitic alteration in IOCG deposits).

We conclude that fundamentally similar tectonomagmatic and hydrothermal processes give rise to these two distinct deposit types. We link the key differences in mineralization style (Fe-sulfide vs. Fe-oxide) and temporal prevalence to oxidation of the deep oceans during the Neoproterozoic Oxidation Event. Following this event, sulfate concentrations in deep ocean waters, seafloor sediments, and seawater-altered oceanic crust increased dramatically, and for the first time in geological history abundant sulfur and sulfate were introduced into subduction zones and arc magmas. Phanerozoic arc magmas were thereafter significantly richer in S than in the Precambrian (Prouteau & Scaillet, 2013) and, combined with their relatively high oxidation state, were ideal transportation agents for Cu and Au into upper crustal magmatic-hydrothermal systems.

In contrast, S-poor Precambrian arc and derivative magmas formed S-poor IOCG deposits in orogenic, and post-orogenic settings, while S-rich conditions were relatively rare (leading to a dearth of porphyry-type deposits). Higher geothermal gradients in the Precambrian, combined with the lower acid-generating potential of S-poor hydrothermal fluids may explain the greater extent of high-T near-neutral pH alteration in IOCG deposits compared to porphyries.

The close relationship between Antarctic temperature and atmopsheric pCO_2 suggests an important role for the Southern Ocean in glacial cycles. Recent high-resolution model results indicate that the sensitivity of Southern Ocean upwelling and global stratification to changes in Southern Ocean wind stress may be low [1]. This may limit the sensitivity of the climate system as a whole to changes in Southern Ocean wind stress, by limiting the change in ventilation of abyssal carbon reseroirs.

We use MITgcm in an idealised configuration to investigate the changes in circulation that occur at both coarse (climate model) resolutions and higher, eddy-permitting, resolutions as the applied wind stress is changed. At coarse resolutions, the mesoscale eddy field is represented by the Gent & McWilliams parameterisation. However, at eddy-permitting resolutions, large geostrophic eddies are well represented by the model. By coupling these physical circulations to MITgcm's simple biogeochemistry package, we are able to elucidate the effect that changes in the mesoscale eddy field, and/or its representation, have on atmospheric pCO_2.

We find that the use of an eddy-permitting ocean model reduces the sensitivity of atmospheric pCO_2 to both increasing and decreasing wind stress. A carbon pump decomposition indicates that the 4 main reservoirs of carbon in the ocean (saturation state, disequilibrim, soft tissue carbon, and hard tissue carbon) vary quite differently when the model is eddying, as opposed to the eddy field being parameterised.

Lithospheric mantle heterogeneities beneath Southern Patagonia

A. MUNDL[1]*, T. NTAFLOS[1], E.A. BJERG[2], L. ACKERMAN[3] AND C.A. HAUZENBERGER[4]

[1]Department of Lithospheric Sciences, University of Vienna, Austria (*correspondence: andrea.mundl@univie.ac.at)
[2]CONICET-Universidad Nacional del Sur, Departamento de Geologia, Bahia Blanca, Argentina
[3]Institute of Geology v.v.i., Academy of Sciences of the Czech Republic, 165 00 Praha 6, Czech Republic
[4]Institute for Earth Sciences, University of Graz, Austria

Thirty samples from Pali Aike Volcanic Field (PAVF) and Tres Lagos in Southern Patagonia comprise Sp-lherzolites, Sp-harzburgites, Sp-Gt-lherzolites and Sp-Gt-harzburgites.

According to Cpx REE and other trace element patterns, the samples can be divided in 3 Groups within Sp-peridotites and 3 within Sp-Gt-peridotites. Group I Sp-peridotites show a depletion in LREE reflecting different degrees of partial melting. Group II shows flat REE patterns from HREE to MREE with an enrichment in LREE indicating metasomatic overprint. Group III samples show an enrichment in MREE over LREE and HREE suggesting basaltic melt percolation. While Group I Sp-Gt-peridotites represents slightly depleted samples with typical REE patterns of Cpx in equilibrium with Gt, Group II Cpx REE patterns show LREE enrichments reflecting metasomatic event(s). The garnets in this group exhibit wide kelyphitic rims that have been formed according to the reaction of Gt+Ol to Sp+Cpx+Opx. Primary Sp inclusions in Gts of Group I and II indicate transitions from spinel to garnet stability field. Group III of Sp-Gt-peridotites is represented by highly depleted samples showing REE patterns otherwise typical for Cpx coexisting with Gt. However, an entire abscense of Gt suggests that all Gt has been consumed during partial melting event(s).

Re-Os analyses of unmetasomatized Sp-peridotites reveal highly variable T_{RD}. While T_{RD} at Tres Lagos range from 1 to 1.6 Ga, samples from PAVF yield ages from 0.3 to 2.3 Ga. A depletion in Pt, Pd and Re reflects different degrees of partial melting. Depleted Os compared to other IPGEs (Ir, Ru) can be connected to sulfide breakdown upon eruption, while a general depletion in IPGEs in comparison to PM is suggested to be due to melt percolation processes.

Trace element patterns, samples showing highly different degrees of partial melting, as well as transition reactions from spinel to garnet stability field reflecing a multi-stage thermal history, suggest a very heterogeneous SCLM beneath S-Patagonia.

Mantle-crust fractionation of the platinum-group elements

JAMES E MUNGALL[1] AND JAMES M BRENAN[1]

[1]Department of Earth Sciences, University of Toronto, Toronto ON; mungall@es.utoronto.ca; brenan@es.utoronto.ca

We use new sulfide melt/silicate melt partition coefficients ~ 10^6 to develop a fully constrained model of PGE behavior during melting to predict the abundances of PGE in mantle-derived magmas and their restites, including mid-ocean ridge basalts, continental picrites, and the parental magmas of the Bushveld Complex of South Africa. Our model constrains mid-ocean ridge basalt (MORB) to be the products of pooled low and high degree fractional melts. A significant control on PGE fractionation in mantle-derived magmas is exerted by residual alloy or platinum group minerals in their source. Within-plate picrites are pooled products of larger degrees of fractional melting in columnar melting regimes. At low pressures (e.g., MORB genesis) the mantle residual to partial melting retains primitive mantle inter-element ratios and abundances of PGE until sulfide has been completely dissolved but then evolves to extremely high Pt/Pd and low Pd/Ir because Pt and Ir alloys form in the restite. During melting at high pressure to form picrites or komatiites Ir alloy continues to appear as a restite phase but Pt alloy is no longer stable due to the large effect of pressure on fS2, which causes large increases in alloy solubility. Magmas parental to the Bushveld Complex of South Africa appear to be partial melts of mantle that has previously been melted to the point of total sulfide exhaustion at low pressure, closely resembling mantle xenoliths of the Kaapvaal craton. Using the new extremely large D^{sul}_{PGE} the the Merensky Reef and UG2 Pt deposits of the Bushveld Complex can be modeled as the result of sulfide saturation due to mixing of magmas with unremarkable PGE contents, obviating the need to postulate anomalously PGE-rich parent magmas or hydrothermal inputs to the deposits.

An extraterrestrial cause for the Silicate Earth's Nb paradox?

C. MÜNKER[1], R..O.C. FONSECA[2], AND T. SCHULZ[3]

[1]Institut für Geologie und Mineralogie, Universität zu Köln, Germany, c.muenker@uni-koeln.de
[2]Steinmann Institut, Universität Bonn, Germany
[3]Dept. für Lithosphärenforschung, Universität Wien, Austria

Although both elements are considered lithophile, the silicate Earth exhibits a marked Nb deficit relative to its geochemical twin Ta, when compared to chondrites [1]. This feature is commonly referred to as "terretrial Nb paradox". Many explanations for this paradox that favour the presence of hidden silicate reservoirs cannot explain the observation that the Early Archean silicate Earth was already depleted in Nb. This would leave core formation at high pressures in a reduced early Earth as the only viable explanation for the terrestrial Nb paradox [2].

In a combined geochemical and experimental study, we investigated, whether low pressure metal segregation on small planetesimal precursors can also account for the Nb deficit. We performed high precision measurements of HFSE concentrations employing isotope dilution and ion exchange separation on representative groups of iron meteorites, their sulfide inclusions and achondrites. This protocol avoids molecular interferences on many HFSE, in particular for iron meteorites and sulfides rich in transition metals. Our results indicate that reduced achondrites exhibit strongly subchondritic Nb/Ta (as low as 1), whereas more oxidised achondrites (e.g., eucrites) exhibit near chondritic Nb/Ta. As expected, iron meteorites exhibit extremely low Nb-Ta concentrations (<1 ppb), whereas Nb can be strongly enriched relative to other HFSEs in sulfides (to ppm levels).

To simulate metal-sulfide segregation on small planetesimals, we performed experiments at ~1300ºC and 10 kbar using a piston cylinder apparatus. Measured sulfide-silicate partition coefficients for Nb are ca. 2 orders of magnitude higher than for Ta. At fO_2 lower than IW-3, Nb becomes chalcophile while Ta remains lithophile, and the silicate melt is thus depleted in Nb, as found in our study for more reduced achondrites.

Collectively, our results reveal that Nb may be sequestered into planetesimal cores at low pressures and low fO_2, provided that immiscibile sulfide and metal liquids were segregated. Therefore, the silicate Earth's Nb deficit may be a feature inherited from differentiated planetesimals that did not fully equilibrate with the proto-Earth upon their accretion.

Pb, Zn and Cd dynamics in mining areas under Mediterranean climate and carbonated geologic context: northern Tunisia example

MUNOZ MARGUERITE[1] AND GHORBEL MANEL[2]

[1]GET, Observatoire Midi Pyrénées, Université de Toulouse, CNRS, IRD, 14 avenue E. Belin, F-31400 Toulouse, France. margot.munoz@get.obs-mip.fr

[2]RME, Faculté de Sciences de Tunis el Manar, 2092 Tunis, Tunisia. manel.ghorbel@get.obs-mip.fr

Maghreb countries, particularly Tunisia contain large amounts of mining wastes richs in metals such as Pb, Cd and Zn. Wastes are located in active or abandoned mining sites. Metals can diffuse to all environment compartments: water, air and soil.

In wastes, due to carbonated geology, calcite is dominant and metals are mainly associated with carbonates (cerussite, smithsonite and hydrozincite), in addition to silicates (hemimorphite and willemite) and sulphides (galena and sphalerite). Cd substitutes Zn in zinc-carbonates, silicates and sphalerite where it can reach 0.98wt%.

In this carbonated context, drainage water display a basic pH and metals are fixed by precipitation of stable minerals under oxidizing conditions (cerussite, hydrozincite, smithsonite and hemimorphite). Equilibrium between water and secondary minerals in mining drainage controls concentrations of metals at low values.

Ore treatment wastes are fine grained (silt and clay). Their cohesion is variable (15 and 124 kPa) and their permeability is low (10^{-6}-10^{-9} m/s) and limits infiltration process. These features, under Mediterranean climate, promote mechanical erosion of wastes during brief and intense rainfall events. However, the low density of water runoff makes the impact of particulate transport often limited, but highly concentrated, in soils around the waste dumps. Thus, maximum concentrations in soils have been measured up 2% Pb, 3% Zn and 200 $mg.kg^{-1}$ Cd.

This climate, also characterized by a long dry season, allows contaminated dust emissions from dumps especially in summer. Maximum emission flux of dust was estimated to 88.2 g/s of PM10. Resulting concentrations of airborne Pb and Cd exceeded WHO guidelines for air quality, up to 1km from the source in the dominant wind direction (Ghorbel, 2012).

Remediation is intended to support natural processes using phytostabilisation of wastes by covering them with native metal-resistant plants.

Structure and thermal property of dense silicate glasses under high-pressure

MOTOHIKO MURAKAMI[1]

[1]Department of Earth and Planetary Materials Science, Tohoku University, 6-3 Aoba, Sendai, Miyagi 989-8578, Japan motohiko@m.tohoku.ac.jp

The current structure of Earth's interior is believed to have formed through dynamic differentiation from a global magma ocean in the early Earth. Elucidation of the structural changes and heat transport properties of silicate melts in the deep Earth is fundamental to understanding the evolution and structure of Earth's interior. The possible presence of dense, gravitationally stable, silicate melts at the bottom of the current mantle as a remnant of a deep magma ocean has been proposed to explain observations of anomalously low seismic velocities above the core-mantle boundary. However, the nature of silicate melts under such extreme pressures is poorly understood. Direct measurements of structural changes or thermal properties on silicate melts under ultrahigh-pressure conditions remain a great challenge and are currently beyond experimental capabilities. Silicate glasses have alternatively been extensively studied as analogues for quenched silicate melts, to simulate the high-pressure behavior of silicate melts. Previous experimental works on silicate glasses have, however, been still limited to lower pressure condition, which is far below the pressure condition of the bottom of the mantle.

To address this issue, we have conducted several series of ultrahigh-pressure experiments on silicate glasses with chemical compositions ranging from pure silica to more complex system up to ~200 GPa using combined spectroscopic techniques including Brillouin scattering, optical absorption (from visible to near-infrared) and synchrotron Mössbauer measurements in the energy domain. The results based on sound velocity data reveal the possible densification mechanism of silicate glasses above ~100 GPa that is likely associated with the onset of a change in Si-O coordination number to higher than sixfold. Optical and synchrotron Mössbauer data show a significant change in the absorption coefficients of the iron-bearing silicate glasses with pressure, most likely due to their gradual electronic structural changes. Based on the present results, we will discuss the possible implications for the densification mechanisms and heat transport property of the silicate melts at the base of the mantle.

Reconstruction of the accident-derived I-131 deposition in Fukushima through the analysis of I-129 in soil.

YASUYUKI MURAMATSU[1]*, HIROYUKI MATSUZAKI[2], TAKESHI OHNO[1], NAOYA INAGAWA[1] AND CHIAKI TOYAMA[1]

[1] Department of Chemistry, Gakushuin University, Mejiro, Tokyo, Japan, 171-8588; *Corespondence:yasuyuki.muramatsu@gakushuin.ac.jp
[2] Department of Nuclear Engineering and Management, The University of Tokyo, Tokyo, Japan, 113-8656.

Large quantities of radionuclides were released durring the accident at Fukushima Daiichi Nuclear Power Plant which occurred during March of 2011. We have carried out intensive studies on the distribution and behaviour of radioiodine and radiocesium in the environment following the accident. Special attention was paid to I-131 (half-life: 8 days) because of its affinity to thyroid glands and because, at the time of the Chernobyl accident, an increase of thyroid cancer for infants and children was observed as a result. Although the amount of I-131 released from the Fukushima accident is about one tenth of that released from the Chernobyl accident, it is necessary to obtain information on the deposition density of this nuclide in different locations surrounding the nuclear power plant at the time of the accident. However, most of it decayed away after some months due to its short half-life and there were not enough data to construct a deposition map for I-131.

In order to estimate the deposition of I-131, we focused on I-129 (half-life: 15.7 million years) which was also co-released during the accident and deposited in soils across the region. Surface soil samples collected from different places in Fukushima Prefecture were analyzed for I-129 by AMS (accelerator mass spectrometry) after the chemical separation. Soil samples that had been determined for I-131 were used to estimate I-131/I-129 ratio. A good correlation was found between the concentration of I-131 and that of I-129 in soil. This finding suggests the possibility to estimate the I-131 deposition through the analysis of I-129 in soil. We also analyzed soil samples collected from different locations of Fukushima Prefecture within a project organaized by MEXT (Ministry of Education, Culture, Sports, Science, and Technology, Japan) for reconstracting the deposition density of I-131.

Heterogeneous melt involved in formation of a thick Moho transition zone in northern Oman ophiolite: implications for MORB evolution

R. MUROI[1]*, S. ARAI[1], H. NEGISHI[1] AND A. TAMURA[1]

[1]Dept. Earth Sci., Kanazawa Univ., Kanazawa 920-1192, Japan
(*Correspondence: halcyons@stu.kanazawa-u.ac.jp)

The evolution process of MORB from depleted melts in equilibrium with abyssal peridotites has been left unclear. Here a melt with gentle REE pattern like the ordinary MORB is referred to “Melt 1”, and a melt with steeply LREE-depleted pattern like ultra-depleted MORB [1] to “Melt 2”. CPXs (clinopyroxenes) in dunites and wehrlites in the Moho transition zone of Oman ophiolite were generally in equilibrium with Melt 1 [2]. We found dunites-wehrlites containing CPXs in eqiulibrium with Melt 2 in predominant Melt-1 related dunites-wehrlites from a thick Moho transition zone of Wadi Thuqbah, northern Oman ophiolite [3]. Some of the Melt-2 related dunites-wehrlites contain relic OPX (orthopyroxeen) partially replaced with olivine: other Melt-1 related ones are free of OPX, and occasionally contain sulfides [3]. The Fo content of olivine is higher in the Melt-2 related rocks (around 91) than in the Melt-1 related ones (88-90). The Cr_2O_3 content in CPX is higher in the former (1.1-1.3 wt%) than in the latter (0.9-1.1 wt%). The OPX in the former is simar in chemistry to that in the mantle harzburgite downsection.

These features possibly indicate chemical evolution of Melt 1 from Melt 2 through reaction with the mantle peridotite (consumption of OPX combined with olivine production). The Moho transition zone dunites and wehrlites are cumulates from melts enriched with olivine crystals (crustal mush) [3]. The Mlet-2 related rocks sometimes with OPX were formed from an incomplete melt-peridotite reaction product, and the Melt-1 related rocks, from a melt-peridotite reaction product, where OPX digestion was completed. This suggest a possibly imprtant role of the Melt 2-peridotite reaction in formation of ordinary MORB (Melt 1) in the upper mantle [cf.4,5].

The coupling of particle acidity and gas phase ammonia in the biosphere-atmosphere system

JENNIFER MURPHY[1] AND ALEXANDRA TEVLIN[1]

[1]Department of Chemistry, University of Toronto, Toronto ON, Canada

Ammonia is the most important gas phase base in the atmosphere and is known to influence the formation and growth of atmospheric particles. While the magnitude and trends of ammonia emissions are highly uncertain, it is likely that a legacy of synthetic fertilizer application has led to an increased potential for ammonia emissions from many ecosystems. We have obtained observational evidence for the bi-directional exchange of ammonia between the surface and the atmosphere, and the coupling of this process to gas-particle partitioning. From intensive field campaigns in urban and rural environments, simultaneous measurements of particle composition and gas phase ammonia permit the calculation of particle acidity, which affects gas-particle partitioning of ionizable species and may influence toxicity and secondary organic aerosol formation. In a complementary analysis, we use long-term measurements (1990-2010) of particle composition from Canada's Chemistry and Precipitation Monitoring Network (CAPMoN) to calculate trends in strong acidity and infer trends in gas phase ammonia.

Fractionation of $^{238}U/^{235}U$ by reduction during low T uranium mineralisation processes

MELISSA J. MURPHY[1]*, CLAUDINE H. STIRLING[2], ANGELA KALTENBACH[2], SIMON P. TURNER[1] AND BRUCE F. SCHAEFER[2]

[1]GEMOC, Department of Earth and Planetary Sciences, Macquarie University, Australia (*Correspondence: melissa.murphy@mq.edu.au)

[2] Centre for Trace Element Analysis and Department of Chemistry, University of Otago, New Zealand

Investigations of 'stable' uranium isotope fractionation during low temperature, redox transformations may provide new insights into the usefulness of the $^{238}U/^{235}U$ isotope system as a tracer of palaeoredox processes. Sandstone-hosted uranium deposits accumulate at an oxidation/reduction interface within an aquifer from the low temperature reduction of soluble U(VI) complexes in groundwaters, forming insoluble U(IV) minerals. This setting provides an ideal environment in which to investigate the effects of redox transformations on $^{238}U/^{235}U$ fractionation. Here we present coupled measurements of $^{238}U/^{235}U$ isotopic compositions and U concentrations for groundwaters and mineralised sediment samples collected in the vicinity of the high-grade Pepegoona sandstone-hosted uranium deposit, Australia.

The mineralised sediment samples display extremely variable $^{238}U/^{235}U$ ratios, spanning a 5 ‰ range. The groundwaters show a greater than 2 ‰ variation in their $^{238}U/^{235}U$ ratios, and exhibit a clear systematic relationship between $^{238}U/^{235}U$ isotopic composition and U concentration; samples with the lowest U concentrations have the lowest $^{238}U/^{235}U$ ratios. The preferential incorporation of ^{238}U during the precipitation of uranium minerals leaves the groundwaters enriched in ^{235}U, resulting in a progressive shift in $^{238}U/^{235}U$ towards lighter values in the aqueous phase as U is removed. Previous studies on the same groundwaters have shown significant disequilibrium between ^{234}U and ^{238}U. $^{238}U/^{235}U$ ratios however, show a poor correlation with ($^{234}U/^{238}U$) activity ratios, which suggests that mineral leaching during weathering is unlikely to control the observed uranium $^{238}U/^{235}U$ isotopic variability within this low temperature, redox-controlled mineralised system. Rather, the results imply that $^{238}U/^{235}U$ fractionation may be controlled by the nuclear field shift effect during the reduction of U(VI) to U(IV) during mineralisation processes. The findings of this study support the use of the $^{238}U/^{235}U$ isotopic system as a palaeoredox tracer to constrain the nature and timing of palaeoredox conditions.

Stabilising a craton: The 3.1 Ga Mpuluzi batholith (Swaziland / RSA)

R.C. MURPHY[1]*, W.L. GRIFFIN[1], N.J. PEARSON[1] AND SUZANNE Y. O'REILLY[1]

[1]GEMOC/CCFS, Earth and Planetary Sciences, Macquarie University, NSW 2109 Australia (*correspondence: rosanna.murphy@mq.edu.au)

The Barberton Greenstone Belt and Ancient Gneiss Complex in Swaziland and adjacent South Africa are some of the most-studied Early- to Mid-Archean (3.6 to 3.2 Ga) crustal remnants. The granite-greenstone belt is surrounded and overlain by several large granitoid bodies (Mpuluzi, Piggs Peak, and Nelspruit batholiths), all emplaced ~3.1 Ga, and marking the end of TTG magmatism and regional metamorphism in the area.

The granitoids were emplaced as extensive, km-thick sheets and extend over more than 10,000 km^2. Zircon U-Pb ages range from ~3.08 to ~3.15 Ga; emplacement may have occurred over as much as 70 Ma. Some samples also have a minor inherited population at ~3.5 Ga, implying the involvement of older crustal material. Zircon Hf-isotope data show a range of up to 15 epsilon units within each sample, but little variation between samples. Average model ages of the 3.1-Ga zircons are ~3.5 Ga, corresponding to the age of the inherited population. These older grains commonly have model ages back to 4 Ga.

Whole-rock Sr and Nd isotopic data yield isochron ages of 3.022 Ga for both systems, and the initial ratios yield model age of 3.11 Ga for each system, perfectly consistent with the U-Pb data. The tight isochrons for both systems (r^2 for Sr = 0.9974, Nd = 0.9615) strongly suggest that the whole mass formed and cooled together, and the small time gap between the isochron and model ages suggests rapid cooling.

These 3.1 Ga granitoids therefore represent the final stage in the cratonisation of the region; this could represent the "draining" of fusible material from the lower crust, increasing its rigidity and limiting further tectonism. The unusual emplacement style, the large volume of magmas involved and the apparently short timescale of emplacement raise several important questions about the processes involved in the stabilisation of the eastern Kaapvaal Craton in particular and ancient crust in general: (1) What was the heat source for the magmas, and what was the source material? (2) How were these volumes of magma extracted from the deep crust? (3) What controlled the emplacement style as sheets rather than deep-rooted batholiths? These problems will now be addressed by dynamic and thermodynamic modeling.

Zinc Melanterite Formation from Acid Mine Drainage in Pan de Azúcar Mine (Zn-Pb-Ag), Northwest Argentina

JESICA MURRAY[1] ALICIA KIRSCHBAUM[2] AND BERNHARD DOLD[3]

[1,2] IBIGEO-CONICET jesimurray@yahoo.com.ar; alikir2002@yahoo.com.ar ; [3]Bernhard Dold Sustainable Mining Research & Consult (SUMIRCO), Bernhard.dold@gmail.com

Melanterite formation in Pan de Azucar Mine: Evaporation of acid mine waters formed by oxidation of sulfide rich tailings in Pan de Azúcar Mine (Zn-Pb-Ag) favors the formation of soluble sulfates as Melanterite ($Fe^{2+}SO_4 \cdot 7H_2O$), which is one of the most common ferrous sulfates in nature and one of the first phases to precipitate from evaporation of acid mine drainage. One of the most important characteristic of these phases is their ability to store metals as Ni(II), Cu (II), Zn (II) [1] Zn-Melanterite: Acid mine drainage (139 g/L SO_4^{2-}; 8960 mg/L Zn; 99,7 mg/L Cd; 47 mg/L Fe (total); 44 mg/L As; 10 mg/L Cu; 1,4 mg/L Pb) seeps from one of the tailings impoundments during dry season. High evaporation rates and high concentration of sulfate and iron favors the precipitation of melanterite at pH=2.1. Some preliminary SEM-EDS studies show high Zn concentrations in melanterite crystals, which indicates its ability to capture this metal in their structure instead of Cu or Ni, probably due to the Zn excess in the acid water. XRD and field observation suggests that during the dry season, melanterite dehydrates and changes to rozenite ($Fe^{2+}SO4 \cdot 4H2O$) as has been described by Nordstrom [1, 2]. In the following rainy season that phases dissolves and metals are again available to the hydrological cycle. This process has an important influence on temporal variation of metals in surface waters.

Application of Clumped Isotopes to the Dolomite Problem

MURRAY, SEAN T. [1], PETER K. SWART [2] AND MONICA M. ARIENZO [3]

[1,2,3]4600 Rickenbacker Causeway, Miami FL 33149
[1]smurray@rsmas.miami.edu
[2]pswart@rsmas.miami.edu
[3]marienzo@rsmas.miami.edu

The measurement of clumped isotopes has been applied to Miocene to late Pliocene dolomites from San Salvador, Bahamas. These dolomites formed as recently as 500 ky BP, yet are texturally mature and display near perfect stoichiometry (46-48% $MgCO_3$). They were proposed to have formed at low temperatures (20-28**°**C) and from normal to slightly evaporated sea water[1]. Given the well constrained environmental conditions, these dolomites offer the opportunity to test the application and accuracy of the various calibrations for relating Δ_{47} and temperature. Accurate temperatures of formation can than be used to determine which of the multitude of formulas for determining the fractionation of $\delta^{18}O$ between the dolomite and the fluid is most accurate.

The dolomites returned Δ_{47} values from 0.64‰ to 0.68‰. Based on the analysis of these samples and the application of the various formulas for relating Δ_{47} to temperature, we propose a modified Dennis *et al*. (2011)[2] method which takes into account the temperature difference between the theoretical calibrations for dolomite and calcite proposed in Guo *et al*. (2009)[3]. This method produced temperatures ranging from 23.3**°**C to 41.5**°**C. All other methods proposed in the literature produced temperatures that were considered too high considering the well constrained depositional and diagenetic setting of these samples.

Using the modified Dennis *et al*. (2011)[2] method, it has been concluded that the $\delta^{18}O_{dolomite\text{-}fluid}$ fractionation equation of Sheppard and Schwarcz (1970)[4] produces the most reasonable water $\delta^{18}O_{water}$ values considering our interpretation of the temperatures.

[5]Scripps Inst. of Oceanography, CA, 92093, USA

As a part of the Alpine-Himalayan orogenic belt, the Anatolian land has experienced a series of volcanism, plutonism and active tectonism since the Neogene. This unique geologic disposition facilitated occurrence of vast number of fossil and modern geothermal systems which are closely associated with Neogene-Quaternary volcanism in areas of seismic unrest. He-CO_2 systematics of geothermal fluids in Anatolia has been the subject of several studies over the last decade. He-isotope compositions, reported as R/Ra values, vary over a wide range from 0.27 to 7.76 (Nemrut caldera-eastern Anatolia). The mantle-derived helium component, which is likely transferred to the crust beneath Turkey by recent magmatism, constitutes up to 96% of the total He composition in fluids. $CO_2/^3He$ ratios varying from $2.4x10^5$ to $26x10^{13}$ encompass the range of island arcs ($\sim 2.0\times10^{10}$) and continental fluids ($>10^{11}$). Additionally, in this work new helium isotope data are presented for mantle-derived xenolith-bearing basaltic lavas from the Thrace basin in NW Turkey as well as olivine-bearing volcanic rocks from western and southern Anatolian regions. The peridotite xenoliths from the Thrace alkaline volcanic suite are composed of spinel-harzburgites and dunites. Homogenous $^3He/^4He$ ratios (6.7-7.1 Ra) of harzburgites are very close to that of MORB-type mantle. One dunite sample from the same region is represented by a lower helium isotope composition (3.0 Ra). Alkaline basalts from Kula (western Anatolia) and Osmaniye (southern Anatolia) areas have $^3He/^4He$ ratios of 7.9 Ra which is coincident with values typical of upper mantle. Olivine in basalt sample from the Söke area in western Anatolia yielded lower helium composition (1.9 Ra). Our ongoing survey on isotope compositions of noble gases in Turkish volcanics, will lead to a better understanding of these apparent anomalies in regard to temporal changes in crust-mantle dynamics in the eastern Mediterranean.

A bond valence approach to surface energy and crystal morphology

ANDREAS MUTTER[1] AND MARTIN T. DOVE[2]

[1]Department of Earth Sciences, Univeristy of Cambridge, Downing Street, Cambridge CB2 3EQ, UK. am2100@cam.ac.uk

[2]School of Physiks and Astronomy, Queen Mary University of London, Mile End Road, London E1 4 NS, UK. martin.dove@qmul.ac.uk

The aim of our research is to provide a methodology, which can be applied to investigate the interaction and the reactivity of mineral interfaces with the environment. The underlying principle of our approach is to define the interaction between internal structural parameters and surface parameters in order to obtain an ideal abstract crystal morphology. This abstract crystal morphology can then be used as a references morphology to different growth morphologies or crystal morphologies predicted by other atomistic simulations.

The internal parameters choosen on behalf of our model are the number of atoms per surface area (reticular density) and the lattice density. The surface parameters are the number of dangling bonds (bond valence deficiency) per surface area or their corresponding surface energy. The internal parameters are determinate by the crystal structure type and therefore are invariable. In contrast, the surface parameters are variable due to differences in the chemical compositions of different minerals, even though they may agree in their crystal structure type.

In order to obtain the surface energies of different crystal interfaces, our model uses the bond valence approach of Brown [1]. First we calculate the surface specific bond valence deficiency, then we asign to each bond via its bond length a certain bond energy, which then in its sumation over the surface area gives us the surface energy. The main advantage of this approach is, compared to other atomistic simulations, that it does not demand for charged neutral surfaces to obtain the surface energy. Therfore, naturally charged and charged neutral surfaces can be compared likewise, which is a major advantage while comparing different growth morphologies in variably composed solutions.

This performance of our model, its combined approach of internal and interfacial parameters, not only gives results which are in good agreement with literature data, but also enables us to discuss the importance and the occurrence of naturally polar surfaces on behalf of the crystal morphology.

Gold in sulfide wastes - peat system

I.N. MYAGKAYA*, E.V. LAZAREVA, M.A. GUSTAYTIS AND S.M. ZHMODIK.

Institute of Geology and Mineralogy SB RAS, Pr. Koptug, 3, Novosibirsk, 630090, Russia (*i_myagkaya@mail.ru)

Carbonaceous matter is an effective concentrator of precious metals. We study gold partitioning between sulfide material and peat in a halo around the Ursk tailing pit (Kemerovo region, Russia) with ore cyaniding wastes. The wastes of processed primary ore and ore from the oxide zone are piled up in two 10-12 m piles. Being not fastened, the material has been washed out by floods and rainfalls for more than 50 years. The swampy area downstream of the tailings is burnt by acid mine drainage (AMD) and covered by shed material, with remains of peat mounds rising above.

The shed wastes and peat have been sampled in test pits to 20 cm deep. The gold contents are 0.1 to 3.8 ppm (mean 0.6 ppm) in all wastes, and 1.2 ppb in AMD nearby.

Gold in peat varies broadly, from 0.18 to 155 ppm, mostly 0.18 to 19 ppm. The mean and median values are different (5 and 2 ppm). There are three Au zones in the Ursk halo peat: (1) near the piles and mainstream AMD where the primary and oxide zone ore wastes interlayer (max. 40 ppm); (2) same as (1) but farther from the piles and with higher gold (max. 60 ppm); (3) a perennially wet zone 200 m far from the oxide zone wastes with extremely high gold (40 to 155 ppm).

Peat along the oxide zone wastes bears secondary minerals, namely concentric aggregates of Fe(III) compounds, gypsum, Na-jarosite, framboidal pyrites; barite druses and globules; zinc sulfide; euhedral Hg selenides and sulfides: timmanite (HgSe), onofrite (Hg(S,Se)), cinnabar (HgS).

Gold is high (80 ppm) in material rich in Hg sulfides with Cu, Ag, I, and Se impurities. Submicron and nanoparticles of gold largely cover organic detritus and locally form sheaths over bacterial cells. Native Au particles (to 1.5 μm in diamter, purity 947-1000 ‰), at Cu impurity of 7.5-53 ‰, occur in material cemented with secondary Fe(III) compounds. Cu-gold formation may be mediated directly by bacteria. This process in peat was reproduced in laboratory [1]. Formation of secondary Au in the presence of sulfides is mediated first by iron- and sulfur-oxidizing bacteria and then by thiosulfate oxidizers and sulfate reducers [2].

The study was supported by Grant 11-05-01020 from RFBR and an 2012-2013 OPTEC grant for young scientists, and was run as part of SB RAS Integration Project #94

Structures of weakly binding anions at the interfaces of Fe-polymers and Fe-oxides: Evidence from X-ray and infrared spectroscopic studies

SATISH C. B. MYNENI AND NYSSA CROMPTON[1]

[1]Departments of Geosciences and Chemistry, Princeton University, Princeton, NJ 08544, USA. smyneni@princeton.edu

Halides and oxoanions (e.g. CO_3^{2-}, NO_3^-) are common in all aquatic systems, and play an important role on the interfacial reactions of both cations and anions. Several of these ions (e.g. Cl^-, Br^-, NO_3^-, SO_4^{2-}) are considered to interact weakly at the mineral-water interfaces, and thus are used as inert-electrolytes in aqueous geochemical studies for decades. However, our X-ray and infrared spectroscopic data suggest that these ions form strong complexes at the interfaces of Fe-oxides, and play an important role in Fe-oxide transformations.

We examined the reactions of Cl^-, NO_3^-, SO_4^{2-}, and SiO_4^{4-} with soluble Fe-polymers, and freshly prepared Fe-oxyhydroxides. The coordination environments of several of these ligands are highly disputed, and experimental evidence was presented for the formation of both inner- and outer-sphere complexes using different macroscale and molecular methods. We examined the coordination environments of these ions using the X-ray and vibrational spectroscopy techniques. We found that these ions exhibit a variety of complexes at the Fe-oxide-water interfaces; however, H-bonded complexes are identified as the predominant complexes for these ligands at the Fe-oxide-water interfaces.

Differences in the molecular structures of these ions at the Fe-oxide-water interfaces are attributed to the rates at which freshly prepared Fe-oxides transformed to goethite. Our studies indicate that goethite appeared first in freshly precipitated Fe-oxides in the presence of SO_4^{2-} and NO_3^-, when compared to that of Cl^-. However, the rate at which the concentration of goethite increased was much lower in the presence of SO_4^{2-}. In addition, the crystallinity of goethite was affected significantly in the presence of these ligands indicating that these weakly coordinating ligands play a central role on the stability and crystallinity of Fe-oxides. Details of these interactions will be presented.

Strontium Isotope Anomalies and ^{26}Al-^{26}Mg Chronology in CAIs from CV Chondrites

K. MYOJO[1], T. YOKOYAMA[1], Y. SANO[2], N. TAKAHATA[2], N. SUGIURA[3], H. IWAMORI[1] AND M. UNO[1],

[1]Department of Earth and Planetary Sciences, Tokyo Tech, myojo.k.aa@m.titech.ac.jp
[2]Atmosphere and Ocean Research Institute, Univ. of Tokyo
[3]Department of Earth and Planetary Science, Univ. of Tokyo

Many nucleosynthetic isotope anomalies have been documented in calcium and aluminum rich inclusions (CAIs). Recently, Moynier *et al.* [1] found positive $^{84}Sr/^{86}Sr$ anomalies in Allende CAIs, suggesting excess of the p-process component or deficit of the r-process component in the CAIs. In contrast, Brennecka *et al.* [2] measured Ba, Nd and Sm isotopic compositions in Allende CAIs and discovered that the CAIs have r-process excesses only for Ba isotopes. If these anomalies in CAIs were caused by the injection of refractory materials via a nearby supernova, isotopic anomalies could r76ku7have variation due to difference in time and/or location. To reveal the timing of injection toward the early solar system or processes that caused excesses of nucleosynthetic isotope anomalies in CAIs, we first measured Al-Mg ages in type B CAIs from Allende and NWA 2364 and type C CAI from Allende, then we measured Sr isotopic anomalies in the same CAI. For Al-Mg ages, we used NanoSIMS at the AORI, the Univ. of Tokyo, and for Sr isotopic analysis, we used TIMS, Triton plus at Tokyo Tech.

Al-Mg internal isochrones of type B CAIs yielded initial $^{26}Al/^{27}Al$ ratio which are consistent with the canonical value of 5.11×10^{-5} [3]. Two Allende CAIs show $^{84}Sr/^{86}Sr$ anomalies of 187 ppm (type B) and 46 ppm (type C) higher than terrestrial standard, whereas the CAI from NWA 2364 has no anomalies. In addition, we also measured $\delta^{88}Sr/^{86}Sr$ ratio to trace the degree of mass dependent isotope fractionation. Allende type B CAI has 0.3 ‰ higher and other two CAIs have values lower than terrestrial standard. These results suggest that Sr isotope signatures in individual CAIs inherited isotope signatires of their formation locations. The excesses of a p-process nuclide (^{84}Sr) in CAIs are most likely caused by irradiation from the proto-sun, and their heterogeneous isotope signature is attributed to the distance from proto-sun to formation region of individual CAIs.

Impact of crustal elements on global atmospheric deposition of Nitrogen

STELIOS MYRIOKEFALITAKIS[1], NIKOS DASKALAKIS[1] AND MARIA KANAKIDOU[1]

[1] Environmental Chemistry Processes Laboratory, Department of Chemistry, University of Crete, P.O. Box 2208, 71003 Heraklion, Greece; stelios@chemistry.uoc.gr; nick@chemistry.uoc.gr; mariak@chemistry.uoc.gr

Nitrogen (N) deposition plays a significant role in ecosystem functioning and particularly in ocean productivity. Reactive nitrogen also impacts on tropospheric chemistry driving tropospheric ozone production, and on atmospheric acidity. A large number of compounds consist the reactive N pool, like nitrogen oxides, ammonia, nitric acid, organic nitrates, amines, amino-acids etc. Chemical transformations occurring in all phases present in the atmosphere, affect the solubility of reactive nitrogen pool and thus of N-deposition. A significant fraction of N-deposition occurs in the form of particulate matter (PM) deposition. Atmospheric PM is composed of water, inorganic salts, crustal material, organics and trace metals. Important contributors to the dry fine PM are inorganic compounds like ammonium (NH_4^+), and nitrate (NO_3^-), sodium (Na^+), sulfate ($SO_4^=$) and bisulfate (HSO_4^-). Crustal species like Ca^{2+}, K^+, Mg^{2+} are major components of dust and can neutralize part of the acidity of the atmosphere (e.g. NO_3^-, $SO_4^=$). Their presence is thus affecting the partitioning of NO_3^-, $SO_4^=$ and NH_4^+ on atmospheric PM as well as N-solubility and deposition, especially in areas where dust comprises a significant portion of total PM such as the Mediterranean region.

The effect of crustal material on N-containing species deposition is here investigated using the global TM4-ECPL global chemistry-transport model (Myriokefalitakis *et al*., ACP, 2011; Kanakidou *et al*., GBC, 2012 and references therein). The model is able to simulate oxidant chemistry, accounting for non-methane volatile organic compounds and all major aerosol components, including secondary aerosols like sulfate, nitrate and secondary organic aerosols. It also accounts for multiphase chemistry in clouds and aerosol water. Gas-particle partitioning of inorganic and crustal components is solved using the ISORROPIA II aerosol thermodynamics model (Fountoukis and Nenes, ACP, 2007). Global simulations have been performed considering and neglecting crustal material for the partitioning of HNO3/NO3- and H2SO4/SO4=. Differences between the N-deposition amounts and their solubility are presented and thoroughly discussed.

Evaporitic sulfate concretions, Moodies Group (~3.2 Ga, Barberton Greenstone Belt, South Africa)

SAMI NABHAN[1], CHRISTOPH HEUBECK[1] AND MARTIN HOMANN[1]

[1] Freie University Berlin, Institute of Geological Sciences, Malteserstr. 74-100, 12249 Berlin (sami.nabhan@fu-berlin.de; christoph.heubeck@fu-berlin.de; martin.homann@fu-berlin.de)

Quartz-rich sandstones of fluvial to supratidal facies in the Archean Moodies Group (~3223 Ma, Barberton Greenstone Belt, South Africa) include several regionally traceable beds with common to abundant nodular concretions of chert and megaquartz pseudomorphs after gypsum and barite. Electron microprobe analyses show remnants (<20 μm) of these minerals within the concretions but not in the host rock. Petrographic thin sections show characteristic mottled extinction of poikilotopic gypsum cement, now silicified.

Concretions reach up to 8 cm in diameter, are stratiform and commonly associated with aqueously reworked fine-grained tuffaceous sediment of rhyodacitic composition. Detailed geological mapping indicates a braided fluvio-deltaic setting, transitional to sandy supratidal flats which were colonized by microbial mats and occasionally underwent desiccation; the setting is clearly nonmarine. Gypsum pseudomorphs commonly grew inward into concentric hollow or fluid-filled cavities, suggesting mantling followed by dissolution of an unknown precursor mineral, but also grew displacively outward. Nodule growth apparently took place under early diagenetic conditions in unconsolidated sediment in the vadose zone dominated by frequent capillary rise of groundwater brine under mildly evaporative conditions. Partially reworked rhyodacitic tuffs may have delivered alkali cations such as Ca, Na, Ba, and K while carbonates were supplied by atmospheric silicate weathering of mafic to ultramafic volcanic rocks. The provenance of sulphate ions is unknown but may have included microbial and/or abiotic disproportionation of volcanic S or SO2.

Nodular concretions of the Moodies Group may represent the oldest terrigenous evaporites known to date. Their chemical and isotopic composition constrains the occurrence of sulfate in the atmo- and hydrosphere of the Early Earth, its interaction with the emerging biosphere, Archean weathering, possibly local climatic conditions, and vadose-zone hydrodynamics of the world's oldest well-preserved siliciclastic shoreline system.

Petrosomatic Evolution of Montviel Alkaline System and Rare Earth Carbonatites, Abitibi, Canada

O. NADEAU*, R. STEVENSON AND M. JÉBRAK

*(correspondence: nadeau.olivier@uqam.ca) Geotop, Université du Québec à Montréal, Québec, Canada

Montviel is a Paleoproterozoic alkaline complex intruding the Archean TTG and volcanic rocks of the Northern Abitibi Zone, Quebec, Canada. It consists of a series of ultramafic to carbonatitic peralkaline bodies. According to field relations, intrusions of peridotites and pyroxenites were followed by melteigeites / ijolites / urtites, syenites, sodic granite, and comagmatic silicocarbonatites, calciocarbonatites and ferrocarbonatites [1]. The magmatic evolution appears to have ended with a major explosive event which formed carbonatite-bearing polygenic breccia. The carbonatites and the breccia are hosts of one of the largest rare earth element (REE) and niobium mineral deposits being developed in Canada [2]. Detailed petrographic work indicates primary mineralization was partly magmatic, hosted in carbocernaite (REE carbonate) and partly carbothermal, recrystallizing carbocernaite to cebaite and kukharenkoite (REE fluorocarbonates). A second carbothermal event enriched specific parts of the system in heavy rare earths, crystallizing ewaldite (heavy REE carbonate) and heavy REE-enriched qaqarssukite (a fluorocarbonate). A third metasomatic event preferentially remobilized the light REE, further enriching the heavy REE in the areas that were first enriched. Preliminary analyses suggest that the flurorocarbonic stages were followed by an aqueous, hydrothermal stage. The final explosion stage of mineralization preferentially remobilized the light REE enriching the breccia in heavy REE. Trace element concentrations and 143Nd/144Nd ratios are used to investigate the petrogenesis of the system, trace the source(s) of the rare earths and study their behavior in this complex magmatic-carbothermal system.

U-Pb age dating of zircons was conducted on eighteen rocks from Southern Guyana (Guiana Shield). These were collected by geologists of the geological surveys of Guyana and Brazil during a joint geological and geo-diversity mapping project along their common border. A total of 447 U-Pb age determinations in zircons were obtained by Laser ICP-MS at the State Key Laboratory of Mineral Deposit Research, Nanjing, China.

The rocks were taken from the three main stratigraphic units present in Southern Guyana, where little age dating existed and will be presented south to north:

1) The zircons of granitic rocks of the Southern Guyana Granite Complex (most southerly) yielded the youngest age ca 1925-1984 Ma. These rocks contain only a few older zircon xenocrysts clustering at ca 2086 Ma, ca 2138 Ma, ca 2261 Ma and ca 2297 Ma.

2) The metamorphic age of zircons from the Kanuku Complex (centrally located) is estimated at ca 1956-1968 Ma and obtained from one S-type granite and one paragneiss sample. Moreover, several paragneiss samples contain significant proportions of detrital zircons with older age values clustering at ca 2200-2269 Ma, ca 2450 Ma, ca 2520 Ma, ca 2635 Ma and ca 2707-2721 Ma.

3) The rocks of the Iwokrama Formation (most northerly) display the largest range of age due to the presence of numerous zircon xenocrysts. Minimum age of crystallization of the volcanic and subvolcanic granitic rocks is ca 1981-1986 Ma. Older zircon xenocrysts cluster at ca 2196-2202 Ma, ca 2395-2417 Ma, ca 2487-2489 Ma, ca 2852-2882 Ma, ca 2949 Ma, ca 3701 Ma, ca 3778 Ma and ca 4218 Ma. The oldest age obtained is from a zircon core with a concordant age of 4219 Ma +/- 19 (1s). A second zircon core determination from the same crystal yielded a slightly discordant age of 4210 Ma +/- 19 (1s). The rim of the same zircon gave an age of 3733 Ma +/- 23 (1s).

The zircon xenocrysts in the range ca 2520-3811 Ma in the Iwokrama Formation overlap with Archean age of rocks of the Imataca Complex in Venezuela and of the Amapa Complex of northern Brazil dated between ca 2500 and 3700 Ma. The subvolcanic granite and felsic volcanic rocks of the Iwokrama Formation appear to contain zircons from a "Lost Hadean Crust" representing the oldest component of the Guiana Shield and of South America.

Hydrothermal magnetite from the Grasberg porphyry and Ertsberg East skarn Cu-Au deposits

PATRICK NADOLL[1] JOHN WALSHE[1] DAVID FRENCH[2] AND CLYDE LEYS[3]

[1]CSIRO, Australian Resources Research Centre, PO Box 1130, Bentley, WA 6102, Australia
[2]CSIRO, Energy Technology, PO Box 52, North Ryde, NSW 1670, Australia
[3]Freeport McMoRan Indonesia, Jakarta 12310 Indonesia

Recent years have seen an increased interest in the use of hydrothermal magnetite as a pathfinder mineral for exploration. Ongoing research puts further constraints on systematic compositional patterns in hydrothermal magnetite that can help to target deeply covered and remote deposits. We present preliminary data for hydrothermal magnetite from the Grasberg porphyry and the Ertsberg East Skarn System Cu-Au deposits. Both are among the biggest deposits of their types in the world and occur within the Ertsberg mineral district in Papua, Indonesia. Magnetite of igneous and hydrothermal origin is a widespread mineral phase in intrusive rocks and hydrothermal veins as well as in associated skarns. A total of 892 electron microprobe analyses of hydrothermal magnetite have been obtained. The main elements that can be used to characterize and discriminate hydrothermal skarn and porphyry magnetite are Mg, Al, V, Mn, and Zn. Titanium, Cr, Co, and Ni show little to no distinct variation between these two types of magnetite (Figure 1). Magnesium and Mn contents are comparable with concentrations found in hydrothermal magnetite from other skarn deposits. Titanium on the other hand appears to be characteristically enriched in hydrothermal skarn magnetite from the Grasberg deposit compared to skarn magnetite from other deposits.

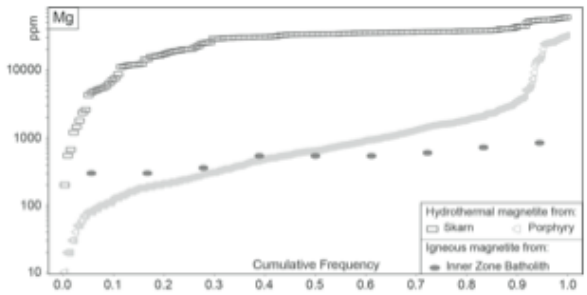

Figure 1 Probability plot for Mg concentrations in hydrothermal magnetite from the Grasberg deposit. Igneous magnetite from the Inner Zone Batholith, Japan is plotted as a reference.

Large scale material transport in the protoplanetary disk and its relevance to the "planetary" oxygen isotopic composition

H. NAGAHARA[1] AND K. OZAWA[2]

[1]Dept. Earth Planet. Sci., The Univ. Tokyo, Hongo, Tokyo 113-0033, Japan. hiroko@eps.s.u-tokyo.ac.jp
[2] (ozawa @eps.s.u-tokyo.ac.jp)

Protoplanetary disk evolvess basically due to the change of the accretion rate with time, of which most significant conseqnece is the change of temperature as a function of the location within the disk and time. Despite most physical models and astrophysical bservaitons, meteoritic and planetary evidence strongly suggest the presence of high temperature stage at least in the early stage that resulted in isotomic homogenization of the inner solar system. Furtherore, the inner edge of the disk was faced to the proto-Sun for a long duration, where condensation /evaporation of planet-forming minerals should have occurred, and it is now well known that some of condensates were transported to the asteroid belt or even the comet regions. Oxygen isotope is one of the exceptions that retained isotopic heterogeneity in chondrites but approximate homegeneity in planets.

Large scale material transport was investigated by using the model by Ciesla (2011; ApJ 740) and the possibility of homogenization by oxygen isotopic exchange during drift of grains within the disk. The basics of the model is the radial advection and diffusion equation, where the stochastic diffusion term is introduced by the Monte Carlo method. The evolution of temperature and density radial profiles were described as a funciton of distance from the proto Sun, and therefore the trajectory of grains enables us to evaluate the thermal history. The disk is in a steady state, number of grains were 10000, oxygen isotope of dust formed in the inner edge is assumed to be -50 permils and ice from outside is +100 permils. We assume that T~1000K is the boundary when grains exchange oxygen isotopes with the ambient gas.

The calculation results show that the average position moves inward with time, and grains larger than cm in order fell quickly to the Sun, but smaller grains remain in the disk, although large fraction of the grains fell into the Sun in 10^6 years witht some grains experiencing T>1000K. If the viscosity of the disk is as small as a=0.0001, most grains remai after 10^6 years. The results suuggest that it it impossible to change oxygen isotopic composition of all the dust grains in the inner disk, and therefore, oxygen isotopes homogenization took place at the very early stage and that was retained through the disk evolution.

Molybdenum Isotopic Compositions in Allende Chondrules

Y. NAGAI[1]*, T. YOKOYAMA[1] AND W. OKUI[1]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology (Tokyo Tech), 2-12-1 Ookayama, Meguro, Tokyo 152-8551, Japan
(*correspondence: yuichiro.nagai@geo.titech.ac.jp)

Chondrules are primordial materials formed in the early Solar system. They have various characteristics of the texture and petrography as well as $\Delta^{17}O$ values that generally correlate with the classes of their host chondrites. It is argued that chondrules have formed in multiple reserviors separated in time and space in the early Solar System. This is also supported by variable $^{84}Sr/^{86}Sr$ ratios in chondrules from different chondrite groups [1]. However, there still remains unclear how individual chondrules have obtained the nucleosynthetic Sr isotope anomalies, nor is clear the linkage between isotope anomalies and the other characteristic properties of chondrules. In this study, we focus on Mo isotopes in chondrules to further constrain their formation processes. Molybdenum has seven isotopes produced by different nucleosynthetic processes (s-, r- and p-process). The Mo isotope anomalies recorded in bulk meteorites and CAIs would provide a clue to decode the material transport in the solar nebula [2], yet no Mo isotope data are available regarding chondrules.

Chondrules samples prepared by the freeze-thaw method. were dissolved using a mixture of HF-HNO_3 (3:1) in Teflon vessels at 180 °C. After drying at 120 °C, they were dissoleved in 0.5M HF and centrifuged for several hours. Mo was purified by a two-step anion exchange column chemistry employing HCl-HF-HNO_3 (modified from [3]]. Molybdenum isotopic compositions in the chondrules were measured by N-TIMS (TRITON *plus* at Tokyo Tech).

Allende chondrules are found to have Mo isotope anomalies (e.g., $\mu^{95}Mo/^{96}Mo$ = 94 ±27 ppm) that are resolvable from those in bulk Allende [4] and Allende CAIs [2]. The anomalies in Allende chondrules are also distinctive from bulk Murchison [2,4], which has an s-process deficit in Mo isotopes. Thus, it is conceivable that chondrite matrices, CAIs and chondrules are formed from separated, isotopically distinctive reservoirs at least for Allende. Our result is consistent with Sr isotope anomalies observed in Allende meteorite [1].

Development of Large-Scale Aparatus for Gas Production from Methane Hydrate Layer

JIRO NAGAO*, YUSUKE JIN AND YOSHIHIRO KONNO

ProTech/MHRC, National Institute of Advanced Industrial Science and Technology (AIST), Sapporo 062-8517, Japan (correspondence: jiro.nagao@aist.go.jp)

Background

To utilize methane hydrate as valuable natural gas resources, a suitable gas production technique and conditions shoul be established. Experimentally the production method and suitable conditions have been investigated using the core samples. The reproducible results on how methane hydrate dissociates under various conditions could be presented from core-sample experiments. Whereas a core-scale experiments in a laboratory can demonstrate the heat transport process, a dissociation of methane hydrates in an actual reservoir is dominated by the material flow process. In order to couple data obtained from core-scale experiments with the results of field-scale production tests, a large-scale gas production apparatus was conducted at the AIST [1], financially supported by MH21 Research Consortium.

Certification of Apparatus

A large-scale production system for methane hydrate production tests can perform the dissociation experiments under the similar conditions of the actual reservoir under a deep sea floor. Developed large-scale apparatus is shown in Fig.1. The steel vessel has an inner diameter of 1000 mm, a height of 1500 mm and a volume of 1710 L. An overburden pressure of up to 16.5 MPa can be applied for sandy sample. The temperature of the vessel can be controlled from −5 to 20°C. A production well of a steel pipe with a diameter of 100 mm and a length of 1000 mm with holes is connected to a gas and water separator. Holes in the side and bottom of vessel are provided to allow the insertion of gas, water and temperature/pressure sensors. Real-time observations of the rate of the production of gas and water can be performed.

[2] Geological Isolation Research and Development Directorate, Japan Atomic Energy Agency, Tokai, Ibaraki, Japan

[3] Geological Isolation Research and Development Directorate, Japan Atomic Energy Agency, Horonobe, Hokkaido, Japan

It is significant to investigate the geochemical groundwater evolution around the nuclear waste repository, because geochemical condition could influence the radionuclide migration behavior and corrosion of barrier materials in the repository. Therefore, a laboratory jar experiment was conducted with deep subsurface sedimentary rock and groundwater, in order to assess the response of the geochemical and microbial communities toward redox processes. The redox process was induced by exposure to air and discontinuation to sediment suspension, which simulated the process occurring during operation of nuclear waste repositories, i.e., tunnel excavation, transport of waste containers, and final backfilling. During the experiments, redox potential, dissolved oxygen, and pH in the suspension were measured, and the concentrations of dissolved ions concentration, HCl-extractable iron, and also head space gasses in the jar were analyzed. Moreover, microbial DNA was extracted from the suspension, and PCR-DGGE analysis was performed to analyze the response of microbial communities toward the geochemical changes. As a results, after discontinuation of air exposure with lactate amendment, redox potentials decreased from ca. +100 mV to -600 m V (vs. Ag/AgCl), and some sequential terminal electron-accepting process (TEAPs) was observed with the reactions of aerobic respiration, iron reduction and hygrogen fermentation. The related species of the microbes along with TEAPs, e.g., *Pseudomonas sp*. for aerobic respiration and *Shewanella sp*. for iron reduction, was also detected. These results indicated that the microbial activities would affect the geochemical changes in nuclear repositories.

This study was performed as a part of “Project for Assessment Methodology Development of Chemical Effects on Geological Disposal System” funded by Ministry of Economy, Trade and Industry, Japan.

Mineralogy, petrology, O and Mg-isotope compositions of AOAs from CH carbonaceous chondrites

KAZUHIDE NAGASHIMA[1], ALEXANDER KROT[1]* AND CHANGKUN PARK[1]

[1]HIGP/SOEST, University of Hawai'i at Manoa, Honolulu, HI, 96822, USA. *(kazu@higp.hawaii.edu)

Amoeboid olivine aggregates (AOAs) in CH chondrites are texturally and mineralogically similar to those in other carbonaceous chondrite groups. They show no evidence for thermal metamorphism or alteration in an asteroidal setting and consist of nearly pure forsterite ($Fa_{<3}$), anorthite, Al-diopside, Fe,Ni-metal, spinel, ±low-Ca pyroxene (Fs_1Wo_{2-3}) and CAIs. The CAIs inside AOAs are composed of Al,Ti-diopside, spinel, perovskite, melilite ($Åk_{13-44}$), anorthite, hibonite, and grossite. The CH AOAs, including CAIs within AOAs, have isotopically uniform ^{16}O-rich compositions ($\Delta^{17}O$ = −23.5±2.2‰) and on a three-isotope oxygen diagram plot along ~slope-1 line. The only exception is a low-Ca pyroxene-bearing AOA that shows a range of $\Delta^{17}O$ values, from −24.3‰ to −15.2‰. Melilite, grossite, and hibonite in four CAIs within AOAs show no evidence for radiogenic ^{26}Mg excess ($\delta^{26}Mg^*$). In contrast, anorthite in 5 out of 6 AOAs measured has $\delta^{26}Mg^*$ corresponding to $(^{26}Al/^{27}Al)_0$ of $(4.4±0.6)\times10^{-5}$, $(4.2±0.6)\times10^{-5}$, $(4.0±0.6)\times10^{-5}$, $(1.7±0.2)\times10^{-5}$, and $(1.7±0.2)\times10^{-6}$. Anorthite in another AOA shows no resolvable $\delta^{26}Mg^*$: $(^{26}Al/^{27}Al)_0 < 2\times10^{-6}$. We infer that CH AOAs formed by gas-solid condensation, aggregation of the condensates mixed with the previously formed CAIs, thermal annealing, and possibly melting to a small degree in a ^{16}O-rich gaseous reservoir during a brief epoch of CAI formation. The lack of resolvable $\delta^{26}Mg^*$ in melilite, grossite, and hibonite in CAIs within AOAs reflects heterogeneous distribution of ^{26}Al in the solar nebula during this epoch. The observed variations of the inferred initial $^{26}Al/^{27}Al$ ratios in anorthite of the mineralogically pristine and uniformly ^{16}O-rich CH AOAs could have recorded (*i*) admixing of ^{26}Al in the protoplanetary disk during the earliest stages of its evolution and/or (*ii*) closed-system Mg-isotope exchange between anorthite and spinel+forsterite+Al-diopside during subsequent prolonged (days-to-weeks) thermal annealing at T>1000°C and slow cooling rates (~0.01 K hr^{-1}) that has not affected their O-isotope systematics. The proposed thermal annealing may have occurred in an impact-generated plume invoked for the origin of non-porphyritic magnesian chondrules and Fe,Ni-metal grains in CH and CB carbonaceous chondrites about 5 Ma after formation of CV CAIs.

Rare-earth element speciation in ferromanganese oxides from the Indian Ocean

B. NAGENDER NATH[1], T.C.VINEESH[2] AND G. PARTHIBAN[3]

[1]CSIR-National Institute of Oceanography, Goa-403004, India, nagender@nio.org

[2]Faculty of Maritime Studies, King Abdulaziz University, Jeddah, Saudi Arabia, vineeshtc@gmail.com

[3]CSIR-National Institute of Oceanography, Goa-403004, India , parthi@nio.org

Oceanic ferromanganese oxides are major sinks for rare-earth elements (REE); hydrogenous oxides being especially suitable for cerium enrichment. Deep-sea muds and ferromanganese nodules and encrustations are considered as potential future sources of REEs. There are differing views on the relative importance of two oxides of Fe and Mn as the REE carriers. Here we present results from sequential leaching experiments performed on different types of ferromanganese oxides from the Indian Ocean in order to quantify the amount of REE associated with the hydrous Mn oxides and Fe oxides. A four-step sequential leaching method is employed here, which is intended to selectively leach metals that are surface adsorbed/loosely bound, Mn-oxide bound, Fe-oxide hosted or held in aluminosilicate residue respectively. Results of this sequential extraction experiment work have revealed that nearly all REEs are closely associated (above 95%) with Fe-bearing phase. The shale-normalized patterns of iron-oxide bound fraction show a distinct similarity in shape and magnitude with the bulk REE patterns except for Ce. Similar magnitude suggests that much of the REEs are hosted by iron-oxyhydroxide phase. Likewise, ~90% of cerium is bound to iron oxide phase and this phase displays a positive Ce anomaly which is typical of low temperature ferromanganese oxides. In contrast, Mn-oxides exhibit a weak positive Ce fractionation. A pronounced positive cerium anomaly in the iron oxide phase suggests an important role of Fe-oxide in acquiring positive Ce anomaly. Enrichment of other tetravalent elements such as Zr, Th and Hf in this phase suggests that the Ce-oxidation must have taken place before the adsorption.

A distinct europium positive anomaly and depleted HREE is seen in the manganese oxide phase in many of the samples. Fractionation of Eu from other REEs and reduction of Eu^{+3} to Eu^{+2} can only occur at temperatures above 200–250°C and characteristic of hydrothermal plume particulates and seawater. This is interesting and may pose a question as to whether the hydrothermal sources are contributing Mn to the CIB nodules.

Mollusc clumped isotope thermometry using a new approach

PRASANNA NAIDU K.[1 A] AND PROSENJIT GHOSH[2]

[1] (prasanna@ceas.iisc.ernet.in)
[2](pghosh@ ceas.iisc.ernet.in)

We present a new approach of calibrating clumped isotope thermometry for mollusc. In our study we sampled growth bands from live mollusc specimens (*Villorita cyprinoides var. cochinensis*) collected from Cochin back water estuary in India. The growth bands represent seasonal carbonate deposition at different temperatures during a year. Simultaneous collection of water samples and co-existing carbonate allowed calculation of temperature using Epstein thermometry [1]. The temperature estimated using this approach showed seasonal range of 20° C to 42 °C.

The Δ_{47} values are derived using the method described in Ghosh *et al* 2006 [2] where heated gas equivalent together with carbonate standards (like NBS-19 and MAR J1) are analysed. The approach in producing this calibration curve varies from Henkes *et al*., 2013 [3] where bulk samples of mollusc species collected from natural marine setup across latitudes along with specimens grown under monitored conditions were analysed for Δ_{47} using carbon dioxide equilibrium scale. Our relation obtained as a function of temperature (in kelvin) is

Δ_{47}= = 0.055 x $10^6/T^2$ + 0.02 (r^2= 0.8996), which matches well with the inorganic calcite precipitation curve. We are monitoring the similar specimens at laboratory condition at different temperatures to further evaluate the thermometry equation.

A first look at boron isotope based pCO_2 values from the eastern Arabian Sea for the last 22 kyr

S. S. NAIK[1]*, P.D. NAIDU[1], S. N. NAIK[1] AND G. L. FOSTER[2]

[1]CSIR-National Institute of Oceanography, Goa, India 403004 (*correspondence: sushant@nio.org)
[2] Ocean and Earth Science, National Oceanography Centre Southampton, University of Southampton, SO14 3ZH,UK (Gavin.Foster@noc.soton.ac.uk)

The Arabian Sea is an unique region with semi-annual reversal of surface water circulation between southwest (SW) and northeast (NE) monsoons. The pCO_2 in the Arabian Sea is always in excess of that in the atmosphere, and the EAS is found to serve as a significant source of carbon dioxide to the atmosphere [1]. However nothing was known up to today about the past pCO_2 variations of the EAS.

We present here for the first time pCO_2 values from the eastern Arabian Sea for the last 22 kyr. We have used planktonic foraminifera species *Globigerinoides ruber* (sensu stricto) from a sediment core AAS9/21, collected at 1807m water depth (14°30.539′N, 72°39.118′E). We have analysed boron isotopes on a MC-ICPMS at the University of Southampton, UK. pH and pCO_2 were calculated from the boron isotopic values. Results show that pCO_2 varied from ~200 to ~440ppmv during the study period. A comparison with atmospheric CO_2 data from Antarctic ice core [2] suggest that the EAS seems to have fluctuated between a source and sink of atmospheric CO_2 in the past, with significant excess (w.r.t. the atmosphere) during the deglacial. Further comparison with western Arabian Sea (WAS) pCO_2 values [3] for the similar period reveals that during most of the time the WAS pCO_2 values were much higher as a result of intense upwelling which brings CO_2-rich sub-surface waters to the surface. The large variations in pCO_2 from the EAS are probably be due to a combination of physical processes such as moderate upwelling, influx of freshwaters from rain and rivers, and winter convective mixing processes.

Cerium stable isotope fractionation as a potential paleo-redox proxy

RYOICHI NAKADA[1]*, YOSHIO TAKAHASHI[1,2], AND MASAHARU TANIMIZU[2,1]

[1] Hiroshima University, Higashi-Hiroshima, Hiroshima, ryo-(nakada@hiroshima-u.ac.jp)

[2] Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Nankoku, Kochi 783-8502, Japan

Cerium (Ce) has anomalously high or low concentrations relative to its neighboring elements, lanthanum (La) and praseodymium (Pr), because of its chemical properties; this phenomenon is known as the Ce anomaly. This redox-sensitive property of Ce allows the estimation of the redox state of paleo-ocean environments and the evolution of the atmosphere. However, a consideration of only the relative abundance of Ce may lead to an incomplete understanding of its oxidation process. In the current study, three important geochemical parameters, namely, abundance, stable isotope ratio, and chemical speciation, were obtained for Ce to derive more information from the Ce anomaly. Assuming equilibrium isotopic fractionation, the mean isotopic fractionation factors between the liquid and solid phases (αLq–So) of (i) Ce adsorbed on ferrihydrite, (ii) spontaneous precipitation of Ce, and (iii) Ce adsorbed on δ-MnO_2 were 1.000145 (±0.000022), 1.000196 (±0.000031), and 1.000411 (±0.000079), respectively. These results indicate that the degree of isotopic fractionation of Ce between the liquid and solid phases becomes larger as the redox condition becomes more oxic in the following order: adsorption without oxidation < spontaneous precipitation < oxidative adsorption. Previously, the appearance of the Ce anomaly and/or XANES analysis constituted the only tool available for exploring the redox state. This study, however, suggests that the degree of mass-dependent fractionation of Ce can be used to clearly distinguish spontaneous precipitation from oxidative adsorption on δ-MnO_2, that occurs under more oxic conditions than the Ce(III)/Ce(IV) boundary. Our results suggest that the combination of the stable isotope ratio and chemical state of Ce can be used to classify the redox condition into the three stages based on Ce geochemistry, thereby offering a powerful tool for exploring redox conditions in paleo-ocean environments.

[1] R. Nakada, Y. Takahashi, and M.Tanimizu, Isotopic and speciation study on cerium during its solid-water distribution with implication for Ce stable isotope as a paleo-redox proxy. Geochim. Cosmochim. Acta 103 (2013) 49-62.

Stable isotopes of heavy elements in the modern ocean

YUSUKE NAKAGAWA, SHOTARO TAKANO AND YOSHIKI SOHRIN*

Institute for Chemical Research, Kyoto University, Gokasho Uji, Kyoto 611-0011, Japan (*correspondence: sohrin@scl.kyoto-u.ac.jp)

Stable isotopes of heavy elements are now emerging as powerful tracers in the modern ocean and proxies in the paleocean (Tanimizu *et al*., 2013). Mass fractionation of heavy elements in marine environments is expected to provide unique information on a number of processes. The isotopic compositions of dissolved heavy metals in seawater are fundamental data for stable isotope marine chemistry. However, the precise analysis of seawater is highly challenging (Boyle *et al*., 2012). The target elements occur at nmol/kg to pmol/kg in seawater. For the precise isotopic ratio determination using MC-ICPMS or TIMS, we have to preconcentrate the analytes quantitatively with a 50-1000-fold enrichment factor from a kg scale sample. It is also important to chemically separate the analytes from interfering major and minor constituents. In addition, it is critical to avoid contamination of the analytes through the sampling, pretreatment, chemical separation, and measurement. Preconcentration using chelating resins seems promising for this purpose.

We have develoed a new method for the precise determination of Mo isotope ratios in seawater on the basis of preconcentration using the TSK-8HQ chelating resin and measurement by MC-ICPMS (Nakagawa *et al*., 2008). Using this method, we have analyzed 172 seawater samples obtained from the Pacific, Atlantic, and Southern Oceans, with an oxygen concentration of 16–373 μmol/kg (Nakagawa *et al*., 2012). The average isotope composition in δMo (relative to a Johnson Matthey Mo standard solution) was as follows: $\delta^{92/95}$Mo = –2.54 ± 0.16‰ (2SD), $\delta^{94/95}$Mo = –0.73 ± 0.19‰, $\delta^{96/95}$Mo = 0.85 ± 0.07‰, $\delta^{97/95}$Mo = 1.68 ± 0.08‰, $\delta^{98/95}$Mo = 2.48 ± 0.10‰, and $\delta^{100/95}$Mo = 4.07 ± 0.18‰. These results demonstrate that Mo isotopes are uniformly distributed in the modern oxic ocean, strongly supporting the possibility of seawater as an international reference material for Mo isotopic composition.

Recently we have develoed a new method for the isotopic analysis of dissolved Cu in seawater (Takano *et al*.). We are now studying the isotopic composition of Cu of the modern ocean. Our data suggest that the combimnation of concentration and isotopic composition of Cu would be useful to evaluate relative significance of biogeochemical processes.

Nature of transition metals on fine and ultrafine particles and the cytotoxicity

Y. NAKAMATSU, T. AOKI AND S. UTSUNOMIYA

Dept. Chemistry, Kyushu University, Fukuoka 812-8581, Japan (utsunomiya.satoshi.998@m.kyushu-u.ac.jp)

Despite of mounting evidence indicting adverse health effects of ultrafine particle (UFP; <100 nm in diameter), it is difficult to appropriately evaluate the toxicity because of the small size, various shape, mixed chemical state and complicated crystal structure. Transition metals are known to be a factor that causes damage by inducing reactive oxygen species (ROS). The aim of this study is to systematically understand the nature of UFP associated with transition metals and the adverse health effects on lung cells based on the rigorous investigation of crystallo-chemical property of individual UFP in the urban atmosphere and the cytotoxicity assessment.

Inductively coupled plasma mass spectrometry (ICP-MS), X-ray absorption near-edge structure (XANES), scanning and transmission electron microscopy (SEM and TEM) have been employed to rigorously characterize particulate matters collected at urban areas of Fukuoka and Tokyo, and at remote area of Nagasaki. Epithelium cells and macrophage cells were exposed to 0.5-50 ug/ml of SRM 1649a, magnetite nanoparticle, and heavy metal ions, Fe, Mn, Ni and Cr, for 12 hours-26 days in a humidified atmosphere at 37 ºC and 5% CO_2. Cytotoxicity assessment was performed using WST assay. Statistic analysis was carried out based on analysis of variance (ANOVA).

All samples revealed that the dominant Fe speciation of the size fraction >1 μm was Fe-bearing aluminosilicaste, while that in submicron-size fraction was ferric Fe oxides. In the urban UFP, major Fe species was spinel-structured Fe oxides such as magnetite or maghemite, and some of them were mixed with Mn, Cr and Ni. In addition, sulfate and SiO_2 coating were identified in some of those particles.

Both urban UFPs and magnetite nanoparticles did not reveal an acute health effects on the lung cells; however, an exposure to aqueous Mn^{2+} significantly decreased the viability. Ni^{2+} also revealed the cytotoxicity in less extent. These results suggest that the speciation of heavy metals in the solution determine their toxicity, and protein and amino acid may decrease the toxicity of heavy metals by forming complexes. Because Fe-bearing nanoparticles did not decrease the viability, the soluble species of the other toxic metals, namely Mn and Ni, are the primary factor determining the acute cytotoxicity. On the other hand, long life-time of magnetite nanoparticles in alveoli solution resulted in the phase transformation from spherical magnetite to needle-shaped oxyhydroxide, which may result in an increase in the toxicity.

Non-ideal fluid geometry in the mantle and lower crust

M. NAKAMURA[1]*, S. OKUMURA[1], T. YOSHIDA[1], O. SASAKI[2], AND E. TAKAHASHI[3]

[1]Dept. Earth Sci., Tohoku University, Aobaku, Sendai 980-8578, Japan (*correspondence: nakamm@m.tohoku.ac.jp)
[2]Tohoku University Museum, Aobaku, Sendai 980-8578, Japan (sasaki@museum.tohoku.ac.jp)
[3]Dept. Earth Planet. Sci., Tokyo Institute of Technology, Tokyo 152-8551, Japan (etakahas@geo.titech.ac.jp)

Fluid phases characterize the physical and chemical processes in subduction zones. The conventional view on grain-scale fluid distribution is based on dihedral angle between minerals and fluids in isotropic monomineralic rocks (i.e. ideal “equilibrium” geometry). Natural rocks are, however, composed of anisotropic multiple phases and undergo textural adjustment to minimize interfacial and strain energy such as grain growth and dynamic recrystallization, which results in microstructural complexity. To understand real fluid distribution in deep-seated rocks, we conducted an X-ray CT study of xenoliths from the lower crust and uppermost mantle from Ichinomegata-Maar, NE Japan. All the observed spinel lherzolite, hornblendite, and hornblend gabbro xenoliths contained upto a few vol% of intergranular pores, indicating that the rocks were saturated with a free-fluid phase (Figure 1). The imaged pore fluids are typically polyhedral and tens–hundreds of micrometers in scale; this suggests that they were formed via coalescence of smaller pore fluids. The fluids are localized in interphase boundaries (between different mineral phases), while most of the monomineralic triple junctions lack pore fluids. All these characteristics are consistent with the results of grain-growth experiments in a fluid-bearing bimineralic system[1]; in other words, the role of interfacial energy anisotropy and grain growth are crucial in determining fluid distribution in nature. The geometry, distribution and thus connectivity of fluids cannot be assessed simply from dihedral angles.

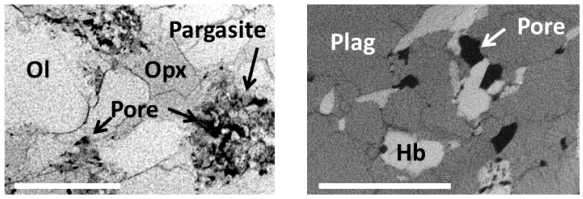

Figure 1: Typical CT images of pores in the lherzolite (left) and hornblende gabbro (right) xenoliths. Scale bars, 500 μm.

Deep-sea hydrothermal vents discharge subsea floor hot and reductive fluids into cool and oxidative seawater. The inter-fluidal oxidation-reduction potential substantially drives various abiotic and biotic oxidation-reduction reactions and supports chemosynthetic ecosystems in the mixing zones. It is predicted that electric current is generated if the two solutions are connected by conductor with electrodes [1]. Here we conducted in situ electrochemical analyses of high temperature of hydrothermal fluids and ambient seawater. We succeeded in measurement of the oxidation-reduction potential as about -39mV at high temperature about 309˚C in deep-sea hydrothermal fluid. The voltammetry analyses indicated that the open circuit voltage between the hydrothermal fluid and ambient seawater bridged by platinum electrodes was up to 0.74 V but the average current density generated in the seawater cathode was much lower than that in the hydrothermal-fluid-anode. By harvesting the natural setting of potential steep, we for the first time show proof of in situ generation of electricity in a newly developed fuel cell installed in deep-sea hydrothermal vents and witness light emitting diode lamp lighting in dark deep-sea environment. The results provide important clues not only to understanding of extracellular electron transports in the deep-sea vent microbial communities but also to future development of in situ electric power plants that will supply the electricity for the exploration of deep-sea resources and the following observatories of the deep-sea environments and ecosystems.

[2] Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University, Sendai, 980-8578, Japan
[3] Center for Chronological Research, Nagoya University, Nagoya, 464-8602, Japan
[4] Association of International Research Initiatives for Environmental Studies, Tokyo, Japan

To investigate the millenial-scale wet and dry climate changes in the south Siberian region for the last 33 kyr, the centennial scale analysis (less than 70 years) of the the inorganic elements (e.g. K and Ti) for the Lake Baikal sediment core (VER99G12) were carried out. The flucutuation of the K/Ti ratio during the last glacial maximum period (LGM; 26–19 cal kyr BP) was observed (Fig. 1). Because of the susceptible to water leaching of K comparing to Ti in soil environment, this fluctuation indicates the millennial-scale wet and dry climate changes during the LGM in the south Sibiran region. Also, the increase in the precipitation at the climate transition period between OIS2 and 1 (OIS2/1, 11.5 cal kyr BP) was indicated by the significant decrease in the K/Ti ratio. The result of the grain size distribution of the same core is also disscussed as well.

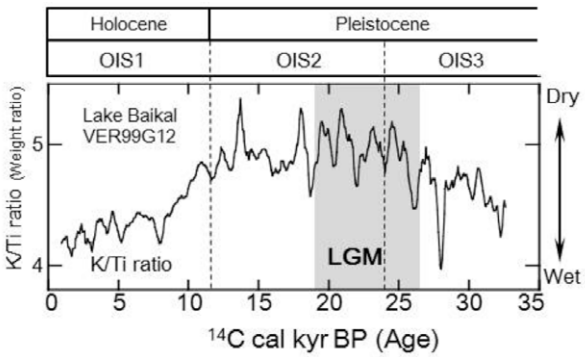

Figure 1. Vertical profile of the K/Ti ratio of the Lake Baikal sediment core (VER99G12).

Mass-independent fractionation of sulfur isotopes for all S-bearing components of Archean sediments

HIROSHI NARAOKA[1], EMI MORIWAKI[1] AND SIMON R. POULSON[2]

[1]Dept. Earth & Planet. Sci., Kyushu Univ., Japan (naraoka@geo.kyushu-u.ac.jp)
[2]Dept. Geol. Sci. & Engneer., Univ. Nevada-Reno, USA (poulson@mines.unr.edu)

Mass-independent isotope fractionation of sulfur (MIF-S) signatures in Archean sediments have been often used to infer the presence of an O_2-poor atmosphere, as UV photolysis of atmospheric SO_2 can produce MIF-S in the absence of an ozone layer [e.g. 1]. However, recent theoretical [2] and experimental [3,4] studies have shown that non-photochemical processes can also produce MIF-S. Hence, key factors controlling the production of MIF-S signatures in Archean sediments remain unclear. In this study, we performed $\delta^{34}S$-$\delta^{33}S$ analyses of S-bearing fractions and bulk samples of ~2.7 Ga black shales from drill core from the Jeerinah Formation, Western Australia. Elemental sulfur (S^0), sulfate (water-soluble and HCl-soluble fractions), pyrite and organic-bound sulfur (kerogen-S) fractions were obtained by solvent extraction and gravity separation,.

A slope of ~1 is observed for many bulk samples in a plot of $\delta^{33}S$ vs. $\delta^{34}S$, but also for the S-bearing fractions (Fig. 1). The S-bearing fractions show large intra-sample heterogeneity (up to 8‰ for $\delta^{34}S$), and positive $\Delta^{33}S$ values for all fractions (up to 6‰). The presence of MIF-S for all S-bearing fractions indicates multiple sulfur sources thr-oughout the Arch-ean sulfur biogeo-chemical cycles, and suggest that possible modern weathering has had little impact upon S-isotope signatures.

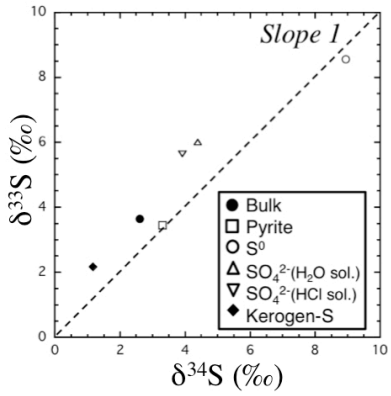

Figure 1. Intra-sample $\delta^{34}S$-$\delta^{33}S$ heterogeneity in Archean sediment.

Use of homogenized sediment in experimental set up: Re-stabilization of redox fronts and artifacts due to sieving methods

M.P. NARDELLI[1]*, E. METZGER[1], C. BARRAS[1], F. JORISSEN[1] AND E. GESLIN[1]

[1] LUNAM University, Université d'Angers, UMR CNRS, 6112UMR, LPGN-BIAF, Angers, France. (*correspondence: mariapia.nardelli@univ-angers.fr)

In experimental microcosms where the addition of marine sediments is needed to mimic natural benthic systems, sieved and homogenized natural sediment is often used (e.g.[1]), but the consequences of sieving methods on early diagenetic processes and their possible effects on experimental results are often neglected.

Our experiment investigated the effects of two different sieving methods on organic matter concentration and mineralization, exchanges at water/sediment interface and geochemical steady state reaching times for the main chemical species (O_2, Fe^{2+}, PO_4^{2-}, NH_4^+, ΣNO_3, H_2S, SO_4^{2-}).

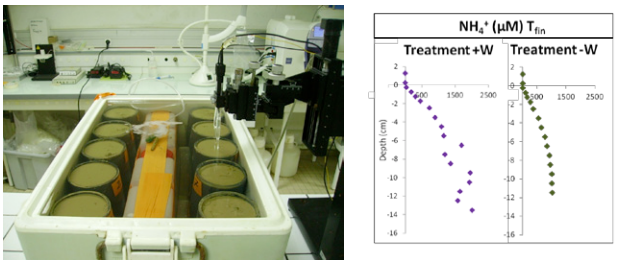

Figure 1 Experimental set up

One set of sediment samples was sieved (<38μm) with natural seawater (+W). The other was sieved without additional water (-W). The results show that while oxygen penetration depth in both treatments is stable within 7 days, the other chemical species show higher concentrations and longer time to reach steady state after the -W sieving treatment compared to the other sieving method. This is suggested to be due to the removal of organic matter during the +W treatment.

Granite compositions in a veined-lower mantle, as indicated by mineral inclusions in diamonds from Juína deposits, Brazil

NARDI, L.V.S *[1]; PLÁ CID, J.[2]; PLÁ CID, C.C.[3]; GISBERT, AND P.E.[4]; BALZARETTI, N.M[5].

[5] Instituto de Física - Universidade Federal do Rio Grande do Sul. Brazil.

The mineral inclusions of diamonds are the only natural samples from lower mantle. Recent studies of the inclusions in the alluvial diamonds from Juina province, Brazil, which are believed to be formed in the lower mantle and in the transition zone, have shown the presence of K- and Na-bearing inclusions with structures corresponding to hollandite and composition equivalent to those of alkali feldspars. Compositional determinations were obtained with electron microprobe, and structural information from RAMAN microspectroscopy. Hollandites, stichovite, phengite, CAS-phase, titanite and Na-Ca-garnet/cpx are in composite inclusions with hydrous MgFeAl-perovskite and almandine-grossularite garnet; isolated inclusions of ferropericlase, ilmenite and pigeonite-augite clinopyroxene were also observed. Na- and K-hollandite can also occur as isolated inclusions. K- and Na-hollandite + SiO_2 in the same diamond grains indicate the presence of melts crystallizing, at the lower mantle, products with compositions corresponding to granitic rocks. The association with abundant inclusions of ferropericlase and MgFeAl-perovskite suggests a highly heterogeneous mantle, probably with a 'veined'-structure similar to that suggested by Foley ([1]), but, with veins of granite composition. The growth of diamonds in the parts of mantle where melting occurred and these veins were formed, is consistent with high concentrations of volatiles, probably originated from subducted oceanic lithosphere.

Crystal-melt partitioning of REE and evolution of Martian melts

W. NASH[1,*] AND B. WOOD[1]

[1]Department of Earth Science, Oxford University, Oxford, UK, (*correspondence: william.nash@earth.ox.ac.uk)

REE concentrations in the SNC (Shergottite-Nakhlite-Chassignite) meteorites preserve information about the nature of their source regions, now widely believed to be the Martian mantle [1]. In particular, the influence of major phases on partial melting and fractional crystallsation can be inferred from REE concentrations in the meteorites, provided mineral-melt partition coefficients are known for each element under the appropriate conditions, and provided the REE concentrations (assumed chondritic) of the source region are known. Such information may then be combined with knowledge of the pressure-temperature-dependences of the inferred phase's stability to yield constraints on the depth of melting within the Martian mantle.

We have experimentally determined mineral-melt partition coefficients for a wide range of trace elements, between a synthetic Martian primary melt [2] and each of the conjectured major mantle-forming minerals (olivine, orthopyroxene and clinopyroxene) [3]. Experiments were conducted in a piston-cylinder apparatus at 15 kbar pressure, 1340°C, in graphite capsules. The fO_2 conditions approximate those anticipated during melting of Mars' mantle [4]. The new data have relevance for questions concerning the degree of relatedness among the SNC meteorites, and by extension the extent of heterogeneity within the Martian mantle.

In addition to their application to Mars specifically, these new partitioning data provide a test of the Wood and Blundy partitioning model [5] for iron-rich systems, and of its extension to similar situations for which experimental data are not currently available. Data for clinopyroxene in particular show close agreement with the model (for trivalent cations occupying the M2 site), with a maximum partitioning value (D_o) of 0.31, and an ideal radius (r_o) 0.97Å similar to the values reported for terrestrial clinopyroxenes under similar conditions [5].

Chromium mobility in Tuscan serpentinite bodies: Inferences from rodingitization and carbonation

C. NATALI[1]*, C. BOSCHI[1], I. BANESCHI[1], A. DINI[1], AND L. CHIARANTINI[1]

[1]CNR-Istituto di Geoscienze e Georisorse, Pisa, Italy (*correspondence: c.natali@igg.cnr.it)

The natural heavy metal enrichment of Tuscan ultramafic rock bodies and derived soils represents an important environmental concern for the area in which they outcrop. Moreover, most of them are superficial acquifers due to their high level of fracturing, thus representing an ideal study case to evaluate the mobility of heavy metal. Despite a comparable whole rock geochemistry, the heavy metal content of spring waters outpouring from the various ophiolitic outcrops reveals significant differences. The highest level of total chromium are detected in spring waters circulating in naturally carbonated serpentinites whereas very low chromium amount is recorded in non-carbonated serpentinite acquifers. Moreover, beside the total chromium content, also the CrVI in the most enriched waters exceed the maximum allowed from the Italian regulation and has therefore monitored and evaluated [1]. The key factors controlling both chromium mobility and carbonation potential have to be referred to the different oceanic history of these rock bodies that led in some occurrences to the alteration of the primary Cr-bearing phases. In particular, in the ophiolitic outcrop of Montecastelli Pisano (PI), serpentinisation and subsequent modal Ca-metasomatism affecting serpentinite promoted the spinel re-equilibration and Cr transfer from Mg-Al-chromite (and chromite) to adjacent newly formed silicate phases (Cr bearing garnet and Cr-chlorite) whose are significantly more sensible to weathering. The intense Fe-brucite (and serpentine) vein crosscutting the whole serpentinites should provided a viable pattern for the CO2-rich fluids circulating in these rocks to leach out Cr, and other elements, from alteration minerals. The carbonation of the serpentinite body, mainly affecting Fe-brucite vein, led to an of increase of the porosity an therefore enhancing the mineral weathering. In addition, the massive Fe-brucite dissolution controlling carbonation, led to the formation of Mg-Fe-carbonates and Mg-Fe-Layered Double Hydroxydes (LDH) in the carbonated veins, in which CrIII can substitutes FeIII and potentially oxidized to CrVI [2].

High precision determination of the terrestrial ^{40}K abundance

M.O. NAUMENKO[1]*, K.MEZGER[1], T.F. NÄGLER[1] AND I.M.VILLA[12]

[1]Universität Bern, Institut für Geologie, Baltzerstrasse 3, CH-3012 Bern, Switzerland. (correspondence: naumenko@geo.unibe.ch)

[2]Università di Milano Bicocca, Piazza della Scienza 4, 20126 Milano, Italy

^{40}K is one of the important constituents of the age equation used for K-Ar and K-Ca dating systems. The main sources of the uncertainty in K-Ca, K-Ar and ^{39}Ar-^{40}Ar ages are the branching ratio of the ^{40}K decay, the total decay constant and the abundance of ^{40}K. The most recent reports [1] imply that the least precisely known term in the K-Ar age equation is the abundance of ^{40}K. A ^{40}K abundance of (1.1672±41) x 10^{-4} was measured on terrestrial material [2], which is to this day the basis of the IUPAC recommendation of the terrestrial K isotope composition. Its uncertainty of 0.35% is much higher than the goal of the EARTHtime initiative, i.e. a total absolute uncertainty of 0.1 % on the absolute age.

In order to improve on this situation we measured the abundances of the K isotopes in terrestrial standards NIST SRM 918b and 985 by thermal ionisation mass-spectrometry on a Finnigan TRITON instrument. Three measurement protocols combined with two amplifier set-ups were applied: (A) dynamic measurement with in-run normalisation to the IUPAC value ^{41}K/^{39}K=0.072168; (B) a simple total evaporation procedure; (C) the "NBL-modified" total evaporation [3]. Two loading techniques and two types of filaments (tantalum and rhenium) were tested. The total ion yields (ionisation+transmission) were tested for the evaporation procedures (B) and (C) and ranged up to 48%. Isobaric interferences of Ca on K were tested and were not observed.

The results all agree with the terrestrial ^{40}K/^{39}K ratio recommended by IUPAC, but have much higher precision. The most reliable results were obtained with the total evaporation protocol with an amplifier configuration that uses 10^{10}, 10^{11} and 10^{12} Ω resistors on Faraday cups. The uncertainty of K-Ar and K-Ca dating systems contributed by the uncertainty of the ^{40}K abundance are now reduced from 0.35% to 0.05%.

Re-Os isotope systematics of sulfides from Olympiada gold deposit (Yenisei Rige, Russia)

NAUMOV E.A.,[1]* TESSALINA S,[2] BORISENKO A.S.[1], NEVOLKO P.A.,[1] AND KOVALEV K.R.[1]

[1] Institute of geology and mineralogy SB RAS, Novosibirsk, Russia, 630090, (*correspondence: naumov@igm.nsc.ru)

[2] John de Laeter Centre, Curtin University, Perth, Australia

The Olympiada Au deposit is located within the Yenisei Ridge in Central Siberia, along with a number of other Au and Au–Sb deposits. The Olympiada deposit occurs in metasedimentary terrigenous–carbonate rocks of Paleoproterozoic to Mesoproterozoic age, metamorphosed to amphibole–epidote greenschist facies. This deposit contains about 550–600 t of Au with the average grade of 3–4 ppm Au in primary sulfide ores and 10 ppm in supergene ores.

The Au mineralisation occurs in the contact zone between quartz–mica and carbonate–quartz–mica schists, and is controlled by a district-scale anticline, incorporating bedding-subparallel fractures and transverse fault zones. The orebodies are composed of carbonate–quartz–mica metasomatites containing 3–5 vol% sulfides (mostly arsenopyrite, pyrite, pyrrhotite, stibnite) and scheelite. Minor chalcopyrite, sphalerite, galena, tennantite–tetrahedrite and Bi-minerals are locally present.

Arsenopyrite is the main Au-bearing mineral and can be subdivided into 2 types according to mineralogical and chemical specific features: coarse-crystalline (Type 1) and acicular aggregates (Type 2), which represent distinct ore forming events differing by Au contents. First type is characterized by elevated contents of Au averaging 330 ppm, whereas Type 2 arsenopiryte contains only about 30 ppm of Au.

Both type of arsenopyrite were studied for isotopic composition of Re and Os. Type 1 arsenopyrite contains 3 ppb of Os and 20 ppb of Re and characterised by high ^{187}Os/^{188}Os ratio up to 14. Type 2 arsenopyrite has lower Os and Re contents up to 0.5 ppb and 5 ppb correspondingly, together with low ^{187}Os/^{188}Os raio of 0.3.

This difference implies different sources for these 2 stages of ore-forming process. Ore-forming fluids which forms gold-bearing arsenopyrites of the first type possibly have some crustal source. Origin of arsenopyrite of the second productive stage requires a source with mantle-like Os isotope signatures.

[5]Geology and Geophysics, University of Wyoming

In many geologic systems pore space is conceptualized as a containment and delivery system for fluids, not unlike a pipe network that delivers water though a city. However, in rocks exposed to reactive fluids, pore networks are not static. The pore network undergoes constant reshaping as minerals dissolve and precipitate. Despite the importance of pore network structure on many fundamental geologic processes, the physical characteristics of pore networks in rocks are poorly understood, in part due to their dynamic nature. Sub-micron sized pores in fine-grained rocks, such as shales and mudstones, require advanced techniques for quantification and characterization. Small angle neutron scattering, a technique that provides statistical data on the topology and architecture of pore networks, was combined with high-resolution imaging, and gas sorption measurements to characterize and quantify the pore network structure in 5 fine-grained rocks. In these rocks a large fraction (up to 80%) of the pore volume and surface area is contained within pores <20 nm in diameter. When two of these rocks were reacted with CO_2 under conditions relevant to CO_2 sequestration or enhanced oil recovery, mineral dissolution and precipitation changed the structure of the pore network with an overall loss of pore connectivity. This study demonstrates the application of neutron scattering to the study of pore networks in fine-grained rocks and the reshaping of these pore networks by mineral reaction.

The Río Mundo dolostones (Spain): Implications for MVT and hydrocarbon formation

D. NAVARRO-CIURANA[1]*, R. CODINA-MIQUELA[1], E. CARDELLACH[1], E. VINDEL[2], D. GÓMEZ-GRAS[1], A. GRIERA[1], L. DANIELE[1] AND M. CORBELLA[1]

[1]Dept. de Geología, Universitat Autònoma de Barcelona, Campus UAB, Edifici C, 08193, Bellaterra, Spain. (*correspondence: didac.navarro.ciurana@gmail.com)
[2]Dpt. de Cristalografía y Mineralogía, Facultad de Ciencias Geológicas, Universidad Complutense de Madrid UCM, 28040, Madrid, Spain.

Dolomitic rocks constitute a potential natural resource as they may host base-metal and hydrocarbon deposits. The study of the dolomitization associated with a Zn-(Pb) Mississippi Valley-type (MVT) deposit in the Río Mundo area (Albacete, SE Spain) may be a breakthrough for mining and hydrocarbon companies, as it is an excellent example to unravel relationships between dolomitization, fluid flow, fractures, host-rock porosity, ore deposition and hydrocarbon accumulation. Petrographical and C/O stable isotope data from carbonates (dolomites and calcites) have been used in order to study these associations. The MVT mineralization consists of sphalerite with hydrocarbon fluid inclusions, galena, pyrite and marcasite. It is hosted by Middle Jurassic dolostones, which are found below Upper Cretaceous age rocks. The hydrothermal dolomitizing event was essential for the ore genesis as it increased the rock porosity up to ~25%. Host limestones have $\delta^{18}O$ values between +27.55 and +27.83‰ (SMOW) and $\delta^{13}C$ from +2.32 to +3.16‰ (PDB). Pervasive dolomitization resulting from interaction with hydrothermal fluids have $\delta^{18}O$ values between +25.07 and +26.89‰ and $\delta^{13}C$ from -0.53 to +0.61‰. The limited $\delta^{18}O$ shift may be explained by interaction of regional limestones with a ^{18}O-enriched dolomitizing fluid at low fluid/rock ratio and constant temperature. $\delta^{13}C$ values indicate that hydrothermal fluids were enriched in ^{12}C, compatible with the presence of hydrocarbons trapped in sphalerite and porosity-filling organic matter. Although part of the ore is disseminated within dolostones ($\delta^{18}O$: +25.85 to +26.34‰; $\delta^{13}C$: -2.31 to -0.15‰), most massive brown to reddish sphalerite zoned crystals appear associated with vein-dolomite ($\delta^{18}O$: +25.13 to +26.93‰; $\delta^{13}C$: -0.75 to +0.59‰) filling fractures. The overlap of the different dolomite isotopic signature ranges suggests an isotopic resetting or the occurrence of a single dolomitizing event. The mineralization and hydrothermal dolomitization event must have occurred during Upper Jurassic to Lower Cretaceous times.

The compared reactivity of different organic matters and clay in the whole soil and at the microscale: Unraveling the reactivities by combining chemical analysis and physical fractionation

A. NAVEL[1], L. SPADINI[1]*, I. LAMY[2], E. VINCE[1] AND JEAN M.F. MARTINS[1]

[1]LTHE Laboratory, UMR5564 CNRS, University of Grenoble 1, France (*correspondence: lorenzo.spadini@ujf-grenoble.fr) (aline.navel@ujf-grenoble.fr, , jean.martins@ujf-grenoble.fr)

[2]INRA, UR251, PESSAC Physico-chemistry and ecotoxicology of soils from contaminated agrosystems - RD10 -F78026 Versailles Cedex, France (isabelle.lamy@versailles.inra.fr)

Organic carbon is one of the most reactive, often the most reactive component of common soils. Despite this, describing inside a complex soil matrix the reactivities of the different habits of organic matter (bioclasts, bacteria, degraded solid and dissolved organic matter) and the relative contribution to reactivity of mineral compounds is still a challenging task. The study focus on the reactivity determination of metals, protons, and generally complexing compound. A procedure is presented based on 'soft' granulometric fractionation separating coarse soil aggregates (>250 and 250-63μm), silty (63-20 μm) and fine (20-2 and <2 μm) soil fractions. The whole-fraction reactivity toward protons and Cu(II) (taken as example of complexing trace elemental cations) is compared to the fraction-specific total organic carbon (T_{OC}) and aqua regalis extracted Al (E_{Al}) content. T_{OC} varies in the soil fractions dependent on 20 years lasting organic amendments in the studied silty-loam soil. E_{Al} content represents the acid, and consequently the relative water accessible clay content in each fraction. Combining linearly these reactivities descriptors allows accessing to the reactivity contribution of different soil organic matters, soil clay and a residual phase. The comparison with referenced reactivity knowledge shows that this method allows accessing representative reactivities of studied components. With this method the soil aggregates are preserved. They are known to represent specific microbial habitats. This opens interesting perspectives relative to the study of biogeochemical site effects in the complex soil matrix.

Thermodynamic Constraints on Stability of Ceramics under Extreme Conditions – Phase Change and Amorphization from Chemical Effects of Radioactive Decay

ALEXANDRA NAVROTSKY[123]

([1]anavrotsky@ucdavis.edu)

In addition to radiation damage, ceramics in a nuclear reactor or waste form undergo chemical changes as a result of fission and radioactive decay. Because ceramics are typically ionic solids with stringent requirements to maintain appropriate cation size and charge balance on various sublattices, and such transmutations change both the size and charge of ionic species, one can expect phase change, exsolution, and/or vitrification arising from these chemical changes as well as from radiation damage. Two examples are discussed: the incorporation of rare earth fission products in UO2 and the effect of the decay of Sr to Y to Zr and of Cs to Ba in titanate waste forms incorporating these short-lived fission products. In the former case, rare earths are accommodated by creation of oxygen vacancies, which change ionic and thermal conductivity and, in many cases, stabilize the fluorite phase. In the latter, using perovskite, pollucite, and fresnoite as examples, a general trend of destabilization is seen, with exsolution of new phases and extensive vitrification arising from the violation of charge balanced substitution within the initial structures. Such behavior has the potential to diminish waste form durability

Bio-influence on the metal precipitation in ferromanganese nodules of the Central Indian Ocean Basin

B. NAYAK*, S.K. DAS AND P. MUNDA

CSIR National Metallurgical Laboratory, Jamshedpur-831007, INDIA (*correspondence: brn69@rediffmail.com)

In deep-sea ferromanganese nodules metals can precipitate by chemical oxidation and/or by microbial enzymatic processes [1-4]. Using high resolution FEG-SEM we have documented varieties of ultra-microfossils in the ferromanganese nodule samples of the Central Indian Ocean Basin (CIOB) (e.g., Fig. 1).

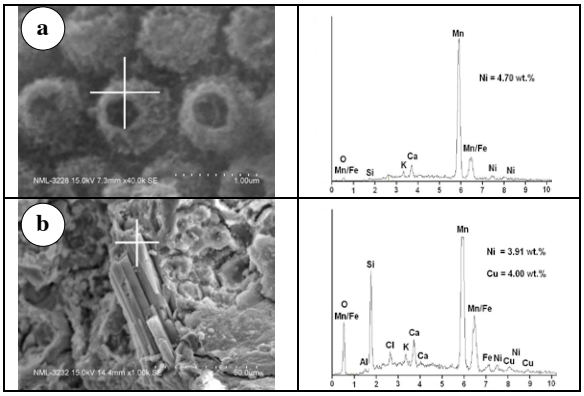

Figure 1: Fossilized microbes with their corresponding EDAX analysis at marked cross points; **(a):** clumpy microbes; **(b):** rod-shaped bacteria.

These fossilized microbes are mostly protozoa belonging to varieties of bacteria, diatoms and foraminifera. The chemical compositions of these ultra microfossils indicate a high-level of manganese precipitation in and around them. While clumpy microbes are enriched with Ni, the rod shaped bacteria are rich in Cu. Up to 4.7 wt.% Ni and 5.3 wt.% Cu have been recorded in the fossilized microbe bodies. The high abundance of ultra-microfossils and their chemical compositions indicate that microbes played a major role in the precipitation of metallic elements in the ferromanganese nodules of the CIOB.

Characterization of Diagenetically Altered Carbonate Reservoirs, Asmari Formation, Dezful embayment, SW Iran

P. NAZARIAN SAMANI[1]*, M. MORADPOUR[1] AND S. A. MOALLEMI[1]

[1] Research Institute of Petroleum Industry-14665, 137-Tehran-Iran (*correspondence: samanip@ripi.ir)

The Oligocene-Miocene Asmari carbonate Formation is wellknown as a major hydrocarbon reservoir in southwestern Iran. Determining the Asmari Formation reservoir quality based on defining diagenetic evolution were deduced from microscopic description of thin sections. Development of reservoir quality appears to be controlled effectively by diagenesis. Investigations reveal that diagenetic factors including compaction, cementation (by anhydrite, calcite and dolomite), dolomitization, dissolution and their effect on porosity changed the reservoir quality. Compaction and significantly cementation reduced the porosity however; this effect was healed by later dissolution and leaching processes. Dolomitization in this Formation enhanced the original porosity in depositional textures and protracted dolomitization created intercrystalline porosity, creating the best reservoir facies in SW Iran [1]. Two kind of distinct dolomitic textures involve fine to medium dolomite crystals (20-100μ) increased the intercrystaline porosity while the other, coarse mosaic of dolomite crystals (>100μ) especially associated with mud residuals are shown degradation effect on reservoir quality. It will be appeared that rock-water interaction lead to dissolution and dolomitization phenomenon which are the most important processes fortify pore spaces and controlling the reservoir quality in the Asmari Formation of SW Iran.

Synchrotron FTIR on melt inclusions, clinopyroxene and olivine from Mt Etna recent explosive eruptions

SABRINA NAZZARENI[1], MASSIMO POMPILIO[2], HENRIK SKOGBY[3], ANDERA PERUCCHI[4] AND PAUL DUMAS[5]

[1]Dip. Fisica e Geologia, Università di Perugia, Italy (sabrina.nazzareni@unipg.it)
[2]Istituto Nazionale di Geofisica e Vulcanologia, Sez. di Pisa, Italy
[3]Dept. of Geosciences, Swedish Museum of Natural History, Stockholm, Sweden
[4]SISSI, Elettra, Trieste Italy
[5]SMIS, Soleil synchrotron, Paris, France

The volatile budget of magmas from active volcanoes are crucial in developing volcanological models. The solubility of H_2O in silicate melts is, on the whole low, and strongly dependent on pressure. As a consequence magmatic melts reaching the surface have lost most of their original volatile contents.

We studied the volatile content of recent eruptions of Mount Etna (the 3930 BP picritic eruption and Cono del piano - 2001 and 2002 eruptions), to reconstruct a model for the ascent and degassing of these magmas. We determined the volatiles content by FTIR techniques measuring the hydrogen content of clinopyroxene phenocrysts and the H_2O and CO_2 contents of melt inclusions entrapped in the same clinopyroxenes (cpx) as well as in olivine (ol) phenocrysts.

Synchrotron FTIR experiments were conducted at SMIS (Soleil, Paris) and SISSI (Elettra, Trieste) beamlines. FTIR spectra were collected in the 900-8000 cm^{-1} range with 4 cm^{-1} resolution using scanning areas of variable size (200-400 μm-long and 200-400 μm-wide) following a regular grid of square-aperture dimension of 10 μm. Thus we measured high resolution chemical maps of H_2O and CO_2 distribution and speciation on melt inclusions to study the diffusion of H between the inclusions and cpx- or ol-host mineral. Line transect across chemical zonations in cpx (from the outer edge to the core of the crystal) showed details on the H_2O distribution with a more water rich core (PDL2001: 214 ppm H_2O; TEF2002-2:204 ppm H_2O) and a more "dry" (PDL2001: 138 ppm H_2O; TEF2002-2: 109 ppm H_2O) rim as detected by polarised FTIR spectra of oriented single-crystals. The water content of the Etna cpx phenocrysts is quite high suggesting a water rich magmatic system and showed only minor variations from the different eruptions: 254 ppm H_2O for 3930 BP picritic eruption; 214 ppm H_2O for 2001 eruption; 161-254 ppm H_2O for 2002 eruption.

Amber and amber-like materials on the Romanian market

ANTONELA NEACŞU[1]*, DELIA GEORGETA DUMITRAŞ[2], MIHAELA ELENA CIOACĂ[2] AND ANGELA MARIA ANASON[2]

[1]University of Bucharest, Faculty of Geology and Geophysics, 1, N. Bălcescu Ave., 010041 Bucharest, Romania. (*correspondence: antonela.neacsu@gmail.com)
[2]Geological Institute of Romania, 1, Caransebes Str., Bucharest, Romania, RO-012271.

Amber is a natural fossil resin with a controversial paleobotanical origin and is a mineraloid for mineralogists. The final internal structure and chemical composition of amber depend on light and oxygen exposure, on temperature and humidity differences, also on the biologic agents that characterized the environment, including the geological one, after resinosis (a large, unrepeatable secretion of resin by some Conifers and flowering trees, during Cretaceous and Tertiary periods). The oxidizing processes into the depositional context are important for the gemological properties of amber (color, cracks and transparency).

There are few amber varities used for manufacturing, including jewelry: the Baltic amber with its variety succinite (Poland, Russia, Baltic Countries, Ukraine, Germany), the amber of Dominican Republic, the Chinese amber, the Burma amber (burmite), the amber from the Romanian Carpathians (rumanite or romanite). In Romania amber is treated as gemstone, including the risk of fake industry, that uses both natural substances (e.g., actual resins, copal and pressed amber), and synthetic polymers (glass and plastics). A distinction between amber and imitations could be made applying Fourier-transform infrared spectroscopy (FTIR) and X-ray diffractometry (XRD) targeting the natural inclusions or proving an internal organizing tendency of material. FTIR curves of amber-like samples found ourdays in gem exhibitions organized by the Geological Institute of Romania are similar to those of romanite samples are similar to those of romanite, succinite, Dominican amber, burmite and copal. On the contrary, plastics, synthetic resins and modern resin of Rosaceous are found on the Romanian market, used as imitations or sometimes sold as genuine amber.

Igneous rocks, ranging in composition from mafic to felsic, show resolvable variations in their stable Fe isotope compositions [1]. These variations are closely related to the oxidation state of Fe in igneous systems, i.e., Fe^{2+} and Fe^{3+}, with heavy Fe isotope compositions predominatly associated with the more oxidized species. Reported Fe isotope variations (δ^{57}Fe relative to IRMM-014) in island arc basalts (IAB) span a range from negative to positive values [2], and are on average systematically lighter than those reported for mid ocean rigde basalts (MORB) [3], a fact that is seemingly opposing their expected oxidation state.

Here we present the stable Fe isotope composition of 13 IAB and 8 subducting sediments sampled along the active Banda Arc (East Indonesia). All samples are well characterised for their Sr-Nd-Pb-Hf-O isotope composition, which record progressive sediment melt contribution along the arc from NE to SW. We find that crystal fractionation increases δ^{57}Fe and identify this process as the dominant factor controlling the Fe isotope composition of this evolved arc suite. The opposite effect is observed upon magnetite saturation at ~4 wt.% MgO. Arc crust assimilation has also a strong influence driving the IAB towards heavier Fe isotopes. Sediment melting appears to have little or no effect on the Fe isotope composition in contrast to signatures for most radiogenic isotope tracers.

We imply that Fe in the sediment melt fully equilibrates with the mantle wedge either prior to or during wedge melting. As a consequence, if it is assumed that sediment melts carry more Fe than aqueous fluids, the slab agent has little or no affect on the redox state of IAB sources. Instead we propose that progressive wedge depletion has the potential to harvest Fe^{3+} and this lowers fO_2 (and δ^{57}Fe). If δ^{57}Fe monitors the redox conditions of evolving arc rocks, then crystal fractionation is the driving force in elevating fO_2 in subduction zones.

Geochemical features of granitoid Central Siberia magmatism in the Permian-Triassic

T.S. NEBERA, AND N.N. BOROZNOVSKAYA

Tomsk State University, Tomsk, Russia (tsnebera@mail.ru)

The granitoids of the Kolyvan-Tomsk folded zone, part of the western segment of the Altai-Sayan region, are the youngest magmatic formations of Late Hercynian tectogenesis. Developing the geochemical criteria of granitoid classification is an important perspective for geodynamic interpretation of the granitoids. The studied rocks are characterized peraluminiferous and have converged features granite S-and I-types. I-granites have a more mafic composition with a high content of calcium amphibole and accessors in the form of magnetite and allanite. They are characterized by a high oxidation of iron and oxygen fugacity, appreciable concentrations of Ba (~ 800-1200 g / t), Sr (~ 1200-2000), and calcium. Derived from the granite-granodiorite -granosyenite series, geochemically similar to rocks of I-type. They can be attributed to the products of latite-type magmatism with K_2O> Na_2O, high the K/ Rb ratios, Mg, high Ni concentrations. Breed from leucugranit series are rather consistent with S-type characteristics. They have a relatively high concentration of Rb in the background of a sharp decrease in the content Ba (up to ~ 120 g / t) and Sr (up to ~ 40 g / t) are enriched in Be and Cs, which makes them similar to Li-F granites. The results of luminescent analysis of the granitoids studied (intensive X-ray luminescence of Fe^{3+}in feldspars) indicates also that they were formed from a high-alkaline melt. The geochemical differences (characteristics) discovered for the granitoids allow us to assume that they were formed under complicated geodynamic conditions from the high alkalinity melt. This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.0686, 14.B37.21.1257).

Cadmium sorption by green rust

S. NEDEL*, K.N. DALBY, K. DIDERIKSEN, B.C. CHRISTIANSEN, AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*correspondance: sorin@nano.ku.dk)

Cadmium pollution, released into soils from agricultural and industrial activities, is considered a potential threat to biota. As with other pollutants, Cd mobility and bioavailability in soils largely depend on sorption-desorption processes at the interface between soil solution and mineral surfaces. Fe (oxyhydr)oxides are ubiquitous in soils. They have a large surface area and can adsorb and incorporate metals, meaning that these minerals are likely to affect Cd migration. The interaction of Cd with soil minerals has been investigated thoroughly but we know of no study on Cd interaction with green rust (GR). GR consists of brucite like layers of Fe(II),Fe(III) hydroxide separared by interlayers of water molecules and anions. These minerals are highly redox active, can form both by biotic and abiotic processes, and are likely to be present in soils and groundwater. The aim of this work was to determine if Cd can be sorbedand effectively immobilized by GR.

GR was synthesised at circumneutral pH by two methods: transformation of ferrihydrite in an Fe(II) solution and oxidation of an Fe(II) solution. Cadmium was added, at a series of concentrations either in the initial Fe(II) solution or in suspensions with preformed GR. X-ray diffraction (XRD) and transmission electron microscopy (TEM) showed that Cd^{2+} was not reduced by preformed GR nor incorporated in freshly forming GR. However, GR_{SO4} partially sorbed the divalent heavy metal, with higher sorption occurring at lower Cd concentrations. Upon oxidation of GR, Cd^{2+} remained associated with the Fe(III) solid. X-ray photoelectron spectroscopy (XPS) showed that it was sorbed by newly formed lepidocrocite.

These results contribute to fundamental understanding of contaminant interaction with green rust and can be implemented in current reactive transport models. We also demonstrated that Cd^{2+} mobility will be affected to some extent by sorption to GR, which can be present naturally in soil and form from iron corrosion, for example in permeable reactive barriers or pipes.

Zircon U-Pb-ages, Hf isotope and trace element composition in the evolution of the IVAC Complex (Urals, Russia)

I.L. NEDOSEKOVA[1]*, E.A. BELOUSOVA[2], B.V. BELYATSKY[3] AND N. PEARSON[2]

[1]Zavaritsky IGG UB RAS, Ekaterinburg, Russia (*correspondence: vladi49@yandex.ru)

[2]GEMOC/CCFS, Macquarie University, Sydney, Australia (elena.belousova@mq.edu.au)

[3]IPGG RAS, St.Petersburg, Russia (bbelyatsky@mail.ru)

It has been widely accepted that Hf isotope composition of zircon is relatively stable and is not affected by significant alteration due to influence of the hypogenic processes [1]. We have studied Hf isotope composition (coupled with U-Pb-age) in different populations of zircon from Ilmeny-Vishnevorsky Alkaline Complex (IVAC), Uralian Fold Belt.

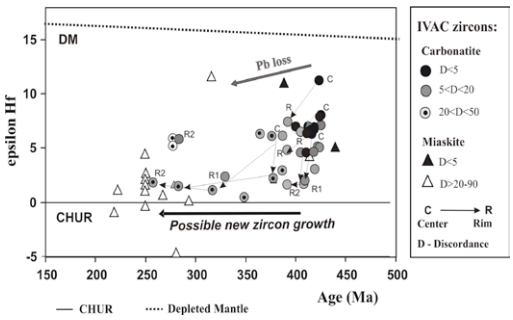

Figure: Hf isotope composition of the IVAC zircons (calculated for individual zircon ages) plotted against U-Pb ages, where D presents percentage of their age discordance.

The results indicate that the early zircons I from IVAC carbonatites and miaskites form concordant age cluster (U-Pb-age 410-424 Ma, D<5) and displays moderately depleted isotope Hf composition (εHf=11.7-4.7), where variations plausibly reflect primary heterogeneity of the magma source(s). The outer zones of the zircon I grains are characterized by disturbed U-Pb systems (5<D<20) and lower εHf values (shifting by 3-4 units in regard to the central parts of grains). These shifts do not correspond to the lines of Hf isotope evolution of zircons compositions or radiogenic Pb loss trends (Figure). The later newforming zircons II dated at T=250-320 Ma (frequently D>50-90, εHf = -5 to +11).

Both, the disturbance of U-Pb-system and formation of zircons with distinct, less radiogenic Hf-isotope composition could be related to the later ca 250 Ma metamorphic event.

Biological fractionation of molybdenum isotopes: Lake Mývatn, Iceland

REBECCA NEELY*[1], CHRISTOPHER SIEBERT[2], KEVIN BURTON[3], EYDÍS SALOME EIRIKSDOTIR[1] AND ÁRNI EINARSSON[1]

[1]* Institute of Earth Sciences, Sturlugata 7, 101 Reykjavík, Iceland (correspondence: ran6@hi.is)
[2] GEOMAR, Helmholtz Centre for Ocean Research, Germany
[3] Department of Earth Sciences, Durham University, UK

Molybdenum (Mo) is an essential enzyme cofactor in nearly all organisms and has been known to be of biological importance for some time [1]. Such biochemical ubiquity may come as a surprise given the relative scarcity of Mo at the Earth's surface. However, its unreactive, conservative behaviour in oxygenated, aqueous solutions makes it the most abundant transition metal in the oceans.

Laboratory based studies have shown that certain soil bacteria and cyanobacteria all favour light isotopes during Mo assimilation, thus causing measurable fractionations [2]. This study aims to bridge the gap between these laboratory experiments and the natural environment. Lake Mývatn is an ideal location to investigate these processes. Located on young, porous lava of the Icelandic rift zone it is almost exclusively sourced by groundwater flow and has only one riverine output, making it a perfect natural "box-model". Groundwater and outlet samples were analysed for Mo isotopes over the course of one growing season.

There are two distinctive groundwater inputs; $\delta^{98}Mo_{hot}$: 0.57 ‰ and $\delta^{98}Mo_{cold}$: 0.35 ‰ (0.1 2s.d.). The Mo concentration of the lake waters is described by simple, proportional mixing of these inputs. However, the Mo isotope value of the lake is heavier than the mixed inputs, consistent with a preferential uptake of light Mo isotopes by *Anabaena* (cyanobacteria), known to bloom in the lake in the summer months. Over the course of the year the outlet varied systematically between δ^{98}Mo 0.36 ‰ and δ^{98}Mo 0.66 ‰ with a signal predicted by a concentration driven model and biological fractionation of between - 0.2 ‰ an - 0.4 ‰. These results represent the first measurements of biological fractionation of Mo in the natural environment and have implications for our understanding of Mo systematics and its potential as a proxy in a geological context.

The analysis of long-term alteration of engineered barriers to be used for the disposal of TRU waste predicted precipitation of calcium silicate hydrate (C-S-H) minerals in the bentonite along the interface with the cement. In order to quantitatively measure the C-S-H predicted to form as a secondary mineral in the bentonite, the authors used XAFS analysis technique. The XAFS analysis which provides information around the concerned element regardless of the crystallinity of the mineral was assumed to be an effective mean to analyze poorly crystalized C-S-H. The local structural environment of calcium in the C-S-H with different Ca/Si ratio was also evaluated based on the EXAFS spectra in this study.

A test piece prepared by contacting a compacted bentonite and a hardened cement paste was immersed in the simulated fresh, reducing and high pH (FRHP) groundwater. The calcium K-edge XAFS measurement was conducted for the compacted bentonite. A synthetic C-S-H with high Ca/Si ratio was prepared and dissolved to generate low Ca/Si ratio C-S-H. These C-S-H minerals were subjected to the XAFS analysis.

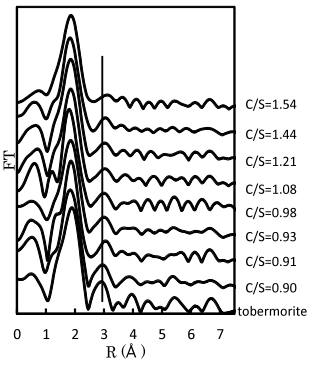

Fig.1 Radial structure function of C-S-H

The XAFS measurement allowed for evaluation of the variation of the quantity of the C-S-H in the bentonite. No significant difference was observed in the EXAFS spectra and conditions around the calcium among C-S-H minerals with different Ca/Si ratio. Conditions around the calcium in the C-S-H were similar to those in the tobermorite (Fig. 1).

This research is a part of "Development of the technique for the evaluation of long-term performance of EBS (FY2007-2012)" funded by the ANRE, METI of Japan.

A new model for biomineralization and trace-element signatures of foraminifera tests

G.NEHRKE[1]*, N KEUL[2], G. LANGER[3], L. DE NOOIJER[4], J. BIJMA[1] AND A. MEIBOM[5]

[1]Alfred Wegener Institute, Bremerhaven, Germany (*correspondence:gernot.nehrke@awi.de)

[5] Laboratory for Biological Geochemistry, School of Architecture, Civil and Environmental Engineering (ENAC), Ecole Polytechnique Fédérale de Lausanne. CH-1015 Lausanne, Switzerland (anders.meibom@epfl.ch)

The Mg/Ca ratio of foraminifera calcium-carbonate tests is used as proxy for seawater temperature and widely applied to reconstruct global paleo-climatic changes. However, the mechanisms involved in the carbonate biomineralization process are poorly understood. The current paradigm holds that calcium ions for the test are supplied primarily by endocytosis of seawater. Here, we combine confocal-laser scanning-microscopy observations of a membrane-impermeable fluorescent marker in living benthic species Ammonia tepida with dynamic 44Ca-labeling and NanoSIMS isotopic imaging of its test. We infer that Ca for the test in A. tepida is supplied primarily via trans-membrane transport, but that a small component of passively transported (e.g. by endocytosis) seawater to the site of biomineralzation plays a key role in defining the trace-element composition of the test. Our model accounts for the full range of observed Mg/Ca and Sr/Ca benthic foraminifera test compositions and predicts the effect of changing seawater Mg/Ca ratio.

Re-Os-PGE constraints on the evolution of backarc oceanic mantle

WENDY R NELSON[1] JONATHAN E SNOW[1] ALAN D BRANDON[1] YASUHIKO OHARA[2,3] AND CIN-TY LEE[4]

[1]Dept of Earth and Atmospheric Sciences, University of Houston, Houston, USA (wrnelson2@uh.edu, jesnow@uh.edu, abrandon@uh.edu)
[2] Hydrographic and Oceanographic Dept of Japan, Tokyo. Japan (yasuhiko.ohara@gmail.com)
[3] Japan Agency for Marine Earth Science and Technology, Yokosuka, Japan
[4] Dept. of Earth Science, Rice University, Houston, USA (ctlee@rice.edu)

Our direct understanding of the evolution of oceanic mantle during backarc extension is limited to exposures of abyssal peridotite and ophiolites. Few direct comparisons of ophiolite and backarc peridotite have been made due to the small number of documented exposures and limited in situ samples from backarc settings. Here we report Re-Os and PGE data for backarc abyssal peridotites from the Godzilla Megamullion (GM), a massive ~9000 km^2 oceanic core complex located in the Parece Vela Basin (Philippine Sea). The distal portion of GM records early, magmatically productive extension marked by moderately depleted spinel peridotites. This transitions into a less melt-productive medial region characterized by more fertile peridotite. The proximal region represents the most recently exhumed portion of the megamullion. Isotopically, the regions are indistinguishable, with whole rock $^{187}Os/^{188}Os$ = 0.1174-0.1704. Elevated $^{187}Os/^{188}Os$ values correlate with MgO loss, suggesting the influence of sea floor weathering. While spinel grains in proximal samples record high TiO_2 and Cr# indicative of melt-rock interaction, PGE abundances are not strongly affected; distal samples record stronger depletions in Pt-Ru-Pd the than proximal samples, consistent with higher degrees of melt extraction. In all samples, Re abundances are low (2-107 ppt) and are positively correlated with TiO_2 abundances in spinel, suggesting that Re is mildly influenced by melt-rock interaction. However, $^{187}Os/^{188}Os$ ratios are not correlated with Re concentration, demonstrating that modest Re addition occurred recently. As a whole, the $^{187}Os/^{188}Os$ data suggest that the backarc oceanic mantle in this region did not experience significant ancient melt depletion. Instead, the geochemical and isotopic signatures of the GM were generated during backarc extenstion associated with the Izu-Bonin-Mariana subduction zone.

Evolution of the Lower Crust in the Point of View of Fluid-Rock Interaction Under the Bakony-Balaton Highland Volcanic Field

BIANCA NÉMETH[1,2], KÁLMÁN TÖRÖK[1], ISTVÁN KOVÁCS[1] AND CSABA SZABÓ[2]

[1] Geological and Geophysical Institute of Hungary, H-1143, Srefánia út 14, Budapest, Hungary

2 Lithosphere Fluid Research Lab, Institute of Geography and Earth Sciences, Eötvös University, Budapest, Hungary, H-1117, Pázmány Péter sétány 1/c

Plio-Pleistocene alkali basalt hosted mafic garnet granulite xenoliths were studied from the Bakony-Balaton Highland Volcanic Field (Hungary). Two particular samples were chosen for analyses (optical microscopy, microthermometry, major and trace element geochemistry, Raman and IR spectroscopy), which contain primary silicate melt inclusions (SMI) in the rock-forming minerals. The samples have non-equilibrium texture in contrast with majority of known mafic garnet granulite xenoliths. SMI were observed in plagioclase, clinopyroxene and ilmenite in both xenoliths. The major element geochemistry of the glass of SMI suggests the presence of a silica rich melt at relatively high temperatures (830-920 °C). The origin of the melts could have been derived by the melting of biotite-gneiss or quartz-amphibolite. Our data suggest that the SMI derived from partial melting of different lower crustal rocks having mafic and metasedimentary origin with an occasional presence of C-O-H±S±N fluids. Petrography suggests at least five fluid events in the lower crust. The IR study of the water content in the rock-forming minerals and in the host minerals, including SMI and fluid inclusions, suggest that the acidic melt contained relatively high amounts of water. The observed SMI and fluid inclusions locally rehydrated the originally dry minerals.

The research was supported by OTKA to Kálmán Török, project number: NN79943 and a MC IRG (NAMs-230937) to István Kovács.

When do insoluble particles act as good CCN?

A. NENES[12]*

[1]School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta GA, USA (correspondence: athanasios.nenes@gatech.edu)

[2] School of Chemical And Biomolecular Engineering, Georgia Institute of Technology, Atlanta GA, USA

The ability of dust particles to serve as CCN under atmospherically relevant supersaturations depends on their mineralogy, size, morphology, and atmospheric processing. Most studies to date focus on the soluble fraction of aerosol particles when describing cloud droplet nucleation, and overlook the interactions of the hydrophilic insoluble fraction with water vapor. A new approach to include such interactions is presented, by combining multilayer Frenkel-Halsey-Hill (FHH) physical adsorption isotherm, Kohler theory and curvature (Kelvin) effects.

The importance of adsorption activation theory (FHH-AT) is demonstrated by measurements of CCN activity of mineral aerosols generated from clays, calcite, quartz, and desert soil samples from Northern Africa, East Asia/China, and Northern America. Based on the dependence of critical supersaturation with particle dry diameter, it is found that the FHH-AT is a better framework for describing fresh (and unprocessed) dust CCN activity than classical Köhler theory (KT). Ion Chromatography (IC) measurements performed on fresh regional dust samples indicate negligible soluble fraction, further supporting FHH-AT.

The results presented reshapes the conventional model of CCN activity, as it demonstrates that dust particles do not require deliquescent material to serve as atmospheric cloud nuclei. A droplet parameterization framework for large scale models that includes the new CCN activation physics is also developed and constrained by laboratory measurements. The framework accounts for aging of dust (via deposition of hygroscopic material), and is included within a global model framework to assess the impact of dust on warm cloud droplet number.

Crystallographic relationships between diamond and its olivine inclusions. An update

F. NESTOLA[1]*, P. NIMIS[1], S. MILANI[1], R. ANGEL[1], M. BRUNO[2] AND J.W. HARRIS[3]

[1]Dipartimento di Geoscienze, Università di Padova, Italy (*correspondence: fabrizio.nestola@unipd.it, paolo.nimis@unipd.it, sula.milani@studenti.unipd.it, rossjohn.angel@unipd.it)
[2]Dipartimento di Scienze della Terra, Università di Torino, Italy (marco.bruno@unito.it)
[3]School of Geographical and Earth Sciences, University of Glasgow, UK (Jeff.Harris@glasgow.ac.uk)

We have investigated the crystallographic relationships between olivine inclusions and their diamond hosts by in-situ single-crystal X-ray analysis. We studied 21 diamonds, all from the same kimberlite source (Udachnaya, Yakutia), containing a total of 51 olivine inclusions with diamond-imposed morphology. Each diamond contained up to nine individual olivines. On a statistical basis, no preferential orientation could be found. In particular, only 3 olivines showed an orientation comparable to that found by Mitchell & Giardini [1], i.e. (101)oli // (101)dia *and* (010)oli // (111)dia, which is believed to be the most favourable in the case of epitaxy. Based on our data, such orientation cannot be considered as "typical" of olivines included in diamonds. Although olivines in different diamonds showed random crystallographic orientations, multiple olivines within the *same* diamond often showed very similar orientations. Up to three sets of iso-oriented inclusions have been found within a single diamond. Our unprecedented data set clearly refutes the long assumed existence of a systematic crystallographic relationship for olivine inclusions in diamonds [1, 2]. The implications in terms of syngenesis vs. protogenesis of the inclusions will be discussed.

Colloid-associated iron and arsenic transport in streams

ELISABETH NEUBAUER[1], FRANK VON DER KAMMER[1], KLAUS-HOLGER KNORR[2], STEFAN PEIFFER[2], MARTIN REICHERT[2], STEPHAN J. KÖHLER[3], HJALMAR LAUDON[4] AND THILO HOFMANN[1]

[1]University of Vienna, Department of Environmental Geosciences, Austria (elisabeth.neubauer@univie.ac.at)
[2]University of Bayreuth, Department of Hydrology, Germany
[3]Swedish University of Agricultural Sciences, Department of Aquatic Sciences and Assessment, Uppsala, Sweden
[4]Swedish University of Agricultural Sciences, Department of Forest Ecology and Management, Umeå, Sweden

Significant correlations between concentrations of arsenic (As), iron (Fe), and natural organic matter (NOM) are often observed in wetland draining streams. However it is not yet understood how the transport of Fe and As along with NOM and iron hydroxide colloids is affected under variable hydrological and hydrochemical conditions.

Analysis with Flow Field-Flow Fractionation coupled to UV-Vis spectroscopy and inductively coupled plasma mass spectrometry revealed that As was associated with NOM and, if present, Fe-organo-mineral colloids in the size range below 25 nm.

The colloid composition in the studied streams was highly variable on a temporal and spatial level: Short-term groundwater level fluctuations affected the release of Fe, NOM and As, and colloid composition with respect to NOM and Fe-hydroxides changed within hours. This is due to changing flow paths of the groundwater that feeds the stream as well as the chemical composition of the hydraulically active soil layers. Under all conditions, 25 to 50% of the total As was associated with NOM. However, the mass of As exported per mass of NOM was considerably higher under baseflow conditions.

The colloid composition was also affected when stream water moved from first order, acidic streams to more basic, larger streams. Fe was mainly transported as Fe-NOM complexes in acidic first order streams. In contrast, in the more basic higher order streams, Fe-hydroxide colloids and particles were present. The amount of colloid-associated As decreased from 75% to 26% with increasing pH, and As in the colloidal size range was mainly associated with NOM.

There is growing interest in quantifying the riverine fluxes of Fe to the oceans. Association with NOM enhances the Fe mobility in streams. Concentrations of NOM bound Fe in the studied catchments were high compared to literature data. In conclusion, wetland-draining catchments are of special importance for riverine Fe and trace element transport.

Nickel and methanogens

A. NEUBECK[1]* AND M. IVARSSON[2]

[1]Department of geological sciences, Stockholm University, Stockholm, Sweden
[2]Department of Paleobiology and the Nordic Center for Earth Evolution (NordCEE), Swedish Museum of Natural History, Stockholm, Sweden

Methanogens require Ni for their growth and as a consequence the microbial fractionation of Ni isotopes can be used as a biomarker for activity of methanogenic communities [1]. Anaerobic laboratory experiments was performed using methanogens to investigate methanogenic growth in a modified nutrient media [2] with olivine Fo91 (5g/l) added as an additional mineral nutrient source and as the only H_2 provider. One of the investigated methanogens showed an increased growth in the experiments with added olivine. There were also a close relationship between the mobilized Ni and the growth of the methanogen. This is the first experimental evidence of a close methanogen-mineral interaction. Ni is an element that previously has been neglected in the study of fossilized microorganisms and their interaction with mineral substrates and, thus, there are no records or published data of Ni in association with microfossils. However, we have detected enrichments of Ni in fossilized microorganisms and ichnofossils, respectively, from three separate locations. Ni is not present in the host rock in none of the samples, thus, it is more probable that the Ni content is primary, a remnant of the live microorganisms. More extensive analysis is required to understand the uptake, preservation and fractionation of Ni by methanogens as well as the preservation and magnitude of Ni in microfossils.

Characterization of microbial diversity of a geothermal plant after long-term shutdown periods

DOMINIK NEUMANN[1], DARIA MOROZOVA[1], JULIA SCHEIBER[2], SEBASTIAN TEITZ[1] AND HILKE WÜRDEMANN[1]*

[1] Helmholtz Centre Potsdam GFZ, International Centre for Geothermal Research, Hermannswerder 15, 14473 Potsdam, Germany. *(Correspondence: Wuerdemann@gfz-potsdam.de)
[2] GEIE Exploitation Minière de la Chaleur, Kutzenhausen, France.

The geothermal plant in Soultz-sous-Forêts, located at the western part of the Upper Rhine Graben, is running as an EGS, including four wells ranging to a depth of 5 km. By long-term circulation of deep brines in the reservoir geothermal fluids with a total dissolved solid content of 97 g/L, a temperature around 160°C and a pH around 4.5 are produced. In order to characterize the microbial diversity and its potential involvement in scaling and corrosion processes after long-term shutdown periods, a series of fluid samples from the production well GPK2, taken during two plant restarts, were analyzed. Characterization of the microbial community was done by genetic fingerprinting (PCR DGGE) and qPCR.

Results indicate a diverse microbial community in the fluid of the production well after shutdown periods. In both sampling campaigns a clear shift in the Bacteria community composition was visible after the restart, which could be explained by the increasing temperature and the increasing amount of reservoir fluid. The diversity of the Archaea was not affected.

Sulfate reducing Bacteria (SRB), as indicated by the presence of their 16S rRNA gene and dsr genes, were found only until a produced fluid volume of 260 m^3 (Two borehole volumes) during the first sampling campaign. This indicates the growth of these microorganisms and biofilm formation on the well casing during the shutdown period and their removal after restart of the fluid production. Preliminary quantification results underline this assumption: highest levels of DNA, 16S rRNA gene copies and dsr gene copies were found in the first samples after the restart, while in later samples values were lower or below the detection limit.

The results, as well as further analyzes like the creation of clone libraries or the detection of cell numbers will contribute to characterize the potential involvement of the found microorganisms in corrosion processes and enhance the understanding of the microbial community associated with geothermal plants.

Effect of Al/B substitution on structure and properties of silicate glasses and melts

D. R. NEUVILLE

CNRS-IPGP, Géochimie&Cosmochimie, Paris Sorbonne Cité, 1 rue Jussieu, 75005 Paris, France.

The relationship between physical properties and structure of glasses and melts in the system $MO-T_2O_3-SiO_2$ (with M= Na_2, Ca and T= Al, B) are technologically and geologically important, in particular to understand the microscopic origin of the configurational thermodynamic properties. The connection of these network former is fundamental to understand the physical properties of magmatic liquids.

The configurational properties of melts and glasses provide fundamental information needed to characterize magmatic processes. A principal difficulty, however is to link the "macroscopic" configurational entropy with the structure of melts. This has been done by combining viscometry with Raman and NMR spectroscopy studies. From the viscosity measurements at low and high temperatures, we have obtained the configurational entropy, Sconf ($\log \eta = Ae + Be/TSconf$, were η is the viscosity, T the temperature and Ae, Be two constants).

Silicon, aluminum, and boron are 3 network formers playing different role on the silicate network, whereas Si is the strongest network former in coordination 4, 5 or 6 as a function of T, P; Al can play different function as a network former in 4- or 5–fold coordination and probably as a network modifier in 6 fold coordination. Boron observed in 3 or 4 fold coordination is always a network former but for very “fragile” glasses.

For the glass the Al/B substitution produce a small decrease of the molar volume while this substitution produced a strong decrease of viscosity and glass transition temperature while the fragility of the network is less affected by this chemical change. Raman spectra show significant change in the D1 and D2 bands. NMR spectroscopies show also significant change as a function of chemical change and temperature. All this observations will be discussed and interpreted in order to link microscopic versus macroscopic changes.

Historical deposition of Polycyclic Aromatic Hydrocarbons in an Amazon estuary

P.A. NEVES*[1], S. TANIGUCHI[1] AND M.C. BÍCEGO[1]

[1]Laboratório de Química Orgânica Marinha, Instituto Oceanográfico da Universidade de São Paulo, 05508-120, São Paulo, Brazil. *(correspondence: ticinev@yahoo.com.br)

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitously distributed in the aquatic environments, coming from natural and anthropogenic sources. PAHs can accumulate in sediments and their historical deposition can show source alterations throughout time. The study area, Guajará Bay, is located in northeastern Amazon and Belém (one of Amazon’s biggest cities) is located in its margins. To evaluate the temporal changes of PAHs in Guajará Bay a sediment core was collected in 2010. Total PAH concentration (∑PAH) ranged from 46.9 to 595 ng g^{-1} (dry weight) along the core. The core can be divided in two periods regarding PAHs sources to the area. In the first period, corresponding from 1900’s to the early 1960’s, ∑PAH remained constant, with an average of 79 ng g^{-1} (d.w.), possibly characterizing base levels of PAHs for this region. Composition of individual PAH showed a predominance of alkyl-PAH over its parental compound such as methylphenanthrene over phenanthrene. Usually, these PAHs are associated with petrogenic inputs, however, there is no evidence of oil during this period in the region. Thus, the higher proportions of alkyl-PAHs could be related to natural sources, such as organic matter diagenetic transformation or biogenic synthesis. During the second period, which starts in the late 1960’s, ∑PAH increases, reaching its maximum value at the top of the core. Diagnostic ratios showed a predominance of pirolitic PAH in the area, suggesting that this input is probably related to the intensification of the urban and industrial development, encouraged by the government since 1950’s. The variation of PAH contents was closely related to the changes in the environment of the Amazon area evaluated.

Following the great oxidation event (GOE), the isotope record of marine carbonate rocks suggests a massive burial of organic carbon in an event known as Lomagundi excursion (LE). It is estimated that during this period atmospheric oxygen attained levels much higher than during GOE [1]. It is proposed that as the LE declined, oxygen dropped to lower levels [1, 2], but the direct geochemical evidence for the state of atmospheric and ocean oxygenation both during and after the LE is missing. This time window is also represented by the 2.2-2.0 Ga Francevillian group of Gabon, well known for the earliest large colonial organisms [3]. In order to investigate the nature of marine water-column chemistry, samples representing the entire section were subjected to multielement (C, S, Fe, Mo, U) biogeochemical study.

Geochemical data show deep water oxic conditions during deposition of the lower part of the section in agreement with the LE. Nevertheless the interlayered Mn deposits occured in ferruginous anoxic conditions reflecting sea-level changes. The upper part of the section reflect euxinic conditions, and together with δ^{98}Mo values, these data confirm a significant decrease in the oxygenation of ocean water in the aftermath of the Lomagundi Event.

Hydration, structure and mobility of Cs^+ and Sr^{2+} in montmorillonite and muscovite clay minerals

BRICE F. NGOUANA W.[1]*, NARASIMHAN L.[1] AND ANDREY G. KALINICHEV

Laboratoire SUBATECH (UMR-6457), Ecoles des Mines de Nantes, 4 Rue Alfred Kastler, La Chantrerie, 44307, Nantes Cedex 3, France (* ngouana@subatech.in2p3.fr)

Clay minerals used as natural and engeenered barriers in geological nuclear waste repositories are able to considerably reduce the mobility of radionuclides in the environment. The radionuclide retention happens through a combination of various physical and chemical processes taking place at the clay-water interface, but their molecular mechanisms are still insufficiently understood.

To obtain detailed microscopic scale information on the structure, dynamics, and energetics of Cs^+ and Sr^{2+} ions at the surfaces of model illite and smectite clays (muscovite and montmorillonite, respectively) we have performed a series of classical molecular dynamics (MD) computer simulations using the CLAYFF force field [1]. New sets of structural models with different degrees of compositional disorder in the octahedral and tetrahedral layers of clay were constructed and investigated in order to quantify the effects of such disorder on the properties of the adsorbed ions.

The structural properties were probed in terms of the atomic density distributions in the direction normal to the clay surfaces, along the planes parallel to the clay surfaces, atom-atom pair correlation functions, and coordination numbers. The 2-dimensional and 3-dimensional diffusion coefficients were calculated to probe the ionic mobility at the clay surfaces and in the interlayer space. In the case of montmorillonite (a swelling clay), the hydration energetics was also systematically investigated by determining the hydration and immersion energies [2].

The atomic density profiles vary with the charge and size of the ions and show a significant layering at the interfacial regions of both studied clays. Pair correlation functions and coordination numbers indicate only one stable adsorption site for cations on the basal surface of muscovite (ditrigonal) in contrast to two adsorption sites on a similar montmorillonite surface (ditrigonal and triangular). Cs^+ and Sr^{2+} mobility is considerably reduced by substrate adsorption, but the diffusion coefficients tend to get closer to bulk solution values when the ions are removed from the surface.

Constraining OH diffusivity in silicate melts

HUAIWEI NI[1,2], ZHENGJIU XU[3] AND YOUXUE ZHANG[3]

[1]CAS Key Labororatory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei 230026, China (*Correspondence: hwni@ustc.edu.cn)
[2]Bayerisches Geoinstitut, Universität Bayreuth, 95440 Bayreuth, Germany
[3]Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI 48109, USA

The transport of water in silicate melts is mostly dominated by molecular H_2O (H_2O_m) diffusion. Diffusivity of hydroxyl (OH), the other water species, has not been well quantified. It has been previously assumed that OH diffusivity is close to the Eyring diffusivity (i.e., inversely proportional to melt viscosity), or essentially approaches zero. However, in our experimental study of water diffusion in an Fe-free andesitic melt, we found that these assumptions do not hold.

Diffusion experiments were performed at 1 GPa in a piston-cylinder apparatus using a double diffusion couple technique. One couple contained a dry glass (with 0.01 wt% water) and a hydrous glass (with ~3 wt% water), and the other contained the same dry glass and a different hydrous glass (with ~6 wt% water). Both couples experienced the same pressure and thermal history, which is crucial for constraining the dependence of H_2O diffusivity on water content. Diffusion profiles perserved in the quenched products were analyzed with both FTIR and confocal Raman microspectroscopy. Nearly identical profiles were obtained from the two methods for profile length > 1 mm (produced at 1619-1842 K), but for profile length <0.1 mm (produced at 668-768 K) FTIR analysis showed marked convolution effects due to its spatial resolution being inferior to that of Raman.

Previous models neglecting OH diffusivity cannot satisfactorily reproduce the measured profiles. We developed a new fitting procedure that simulataneously fits both diffusion profiles from a single experiment and also accounts for the role of OH diffusion. With the new model, OH diffusivity is constrained to be 10%-20% of H_2O_m diffusivity at 1619-1842 K as total water content approaches zero. The obtained OH diffusivity is much higher than the Eyring diffusivity, indicating that in melt structure OH is not necessarily bonded with network-forming cations, such as Si. On the other hand, OH diffusivity is close to reported F diffusivity (both the size and the valence of OH and F are comparable).

Research on heavy metal environmental geochemistry in urban soils in Haikou, China

QIAN NI[1], ZHENGYU BAO[2] AND CHUNYAN WANG[3]

[1] State Key Laboratory of Biogeology and Environmental Geology,(niq1981@163.com)

China University of Geosciences, Wuhan 430074, China

Soil heavy metals constitute serious environmental hazards from the point of view of polluting the soils and adjoining streams and rivers. Therefore, a series of investigations were performed to provide heavy metal signatures of urban soils and to evaluate pollution level. Concentrations of Cd, Zn, Ni, Cr, Cu, Pb, Hg and As were measured on 70 topsoil samples and 16 deep-soil samples collected from green areas in Haikou city, capital of Hainan province. The results indicate that, in comparison with Chinese Environmental Quality Standard IIfor Soils (CEQSSII), urban soils in Haikou have lower metal concentrations as a whole, especially Hg□As□Cu□Pb and Zn (except one maximum) lower than the Chinese Environmental Quality Standard II(CEQSSI). These concentration levels are comparable to those in other studies, such as London, Hong Kong, Shanghai, and so on, we found that these values are lower in Haikou except Cr and Ni. Histograms of distributions of these concentrations show “double peak” or “long tailed”, which may be related to soil parent material types and anthropic contributions. Pollution evaluations of single factor index and comprehensive index indicate that soils in study area are unpolluted by most heavy elements, except that Hg and Cd are medium polluted elements which should be noticed. Speciation analyses show that Zn, Ni, Cr, Cu, Pb and As are mainly in the residual and Fe–Mn oxide phases, while Hg is associated with the organic, humic and residual fractions. The high exchangeable Cd(about 24%) in urban soils need further investigation for ecological and health implications.

Alteration at bentonite-cement interfaces – An experimental approach

CLAUDIA NICKEL[1,2], ANDRE BALDERMANN[1], MARTIN DIETZEL[1], GEORG H. GRATHOFF[2] AND LAURENCE N. WARR[2]

[1]Institute for Applied Geosciences, Graz University of Technology, Rechbauerstraße 12, 8010 Graz, Austria; (claudia.nickel@tugraz.at)

[2]Institute for Geography and Geology, Ernst-Moritz-Arndt Universität Greifswald, Friedrich-Ludwig-Jahn-Str. 17a, 17487 Greifswald, Germany

The identification of alteration processes at the interface of clay and contacting cement is crucial for ensuring the long-term stability of underground nuclear waste repositories, i.e. the Aspö field test site (Sweden).

In order to investigate alteration features directly at the bentonite-cement interfaces, three flow-through laboratory experiments were realized. Differences in the water uptake behavior and related changes in the mineralogy and chemistry of Portland cement clinker and air-dried MX-80 bentonite were monitored using wet-cell X-ray diffraction (XRD) and transmission electron microscopy analyses, covering an experimental period of 1 year.

The water uptake rate was ~44-times higher in the clay-cement experiments than that of the pure MX-80 bentonite reference experiment, and the steady state was reached after ~22 and ~963 h, respectively. XRD data display progressive hydration of the Na-montmorillonite interlayer sites, as expressed by the stepwise increase of the water layers (WL) from 12.4 Å (1 WL) and 15.7 Å (2 WL) to 18.6-19.1 Å (3 WL). *CALCMIX* modeling of the montmorillonite revealed 65 ± 2% 3 WL and 35 ± 2% 4 WL at the steady state, suggesting complete hydration of the cement and bentonite was reached in the less altered zone. In contrast, cation exchange of Na^+ (0.36 to 0.08 a.p.f.u.) for Ca^{2+} (0.08 to 0.12 a.p.f.u.) was recognized in the montmorillonite interlayer sites close to the clay-cement contact, corresponding with a general depletion in CaO of the contacting Portland cement by a factor of 2.5. In addition, various of original cement phases were preserved, and only minor proportions of C-S-H phases were found.

Cation exchange within the clay and the preservation of original cement phases suggests that intense alteration processes occurred at the bentonite-cement contact. The Ca for Na substitutions strongly reduced the smectites swelling pressure and inhibited the formation of stable cement phases, by quantitative removal of CaO. These processes destabilized the clay-cement buffer and need further investigation for long-term nuclear waste disposal in sustainable underground repository sites that require clay-cement sealings.

Coupled spectromicroscopic investigations for improved conceptual models of soil carbon cycling

Useful numeric models can only be constructed from accurate conceptual models. Biogeochemical interfaces or hotspots result from the spatial and temporal convergence of two or more different materials or processes. A comprehensive understanding of interfaces requires analytical techniques that complement each other in spatial, temporal, and elemental sensitivity. Our team has built expertise in the application of multiple (spectro)microscopic techniques to laboratory investigations of soil carbon cycling. We have sought to understand the interface between in inorganic mineral phases, organic compounds, and biological organisms occurring at the micron scale. We have made particular use of synchrotron based (spectro)microscopic techniques such as SR-FTIR, STXM/NEXAFS, hard X-ray microprobe, and X-ray microtomography as well as high resolution secondary ion mass spectrometry (NanoSIMS). This presentation will include technical considerations and challenges associated with sample preparation and handling required for successful application of multi-modal imaging analysis. In addition, the specific findings from several different investigations and the associated insights will be presented. The data shown will illustrate the challenges associated with obtaining statistically robust and quantitative measurements with this approach along with its' power for improving conceptual mechanistic models.

Leucosome formation by desequilibrium melting and melt loss: Perspectives from the South Marginal Zone (SMZ) of the Limpopo Belt, South Africa

G. NICOLI[1]*, G. STEVENS[1], J-F MOYEN[2,] AND J. TAYLOR[1]

[1]Stellenbosch University, PB X1, Matieland 7602, South Africa (*correspondence: gnicoli@sun.ac.za)
[2]UMR 6524 CNRS, Université Jean Monnet, 23 rue du Dr Michelon, 42023 Saint-Etienne, France

This study investigates the details of the anatectic process which result in the formation of dm- to m-scale, markedly low K_2O content leucosomes during biotite incongruent melting.

Two hypotheses exist for the origin of such leucosomes; that they represent the products of fractional crystallization of plagioclase and quartz [1]; and, the redistribution of K_2O and H_2O from the segregated melt back into the residuum [2]. Evidences from metapelites in the SMZ do not support either hypothesis. The peritectic assemblage is well preserved in zones of residua adjacent to leucosomes [3]; leucosomes are characterised by strong positive Eu anomalies, whilst the gneisses from which they were derived have insignificant Eu anomalies; Na:Ca ratios in the leucosomes are similar to those in their source rocks; field-based XRF profiles of K_2O content across leucosomes and their hosting gneisses does not show substantial K_2O enrichment in the gneisses adjacent to the leucosomes. In addition, leucosomes formed by biotite + sillimanite melting are shown to have become rheologically solid prior to the occurrence of biotite melting in the absence of sillimanite at higher temperature.

These findings suggest that the leucosomes formed by biotite fluid-absent melting involving disequilibrium behaviour of plagioclase. Such a mechanism fits with the entire spectrum of field, textural and chemical data from the SMZ and open new perspectives on the role played by disequilibrium processes during S-type granite genesis. The results argue that the melt leaves the source instantaneously, that individual leucosomes are constructed incrementally; that leucosome volumes do not represent the volume of melt present at any time; and the leucosomes in such granulites constitute part of the residuum after partial melting.

Changes of magma geochemistry at Mt. Etna during the last 45ka due to sampling of a variegated mantle

EUGENIO NICOTRA[1,2]*, MARCO VICCARO[2], RENATO CRISTOFOLINI[2] AND SANDRO CONTICELLI[3]

[1]Università della Calabria, Via P. Bucci 15/B, 87036, Arcavacata di Rende (CS), Italy, (eugenio.nicotra@unict.it)
[2]Università di Catania, Corso Italia 57, 95129 Catania, Italy
[3]Università di Firenze, Via G. La Pira 4, 50121, Firenze, Italy

Mt. Etna magmas show long- and short-term variations especially for K contents, some LILEs and HFSEs as well as Sr-Nd-Pb-Hf isotope ratios, a feature increasingly more evident during the last four decades of activity. Nonetheless, magma source characteristics are still debated. Contributions to this discussion arise from focusing the attention on volcanic products of Etna of the last 45 ka of activity, belonging to the "*Ellittico*" and "*Recent Mongibello*" volcanic successions. Incompatible trace elements for mantle-equilibrated compositions of the most basic products reveal that the Etnean magmas under consideration can be produced by rather low partial melting degrees of a peridotite variably enriched by metasomatic phases such as amphibole and/or phlogopite. Sr-Nd-Pb-Hf isotopes suggest that recycled and altered oceanic lithosphere is a dominant component in the Etnean mantle source. A dominant FOZO reservoir has been inferred [1], although not sufficient to satisfactory explain the observed isotopic variations. Addition of variable proportions of an EM1-type component (up to 10%) has been then suggested. Hf isotopes provide further evidence that the enriching component at Mt. Etna could be related to the metasomatizing action of high-T fluids (i.e., silicate melts), which may be frozen in the form of pyroxenite veins at mantle conditions. Our calculations confirm that involvement of variable amounts of this enriched component in magma genesis is able to explain the long- and short-term geochemical and isotopic variations observed throughout the last 45 ka.
