The carbonation of ultramafic and mafic rocks has been proposed as a carbon capture and storage (CCS) method. This method is promising because CO_2 would be captured in carbonate minerals that are stable for geological time spans. The challenge, however, is that the reactions which lead to the formation of carbonates are very slow. Learning more about it might offer the possibility of enhancing reaction kinetics.

Forsterite (Mg_2SiO_4) is an abundant mineral in mafic and ultramafic rocks. The purpose of this study was to investigate the differences in reactivity between synthetic and natural forsterite when exposed to pure deionised water and supercritical CO_2 (120 °C, 80 bars and 7 days of reaction). Solids were characterised with scanning electron microscopy (SEM), transmission electron microscopy (TEM), energy dispersive X-ray spectroscopy (EDXS), X-ray powder diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) and solution composition, with atomic absorption spectroscopy (AAS).

After reaction, synthetic forsterite had transformed partly to magnesite ($MgCO_3$), with well defined crystals of up to 25 μm in size and to spherical particles, consisting dominantly of SiO_2.

Unreacted natural forsterite ($Fo_{91.1}$) had highly heterogeneous surface composition and morphology. Reaction produced very fine grained alteration products that were difficult to identify unambiguously. Thus, only a few indications of carbonate mineral formation could be observed. Our results show that natural and synthetic forsterite react very differently. After reaction, etch pits are visible on the natural samples and AAS shows Mg in solution, suggesting that the different behaviour could be caused by inhibited magnesite nucleation and growth. This implies that the complex nature of natural material should be taken into account when predicting mineral carbonation.

Dissolved and particulate iron concentrations and isotopic compositions in the South Atlantic and Southern Ocean

C. ABADIE*[1], F. LACAN[1], A. RADIC[1] AND F. POITRASSON[2]

[1]LEGOS (CNRS/UPS/IRD/CNES), Observatoire Midi Pyrénées, F-31400, Toulouse, France (*correspondance : cyril.abadie@legos.obs-mip.fr)
[2]GET (CNRS/IRD/UPS), Observatoire Midi Pyrénées, F-31400, Toulouse, France

Iron is an essential micronutrient for phytoplankton. It has been shown that in High Nutrient Low Chlorophyll areas (HNLC), Fe is a limiting factor for phytoplankton growth. Therefore, Fe has an influence on the carbon cycle. Its sources to the ocean remain a matter of debate. It has been suggested that aerosol inputs and reductive dissolution within oxygen depleted sediments were the main sources of Fe to the water column, although recent studies highlighted that the non-reductive dissolution within oxic basins is another potential source of Fe.

We obtained new results on Fe concentrations and isotopic compositions in both the particulate and dissolved phases of Fe (PFe and DFe) in seawater, in the oxic South Atlantic and Southern Ocean, off the South African coast towards Antarctica. During the Bonus GoodHope cruise in 2008, seawater samples have been taken from five stations, along a section from 36.50°S 13.12°E to 57.55°S 0.04°E. Dissolved and particulate Fe concentrations range from 0.05 to 0.72 $nmol.L^{-1}$ and from 0.13 to 4.65 $nmol.L^{-1}$, respectively. Particulate Fe and Al concentrations are correlated for three stations in the Northern part of the section suggesting lithogenic inputs of particulate iron originating from the Aghulas Current.

Iron isotopic compositions obtained so far range from -0.04‰ to 0.32‰ in δ^{56}Fe for PFe and from -0.71‰ to 0.27‰ for DFe. With an average isotopic composition of 0.09‰ in the Northern part of the section –close to that of the continental crust, ~0.07‰ - the signature of the particles confirm their lithogenic origin. The lighter isotopic signatures for both DFe and PFe in the Upper Circumpolar Deep Water (UCDW) may be related to the remineralization of organic matter.

Isotopically sligthly heavier DFe than PFe at the northernmost station of the transect (~500 km away from the African margin) suggests a non-reductive release of DFe from the African margin sediments. This could be a major source of Fe in oxic basins, which are much more widespread than oxygen minimum zones in the global ocean.

Rare earth elements in marine sedimentary pore fluids

APRIL N ABBOTT[1], BRIAN HALEY[2], JAMES MCMANUS[3] AND CLARE REIMERS[3]

[1]CEOAS, Oregon State University, USA (aabbott@coas.oregonstate.edu)
[2]CEOAS, Oregon State University, USA (bhaley@coas.oregonstate.edu)
[3]CEOAS, Oregon State University, USA (mcmanus@coas.oregonstate.edu)
[4]CEOAS, Oregon State University, USA (creimers@coas.oregonstate.edu)

The rare earth elements (REE) are powerful geochemical tracers with a number of geochemical applications. Here, we present REE concentrations from sediment pore fluids extracted from cores taken from sites along the Oregon and California margins. Our sites represent continental shelf-to-slope settings, which lie above, within, and below the oxygen minimum zone of the Northeast Pacific. These sites are characterized by varying degrees of net iron reduction; the shelf sites are generally iron-rich (where near surface, pore water Fe concentrations can exceed 100 μM), whereas slope sediments generally have less-pronounced iron reduction zones that penetrate deeper into the sediments. REE concentrations show a shallow (upper 2-10 cm) subsurface peak across all sites (up to two orders of magnitude higher than sea water), and notably these peaks do not consistently coincide with peaks in dissolved iron. Normalized patterns of fourteen REEs show distinct and large variation in the MREE enrichments and HREE to LREE ratios with core depth. These REE pore fluid enrichments highlight the potential importance of continental shelf and slope sediments as a source of REEs to the ocean's water column.

Sr-Nd isotopic study of Papandayan area, West Java: Mapping the extent of Argoland beneath Java, Indonesia

M. ABDURRACHMAN[1]* AND M. YAMAMOTO[1]

[1]Bandung Institute of Technology,Bandung 40132, Indonesia (*correspondence: mirzam@gc.itb.ac.id)
[2]Akita University, Akita-shi 010-8502, Japan

Southern West and East Java have been suggested by several researchers as the "home" of micro continent since Late Cretaceous [1, 2, 3], uncertainty still remains as to whether the two fragments are linked forming part of a larger micro-continent. For this reason, Sr-Nd isotopic ratios of Papandayan and adjacent Cikuray volcanoes (Papandayan area) on the volcanic front in the Triangular Volcanic Complex (TVC) were employed to gain a better of tectonic development in Java. The eruptive product of Papandayan volcano comprises medium-K series with high $^{87}Sr/^{86}Sr$ (0.705243-0.705907) and low $^{143}Nd/^{144}Nd$ (0.512504-0.512650) ratios. The Cikuray volcanic rocks are in contrast to Papandayan, belong to low-K series, with low $^{87}Sr/^{86}Sr$ (0.704172-0.704257) and high $^{143}Nd/^{144}Nd$ (0.512823-0.512858) ratios. Our study shows that the contrasting Sr-Nd isotopic ratios in Papandayan area can be explained by the mixing of clear mantle wedge (I-MORB + AOC ± Indian Sediments) with Australian Granites as the missing "Argoland" which have separated from Western Australia in the Late Jurassic and collided to SE Sundaland in the Late Cretaceous [4]. We argue that the presence of "Argoland" beneath Southern West Java was responsible for Sr-Nd isotopic ratios diversity in Papandayan area as well as in TVC. Therefore, the suture zone should be laid between both volcanoes and Papandayan volcano probably is the only of Quaternary volcanoes which is underlain by "Argoland". If that so, the extension of East Java continental fragment can be continued to the West Java.

Multidisciplinary study on the oceanic plate: implications from the research on petitspot volcanoes

N. ABE[1] AND T. FUJIWARA[2]

[1]IFREE, JAMSTEC, Japan (abenatsu@jamstec.go.jp)
[2]IFREE, JAMSTEC, Japan (toshi@jamstec.go.jp)

Petitspot is a cluster of small volcanic knolls on the oceanic lithosphere [1]. It is a kind of intraplate volcanism, similar to monogenetic volcanoes of alkaline basalts in continental plate, although there is no mantle upwelling beneath the eruption fields. Therefore, it is not related any OIB activities. The source region of the petitspot magma is expected not at very deep, but just around the boundary between the lithosphere and asthenosphere [2]. It is thought to be erupted through the small fracture on the oceanic lithosphere [1]. Petitspot volcanoes often include ultramafic xenoliths and xenocrysts that provide us many information about the chemical and physical properties of the lower oceanic lithosphere between 40 to 70 km deep without any affection of OIB [3-5]. Therefore, studiy on the petitspot volcanism and its ejecta is one of the most suitable research on the actual state of the oceanic plate [6, 7]. The multidisciplinary research including rock and sediment samplings, and surface and sub-seafloor geophysical surveys on the petitspot and the plain old oceanic plate around have been conducted since 2005 to reveal mechanism of the petitspot volcanism and background physics of the oceanic lithosphere and asthenosphere beneath the northwestern Pacific [6, 8-10]. However, the petitspot volcanism and its global activities are still unclear due to few rock and data samplings from the petitspot fields and the scarcity of the global detail bathymetry data.

Here we present the petrology of the ultramafic xenoliths, which shows less deformed, and the fertality and variation of the melt extraction, and the feature of the petistspot volcanism with geophysical and morphological features in the eruption fields found up to now. Then, we would like to propose the next step of the oceanic lithosphere.

Archaean TTG magmas are regarded to have formed by melting of amphibolite or eclogite. They are succeeded by more potassic melts in the late Archaean, suggesting that the latter melts might have formed by successive melting of the earlier TTG gneisses. Here we use Si isotopes to test this model because the light Si isotopes are expected to be enriched in the residual Mg-rich phases [1,2]. The comparison of leucosomes and melanosomes from two amphibolitic migmatitic TTG gneisses from the Archaean Iisalmi block (central Finland) confirms an isotope fractionation linked to partial melting in the range of $\Delta^{30}Si$=+0.2‰ with the restite being isotopically lighter. Si isotopes determined on four different generations of granitoid plutons from the Barberton Mountain Land (South Africa) demonstrate a gradual $\delta^{30}Si$ change from -0.17‰ at 3.55 Ga up to +0.02‰ at 3.1 Ga, the earliest TTGs being close to products of mantle differentiation and I-A granite types [1,3], while the younger K-rich granites are isotopically heavier, in agreement with their derivation by melting of older TTG gneisses.

Assessment of seasonal variations in the mineralogical and geochemical features of sulfide mine tailings

P. ACERO[1], R. PÉREZ-LÓPEZ[2], C. AYORA[3], D. QUISPE[2] AND J.M. NIETO[2]

[1]Earth Sciences Department, Univ. Zaragoza, c/Pedro Cerbuna 12, 50009 Zaragoza, Spain. (*correspondence: patriace@unizar.es)
[2]Geology Department, Univ. Huelva, Campus 'El Carmen' s/n, 21071 Huelva (Spain)
[3]Institute of Environmental Assessment and Water Research, IDÆA-CSIC, c/Jordi Girona 18, 08034 Barcelona (Spain)

Two sulfide mine tailings impoundments with very different proportions of pyrite from the Iberian Pyrite Belt (SW Spain) have been exposed to weathering during more than forty years under semi-arid climate conditions. Therefore, the examination of their evolution may contribute to shed light on the main processes controlling the element mobility in sulfide mine tailings with a well-developed and variable vadose zone.

For this purpose, a combination of different methodologies and techniques was applied, including the characterisation of primary and secondary mineralogy by XRD and μ-XRD, SEM-EDS and μ-XRF, study of mineral geochemistry and elemental mobility by sequential extractions and determination of pore gas profiles. The evolution of pore water hydrochemistry in vertical profiles was also examined and interpreted by geochemical and reactive transport modelling. These methodologies were applied both at field scale and in complementary laboratory column experiments.

The results of this study suggest that the main factors controlling the evolution of abandoned mine tailings under semi-arid conditions are their initial mineralogy and the degree of water saturation, which is mainly determined by the grain size and by the balance between evaporation and water infiltration. These factors determine not only the input of oxygen (and, therefore, the dissolution rate of sulfide minerals and the redox conditions) but also the type of secondary minerals precipitated, which is key for the mobilization of potentially pollutant elements. For instance, the existence of pyrite amounts larger than 80% in the vadose zone of one of the studied impoundments seems to promote not only a greater sulfide dissolution but also the existence of extremely acidic pH (below 1) that hinder the formation of secondary precipitates and give the apparence of unreacted tailing. However, the extreme low pH allows the solute load to remain in solution, increasing its pollutant potential.

Development of the U-series dating technique for the EDML ice core

S.M. ACIEGO

Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI 48109-1005, USA (*correspondence: aciego@umich.edu)

Determining the absolute ages of ice within ice cores, ice sheets and glaciers remains non-trivial especially for the oldest ice (>100ka). While both insolation and Be-10 records have proven invaluable in creating ice-core timescales, neither can be used to evaluate the length of hiatuses, the extent of ice folding in ice cores, or the age of ice at the bottom sections of ice cores. U-series recoil from mineral aerosols (dust) into the ice matrix is one possible technique for determining the absolute age of ice, independent of any other parameters [1].

The well-dated upper section of the EPICA Dronning Maud Land (EDML) ice core (down to 150 ka at 2415.7 m) provides excellent constraints to verify uranium ages in a high accumulation site in the Atlantic sector of East Antarctica. In the lower 300 m the ice core climate records are disturbed due to tilting and folding of the ice. And, due to the uncertainties in flow models, it is impossible to determine if the discontinuity is resolvable (i.e., some climate record is accessible), or if the ice is too incoherent. Here, we show initial results verifying the U-series technique on samples of known age, which will allow us to apply the technique to disturbed ice in the future.

U-series recoil ages of ice samples are calculated using an age equation that includes an ejection factor, the fraction of daughter products implanted into the ice relative to the total number produced, based on the surface to volume ratio of the dust grains. This parameter is measured by specific surface area determination (BET) using a magnetically levitated balance designed at ETH [1] and manufactured by Rubotherm GmBH for the University of Michigan. Standard measurements of BAM PM103 indicate that we have achieved S_{BET} precision of better than 0.5%, equivalent precision to that of the original prototype.

Results from the well-dated section of the ice core, including surface area of dust, radiogenic and radioactive isotopic compositions of the soluble seasalt component and ^{238}U parent concentrations in the soluble component and mineral dust are applied to the U-series age equation.

Highly siderophile element geochemistry of upper mantle xenoliths from NE Bavaria

L. ACKERMAN[12], YU. KOCHERGINA[23], P. ŠPAČEK[4] AND T. MAGNA[2]

[1]Inst. Geology, Academy of Sciences CR, Rozvojova 269, CZ-16500 Prague, Czech Republic; (ackerman@gli.cas.cz)
[2]Czech Geological Survey, Klarov 3, CZ-11821 Prague, Czech Republic
[3]Faculty of Science, Charles University, Albertov 6, CZ-12843 Prague, Czech Republic
[4]Inst. Geophysics, Academy of Sciences CR, Bocni II, CZ-14134 Prague, Czech Republic

Concentrations of highly siderophile elements (HSE) in upper mantle xenoliths reflect variable degrees of partial melting and melt/fluid metasomatism by the agents of variable compositions (e.g., basaltic, alkaline, carbonatitic). During melt percolation, HSE can be strongly fractionated between each other depending on sulphur saturation of the infiltrating melt and melt/rock ratios; this can also affect $^{187}Os/^{188}Os$.

Osmium isotope compositions coupled with HSE abundances are presented for a suite of spinel lherzolite/harzburgite xenoliths from NE Bavaria, Bohemian Massif, that underwent variable degrees of partial melting (~4–18%) and subsequent pervasive metasomatism by alkaline–carbonatitic melts with a significant contribution of recycled crustal material.

The samples have highly variable Re–Os concentrations (9–123 ppt and 0.1–3.5 ppb, respectively) and display subchondritic to superchondritic $^{187}Os/^{188}Os$ (0.11348–0.13304). Primitive upper mantle-normalized patterns exhibit convex-upward shapes with significant I-PGE fractionation. Palladium contents are very low (0.09–2.07 ppb) whereas Pt contents vary greatly (0.16–6.4 ppb). Depletion ages (T_{RD}) for the whole suite scatter between 0.3 and 2.0 Ga suggesting variable perturbation of Re–Os system during metasomatism. However, the 2.0 Ga age obtained for the sample with the most depleted character appears to represent the age of the lithospheric mantle from the studied area.

While low Pd and Re contents can be explained by varying degrees of partial melting, the low I-PGE contents imply that they were removed during melt percolation of sulphur-undersaturated melt causing sulphide breakdown and I-PGE removal. On the other hand, subchondritic $^{187}Os/^{188}Os$ ratios in majority of samples suggest that metasomatism has only a collateral effect on Os isotopic compositions which, therefore, may provide reliable depletion ages even in pervasively metasomatized mantle.

Crystal/melt partitioning of volatiles during near-solidus melting of peridotite

JOHN ADAM[1], MICHAEL TURNER[1], ERIC HAURI[2] AND SIMON TURNER[1]

[1]GEMOC, Department of Earth & Planetary Sciences, Macquarie University, NSW, 2109, Australia
[2]Carnegie Institution of Washington, 5424 Broad Branch Road, Washington, D.C. 20005, USA

Concentrations of H_2O, F, Cl C and S in experimentally produced peridotite phases (including clinopyroxene, orthopyroxene, olivine, garnet, amphibole, mica) and co-existing melts were analysed by secondary ion mass-spectrometry (SIMS). The experiments were conducted at 1025-1190 °C and 1.0-3.0 GPa on hydrous nepheline basanite mixes. Mineral/melt partition coefficients calculated from the data indicate that there is a negative correlation between partition coefficients for H_2O and absolute H_2O concentrations in melts. Because of this, the relative compatibilities of H_2O and other (non-volatile) incompatible elements (e.g. La and Ce) also depend on H_2O concnetrations in melts. This may explain some of the variability in H_2O/LREE found in undegassed MORB and OIB glasses. Cl appears to be less compatible than H_2O during peridotite melting, whereas F is more compatible. Neither C nor S is significantly retained in silicate minerals during peridotite melting but may be held in residual graphite and sulphides. Thus they may be relatively compatible during mantle fractionation. The experimental data have implications for the history of volatile recycling within the mantle and thus also for the development of MORB and OIB magmatism.

Characterizing the mechanisms of soil organic matter stabilization as organo mineral complexes

NADIA K. ADAM

[1]Department of Geology & Geophysics, University of Wyoming, Laramie, WY 82071, USA; Biomineral Systems LLC, South Bend, IN, 46615, USA (*Nadia.K.Adam@gmail.com)

Terrestrial soils constitute the principal pool of terrestrial carbon with 2300 Peta g organic carbon in the top 3 m of which 50-75% exists as < 2 µm sized organo-mineral complexes [1]. It is therefore critical to uncover mechanisms of SOC stabilization in organo-mineral complexes. Because C K- NEXAFS (Near edge x-ray absorption fine structure) spectroscopy has shown that SOC is composed of individual biopolymers of plant and microbial orgin such as lignin, polysaccharides and lipids [2], our goal was to characterize the mechanism of sorption of organic biomolecules on a dominant, and well-characterized Fe-oxide mineral, hematite.

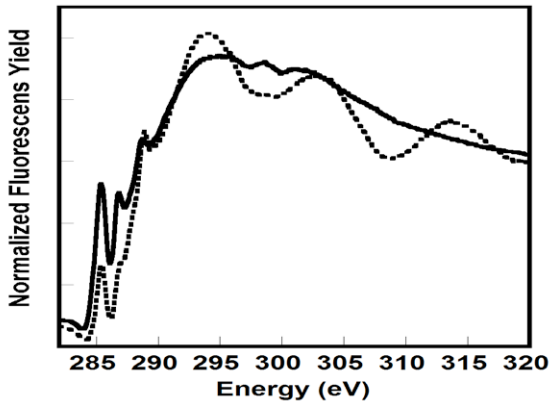

Figure 1: C K-XANES spectra of dextrose (black) and dextrose sorbed on hematite (grey) obtained in electron yield mode at Synchrotron Light Source, Wisconsin.

The C K-XANES spectrum of dextrose sorbed on hematite show marked differences compared to the spectrum for free dextrose. These changes could be attributed to C-O-Fe bonding through hydroxyl groups on heamtite as shown below. This bonding upon soprtion is hypothesized to shield organo-mineral complexes from enzymatic mineralization.

Combining life cycle (LCA) and risk (RA) assessments of TiO_2 nanomaterials: Use of a Bayesian network

VERONIQUE ADAM[1], GAETANA QUARANTA[2] AND STEPHANIE LOYAUX-LAWNICZAK[3]

[1]LHyGeS – 1 rue Blessig – 67084 Strasbourg Cedex (veronique.adam@etu.unistra.fr)
[2]LHyGeS – 1 rue Blessig – 67084 Strasbourg Cedex (quaranta@unistra.fr)
[3]LHyGeS – 1 rue Blessig – 67084 Strasbourg Cedex (s.lawniczak@unistra.fr)

Nanomaterials are more and more present in consumer products, and are released into environmental compartments at every stage of their life cycle. Consequently, risks associated with nanoparticles need to be characterized, even if they still include a lot of uncertainties. We will focus in this communication on the production of TiO_2 nanoparticles and their insertion in cements. An assessment tool combining lifecycle and risk assessments would allow stakeholders to make decisions based on absolute results that could be compared from one life cycle to another (e.g. comparison of the sulfate process with the chloride process for the manufacturing of TiO_2 nanoparticles). Furthermore, a wider range of impact/risk categories (e.g. terrestrial ecotoxicity, aquatic ecotoxicity, or impact on human health) would be assessed, giving a comprehensive view of the system under study.

Bayesian networks are used in the risk assessment of contaminants, especially regarding ecotoxicity [1,2]. Major advantages of these networks are that they can provide satisfying results even under high uncertainty, and that they can be readily updated as new information becomes available. Given the little knowledge acquired at present regarding environmental impacts of nanomaterials, both these points make Bayesian networks very useful for their risk assessment.

The objective of this commuication is to present a Bayesian network as a tool for the combined risk and lifecycle assessment of TiO_2 nanomaterials. A new methodology for a combined risk and lifecycle assessment could be presented, including a primary modeling structure and a new score combining the results of life cycle assessment and risk assessment.

^{238}U-^{230}Th and ^{235}U-^{231}Pa disequilibria from the island of Fogo, Cape Verde

KATHERINE ADENA[1]*, TIM ELLIOTT[1] AND RICARDO RAMALHO[12]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol (katherine.adena@bristol.ac.uk, tim.elliott@bristol.ac.uk)

[2]Lamont-Doherty Earth Observatory, Columbia University

The Cape Verdes Archipelago sits on one of the largest bathymetric swells in the ocean, rising 2.2km above the abyssal plain in the tropical North Atlantic. The rise is located near the point of rotation of African plate, such that the islands have experienced very little lateral movement in relation to the underlying plume over their ~20Ma lifespan. This makes Cape Verde an excellent location to examine plume dynamics under an ocean island, without the complication of lateral plate movement. There are ten islands arranged in a horseshoe, open to the west. The northern and southern islands display distint istopic signatures, depite their close poximity to one another. A suite of samples historical samples has been collected from the island of Fogo in the southern island chain. Samples have been collected from the 1995, 1951, 1852, 1847, 1816, 1785, 1769 and 1680-1725 eruptions, all located within the caldera. These samples have been analysed for Pb isotopes show little significant variation ^{206}Pb/^{204}Pb = 18.93-19.24, ^{207}Pb/^{204}Pb = 15.55-15.63 and ^{208}Pb/^{204}Pb = 38.81-39.04. On the contrary the samples show a notable range in (^{230}Th/^{238}U) disequilibrium (1.091-1.226). The variation in (^{230}Th/^{238}U) is not clearly related to crustal contamination and we are exploring the influence of melting rate.

Coupled ^{238}U-^{230}Th and ^{235}U-^{231}Pa disequilibria measurements from young mafic lavas are strongly dependent on the melting rate of their mantle source. Pyroxenite and egologite lithologies have much higher melt productivities than peridotite and this is reflected in ^{230}Th and ^{231}Pa excesses. We will attempt to explore the range in (^{230}Th/^{238}U) by coupling these measurements with analyses of (^{231}Pa/^{235}U) to get a more detailed picture of the melting process and to see if this variability can potentially be related to changes in the modal mineralogy of the source. Initial data shows large excesses for (^{231}Pa/^{235}U). We will present a fuller data set and its interpretations for the meltig processes occuring beneath the Cape Verde Islands.

N isotope geochemistry during low grade metamorphism of coal and coal-related rocks: Case study of the anthracite field of Pennsylvania

MAGALI ADER[1]*, JEAN-PAUL BOUDOU[2] AND ERIC DANIELS[3]

[1]Institut de Physique du Globe de Paris (*correspondence: ader@ipgp.fr)

[2]LAC, CNRS, UPR3321, University of Paris South, 91405 Orsay cedex, France (jpb.cnrs@free.fr)

[3]ChevronTexaco Energy Research & Technology Company, Richmond, California, USA (ericdaniels@chevron.com)

The evolution of the nitrogen speciation and isotopic composition in sedimentary rocks undergoing burial diagenesis and very low grade metamorphism has been seldom investigated so far. Yet it a key issue in the reconstruction of the past nitrogen biogeochemical cycle, in the estimation of nitrogen input fluxes in subduction zones and in the understanding of molecular nitrogen genesis in the crust. Here we intend to partly fill this gap by studying the nitrogen partitioning and isotope fractionation between organic matter and minerals in coals and carbonaceous shales of the anthracite field of Pennsylvania. In this work, δ^{15}N results have been obtained on fixed-amonium in the mineral phase of samples for which previous results on the kerogen δ^{15}N were available [1,2]. Taken together these results show that in organic and ammonium-rich samples, ammonium δ^{15}N values are more positive than the source organic nitrogen. Since, during the maturation process, nitrogen is liberated from the organic matter without isotopic fractionation [1,2], it comes that part of the generated nitrogen must have been lost with a lower δ^{15}N than its source organic matter. This nitrogen may have been lost in the form of molecular nitrogen which can then migrate and accumulate in reservoir structures. In contrast, in organic and ammonium-poor samples, ammonium δ^{15}N values are similar to those of the organic matter, suggesting that the generated nitrogen has been quantitatively fixed as ammonium in the mineral phase. In these sampkes, the effisciency of nitrogen retention as fixed-ammonium in the rock seems to be controlled by the ratio of generated nitrogen over the amount of host minerals for ammoniun. The possibility that nitrogen was lost at this stage therefore needs to be carefully considered in studies aiming at reconstructing the past nitrogen biogeochemical cycle from bulk sedimentary rocks δ^{15}N.

Fluid evolution recorded by alteration minerals along the P2 reverse fault and associated with the McArthur River U-deposit

E. E. ADLAKHA*[1], K. HATTORI[1] AND E.G. POTTER[2]

[1]Department of Earth Science, University of Ottawa, Ottawa, Ontario, Canada, K1N 6N5 (*correspondance: eadla028@uottawa.ca); (keiko.hattori@uottawa.ca)

[2]Geological Survey of Canada, Ottawa, Ontario, Canada, K1A 0E8 (eric.potter@nrcan-rncan.gc.ca)

The basement rocks along the P2 fault are extensively altered, particularly where they host the McArthur River Zone 2 uranium ore body. Two generations of tourmaline occur along the P2: i) early, euhedral-subhedral, coarse-grain (>0.5 mm), 1-2 cm wide veins and isolated grains of dravite (Mg-tourmaline), and ii) later fine-grain (<0.2 mm), radial magnesiofoitite (alkali-deficient dravite) forms veinlets (< 2 mm), overgrowths on earlier dravite, and grains disseminated within fine-grain illite. Fe-clinochlore, coarse-grain illite, rutile and hematite are ubiquitous along the P2 and occur as pervasive replacement minerals or veins, and post-date dravite crystallization.

To ensure minerals were free of inclusions, individual grains were first inspected with BSE-SEM at highest magnification and elemental peaks were then carefully monitored during trace element analysis (LA-ICPMS). Dravite $[(\square_{0.4}Na_{0.6})(\square_{0.2}Mg_{1.9}Fe_{0.5}Ca_{0.2}Ti_{0.2})(Al_{5.9}Fe_{0.1})(Si_{5.7}Al_{0.3}O_{18})(BO_3)_3(OH_{3.8}F_{0.2})]$ contains 1.24 (± 0.09, 1σ) wt% TiO_2, 89 – 280 ppm Zn, 51 - 630 ppm Cr, 190 - 1500 ppm V, and atomic F/Cl ratios range 98 – 11000. Magnesiofoitite $[(\square_{0.7}K_{0.1}Na_{0.2})(\square_{0.4}Fe_{0.1}Mg_{2.0}Al_{0.5})Al_6(Al_{0.1}Si_{5.9}O_{18})(BO_3)_3(F_{0.02}OH_{3.98})]$ contains 65 – 260 ppm V, 2.9 - 110 ppm Cr, 0.2 – 3.7 ppm U, and 0.2 – 34 ppm Th, and ranges 3.2 - 80 atomic F/Cl. Dravite and magnesiofoitite contain low Li (< 12 ppm) and high Ni (1 – 28, 13 – 250 ppm, respectively); however, they also show contrasting trace element behaviours: dravite is enriched in LREE relative to HREE $([Ce]_N/[Ce]^*_N) > 1$, and has a positive Eu anomaly, whereas, magnesiofoitite is enriched in HREE relative to LREE $([Ce]_N/[Ce]^*_N) < 1$, and has a negative Eu anomaly. Chlorite $[(Fe_{1.9}Mg_{2.6}Al_{1.4})(Si_{2.7}Al_{1.3}O_{10})(OH)_8]$ contains significant Li (40 - 669 ppm), and Mn (803 – 4083 ppm); illite $[(K_{0.9})(Al_{1.8}Mg_{0.1}Fe_{0.1})(Si_{3.2}Al_{0.8}O_{10})(OH)_2]$ contains significant B (17 – 250 ppm), Li (<4.9 – 144 ppm), Ti (36 – 14500 ppm), Rb (343 - 692 ppm), U (<0.01 – 0.6 ppm), Sn (1.2 – 148 ppm), and Ba (78 – 1670 ppm); and both minerals show atomic F/Cl ratios > 10. High F/Cl, U, Th and B, and a negative Eu anomaly in alteration phases suggests a contribution of pegmatite to the fluid.

The non-trivial limitation of methanogenesis in the deep sediment of Lake Kinneret (Israel)

M. ADLER[1]*, W. ECKERT[2], Z. RONEN[3] AND O. SIVAN[1]

[1]Dep. Of geologiacl and Environmental Sciences, Ben-Gurion University of the Negev, Israel (*correspondence: sela@post.bgu.c.il, oritsi@bgu.ac.il)

[2]Israel Oceanogrphic and Limnological Research, Yigal Allon Kinneret Limnological Laboratory (werner@ocean.org.co.il)

[3]Zuckerberg institute for water research, the J. Blaustein institutes for desert research, Ben-Gurion University of the Negev, Sde-Boqer campus (zeevrone@bgu.ac.il)

The goal of this study was to investigate the non-trivial ending of methanogenesis in the deep sediments of Lake Kinneret, where substrate is still available. *in situ* profiles showed that in the deep sediment acetate and dissolved organic carbon concentrations increase. Incubation experiments showed acetate accumulation in the non-treated samples with time in the deep sediment, indicating that this substrate is not used, and that acetogenesis rather methanogenesis dominate the deeper sediments. Addition of substrates (acetate; dimethyl sulfide (DMS); H_2/CO_2 4:1 atmosphere) did not significantly enhance methanogenesis in the deep sediments within the first 3 weeks. After 100 days of incubation with DMS methane concentration increased in all depths and in the deep sediment there was a change in the colour from brown to black as a result of iron sulfide mineral precipitation. The results indicate that methanogenesis is limited in the deep sediment of Lake Kinneret and that acetate or other electron donors are not limiting factors. The results give indication for the mechanism of methanogenesis inhibition.

Geochemistry of ancient estuarine deposits on the example of pokurskaya suit sediments (West Siberia)

AFONIN I.V., TATYANIN G.M. AND TISHIN P.A.

Tomsk State University, heaven05@list.ru Tomsk, Russia

An object of study is the fragment of the pokurskaya suit (upper cenomanian) situated in the axial part of the West Siberian sediment pool (J_1-Pg) in the zone of changing sea facies to land ones. Geochemical regime of accumulating the sediments (precipitation) of the local estuarine basin was studied. Within the cut studied, there are four rock complexes fixing two transgressive cycles. First of them consolidates the beds (пласты) PK2 and PK1-2, and second one consolidates beds PK1 and K (turonian). At the same time PK1, PK2, PK1-2 fix (set) estuarine facies, whereas K sets shelf ones. The pattern of distribution of $Na_2O+K_2O)/Al_2O_3$, Mn/U, Sr/Ba, Ce/Ce*, Ti/Zr, Fe/Mn let us mark out eight geochemical cycles within the estuarine cut. Maximum values are $(Na_2O+K_2O)/Al_2O_3$, Sr/Ba, Mn/U that indicates high activity of P_2O_5 and sets local peaks of the upwelling.

Lateral geochemical variability of sediments demonstrates their facial conditions. Thus, sediments of the main channel are characterized by high ratios of Mn/U (over 200), Ce/Ce* (1,2-1,45), Ti/Zr (0,04-0,86), and low content of Sr/Ba (0,23-0,13).

Sediments of the rising tide-low tide zone of the mouth differs from the channel zone by lower contents of Ce/Ce* (1,05-1,10), Mn/U (90-120), and higher content of Sr/Ba (up to 0,30).

The rocks formed in “bor” lagoons are diagnosed using parameter values, which show increasing of Sr/Ba (0,26-0,43), relative stability Ce/Ce* (0,99-1,02), and abrupt change of Fe/Mn (38-84).

Variety of coefficients Sr/Ba (0,28-0,32), Fe/Mn (44,9-35,1), and dispersion Ti/Zr (0,01-0,04) determine facial conditions of the coastal-sea zone.

This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.0686, 14.B37.21.1257).

Multi-observable thermochemical tomography: A new framework in integrated studies of the lithosphere

JUAN C. AFONSO[1], JAVIER FULLEA[2], JAMES CONNOLLY[3], NICHOLAS RAWLINSON[4], YINGJIE YANG[1] AND ALAN G. JONES[5]

[1]CCFS-GEMOC, Macquarie University, Sydney, Australia
[2]IGEO, Universidad Complutense de Madrid, 28040, Spain
[3]Inst. Geochem. Petrol., ETH Zurich, Switzerland
[4]RSES, Australian National University, Canberra, Australia
[5]Dublin Institute for Advanced Studies (DIAS), Ireland

Current knowledge of the present-day thermochemical structure of the lithosphere and upper mantle essentially derives from four independent sources: i) gravity field and thermal modelling, ii) modelling of --different-- seismic data, iii) magnetotelluric studies, and iv) thermobarometric and geochemical data from exhumed mantle samples. Unfortunately, significant discrepancies and/or inconsistencies in predictions between these sources are still the rule rather than the exception, which leads to a lack of confidence in our knowledge of important features of the lithosphere and upper mantle. Moreover, thorough analyses of uncertainties and sensitivities within and between these methods are often neglected, which further exacerbates the problem.

In this talk, I will present a new thermodynamically-constrained multi-observable probabilistic inversion method, particularly designed for high-resolution (regional) studies of the present-day thermochemical structure of the lithosphere and upper mantle. The key aspects of the method are: (a) it exploits the increasing amount and quality of geophysical datasets; (b) it combines multiple geophysical observables with different sensitivities to deep/shallow, thermal/compositional anomalies into a single thermodynamic-geophysical framework; (c) it uses a general probabilistic (Bayesian) formulation to appraise the data; (d) no initial model is needed; (e) a priori compositional information relies on robust statistical analyses of a large database of natural mantle samples; and (f) it provides a natural platform to estimate realistic uncertainties. Assembling this “large” problem required a collaborative effort between thermodynamicists, mineral physicists, geophysicists and geochemists, and marks the first step towards real multi-observable thermochemical tomography studies of the Earth (as opposed to traditional seismic tomography). I will present results for both synthetic and real case studies, which serve to highlight the advantages and limitations of this approach.

Paleoarchean felsic magmatism: A melt inclusion study of 3.45 Ga volcanic rocks from the Barberton Greenstone Belt

A. AGANGI[1], A. HOFMANN[2] AND V. KAMENETSKY[3]

[1]Department of Geology, University of Johannesburg, Auckland Park 2006, South Africa. (aagangi@uj.ac.za)
[2]Department of Geology, University of Johannesburg, Auckland Park 2006, South Africa. (ahofmann@uj.ac.za)
[3]Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Tasmania 7001, Australia. (dima.kamenetsky@utas.edu.au)

Archean felsic magmatism spatially and temporally associated with the Barberton Greenstone Belt (BGB) of Southern Africa can be broadly subdivided in an early (≥3.2 Ga), Na-rich series that formed the tonalite-trondhjemite-granodiorite (TTG) series, and a generally later (~3.1 Ga), K-rich series akin to modern granites [1].

Felsic volcanic rocks in the BGB are less abundant than their intrusive counterparts, and are mostly strongly deformed. The 3.45 Ga old Buck Ridge Volcanic Complex (BRVC; [2]) contains the least deformed felsic volcanic rocks in the BGB. However, widespread alteration (silicification, K-metasomatism) of these rocks involved strong mobilisation of major and some trace elements [3].

Quartz-hosted melt inclusions have been used to obtain infomation on the unaltered melt composition. Whole-rock compositions of the least altered samples bear strong resemblance with coeval TTG intrusions, and can be modeled as a mixture of modal phenocrysts (Na-plagioclase, quartz, Fe-Ti oxide, apatite) and melt as indicated by melt inclusion analyses, thus suggesting a cogenetic relationship between the BRVC and TTG intrusions. This is also confirmed by whole-rock concentrations of fluid-immobile trace elements. Further, melt inclusions have moderate Cl contents (≤0.7 wt.%), low F and low S (≤0.12 and <0.02 wt.%, respectively). The moderate Cl and low F/Cl suggest a sea water contribution to the melting protolith [4]. These characteristics are interpreted as due to melting of source rocks that have undergone sea floor metamorphism, although in an Archean context this does not have immediate tectonic implications.

Magmatic and hydrothermal history of felsic rocks within oceanic core complex (MAR, 13º31'-13º35' N)

O.A. AGEEVA*, A.N. PERTSEV AND O.M. ZHILICHEVA

IGEM RAS, Staromonetny per., 35, Moscow, 119017 Russia (*correspondence: ageeva@igem.ru)

Felsic plutonics and dykes – oceanic plagiogranites (OPG) – spatially associate with inactive hydrothermal fields and are regarded as the products of gabbro/dolerite hydrous melting within the oceanic core complex at 13º31'-13º35' N, Mid-Atlantic Ridge. We used cathodoluminescence (CL) and SIMS analytics to reveal mineralogical and geochemical features, and distinguish main stages of the OPG formation.

The OPG lithology includes: metadolerite - amphibolite veined by hornblende plagiogranite; coarse-grained gabbro with biotite-bearing plagiogranite veins; massive hornblende and amphibole-free OPG. The CL image (Fig. 1) demonstrates relationships between mineral assemblages, corresponding to three successive stages: mafic igneous (Pl_1, Cpx_1), felsitic igneous (Qtz, Bt, Pl_2, Cpx_2, Zrn) and hydrothermal (Qtz, Pl_3, Chl ± Cpx_3).

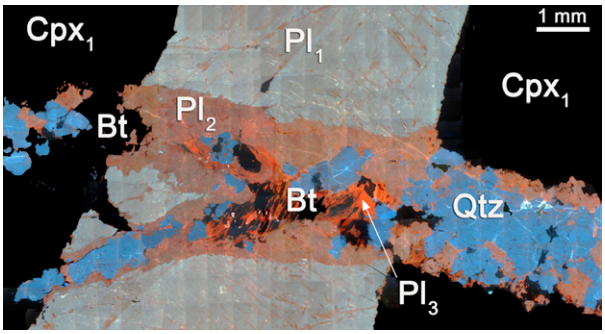

Figure 1: The OPG- vein in gabbro (CL image).

The trace-element data allow distinguishing: (1) mafic (gabbroic) fractionation; (2) felsic (OPG) fractionation; and (3) hydrothermal processing. Pl_1 (An65-60) and Cpx_1 show core-to-rim REE enrichment being appreciably depleted as compared to Pl_2 and Cpx_2 respectively. Felsic stage associates with subsequent REE enrichment of Pl_2 (An47-27) and Cpx_2. The hydrothermal stage exhibits Pl_3 (An17-5) and Cpx_3 that are significantly depleted in REE.

Modelling the impact of C4 Biofuel Crops (*Miscanthus* spp) on soil carbon storage in different climates

F. A. AGOSTINI[1]*, N. RONCUCCI[2] AND G. M. RICHTER[1]

[1]Rothamsted Research Harpenden, Herts AL5 2JQ UK (*correspondence: francesco.agostini@rothamsted.ac.uk)
[2]Scuola St. Anna Universita di Pisa (N.Roncucci@sssup.it)

Background and Methods

The simulation of soil organic carbon (SOC) dynamics under biofuel crops, in addition to their fossil fuel offset, is critical for the evaluation of carbon (C) sequestration [1]. We tailored the RothC model [2] to simulate C3- and C4-SOC stock changes under Miscanthus. The expanded model (RothC_M) is designed to be coupled to a crop model, using residue inputs to the soil from the respective plant parts. The model used data from a 14-year Miscanthus trial at Rothamsted (UK) to calibrate turnover rates of C in litter, rhizomes and roots and the decomposability of their residues. Parameters were evaluated on a 10-year trial at Pisa (Italy).

Results and Discussion

Combining residues when applying inverse modelling (A) underestimates inputs (Tab. 1), while the estimate based on yield (B) matches RothC_M for M x giganteus, but not for M. sinensis, possibly due to overestimating belowground inputs.

Method	A		B	C
Genotypes	Low	High		
Gig-1 (Italy)	3.50	6.12	8.20	8.01
Gig-1 (UK)	3.55	6.40	6.09	6.38
Sin-11	1.60	3.13	5.97	3.24

Table 1 Estimated C inputs (t ha^{-1} yr^{-1}) to SOC by inverse modelling using RothC 26.3 [2] with default values of residue decomposability (A), based on yield [3] (B), and RothC_M (C)

Calibrated RothC_M simulates accurately SOC changes in the UK. However, in Italy the calibrated model needed further adjustment of rhizome, root and root exudate turnover to simulate observed SOC. Observations and modelling of C3 and C4 SOC indicate a C sequestration of approximately 1.8 and 3 tC ha^{-1} yr^{-1} in the UK and Italy, respectively.

Further simulation will test the hypothesis of a delay in rhizome turnover using new observations, and discuss the sensitivity of the model to parameter changes.

Synergistic Arsenic and Pb incorporation into synthetic jarosite

J. AGUILAR-CARRILLO*, M. VILLALOBOS AND F.M. ROMERO

Geochemistry Department, Geology Institute, UNAM, 04510 México D.F., Mexico (*correspondence: jaguilarc@geologia.unam.mx)

Jarosite can incorporate many ionic substitutions into its general structure $KFe_3(SO_4)_2(OH)_6$ [1], making it especially suitable for trapping unwanted, potentially toxic species in the environment. This mineral has been shown to incorporate arsenic in acidic environments (e.g. acid mine drainage), as well as in metallurgical processes where its precipitation is used for the long-term disposal of arsenical waste [2,3]. Anionic substitutions in jarosite have been reported to affect in turn its cationic substitutions [4]. However, the effect on its cationic retention capacity is not yet well understood. The goal of this work was to investigate the influence of As(V) incorporation into the jarosite mineral structure on its Pb(II) retention capacity.

K-jarosite and arsenojarosites $[KFe_3(SO_4)_{2-z},(AsO_4)_z)(OH)_6]$ were synthesized, for which the arsenate substitution ranged from 16 to 80 mol% (of As+S), and Pb(II) retention experiments were performed equilibrating these at pH 2.

The Pb(II) retention capacity was increasingly enhanced by the presence of As(V) in the jarosite structure, reaching values of up to almost one order of magnitude higher Pb(II) retention for the highest As-jarosite investigated as compared to the As-free jarosite. This suggests a generalized synergistic effect of cationic heavy metal retention with arsenate incorporation.

The specific mechanisms of Pb(II) retention in this synergistic process will be presented for the different systems investigated, as well as their influence on the jarosite structure. Also, the effect of different modes of incorporation of both species during the jarosite synthesis will be shown.

The results of this work have important environmental implications: through the synergistic process encountered, remediation enhancement of cationic pollutants is possible in a concomitant fashion with arsenate attenuation in acidic mining and metallurgical environments.

Isotopic signatures in a tropical transitional estuarine/marine ecosystem influenced by the largest agricultural and aquiculture activities in Mexico

AGUÍÑIGA-GARCÍA S., G. RODRÍGUEZ-FIGUEROA, A. SÁNCHEZ-GONZÁLEZ AND F.J. ROMO-RÍOS

Centro Interdisciplinario de Ciencias Marinas, Instituto Politécnico Nacional, Avenida de IPN s/n, Col. Playa Palo de Santa Rita, Apto Postal 592, La Paz, Baja California Sur 23096, Mexico

Assess the anthropogenic pressures on coastal ecosystems are of primary concern. This project is focused in San Ingnacio-Navachiste-Macapule, Sinaloa, Mexico, a transitional ecosystem influenced by the largest agricultural and aquiculture activities. Nitrogen and carbon stable isotopes have been evaluated in sediments to estimate spatial variability and its correlations with inputs of carbon and nitrogen derived from natural and anthropogenic sources. The d-15N values ranged from 6 to 10.6‰ from marine-estuarine gradient. Sedimentary organic matter positive d-15N values were influenced by a mixture of aquiculture (sediment pond d-15N = 8.53‰), sewage (12‰) and agriculture drainage (3‰). These land-marine areas were associated with fine grain size, high content of the macronutrient (15 μM NO_3) and negative d-13C values (–25.4‰) as a result of mangrove (−27.3‰), aquiculture (-16.8‰) and positive C4 terrestrial plants (-14.6‰). In contrast, lowest d-15N values were correlated with coarse grain size, 5 μM NO_3 and positive (-19 ‰) d-13C values, of marine environment. The estuarine/marine pattern has an anthropogenic component that be traced in the spatial scale.

The origin of myrmekite in the Boroujerd granitoids, Sanandaj-Sirjan Zone

VAHID AHADNEJAD

Geology Department, Payame Noor University, Tehran 19395-4697, I. R. Iran. (v.ahadnejad@gmail.com)

The Boroujerd Plutonic Complex (BPC) is one of the major Jurassic plutonic complexes in the Sanandaj-Sirjan Zone (SSZ). The BPC consists of a suite of calc-alkaline dioritic to granitic rocks. The abundance of myrmekitic texture is a major petrographic characteristic in the BPC that implies an emplacement into a high-strain shear zone. This is confirmed by mylonitic microstructures in the studied rocks [1]. The aboundance of calcic plagioclase rather than its sodic type and absence of K-feldspar imply a Ca-metasomatism as a major geochemical factor for myrmekites. Locally, there is some K-metasomatism signs such as K-feldspar overgrowth on plagioclase [2], remnant plagioclase islands in microcline crystals, and paths of microcline in plagioclase.

Regional deep water anoxic conditions during the Hirnantian extinction event

ANNE-SOFIE C. AHM[1]* CHRISTIAN J. BJERRUM[1] AND EMMA U. HAMMARLUND

[1]Nordic Center for Earth Evoltion and Department of Geoscience and Natural Resourse Management, University of Copenhagen, DK-1350 Copenhagen K, Denmark (*correspondence: annes.ahm@geo.ku.dk)
[2]Nordic Center for Earth Evolution (NordCEE) and Institute of Biology, University of Southern Denmark, DK-5230 Odense C, Denmark

The Late Ordovician Hirnantian glaciation (~444 Ma) coincided with a marine carbon cycle perturbation, and one of the largest mass extinction events in the Phanerozoic. However, the underlying causes leading up to the extinction event are not fully understood. It has been suggested that a Hirnantian expansion of anoxic conditions, driven by the glacio-eustatic sea-level fall, acted together with the reduction of habitats as the major kill mechanism [1]. To further resolve the end-Ordovician water column chemistry, a multi-proxy geochemical approach was applied to a new drill core and surface material from a deep-water section in central Nevada. Here, enrichments in U and Mo suggest euxinic conditions at the onset of the Hirnantian. Furthermore, ratios of highly reactive iron over total iron (Fe_{HR}/Fe_T) increases from the Katian to values of ~0.5 in the Hirnantian stage, indicating an anoxic water column. We argue that the onset of the Hirnantian can be linked to an euxinic event and that these observations are evidence of expanding anoxia during the first stages of the marine regression which has been lacking documentation at shallower-water sections.

Petrography and diagenesis of Pab sandstone, implications for hydrocarbon exploration in southern Pakistan

SAJJAD AHMAD

Department of Geololgy, University of Peshawar, Khyber Pukhtunkhwa, Pakistan, 25000 (dr.s_ahmed@upesh.edu.pk)

In this study the petrography, diagenetic fabric and hydrocarbon reservoir rock characterization of the Cretaceous Pab sandstone is carried out. Mostly the rock type is arkosic arenite but feldspathic Greywacke is also seen. The dominance of mono-crystalline quartz, alkali feldspar and heavy minerals (Tourmaline, Zircon, and Garnet) point to a provenance source dominated by acidic igneous rocks. Presence of the Quartz overgrowth with mostly concavo-convex boundaries along with the presence of some point and sutured contacts is the major modification caused by the increased geothermal gradient and pressure in the middle to final phase of diagenesis. The synthesis of petrographic, digenetic and plug porosity permeability data confirms a good hydrocarbon prospect of the unit in the region.

The Microbe-Mineral Interactions In The Acidic Podzol Soil

ENGY AHMED* AND SARA HOLMSTRÖM

Department of Geological Sciences, Stockholm University, Stockholm, Sweden (engy.ahmed@geo.su.se)

Iron is a key component of the chemical architecture of the biosphere. Due to the low bioavailability of iron in the environment, microorganisms have developed specific uptake strategies, like siderophores, which are operationally defined as low-molecular-mass biogenic Fe(III)-binding compounds, that can increase iron's bioavailability by promoting the dissolution of iron-bearing minerals. In the present study, we aimed to investigate the composition of hydroxamate siderophores in the soil horizons of the acidic podzol, and study how they are affected by the presence of specific mineral types and microbial communities.

Three different minerals (apatite, biotite and oligioclase) were inserted in the soil horizons (O (organic), E (eluvial), B (upper illuvial), and C (mineral)). After two years, soil samples were collected from both the bulk soil (next to the minerals) and from the soil attached to the mineral surfaces. The concentration of ten different fungal tri-hydroxamates and five bacterial ones were determined by high-performance liquid chromatography coupled to electrospray ionization mass spectrometry (HPLC-ESI-MS). In addition, total microbial composition and diversity were studied.

Our field experiment succeeded in describing the relationship between the presence of siderophores, soil horizon and mineral type, in addition to understanding the interaction between mineral type and soil microbial composition. A wide range of fungal and bacterial hydroxamates were detected throughout the soil profile. On the other hand, the presence of the minerals completely altered the diversity of siderophores. In addition, each mineral had a unique interaction with hydroxamates in the different soil horizons. There were also a good relationship between the microbial diversity and the siderophore distribution.

Hydraulic properties and fresh water prospect of the Ganges River Basin, Bangladesh

NUR AHMED

Hydrogeologist, Institute of Water Modeling, Dhaka-1206 (nurgeo3@gmail.com)

Bangladesh is a lower riparian country in the floodplains of three major rivers- the Ganges (Padma), the Bhramaputra and the Meghna and their tributaries and distributaries which forms the largest delta in the world. Ganges River Basin in Bangladesh has been strongly influenced by tectonics, manifested as delta switching and subsidence and shows fluvio/deltaic plains depositional environments. Groundwater development was started in the early sixties and extended rapidly during the late 1976. Presently, 80% of our national water demand fulfill by groundwater. The lean season flow of the Ganges has decreased since the commissioning of the Farakka Barrage in India during 1975. Climatic change is accelerating the siltation and subsequent dry season, and also limitation of the surface water that's why total water demands stressed on the groundwater. Ganges River basin areas of Bangladesh have started facing water problems, including the drying up of wells during peak irrigation period and lowering of water table and chemical(As,Fe,Cl,Mn,Mg^{2+}) problem. The study area shows arsenic contamination in shallow groundwater aquifers which makes the water unfit not only for human consumption but also for agriculture and environment. In some places deep aquifers show saline water. Between these two aquifers fresh water aquifer is found which the main water source of the area. This paper is mainly concerned with the delineation, extension, recharge and discharge areas of the fresh water aquifer and calibrates hydraulic properties of the aquifer. It also throws light on scope of development of the fresh water aquifer without arsenic contamination or saline water intrusion.

Key words: Ganges river Basin, groundwater, water quality.

[4]Ankara University Earth Sciences Application & Research Center, Ankara, Turkey

Yozgat Intrusive Complex (YIC) is located in the north part of the Central Anatolian Crystalline Complex (CACC). YIC represents the biggest intrusive body of the CACC and clarifies magmatism evolved during the late Cretaceous and Paleocene. YIC is mainly composed of granitic, gabbroic, monzonitic and syenitic rocks forming a complex of different sources and compositions in Central Anatolia. The composition of granitic rocks of YIC is in the range from alkali feldspar granite to the tonalite. The monzonitic rocks are in composition of monzonite and quartz monzonite. The syenitic rocks are in composition of syenite, foid syenite and foid monzosyenite. The gabbroic rocks of YIC are mostly exposed at the top of the hills and have a sharp contact with the felsic intrusive body.

Whole rock geochemistry reveals that granitic, gabbroic and monzonitic rocks are subalkaline whereas syenitic rocks are alkaline in nature. Granitic and monzonitic rocks have a calc-alkaline and gabbroic rocks have a tholeiitic character. Granitic rocks are peraluminous and metaluminous, and monzonitic and syenitic rocks are metaluminous in character. Tectonic discrimination diagrams suggest that the most granitic rocks of YIC are syn-collisional granite whereas monzonitic and syenitic rocks are post-collisional granite. The ORG-normalized elemental patterns of all the felsic intrusive rock units show similar patterns which are characterized by enrichment in large ion lithophile (LIL) with respect to high field strength (HFS) elements. Chondrite-normalized rare earth elemental patterns of granitic, monzonitic and syenitic rocks reveal almost a slight trend. Light rare earth elements (LREE) show enrichment compared to heavy rare earth elements (HREE). These elemental patterns show that the magma is mostly influenced by the crust. All these geological, petrological and geochronological data indicate the progressive evolution of the YIC magmatism respectively from calc-alkaline granites through shoshonitic monzonites to alkaline foid syenite compositions caused by crustal thinning.

Diversity of melts migration process within the uppermost mantle along a mid-ocean ridge: An example from the northern Oman ophiolite

N. AKIZAWA[1], S. ARAI[1], A. TAMURA[1] AND K. OZAWA[2]

[1]Department of Earth Sciences, Kanazawa Univ., Kakumamachi, Kanazawa, Ishikawa, 920-1192, JAPAN
[2]Department of Earth and Planetary Science, Tokyo Univ., Hongou7-3-1, Bunkyouku, Tokyo, 113-0033, JAPAN

Dunite bands and veins in the ophiolitic mantle peridotite are interpreted as fossil melt conduits within the suboceanic mantle. In particular, concordant dunite bands are possibly important as the melt conduits through which parental melts of MORB (mid-ocean ridge basalts) were transported to shallower mantle beneath the ridge axis. However, no detailed petrological data of concordant dunite bands and surrounding peridotites have been published. We conducted sampling of concordant dunite bands and its aureole from various "stratigraphic levels" in the mantle section of an estimated ancient-segment center and its end in the northern Oman ophiolite. They are thick and high in frequency at segment center, but are thin and low at segment end. Dunite bands are almost pyroxene-free, and their orthopyroxenes, if any, are vermicular in shape.

Mineral chemistry shows systematic variations in the wall peridotites toward the dunite bands. In ambient residual peridotites, rare earth element (REE) patterns of clinopyroxene incline from light-REE (LREE) to heavy-REE (HREE) monotonously. The REE pattern of clinopyroxene in dunites and surrounding peridotites show various shapes, depending on the position, the segment center to end: U-shaped at the segment center, and gentle slope from HREE to LREE at the segment end.

We conducted calculation for REE enrichment of clinopyroxenes in dunites by using 1-D steady state modeling, which duplicates simple fractional melting process and influx melting process. The results indicate that melt volume was less to form dunite bands of segment center, whereas was high at segment end. This contrast dues to difference of dunite band distribution between segment center and end; degree of melt/peridotite interaction was high at segment center to form dunite bands, but not at segment end.

Trace element distribution in an extremely basic environment in mine tailings

L. ALAKANGAS AND L. JINMEI

Luleå University of Technology, 97187 Luleå, Sweden

Element distribution in a10 years old low-sulphide and high-carbonate tailings profile covered with a 50cm thick fly ash layer have been investigated. The dissolution of fly ash created an extremely basic environment (pH >11) in the underlying tailings. This resulted in a depletion zone where weathering of Ca-, Fe-, Mg- and Mn-silicates was extensive. Only quartz and K-, Na-, Ca-feldspars covered with $CaCO_3$ remained. The depletion zone was 47cm thick, which indicates a very high weathering rate due to the presence of hydrated hydroxyl ions. Chromium and Ni were accumulated in the depletion zone, while Cd and Cu showed a relatively unchanged content. These elements were added from the ash layer. Chromium and Ni were not identified by scanning electron microscope, but found in the residual phase by sequential extraction, indicating insoluble phases. Elements such as Fe, Pb and S were depleted in the upper part of the tailings, but accumulated together with Cd and Cu, 20cm below the depletion zone, where the pH decreased to circum-neutral. Detailed determination of secondary phases present in the accumulation zone is in progress and the result will be presented. The ash layer was hardened due to pozzolanic properties which reduced the oxygen diffusion which was confirmed by oxygen analysis. Alkaline materials are often used in remediation of contaminated areas, but should be carefully used to avoid leaching of metals. Accumulated elements can be remobilized by changes in the chemical environment when for example the weathering front moves downward and/or the lime content is exhausted.

Development of *in situ* measurements of REE in deep groundwater using Diffusive Gradient in Thin Film

L. ALAKANGAS[1]*, M. ÅSTRÖM[2], F. MATHURIN[2], M. FAARINEN[3] AND B. WALLIN[4]

[1]SKB, Äspö HRL, SE-572 29 Oskarshamn, Sweden (*correspondence: linda.alakangas@skb.se)
[2]School of Natural Sciences, Linnaeus Univ., SE-391 82 Kalmar, Sweden
[3]ALS Scandinavia, SE-977 75 Luleå, Sweden
[4]Geokema AB, SE-181 46 Lidingö, Sweden

The Äspö Hard Rock Laboratory (HRL), SE Sweden, is an underground facility where the Swedish concept for storage of nuclear fuel waste is tested under natural repository conditions [1]. This laboratory also offers an environment for researchers interested in conducting experiments as well as testing equipment *in situ* at the deep granitodic subsurface.

An ongoing activity at the Äspö HRL is monitoring of hydrogeochemistry where several borehole are characterized och sampled every year since two decades. The program includes the rare earth elements (REE), which generally however occur in concentrations below detection limit with the utilizes convential sampling and analytical techniques.

In order to develop a monitoring-technique with which the REEs can be detected above the detection limit, a principle with passive samplers, DGT (Diffusive Gradient in Thin-Film) [2], has been tested. The DGT technique makes it possible to determine labile trace elements, such as REE, by allowing the metals in solution to accumulating to binding agents over a defined period of time.

To obtain as little disturbance as possible and maintain the pressure and the reduced state in the bedrock fractures a special designed container was constructed. The container can hold three DGT's and are constructed in stainless steel to maintain a high pressure of 50 bar and the inside is made of PEEK polymer material to minimize the risk of contamination.

The sampling was performed in three boreholes at depths of -144 m, -280 m and -450 m at three different locations in the Äspö HRL tunnel. Different deployment times were tested (1-4 weeks) and the results are compared with spot sample measurements (<0.45 µm). Overall, the technique works well and the results show that DGT can be used to monitor low-levels of REE (and other trace metals) in reduced groudwater in deep-lying bedrock fractures.

Contrasting volatile contents in the lunar mantle and anorthosites

EMMANNUELLE ALBALAT[1], PETER LUFFI[2], CIN-TY LEE[2], AND FRANCIS ALBARÈDE[1-2],

[1]Ecole Normale Supérieure de Lyon, 69007 Lyon, France, (emmanuelle.albalat@ens-lyon.fr)
[2]Department of Earth Science, Rice University, Houston TX 77005, USA

The enrichment of lunar basalts in heavy Zn isotopes has been used to support large-scale evaporation of lunar volatiles in the aftermath of the Moon-forming event [1]. A remarkable property of Zn is that the Zn/Fe ratio does not significantly fractionate during magmatic processes [2], which reflects the very similar ionic radii of the two elements. We measured trace and major elements by LA-ICP-MS in individual mineral grains and basaltic fragments from 17 lunar samples, among which high-Ti and low-Ti basalts, pyroclastics, the Mg-suite, ferroan anorthosites (FAN), breccias and soils. Among the volatile elements, some of them are siderophile (Ge, T_{50} = 883 K), some other lithophile (Zn, T_{50} = 726 K) or chalcophile (Cu, T_{50} = 1037 K)[3]. Here we show that the Zn/Fe ratios in the source of mare basalts is about two orders of magnitude less than in the terrestrial mantle, which demonstrates that the interior of the Moon is very depleted in volatiles. On the other hand, the Zn/Fe ratios of FAN plagioclase are 1-2 orders of magnitude higher than in lunar basalts. Mineral and melt data indicate that plagioclase preferentially incorporates Zn and Cu relative to Fe by more than an order of magnitude. The nearly constant Ge/Si ratios observed for all samples argue against variable Zn/Fe fractionation upon core segregation. A first possibility is that the higher contents of volatile elements in anorthosites relative to the source of mare basalts reflects the preferential uptake of these elements from the magma ocean by crystallizing anorthite. Alternatively FAN may have been derived from a magma ocean distinctly enriched in volatile elements relative to the deep lunar mantle. The non-chondritic Th/U ratio of FAN inferred from their Pb isotopes [4] is representative of their parent melts and suggests that the latter interpretation should probably be preferred.

The URGE project in Italy: The Acerra–Pomigliano-Marigliano conurbation

S. ALBANESE*[1], A. LIMA[1]; C. REZZA[1], G. FERULLO[1], B. DE VIVO[1], W. CHEN[2] AND S. QI[2],

[1]Università degli Studi di Napoli Federico II - Napoli, Italy. (* correspondence: stefano.albanese@unina.it)
[2]School of Environmental Studies, China University of Geosciences, Wuhan, China

The URGE project has as the main objective the production of the geochemical maps of 12 european urban areas using a shared sampling and analytical procedures.

In the framework of the URGE (Urban Geochemistry) project, aiming at the production of the geochemical maps of 12 european urban areas, the north-eastern sector of the Napoli metropolitan area (Italy), namely the Acerra-Pomigliano-Marigliano area has undergone a geochemical characterization based on 145 soil samples collected over an area of 90 sqkm.

This area has been selected on the basis of previous regional studies [1, 2, 3] and because of both the presence of an historical industrial settlement on it (mainly devoted to plastic materials and synthetic fibres production) and of an incinerator which came into operation in March 2009.

The main objective of the study was to define the local geochemical baselines both for 53 elements (among which the toxic ones) and for some organic compounds, including PAHs and OCPs. Furthermore, the study aimed at supporting epidemiological researches and at establishing a record of the actual environmental conditions to evaluate the future impact of the incinerator on both the territory and the public health.

Preliminary results showed that 1) the most urbanized areas of the conurbation are characterized by concentrations of Pb, Zn and V exceeding the trigger limits established by the Italian Environmental law (D.Lgs. 152/2006); 2) agricultural soils, in the surroundings of the urbanized areas, are enriched in Cu, Co, Cd, Be and Ni, 3) in the incinerator area Se, Hg, Cu, Cd and Sb baselines are generally higher than in the rest of the territory.

Furthermore, the PAHs distribution pattern and their diagnostic ratios suggested that the agricultural waste burning in the rural sector of the study area could be a relevant source of pollution.

[5]National Center for Atmospheric Research, Boulder CO, USA

Aerosol-climate interactions constitute one of the major sources of uncertainty in assessing anthropogenic and glacial radiative forcing. We recently focussed on improving the representation of mineral dust in the Community Atmosphere Model and assessing the impacts of the improvements in terms of direct effects on the radiative balance of the atmosphere and climate impacts.

We simulated the dust cycle while using different parameterization sets for dust emission, size distribution, and optical properties. Comparing the results of these simulations with observations of concentration, deposition, and aerosol optical depth allow us to refine the representation of the dust cycle and its climate impacts. Our findings indicate that the magnitude of the dust cycle is sensitive to the observational datasets and size distribution. In addition, the direct radiative forcing of dust is strongly sensitive to the optical properties and size distribution.

Our results from simulations applying the refined parameterization set indicate a net top of atmosphere direct dust radiative forcing of -0.22 ± 0.12 W/m2 for present day and -0.33 ± 0.18 W/m2 at the Last Glacial Maximum. These estimates are smaller than previous model simulations due to changes in size distribution, modeled spatial distribution and optical parameters.

We analyze the climate impatcs in response to the direct radiative forcing deriving from the refined dust parametrizations.

Isotopes of disease

FRANCIS ALBARÈDE

Ecole Normale Supérieure de Lyon, 69007 Lyon, France (albarede@ens-lyon.fr)

Transition metals are essential components of hundreds of proteins in the human body. They achieve a large spectrum of critical biological functions, such as oxygen transport (Fe), electron shuttling (Cu), structural control and protein degradation (Zn). Their binding to a variety of amino acids is controlled by bond energy, e.g., 'hard' histidine vs 'soft' cysteine, by their structural environment, and by the redox and pH conditions of biological fluids. The different cellular stores of metal are in constant flux and are regulated by gene expression which reacts to a complex pattern of physiological signals. Metal isotope compositions in organs and body fluids provide an enormous source of untapped information relevant to normal and pathological conditions. Spectacular patterns of isotope fractionation are observed in some organs such as the liver and the kidney, and in blood components as well. To a large extent, these patterns reflect the binding of metals with different amino acids, variable redox states and electronegativity. Ab initio calculations indicate that heavy isotopes tend to bind to O-rich ligands (hydroxide, carbonate, phosphate), whereas light isotopes are positively fractionated by S-bonds. Formation of blood cells (erythropoiesis) takes place with very large and coupled Cu-Fe isotope fractionation, the disruption of which clearly signal pathological, and in general, abnormal conditions. The recent years have seen the emphasis being laid on genetic diseases, such as Fe in hemochromatosis and Cu in Wilson disease, and neurodegenerative pathologies such as the Alzheimer disease for Zn. Now that preliminary ground work on metal isotopic variability in the human body is being laid, the opportunity of using some isotopes as biomarkers has never been stronger. Particularly promising are the isotopes of Cu, the concentrations of which are known to vary in multiple forms of cancer, and of Zn, which is making a forceful entry as a biomarker of prostate cancer in the wake of PSA discredit. The enormous challenge of using isotopes to quantitatively assess the parameters of metal homeostasis at the cellular level in relation with gene expression and regulation will clearly engage the upcoming generation of isotope geochemists, biochemists, and health scientists.

A mass fractionation law for high-transmission MC-ICP-MS

FRANCIS ALBARÈDE, PHILIPPE TELOUK AND EMMANNUELLE ALBALAT[1]

[1]Ecole Normale Supérieure de Lyon, 69007 Lyon, France, (albarede@ens-lyon.fr)

Russell *et al*'s [1] exponential law provides the standard form used for the correction of the mass bias on isotopic ratios measured by mass spectrometry and more specifically since 1992 for MC-ICP-MS. It is nevertheless expected to fail as soon as the ion/atom efficiency exceeds the percent level and preliminary observations on new-generation MC-ICP-MS confirms this prediction. At 100% transmission, the mass bias must by unity. The physics of mass fractionation in the torch involves collisions with abundant neutral argon atoms, the formation of a shock wave in the interface, and the presence of a boundary layer in the nozzle, and is therefore particularly complicated. At low transmission, the ratio between two isotopes 1 and 2 is affected by a factor $(M_1/M_2)^{\beta}$, where M is the atomic mass. The mass fractionation factor β remains essentially constant and equal to ~2 across the mass range, which suggests that the velocity of radial expansion is proportional to mass [2], but this law has not received a universally accepted.physical justification.

At high transmission, the exponential law breaks down. What is the relationship between mass fractionation and transmission? A simple conservation principle applied to the fraction lost suggests an example of a transmission-compliant mass fractionation law:

$$R_{\text{meas}} = R_{\text{true}} \times \frac{(M_1/M_2)^{\beta}}{(1 - n/n_0) + (n/n_0)\,(M_1/M_2)^{\beta}}$$

in which n/n_0 is the transmission. At the limit, the exponential law is obtained when $n/n_0 \rightarrow 0$, while the mass bias disappears when $n/n_0 \rightarrow 1$. Other forms involving different functional relationships are also possible and need to be tested. The instrument transmission for a particular element is an essential parameter of mass fractionation laws and should therefore be recorded with the best possible precision. We will present data on the isotope compositions of various elements across the mass range that will allow the present model to be tested.

The Y-3 tephra: New insights

P. G. ALBERT[1,2]*, M. HARDIMAN[3], J. KELLER[4], E.L. TOMLINSON[5], U.C. MÜLLER[6], V.C. SMITH[2] AND M. MENZIES[1]

[1]Earth Sciences, Royal Holloway University of London, UK
[2]RLAHA, University Oxford, UK (paul.albert@rlaha.ox.ac.uk)

[4]Albert-Ludwigs-University Freiburg, Germany
[5]Geology, Trinity College Dublin, Ireland.
[6]Institute of Geosciences, Frankfurt, Germany

The 'Y-3' tephra is a crucial stratigraphic marker within the central Mediterranean region, reported occurrences within palaeoenvironmental archives occur at or close to the Marine Isotope Stage 3/2 transition, which in turn is linked to the onset of Heinrich Stadial 3 (HS3) [1]. Consequently this tephra offers enormous potential to assess potential leads and lags between Mediterranean archives. Until now the type locality Ionian Sea Y-3 tephra has remained poorly characterised. Consequently, numerous other distal tephras occurring in broadly similar stratigraphic positions and displaying a similar trachyte composition have been correlated to the Y-3 tephra without the appropriate geochemical validation.

Here we present the first grain-specific major, minor (EPMA) and trace element (LA-ICP-MS) characterisation of the Y-3 tephra recorded in its type locality of the Ionian Sea (M25/4-12). The High-K phono-trachyte geochemistry of the Ionian Sea Y-3 supports a provenance from within the Campi Flegrei caldera consistent with previous interpretations. Geochemical glass data reveals problems with a correlation between the Ionian Sea Y-3 and the proposed proximal equivalent, the VRa Tufi Biancastri unit. As a result the VRa age must not be imported to the Ionian Sea Y-3 tephra.

Using the new diagnostic major, minor and trace element chemistry of the type locality Y-3 tephra we are able to assess and establish precise distal-distal tephra correlations. Robust identification of the Y-3 in the Tenaghi Philippon (Greece) sedimentary archive both offers an opportunity to determine a precise age for this distal marker and assess its stratigraphic position in the context of a high resolution palaeoenvironmental archive. A Bayesian-based ^{14}C age model provides an age of 29, 350-30, 160 cal yrs BP for the Y-3 tephra. The Y-3 tephra resides within the latter part of a period of reduced total tree pollen percentages, which is related to drier stadial conditions. The independent age of the Y-3 tephra and it environmental context suggests that this marker tephra post dates the onset of both HS3 in the Mediterranean region and GS-5 in the INTIMATE event stratigraphy [2].

Biogeochemistry of manmade lake nearby industrial city, Riyadh, Saudi Arabia

IBRAHIM MASHHOUR AND MAJED ALBOKARI*

Atomic Energy Research Institute (AERI), King Abdulaziz City for Science and Technology (KACST), P. O. Box 6086, Riyadh 11442, Saudi Arabia. (mbokari@kacst.edu.sa)

Extremophiles are microbes that have the ability to maintain a life cycle in severe environments such as those characterized by high salt (halophiles) and high temperature (hyperthermophiles). A manmade lake (pond) nearby the second industrial city at the south of Riyadh, Saudi Arabia with estimated area of 25 square kilometer and 20 meter depth, which was created accidentally, is characterized as extreme environments whereas TDS reaches around 7700 ppm and the temperature of surrounded area hits 60 °C in summer and goes down -2 °C in winter. The lake has been fed by all type of wastewater ranges from treated wastewater generated from facilities of the industrial city, draining system of rainfall and portable sewage tanks. A discharge channel (stream) somehow connected to the lake from facilitits of industrial city via underneath the highway was bulit recently. This work aimed to measure phyisco-chemical properties, selected heavy metals (Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Cd, Pd) and presenting bacteria along the stream and the lake itself in order to propose a hypothesis regarding biogeochemistry behaviour of indigenous microorganisms.

Practically, nitrates, carbonates and sulfates clearly decreased by 41.5%, 28.5%, 14.0%, respectively, from stream part to lake itself. Similarly, level of Cr, Mn, Fe, Co, Zn, Cd and Pd decreased as sampling have been collected along stream to lake. On the other hand, concentrations of Ni and As increased by 46% and 27 %, respectively while Cu didn't show any significant change. On the bacterial level, microbiological conventional methods produced 62 isolate (38 isolated from lake's samples and 24 isolated from stream's samples) and identified using state-of-art RiboPrinter microbial characterization system, which is based on pattern of DNA bands. *Aeromonas hydrophila* species represented 10% of total isolates from lake's samples while *Klebsiella pneumonia* species found to be 50% of isolates from stream's samples. In such an open complex ecosystem, many variables are accounted to have certain behavior like chemistry of elements and geological structure of the area. Moreover, shifts in bacterial species profiles and changes in physcio-chemical between stream and lake can be linked to each other and lead to isolate novel species.

Analysis of fluid inclusions with fs-LA-ICP-MS

M. ALBRECHT*[1], I.T. DERREY[1], I. HORN[1], S. SCHUTH[1], F. MELCHER[2] AND S. WEYER[1]

[1]Leibniz Universität Hannover, Institut für Mineralogie, GER
[2]Federal Institute for Geosciences & Natural Resources, GER (*correspondence: m.albrecht@mineralogie.uni-hannover.de)

Hydrothermal Cu deposits are one of the most significant type of ore deposits for many metals (e.g. Cu, Zn, W, Mo, Au). Fluids are responsible for the transport and the enrichment of those metals [1]. To learn about the conditions that led to metal enrichment in fluids, we want to investigate the composition of fluid inclusions from ore deposits *in situ* by femtosecond laser ablation inductively coupled plasma mass spectrometry (fs-LA-HR-ICP-MS; using an ElementXR® MS).

For this purpose a new analytical setup is developed by combining a heating freezing stage with our deep UV (λ = 196nm) fs-LA-HR-ICP-MS system. By freezing the fluids, we are aiming to expand the signal length of the ablated fluid inclusion and with that to minimize analytical uncertainties compared to previously applied nanosecond LA-ICP-MS techniques [2].

Preliminary test measurements of a frozen standard solution relative to the NIST610 glass, resulted in an analytical uncertaity of 10% (1σ) for the analyses of e.g. Cu, Zn, Pb, Ag and other trace elements. We also tested our method by the analyses of natural high saline (>20wt% $NaCl_{eq.}$) fluid inclusions in hydrothermal quartz veins from Cornwall, UK and with synthetic fluid inclusions in quartz of different salinities. First results indicate that inclusions of a size between 10μm to 30μm and in a depth up to ~50μm can be analysed with a succes rate of > 60%. ^{23}Na is used for internal standardization. For several isotopes, including ^{44}Ca, ^{66}Zn, ^{95}Mo, ^{85}Rb, ^{133}Cs and ^{208}Pb we achieved signals significantly above the detection limit (3σ of background) for a duration of 20 to 40 seconds.

In future investigations, we want to apply this technique to analyse natural fluid inclusions from different ore deposits and synthetic fluid inclusions from HP/HT experiments.

High pressure fluid evolution derived from veins in UHP eclogites (Dabieshan, China)

N. ALBRECHT[1]*, G. WÖRNER[1], Y. XIAO[2] AND A.M. VAN DEN KERKHOF[1]

[1]Geoscience Center Göttingen, 37077 Göttingen, Germany (*correspondence: nalbrec@gwdg.de)
[2]School of Earth and Space Sciences, Hefei 230026, China

Fluids linked to deep burial form and evolve under (ultra-) high pressure (UHP) conditions and are characterized by enhanced element solubilities [1], resulting in transport and fractionation of both fluid-mobile and nominally immobile elements [2]. Reconstructing UHP fluid evolution is thus essential for a better understanding of element mobility and redistribution among Earth's reservoirs.

Representing fossil pathways of fluid flow, we sampled mineral veins in UHP eclogites from the Triassic Dabieshan continental collision zone. Three vein generations are distinguished based on mineralogy and field evidence: (1st) early UHP near-peak qtz + rt veins, (2nd) HP post-peak phg + ep/czo + brs + ap + qtz + rt ± ky ± omp ± pg ± zo veins and (3rd) late HP retrograde ab + phg + ep/czo + qtz veins.

Petrography, microthermometry and Raman analyses reveal pure high density N_2 inclusions (0.56 g/cm^3) in eclogitic quartz and three assemblages of aqueous inclusions in vein and eclogitic qtz: (i) primarily trapped $CaCl_2$ + NaCl ± $MgCl_2$ brines (30–35 wt% $NaCl_{eq}$), (ii) primary to pseudosecondary $CaCl_2$ + NaCl solutions (17–27 wt% $NaCl_{eq}$), (iii) secondary NaCl-bearing fluids (0–12 wt% $NaCl_{eq}$). Homogenization temperatures among the aqueous groups are bimodally distributed, clustering at 200 and 400°C. High salinities clearly correlate with high T_H and low salinities with low T_H. Zoning in vein epidote minerals from LREE- and LILE-rich allanitic cores to slightly resorbed, depleted clinozoisite and overgrowths of trace element-poor epidote mirrors the solute depletion trend indicated by fluid inclusions.

The results reflect an evolution from highly saline, trace element-rich brines near the metamorphic peak towards low salinity, trace element-poor solutions along the retrograde path. The earliest fluids are interpreted to originate from prograde dehydration and their initially high solute content is 'consumed' by precipitation of vein minerals and likely by late dilution with meteoric waters. The nitrogen is suspected to be progradly inherited from metasedimentary lithologies in which the sampled eclogite bodies are embedded.

Primary magmas, fractionation modelling and mantle sources of Etnean lavas

G. ALESCI [1], P.P. GIACOMONI [1], M. COLTORTI[1] AND C. FERLITO[2]

[1]Univ. of Ferrara, Italy (giuseppe.alesci@unife.it)
[2]Univ. of Catania, Italy (cferlito@unict.it)

A backward mass balance fractionation was used to reconstruct the primary composition of Etnean magmas and get some inferences on the petrological composition of their mantle sources. The entire evolution of Etna magmatism, from Tholeiitic period to Recent Mongibello, were taken into consideration. fO_2 activity was estimated using [1] and Fe^{3+}/Fe^{2+} ratio were calculated according to [2] equation. The least differentiated products for each alkaline period were identified and about 15 to 20% of a solid assemblage made up of olivine (87 to 100%) was added to re-equilibrate the basalts with mantle olivine (Fo_{87}). If clinopyroxene is added to equilibrate the lavas with mantle olivine a much higher percentage (>40%) of solid fractionation is needed. A further subtraction of 20-25% of a solid assemblage constituted by ol (6-18%), cpx (26-55%) and plag (25-48%) is needed to get to the most differentiated erupted lavas. Taking into account the volume of the erupted magmas this modeling can be used to evaluate the quantity of material intruded below the volcano edifice. Calculated major element compositions of the primary magma is well comparable with those obtained by melt inclusions study [3] and references therein, while trace element patterns fit well with those reported in the literature. These compositions are also similar to those found in the Iblean Plateau [4] apart from a slight enrichment in Rb, Th and U and a depletion in Ti, Hf, Y and Yb, indicating the presence of discrete percentages of volatile-bearing phases, that is amphibole and phlogopite, in the Etnean mantle sources.

Uranium bioremediation strategies focus on the addition of a reduced carbon source to stimulate the growth of indigenous microbial communities in subsurface sediments. This growth leads to conditions that promote the reduction of soluble U(VI) species in groundwater to relatively insoluble and immobile U(IV) species. Field studies to date focus on U(IV) products formed in deep sulfate reducing conditions, which have been identified as uraninite (UO_{2+x}), monomeric or mononuclear U(IV) species that lack crystal structure and are associated with biomass or iron-bearing minerals, and phosphate coordination polymers to which U(IV) is bound. However a systematic molecular-to-pore scale characterization of changes in U(IV) product speciation and stability as bioremediation proceeds is not extant.

In this study, we deployed sediment reactors into a groundwater well at the Old Rifle, CO aquifer during biostimulation with acetate. Sediments were harvested as the aquifer progressed through metal- and sulfate-reducing regimes, and were characterized by spectroscopic, microscopic, wet chemical, and microbiological techniques. U(IV) product local structure and reactivity exhibits little apparent change despite large changes in redox state, accumulated uranium in the sediments, and microbial community structure. This result suggests that similar U(VI) reduction mechanisms may be operating throughout the biostimulation campaign.

The link between the origin of organic matter and GEMS in extraterrestrial materials

CONEL M. O'D. ALEXANDER[1]*, LARRY R. NITTLER[1] AND RHONDA M. STROUD[2].

[1]DTM, 5241 Broad Branch Rd., NW, Washington DC 20015, USA (*correspondence: alexander@dtm.ciw.edu).
[2]Naval Research Laboratory, 4555 Overlook Av., NW, Washington DC 20375, USA.

There appears to be a genetic relationship between chondrite matrices, interplanetary dust particles (IDPs) and cometary material. All are dominated by fine-grained, crystalline silicates (predominantly olivine and pyroxene) with similar ranges of properties, along with amorphous silicates or GEMS (glass with embedded metal and sulfide) and organic matter. They also contain circumstellar grains (stardust), many of which are GEMS-like.

There have been longstanding debates about whether GEMS and the organic matter are interstellar or solar in origin, although these are rarely linked. Interstellar silicates are almost entirely amorphous. Therefore, the crystalline material must be products of high temperatures in the nebula. In primitive materials, crystalline silicates into which Na, Al, Ca, etc. could have gone are rare, and they are presumably in GEMS that formed along with the crystalline material. Organic matter is abundant in the ISM, but would have been destroyed during formation of the crystalline silicates. If all GEMS are also high-T nebular products, then almost no ISM dust can have survived and the organic matter in chondrites, IDPs and comets must also be solar in origin. Hence, it is of paramount importance to determine whether or not most GEMS are solar or interstellar [1].

The fraction of ISM silicate grains that are circumstellar is estimated to be ~0.3% [2]. Therefore, the stardust in chondrites/comets should have been accompanied >100 times as many ISM grains. 1-6% of GEMS are stardust [3], which suggests that the remaining GEMS must be interstellar. Yet the crystalline silicates require that a significant fraction of GEMS are solar. We will use meteoritic and IDP data to try to resolve the conflicting estimates of the abundances of solar and interstellar GEMS. This will provide important constraints on the production and processing of dust in the ISM, and on the origin of organic matter in primitive extraterrestrial materials.

High-Cr minerals from the Matoush uranium deposit in the Otish Basin, Quebec, Canada

P. ALEXANDRE[1], R. PETERSON[1], K. KYSER[1], D. LAYTON-MATTHEWS[1] AND B. JOY[1]

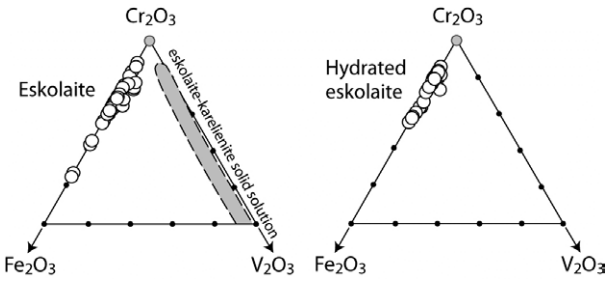
[1]Queen's University, Department of Geological Sciences, Kingston, ON, K7L 3N6, Canada (alexandre@geol.queensu.ca, peterson@geol.queensu.ca, kyser@geol.queensu.ca, lmatthews@geol.queensu.ca)

High-Cr paragenesis is observed at the enigmatic Matoush uranium deposit, Otish Basin (Quebec, Canada), which is associated with the bimodal and very narrow (<2 m) Matoush dike intruding the sandstones of the Indicator Formation. In addition to uraninite, both silicate (Cr-dravite and Cr-muscovite) and oxide (eskolaite) high-Cr minerals are present in large amounts. While high-Cr dravite and high-Cr muscovite have been described previously, eskolaite, Cr_2O_3, has not been studied extensively.

The highest Cr contents observed in the Matoush silicates, obtained by electron microprobe, are comparable with those documented in the literature, with Cr_2O_3 of up to ca. 22 wt% in Cr-muscovite (or chromphyllite) and ca. 37 wt% in Cr-dravite.

Complete solid solutions between hematite (Fe_2O_3), eskolaite, and karelianite (V_2O_3) are theoretically possible, but only the complete Cr-V substitution has been documented. In contrast, the Matoush eskolaite contains significant amounts of Fe, with up to 37% wt% Fe_2O_3 substitution, and minimal V (typically under 0.5 wt% V_2O_3).

A hydrated Fe-Cr oxide with the hematite structure is also observed to be closely associated with eskolaite at Matoush, This phase has the same Cr-Fe-V ratio as eskolaite, but with ca. 14 wt% H_2O. Synthetic hematite with significant OH is known to occur and exhibits increased c axis length with increased OH substitution. Rietveld analysis of the X-ray powder diffraction data of the Matoush material is best fit using a model that includes anhydrous eskolaite and a second hydrated crystalline Fe-Cr oxide with the hematite structure and a larger c axis dimension.



Measurement of $\delta^{34}S$ and $\delta^{33}S$ values in wild animal hair samples by MC-ICP-MS

Y. ALFAYFI[1]*, M. WIESER[1], C. DUBESKY[2] AND M. MUSIANI[3]

[3]Faculty of Environmental Design, University of Calgary, Canada.

Sulfur isotopic compositions vary widely in nature, which give much scope to trace sources and processes of sulfur components in biological systems. The investigation of the diets of wild animals using the sulfur isotopic composition of hair has been demonstrated to be a powerful tool in ecological investigations [1]. The challenge is to measure these differences in sulfur isotope abundances accurately from small amounts of sample. The use of multiple collector inductively coupled plasma mass spectrometry enables reliable determination of the isotopic composition of ^{32}S, ^{33}S, and ^{34}S from microgram quantities of S [2, 3, 4]. This requires that the sulfur is separated from the sample matrix and possible spectral interferences are resolved by the mass spectrometer. Sample digestion using microwave techniques or on-line combustion of the sample to SO_2 using an elemental analyzer ensures that sulfur is prepared in a form suitable for analysis. The high mass resolving power of the Thermo Scientific Neptune ensures that isotopes of sulfur are resolved from polyatomic ions, in particular isotopologues of oxygen. We developed a method to measure accurately and precisely $n(^{34}S)/n(^{32}S)$ and $n(^{33}S)/n(^{32}S)$ free from spectral interferences that might affect the results, which was demonstrated by plotting $\delta^{34}S$ and $\delta^{33}S$ values on a three-isotope plot. The analytical methods for the MC-ICP-MS were applied to study the diet of wolf and caribou in Canada revealing subtle variations in sulfur isotopic composition in the hair samples from these animals. Initial data show that these results can be used to assist in the identification of the principal sources of food in wild animal populations.

Distribution of Ta and Nb between silicate and aluminofluoride (salt) melts

Y.O. ALFERYEVA*, T.I. SHCHEKINA AND E.N. GRAMENITSKIY

Lomonosov Moscow State University, Russia, Moscow, GSP-1, Geological dep, Petrology 119991 (*correspondence: YanaAlf@ya.ru)

Experiments in the model system Si-Al-Na-Li-H-F-O at T=800°C and p=1kbar show possibility of equilibrium crystallization of fluorine minerals (cryolite, topaz, villiomite) or the origin of immiscible aluminofluoride melt (brine) in case of high fluorine concentration in the system. The area of coexistence of two immiscible silica and salt melts extends for both nepheline- and quartz-normative compositions of silica melts.

In case of two melts coexistence tantalum and niobium are distributed into the silicate melt. By virtue of the different values of partition coefficients the ratios of tantalum to niobium in residual aluminosilicate melt increase.

The experimentally determined phase relations are in general agreement with compositions of topaz and/or cryolite bearing granites from different regions.

In natural systems, in the final stages of crystallization high amounts of incompatible elements can lead to the separation of salt melt. Brine appears to be an effective concentrator of significant ore elements such as REE, Y, Sc, U, Th, Mo, W etc. [1]. Occurrence of salt melt can also lead to increasing of Ta/Nb ratio in the most evolved varieties of rare metal granites observed in numerous massifs [2].

Modelling single phase bimolecular reactive transport directly on pore-scale images

ZAKI ALHASHMI*, BRANKO BIJELJIC AND MARTIN J. BLUNT

Department of Earth Science and Engineering, Imperial College London, London SW7 2AZ, United Kingdom (*correspondence: zaki.al-nahari09@imperial.ac.uk)

Geochemical reaction rates estimated in geological porous media are found to be significantly lower than those measured in the laboratory. Traditional advection dispersion reaction equatiosn (ADRE) frequently cannot accurately describe reactive transport in heterogeneous porous media. Therefore, there is still a lack of understanding of the integration between coupled transport and geochemical reactions at multiple scales. We simulate the transport of fluid reactants (A and B) directly on *mm* sized images obtained using micro-CT scanning with a resolution of a few microns. We use a streamline-based particle tracking method for simulating flow and transport. For reaction to occur, both reactants must be within a diffusion distance of each other in a time step. We assign a probability of reaction (P_r), which is a function of the reaction rate constant (k_r) and the diffusion length. Firstly we validate our model for reaction only against analytical solutions of the bimolecular reaction (A + B $\square$ C). Then we couple reaction and transport to perform simulation on the micro-CT images. We find that heterogeneity of the pore structure plays a significant role in altering the average reaction rates. The heterogeneous pore stucture prevents contact between reacting species, thus decreasing the reaction rate. We validate the model through predicting the experiments by Gramling *et al* [1].

Triple O-Isotope analyses of pallasite olivine revisited: A cautionary tale

ARSHAD ALI[1], NEIL R. BANERJEE[1], IFFAT JABEEN[1], KIM TAIT[2], BRENDT HYDE[2] AND IAN NICKLIN[2]

[1]Western University, London, ON, Canada; aali287@uwo.ca
[2]Royal Ontario Museum, Toronto, ON M5S 2C6, Canada

Pallasites belong to the stony-iron meteorite group consisting of almost equal amounts of olivine and metal. Precise O-isotope compositions of olivine from 10 main group pallasites are determined using an improved laser fluorination IRMS method [1]. Our data from all pallasites are consistently more enriched than previous studies [2, 3]. However, the $\Delta^{17}O$ values are in agreement with [3]. Ziegler & Young [4] obtained similarly enriched $\delta^{17}O$ and $\delta^{18}O$ values for pallasites and unpublished data from the Carnegie Institution (CIW) in [4] also agrees with our data. To explain the observed discrepancy in delta values for same pallasites, we partially lased Brahin's single olivine grain in 5 steps at increasing degree of laser power. Our hypothesis is the discrepancy in delta values might be due to incomplete reaction of olivine, one of the most resistant minerals to fluorination. The $\delta^{18}O$ values are observed to increase ~1.8‰ from the 1st (least complete) to 5th (most complete) reaction step and the triple O-isotope plot of these data fall on a half-slope line. Our data demonstrate that partial or incomplete reaction causes mass-dependent fractionation and results in lighter $\delta^{17}O$ and $\delta^{18}O$ values. Our experiment explains the discrepancy of data between reaction of olivine in conventional Ni-tubes [2] and laser reactions with BrF_5 (this study). Inconsistencies in reaction progress may also help explain differences observed in laser fluorination methods at different labs worldwide [e.g., 3,4]. Our study highlights the importance of considering factors that might affect reaction progress such as: 1) the effect of fluoride residues covering unreacted sample; 2) the sample holder dimple profile (i.e., V-shaped; this study); and 3) the effect of melting the sample before fluorination as adopted by [3]. In our study we utilized a sample size optimized in order to limit the effect of buildup of fluoride residues. We also make use of continuous and blast laser modes to uncover the unreacted sample during the final stages of the reaction. Our specially designed sample holder dimples have a V-shaped profile that concentrate the material in the center to more effectively lase the sample. We are now applying these improvements to a wide variety of pallasites and other meteorites to decipher their origin.

Origin of the orthopyoxene fibrous in the ultrarefractory lithospheric domains beneath easternmost Canary Islands

MOHAMED M ALI ABU EL-RUS

Geology Department, Assiut University, Assiut 71516, Egypt
aliabuelrus@yahoo.com

The mantle xenoliths from easternmost Canary Islands, exhibit a complex evolutionary history comprising events of depletion, serpentinization, dehydration and enrichment. Each of these events left imprints on both texture and chemistry of the xenoliths. The imprints of depletion event(s) are shown in the complete disappearance of the clinopyroxene porphyroclasts and the ultra-refractory nature of the xenoliths compared to the abyssal peridotites sampled along mid-ocean ridges and oceanic fracture zones. Compositionally, the study xenoliths resemble the recycled oceanic mantle peridotites (OI1-u) sampled by worldwide ocean island volcanism. The development of porous clusters of fibrous orthopyroxene at the expense of primary olivine and orthopyroxene characterizes the event of hydrothermal alteration forming serpentine minerals which were later dehydrated into fibrous orthopyroxene. The signature of serpentinization is also shown in the wide variations of several highly incompatible element ratios that might remain constant over variable degrees of melting (e.g. Rb/Ba, U/Th); the poor correlations between several LILE with HFSE and the decoupling between Sr and Nd isotope ratios. During the Canary Islands magmatism, the peridotite xenoliths have been subjected to interaction with silicic carbonatite melt which is shown in the development of clinopyroxene rims and neoblasts at the expense of olivine and orthopyroxene minerals and the enrichment in strongly LREE relative to HREE. The petrographic observations, however, indicate that dehydration of serpentine minerals and formation of anhydrous fibrous domains has occurred long time before the activity of Canarian plume. We therefore favour a model in which serpentinization of the mantle xenoliths might occur when they, like other Ol1-u peridotites, were parts of a mantle wedge in an old subduction zone fluxed by large volume of aqueous fluids released from downgoing oceanic crust. Dehydration of the xenoliths might occur during their residence for a while in the hot convecting asthenospheric mantle and before their accretion to the present oceanic lithospheric mantle and interaction with Canarian intraplate magmatism.

Apatite exsolution as an indicator of Udachnaya grospydite UHP history

T.A. ALIFIROVA[1]* AND L.N. POKHILENKO[1]

[1]V.S. Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, 630090, Russia (*correspondence: taa@igm.nsc.ru)

Earth's mantle interiors characterizing by their heterogeneous composition contain a small fraction of rare rock types. Grospydite xenoliths well studied in kimberlites of Daldyn-Alakit region (Yakutia, Russia) [1, 2] are of special interest among the representatives of unusual rocks composing mantle. We represent new data on mineralogy and evolution of grospydite xenolith LUV134/10 from Udachnaya kimberlite pipe (Yakutia).

Kyanite and Grt-1 are poikiloblastically included into the Cpx-1. Grt-2 + polycrystalline Qtz compose large (up to 8 mm) symplectites. Cpx-1 is nearly all replaced by tiny Cpx-2 + Pl symplectites and preserved in relics and inclusions in kyanite and garnet. Kyanite usually contains quartz inclusions, some of them may indicate their high-pressure origin [3]. Minerals contain evident exsolution textures. Grt-1 comprise numerous rutile and apatite needles. Kyanite is with rutile lamellae. Cpx matrix has Rt + Ilm rods, and Cpx-1 relics contain tiny apatite precipitates (confirmed by Raman).

Grossular garnet usually has 3.02-3.04 Si apfu and Na_2O up to 0.15 wt %. Cpx-1 is omphacite with significant admixtures of Ca-Ts and Ca-Es components (7 and 4 mol. % respectively). The presence of majoritic component in preserved garnet suggests its stability at pressures > 6 GPa, but reconstructions of original garnet composition presumably will raise the bar. Apatite precipitation in Cpx-1 allows us to declare original pyroxenes could have had about 200-400 ppm P. Considering experimental data [4], precursor pyroxene is believed to be stable at pressures no less than 6 GPa. Thus, the further findings of apatite lamellae in pyroxenes may serve as reliable indicator of ultra-high pressure stage in rock history.

With respect to mineralogical data we suppose the rock to be subjected to successive decompression and cooling within mantle reservoir.

The study was supported by RFBR grant No. 12-05-31411, and Grant of President of Russia MD-1260.2013.5.

Grain size and REE patterns as tools to identify coastal depositional environments in Moreton Bay (southeast Queensland, Australia)

F. AL-KAABI[1]* AND M.GASPARON[1,2]

[1]School of Earth Sciences, The University of Queensland, Brisbane, QLD, 4072, AUSTRALIA (*f.alkaabi@uq.edu.au)

[2]National Centre for Groundwater Research and Training, AUSTRALIA

Statistical grain size analysis of Holocene sediments across Moreton Bay revealed three different depositional environments: fluvial, aeolian and marine-tidal. The distribution of rare earth elements (REE) and yttrium was analyzed in each type of deposit to assess their suitability as a geochemical indicator of depositional environments.

Fluvial deposits are characterized by almost flat REE patterns and a positive Eu anomaly. In contrast, aeolian deposits are enriched in heavy REEs (HREE) relative to light REEs (LREE), and show a negative Eu anomaly. Fluvial deposits are enriched in REEs compared with aeolian deposits. Tidal deposits along small embayments are enriched in LREE relative to HREE, but show variable Eu anomalies. Relative to Ho, Y shows a strong negative anomaly in some of the fluvial sediments, but only a slight negative anomaly in tidal sediments. In contrast, Y/Ho>1 values characterize aeolian sediments. The presence and abundance of organic matter within the deposits does not seem to have any influence on REE abundances and patterns.

In general, total REE concentrations mimic Th distribution across all depositional environments, and the extent of LREE/HREE fractionation correlates with Nd/Fe ratio [1]. The distribution of europium anomalies (Eu/Eu*) [2] is consistent with variations in Hf, Nb and Zr distributions.

This study confirms that REEs are a powerful geochemical indicator of depositional environments even in a complex and dynamic setting such as a tidal estuary.

Dust deposition in southern Belgium is estimated from the geochemical signature of an ombrotrophic bog. The analyses of Rare Earth Elements (REE) and lithogenic element concentrations as well as Nd isotopes were performed by HR-ICP-MS and MC-ICP-MS respectively, in a ~ 6 m peat section representing 5300 years, from 30 BC to 5300 BC dated by the ^{14}C method. REE concentration variations in peat samples were used as a dust proxy and the Nd isotopes to trace the sources. Peat humification and testate amoebae were used to evaluate hydroclimatic conditions. The range of dust deposition varied from 0.03 to 4 g m^{-2} yr^{-1}. The highest dust fluxes were observed from 800 to 600 BC, and from 3200 to 2800 BC and correspond to cold periods. The εNd values show large variability, between -5 and –13, identifying three major sources of dust: local soils, distal volcanic and desert particles. By comparing our results with the dust recorded in other peat bogs and ice cores from different latitudes, we evidence that the Misten peat is a valid archive for dust deposition.

CO_2 emissions from arc volcanism: sources, rates and uncertainties

P. ALLARD

IPGP-Sorbonne Cité, UMR7154 CNRS, 75005 Paris, France (pallard@ipgp.fr)

Arc volcanism is one key geological manifestation of chemical exchanges bewteen the Earth's mantle and surface reservoirs through plate subduction processes. Global quantification of the deep carbon cycle, in particular, requires improved knowledge of the CO_2 output from arc volcanoes, of respective carbon contributions from subducted slabs, mantle degassing and arc crusts, and hence of the porportion of total subducted carbon recycled back into deeper mantle. Here I present an updated review of theses different aspects and their uncertainties.

Chemical and isotopic data for high-temperature (450-1040°C) volcanic gases from various subduction zones worldwide, combined with melt inclusion data, provide the most pristine information on magmatic arc volatiles. High $CO_2/^3He$ ratios in these gases compared to MOR fluids evidence systematic addition of crustal-derived carbon whose origin (sudbucted sediments, altered oceanic slab, or arc crust) can be discriminated from the $\delta^{13}C$ vs $CO_2/^3He$ relationship and other geochemical tracers. In most cases, slab-derived carbon is the prevalent (70-95%) component of CO_2 emitted by arc volcanoes, except at a few documented volcanoes in continental arcs (e.g. Italy) where magma-carbonate crustal interaction is a significant to important source.

Published estimates of the global CO_2 output from arc volcanism, assessed from different proxies (fluxes of S, ^3He, ^{210}Po or/and magma supply rates), vary within an order of magnitude and, over time, tend to increase with increasing data for volcanic plume emissions but also crater lakes, hydothermal systems and soil degassing. When compared to global budgets for subducted carbon, the current figures suggest a carbon recycling efficiency of between ~50 and 100% through arc volcanism, with obvioulsy contrasted implications for the deep carbon cycle. Hence, measuring CO_2 fluxes and $\delta^{13}C$ vs $CO_2/^3He$ at much more numerous arc volcanoes worldwide is badly needed in order to better constrain this important aspect. This is one key objective of the international DECADE project sponsored by the Deep Carbon Observatory (DCO).

Mount Etna: Storyboard of an exceptional basaltic volcano

P. ALLARD

IPGP-Sorbonne Cité, UMR7154 CNRS, 75005 Paris, France (pallard@ipgp.fr)

Mount Etna, in Sicily, has fascinated observers since the Antiquity and, over the past decades, has gradually become one the most intensively studied/monitored volcanoes on Earth. Several features contribute to make it one exceptional basaltic volcano-laboratory: its peculiar tectonic setting and magma geochemistry (intraplate-type alkali basaltic magmatism in the context of African-European continental plate collision), its persistent activity and wide spectrum of eruptive styles (from lava effusions, lava fountains, Strombolian to Plinian explosions), its huge gas emissions (among the strongest ones worldwide), and its quite easy access (favourable to maintenance of dense monitoring networks and field testing of new technologies). These different aspects have long attracted scientists from various disciplines but also promoted increasingly pluri-disciplinary sounding of the deep roots of the volcano and its behaviour. Moreover, the continuous survey of Etna, under the responsibility of INGV, responds to the need of forecasting its eruptions and mitigating the risks to which its densely populated surroundings are exposed.

In this keynote talk, I'll provide a review of the progresses in our present-day understanding of how Mount Etna works, based on available geophysical, geochemical, petrologic and modelling information. I'll outline how multi-disciplinary investigations of major eruptive events in the past 15 years has greatly improved this understanding and the eruption forecasting capability. Finally, I'll attempt to show how the lessons learnt on Mount Etna, as well as the methodologies used on this volcano, can have broad applications to numerous other volcanoes worldwide.

Nonlinear chlorinated solvent sorption and its impact on remediation in surficial sedimentary aquifers

R.M. ALLEN-KING[1]*, Z.W. MUNGER[1], D. CARLONE[1], I. KALINOVICH[1], J.A. SALVADÓ[1], A.J. RABIDEAU[2], L.S. MATOTT[2], A. SINGH[2] AND D. LAMBERT[2]

[1]*correspondance: richelle@buffalo.edu

[3]Dept. of Civil, Structural, and Environmental Engineering, University at Buffalo, SUNY

Contaminants stored in aquifer regions accessible only by diffusion produce 'tailing' in response to remediation wherein a rapid initial mass and/or concentration reduction is followed by sustained release at a low rate (or concentration). Our project combines laboratory experiments to parameterizing nonlinear sorption and intragranular diffusion with field scale simulations to explore the importance of contaminant sorption on tailing in surficial sedimentary aquifers.

The project examines chlorinated solvent behavior using trichloroethene (TCE) as our probe compound. The samples selected for study are kerogen-containing marine sedimentary rocks representative of the source rocks for surficial glacial aquifers in our region (southern Ontario, Canada and New York, USA). The equilibrium sorption isotherms collected spanned nearly five orders of magnitude in aqueous concentration. All samples showed nonlinear behavior with Freundlich isotherm slopes less than unity. Of the 11 candidate models common in the literature fit to the isotherm data, the dual-mode Polanyi-partition was the only model ranked as plausible for all of the samples via the corrected Akaike Information Criterion. We find that the best fit parameter sets for the three samples taken from a stratigraphic sequence in Ontario are consistent (within a factor of three) when the partitioning and sorption capacity parameters are normalized by the fraction organic carbon content. This finding is consistent with prior reports that document greater isotherm nonlinearity for more condensed carbonaceous matter.

Ongoing experiments are documenting TCE uptake and release rates to granular samples that are modeled as intragranular diffusion retarded by nonlinear sorption. Projection to plume scale transport and remediation through simulation shows that the influence of nonlinear sorption and/or pore diffusion is variable and sensitive to the combination of aquifer material (sorption characteristics and particle size) and plume history (age).

A record of carbonyl sulfide from Antarctic ice over the last 1000 years

SAMUEL J. ALLIN[1] , WILLIAM T. STURGES[1], JOHANNES LAUBE[1], DAVID ETHERIDGE[2], MAURO RUBINO[2], CATHY TRUDINGER[2], MARK CURRAN[3], ANDREW SMITH[4] AND ROBERT MULVANEY[5]

[3]Australian Antarctic Division and Antarctic Climate & Ecosystems Cooperative Research Centre, AustraliaS,
[4]Institute for Environmental Research, Australian Nuclear Science and Technology Organisation, Australia
[5]British Antarctic Survey, National Environment Research Council, Cambridge, UK

Carbonyl sulfide (COS) is a trace gas, present in the troposphere, and also in the stratosphere, where it contributes to the stratospheric sulfate aerosol layer. It has both natural and anthropogenic sources. Natural processes include uptake by plants, while oceans, wetlands, volcanism and biomass burning all contribute to natural COS emissions.

We have measured COS in Antarctic ice cores from Dronning Maud Land, drilled in 1998, the DE08 core drilled at Law Dome in 1987, and the DSS0506 core drilled in 2006. Ice samples with COS gas ages between about 1050 AD and the early 20th centrury have been examined. A large volume ice crusher at the CSIRO Marine and Atmospheric Research laboratory was used to extract air from bubbles occluded in the ice cores. These air samples were analysed for CO_2, CH_4, CO and $^{13}CO_2$ at CSIRO, and then for COS and several halocarbons at the University of East Anglia on a high sensitivity gas chromatograph/tri-sector mass spectrometer system.

Initial results indicate that good sample integrity can be achieved. Measurements from the DML samples indicate low and uniform abundances across the last few hundred years, and at concentrations significantly below those in the modern-day atmosphere. Measurements in more recent ice from DE08 show the start of increasing concentrations in the early 1900s, confirming earlier evidence that the global atmospheric abundance of COS has increased as a result of industrial activity during the 20th century.

Enhanced subsidence and sediment dynamics in Galveston Bay- Implications for geochemical processes and fate and transport of contaminants

M.E. ALMUKAIMI[1]* AND T.M. DELLAPENNA[1]

[1]Texas A and M University at Galveston., Galveston, TX 77554, USA (*correspondence: malmukaimi@tamu.edu; dellapet@tamug.edu)

Galveston Bay is the second largest estuary in the Gulf of Mexico. The bay's watershed and shoreline contains one of the largest concentrations of petroleum and chemical industries in the world, with the greatest concentration within the lower 15 km of the San Jacinto River/Houston Ship Channel (SJR/HSC) [1]. Extensive groundwater withdraw to support these industries and an expanding population has resulted elevated subsidence, with the highest subsidence in lower SJR/HSC, of over 3 m (3 cm yr^{-1}) and has decreased seaward throughout the bay to 0.6 cm yr^{-1} near Galveston Island [2]. Mercury (Hg) contamination is well documented throughout the bay sediments [1, 3]. Sediment vibra-cores were collected throughout the bay systems. ^{210}Pb and ^{137}Cs geochronologies from these cores were used to determine sedimentation rates and correlated to Hg profiles to estimate input histories. The results shows sedimentation rates of 4 cm yr^{-1} in areas with subsidence of comparable rates, indicating that sedimentation kept pace with subsidence. Moreover, Hg core profiles correlated with radioisotope geochronologies and show significant input of Hg beginning around 1940, with a peak around 1971, and a dramatic drop off in concentration afterwards, demonstrating it to be a valuable geochronology tool. In addition, Hg concentrations were found to be dramatically higher proximal to the SJR/HSC and progressively decreasing seaward and to distal parts of the bay.

Deep geothermal reservoir analysis in the Upper Rhine Graben using a geochemical and isotopical multi-tracer method - first results

S. AL NAJEM[1]*, F. FREUNDT[2], M. ISENBECK-SCHRÖTER[1], AND W. AESCHBACH-HERTIG[2]

[1]Institute of Earth Sciences, Heidelberg University, INF 236, 69120 Heidelberg, Germany (*correspondence: Sami.AlNajem@geow.uni-heidelberg.de)
[2]Institute of Environmental Physics, Heidelberg University, INF 229, 69210 Heidelberg, Germany

It is state of the art in geothermal exploration to use various geophysical methods (eg. 3D-seismic), which are rather expensive. This work presents the first results of a new characterization of a hydrogeochemical reservoir in the Upper Rhine Graben with a combination of methods from hydrogeochemistry and isotope hydrology in near surface groundwater. For this purpose natural geochemical tracers as well as rare earth elements, $^3He/^4He$ ratios, and radiogenic isotopes (Sr, Nd, Pb) are investigated in the northern Upper Rhine Graben, close to Groß-Gerau, Germany.

Geochemical analysis show three different types of fluids and various mixtures. $CaHCO_3$-dominated waters represent quaternary aquifer conditions whereas $MgSO_4$-dominated waters have a tertiary origin. Higher saline NaCl-dominated waters show an impact of mantle fluids revealed by $^3He/^4He$ isotope analysis [1]. The ratio is highest where the main fault of the northern Upper Rhine Graben crosses the Rhine river. This suggests that the fault is hydraulically active and connects deep fluids with the shallow aquifer.

Further investigations of rare earth element patterns as well as radiogenic isotopes (Sr, Nd and Pb) identify the origin, the ascent as well as the retention time of the deep fluids more precisely [2]. Water-rock interactions and mixtures of different fluids in the reservoir and during the ascent are estimated and simulated using geochemical and hydraulic models. Thus, the geometry of the aquifer, the temperature and the quantity of the ascending deep fluid in the reservoir is estimated.

The region was chosen to test the multi-tracer method due to its well-studied geology and the marked saltwater anomaly. The aim is to identify the most useful tracers of deep geothermal fluid circulation, which consecutively can be applied to other regions with less prior information.

Se(IV) uptake by Äspö diorite: Micro-scale distribution

URSULA ALONSO[1] , TIZIANA MISSANA[1], ALESSANDRO PATELLI[2], DANIELE CECCATO[3], MIGUEL GARCÍA-GUTIÉRREZ[1] AND VALENTINO RIGATO[3]

[1]CIEMAT, Avda. Complutense 40, 28040 Madrid, Spain
[2]CIVEN, Via delle Industrie 9, 30175 Marghera, Italy
[3]INFN-LNL Viale dell' Università 2, 35020 Legnaro-Padova, Italy

Selenium is one of the radionuclides with major contribution to the total radiation dose in nuclear waste geological repositories. The performance assessment of a repository demands sound retention data sets with minimised uncertainties, for all the material composing the natural and engineered barriers. The high heterogeneity of crystalline rock necessarily contributes to the high uncertainties on sorption parameters. Furthermore, Se is a redox sensitive element, with a complex geochemical speciation, for which to maintain controlled redox conditions during the whole experiment is particularly relevant.

In this study, Se(IV) sorption onto diorite samples from the Äspö underground research laboratory was studied by micro-Particle Induced X-ray Emission (μPIXE). Äspö diorite samples were extracted, handled and transported under anoxic conditions. Sorption experiments were carried out in Äspö groundwater (pH 7.9 and EC = 13.36 mS/cm), both under oxic and anoxic conditions, for comparison.

Selenite distribution on Äspö diorite surface was heterogeneous both under oxic and anoxic conditions, being higher its retention under anoxic conditions. The main retentive minerals were identified and surface distribution coefficients (Ka) were determined on main diorite minerals. Sorption values ranged from zero, on quartz or K-feldspars, to higher values in Fe-bearing minerals (Ka ~ $7 \cdot 10^{-5}$ m) under anoxic conditions.

Average surface distribution coefficients could be determined accounting for the mineral occurrence (%) of diorite samples and the obtained values were compared to the bulk distribution coefficients (Kd) determined on same samples by batch experiments (Se-Kd (oxic) ~ 2 mL/g and Se-Kd (anoxic) ~ 8 mL/g).

Acknowledgments: This study has received funding from EU Seventh Framework Programme (FP7/2007-2011) under the grant agreements Nº 269658 (CROCK, Crystalline Rock Retention processes and Nº 2620109 (ENSAR, European Nuclear Science and Applications Research).

Reactivity of acid gases in gas-brine-mineral systems

T. ALPERMANN[1]* AND C. OSTERTAG-HENNNING[1]

[1]Federal Institute for Geosciences and Natural Resources, Stilleweg 2, 30655 Hannover, Germany (*correspondence: Theodor.Alpermann@bgr.de)

Acid gases like CO_2 and H_2S may constitute a substantial fraction of the raw natural gas in sour gas fields, large gas fields in e.g. Kazakstan and China exhibit H_2S contents of more than 10 %. Because of its toxicity, H_2S requires a proper waste management which is usually assured by a *Claus*-type sulfur plant producing elemental sulfur from H_2S. However, selling problems of produced sulfur on the world market and costly procedures due to governmental allowance of low SO_2 emissions by sulfur plants provoke economic challenges for sour gas production. The ever increasing global production of sour gas thus raised the question of other disposal options than *Claus* plants for H_2S and acid gas mixtures.

The geologic storage of acid gases in deep strata is one alternative disposal option with potentially economic advantages. Therefore, the injection of CO_2/H_2S mixtures of diverse composition has been practiced in Canada since 1989 [1]. Surface monitoring of the injection sites did not reveal any leakage, yet, but possibly occurring subsurface processes related to acid gas injection have been scarcely investigated.

To gain insight into potential geochemical reactions within the injection horizon, experiments were conducted which investigate the interaction of acid gases, brines and different types of minerals under the anticipated storage conditions. The experiments were carried out in sealed gold capsules which were first loaded with a mineral and brine followed by the application of CO_2 or CO_2/H_2S by a specifically manufactured gas-loading device [2]. After the treatment of the reaction matrices at 120°C and 120 bar, the obtained product mixtures were analyzed by means of headspace GC-TCD/FID/SCD for CO_2, hydrocarbon and sulfur gases. In addition, the fluids and solids have been analysed by ICP-OES and a variety of microscopic methods.

The results of the experiments will contribute to a more detailed understanding of geochemical processes connected to the geologic storage of acid gases that may affect the integrity of the reservoir rock and the cap rock.

Geochemical Exploration for Platinum-Group Elements in Mafic/Ultramafic Complexes from the Arabian Shield

AL-SALEH AND AHMAD MUHAMMAD

Geology and geophysics Department, King Saud University, Riyadh, Saudi Arabia

The Arabian Shield, which occupies most of the western half of the Arabian Peninsula, has been the target of extensive exploration activities for the past four decades. So far no platinum occurrences have been documented, and the relatively high PGE values reported for certain areas are associated with uneconomic chromite and Cu-Ni deposits. This project was launched as a reconnaissance program intended for the assessment of the PGE potential of some of the more promising mafic/ultramafic complexes in the Arabian Shield, with more detailed follow-up work to be undertaken at a later stage if significant anomalies were identified. Alaskan-type complexes are considered highly prospective for PGE, and a number of these were selected for preliminary soil surveys and lithogeochemistry. No anomalous values for Pt, Pd or their pathfinders were detected from the heavy mineral concentrates, and any associated Cu mineralization correlates poorly with the compatible elements thus indicating a hydrothermal origin. The very high Cu/Pd ratios from rock samples devoid of copper mineralization suggests that separation of a sulphide liquid had occurred and that PGE were largely scavenged from the magma reservoir prior to emplacement. If true, this would render these Complexes unlikely hosts for PGE mineralization.An unexpected result was the extremely low concentrations of PGE in the stream sediments of layered complexes in comparison with those from massive, gabbroic sub-volcanic plutons; on average, a sub-volcanic intrusion would have a soil content of Pt ranging from 0.5 to 3 ppb, whereas sediments derived from layered complexes would typically return values of no more than 0.1 ppb for both Pt and Pd. However, the Wadi Kamal layered complex is an exception since it contains well-known horizons of Ni-Cu mineralization overlain by conspicuous gossans; the PGE values from soil and rock samples obtained so far were highly erratic and the overall PGE potential of this complex awaits further work in the next stage of the project. An interesting discovery was made at the pyroxenite body of Wadi Amarah where well-developed soil anomalies (60-75 ppb combined Pt & Pd) are encountered at the outer contacts of this intrusion; follow-up work is planned to locate the source of these anomalies.

Numerical simulation of fluid–rock interaction upon CO_2 injection into a carbonate-hosted saline aquifer

PETER ALT-EPPING[1] AND LARRYN W. DIAMOND[2]

Rock–Water Interaction, Institute of Geological Sciences, University of Bern, Switzerland (*correspondence: alt-epping@geo.unibe.ch)

We run reactive transport simulations to understand the transient chemical processes that occur in a carbonate-dominated aquifer during and after the injection of CO_2. The model, its design and its initial and bounding physico-chemical conditions, are patterned after the Upper Muschelkalk-Gipskeuper aquifer-seal pair in the Molasse Basin in Northern Switzerland. Porosity and permeability measurements on samples from the Muschelkalk indicate a strong correlation. Both the porosity and permeability distribution reflect natural hetergeneity related to the sedimentary, diagenetic and tectonic history of the aquifer. The heterogeneous permeability structure of the aquifer controls the dynamics and the shape of the CO_2 plume and thus affects the efficiency of residual and solubility trapping. The dissolution of CO_2 into the brine entails a lowering of the *pH* and hence the dissolution of the primary carbonate mineralogy. Because the brine remains at local equilibrium with the carbonates, the dynamics of the CO_2 plume and the CO_2-enriched brine is reflected by the mineral alteration pattern. Although the drop in *pH* is associated with carbonate dissolution, the *pH* recovers in certain regions of the aquifer faster than in others, thus leading to a complex pattern of carbonate dissolution and reprecipitation. This evolving pattern of carbonate dissolution/reprecipitation implies that chemical constituents that are initially incorporated in or that coexist with primary carbonate minerals may be released into the fluid, then later removed from the fluid by reprecipitation when conditions have changed.

Mass balance calculations suggest that CO_2 injection into a carbonate rock releases additional CO_2 due to mineral dissolution. Thus trapping of CO_2 in a carbonate aquifer requires that the seal remains tight over long periods of time. The increase in reservoir pressure during injection, the dynamics of the CO_2 plume and the perturbation of chemical conditions in the reservoir will initiate mass transfer across the aquifer-seal interface and initiate chemical reactions on either side of the interface. We explore the extent of species mobilization and transfer across the reservoir/seal interface, identify the type of reactions that occur as well as their implications for the tightness of the caprock.

Organic facies variation from well data on the bituminous Miocene units, Northwesthern Anatolia (Sevinç/Ağapınar-Eskişehir), Turkey

MEHMET ALTUNSOY[1]*, ILKER ŞENGÜLER[2], NESLIHAN ÜNAL[1], SELIN HÖKEREK[1] AND ORHAN ÖZÇELIK[1]

[1]Department of Geological Engineering, Akdeniz University, 07058 Antalya, Turkey (*correspondence: altunsoy@akdeniz.edu.tr); (oozcelik@akdeniz.edu.tr; nunal@akdeniz.edu.tr; selinhokerek@akdeniz.edu.tr)

[2]General Directorate of Mineral Research and Exploration, 06800 Ankara, Turkey (ılkersenguler@gmail.com)

In the region, the Miocene units consist of conglomerate, sandstone, claystone, coal, marl, siltstone, bituminous shale and limestone. Some 60 samples of bituminous units from the Miocene succession were collected from ES-07 well, in the north-westhern part of Turkey (Sevinç/Ağapınar-Eskişehir). 24 core samples were screened for total organic carbon (TOC) content. Selected samples were than analyzed by Rock-Eval pyrolysis. Visual kerogen analysis and vitrinite reflectance measurements were also undertaken. Detailed data from bituminous Miocene sediments made it possible to construct an organic facies framework using different zonations.Organic facies type B, C, CD and D were identified in the investigated units. Alteration colors of organic materials are yellow and dark yellow. Spore colors of these samples are yellow and dark yellow (SCI:2-3.5). Organic facies B is related to bituminous shale lithofacies. This facies is characterized by average values of HI around 509 (equivalent to type II Kerogene), TOC around 7.77%, and an average of S2 of 40.81 mg HC/g of rock. This facies is laminated and well bedded, and usually contains a higher persentage of terrestrial residual organic matter. Organic facies C is related to marl, coaly marl and coal lithofacies. This facies is composed of organic matter with average values HI around 153 (equivalent to Type II/III Kerogene), TOC around 28.05 and S2 between 3.97 and 83.77 mg HC/g sample. Organic facies C is the “gas-prone” facies. The organic matter is dominated by terrestrial debris in various stages of oxidization. Most coals are organic facies C. The organic facies CD is related to the coaly marl, marl and shale lithofacies. This facies is characterized by average values of HI around 73 (equivalent to Type III Kerogene), TOC around 13.10%, and an average of S2 of 13.97 mg HC/g of rock. An organic facies D, associated with marl, sandy marl, coaly marl and limestone lithofacies, displays values of HI around 163 (equivalent to Type III Kerogene) and TOC around 2.94%. S2 varies between 0.01 and 5.53 mg HC/g of rock.

Source and sinks of iodine in the hyperarid Atacama Desert of northern Chile

F. ALVAREZ[1]*[,2], A. PEREZ[1,2], G.T. SNYDER[3], G. VARGAS[1,2], Y. MURAMATSU[4] AND M. REICH[1,2]

[1]Department of Geology, University of Chile, Santiago, Chile (*correspondence: fernanda.alvarez.a@gmail.com)
[2]Andean Geothermal Center of Excellence (CEGA)
[3]Department of Earth Science, Rice University, Houston, TX, USA [4]Chemical Department, Gakushuin University, Tokyo, Japan

Iodine is a strongly biophilic element. and its global distribution is dominated by marine sediments. In continental settings, the occurrence of iodine minerals is restricted to hyper-arid environments. The Earth's largest iodine crustal anomaly is hosted in the Atacama Desert where the occurrence of iodine minerals is constrained to the nitrate-iodine deposits located along the eastern side of the Coastal Cordillera, and the supergene zones of copper deposits in the Central Depression and Precordillera.

The iodine ocurrence, source and mechanism(s) of enrichment in this region have been scarcely studied. In this work, we present iodine concentrations and isotopic ratios (^{129}I/I) of the nitrate deposits, supergene copper ores, marine sedimentary rocks, geothermal fluids, groundwater and meteoric water of the Atacama Desert.

Iodine is highly enriched in the nitrate deposits, with a mean concentration of ~700 ppm. These anomalous values are followed by soil samples above supergene copper deposits, and Mesozoic shales and limestones averaging ~50 ppm. Regarding the aqueous reservoirs the highest concentrations were measured in groundwater below nitrate deposits (3.5-10 ppm) and in geothermal fluids (1-3 ppm). In nitrate ores, the calculated ^{129}I/I ratios range from ~300 to ~400x10^{-15}. Supergene iodine minerals in copper deposits present values between 200 and 550x10^{-15} and ratios obtained from marine rocks vary from 300 to 400x10^{-15}. Isotopic ratios of groundwater below nitrate deposits is ~200x10^{-15}.

Results show a strong iodine enrichment in Atacama reservoirs compared to average crustal values. Three essential processes are required to reach such concentrations: (1) the presence of an enriched iodine source, (2) the removal of iodine by fluids from the source to the surficial reservoirs, and (3) the accumulation and preservation of iodine in these reservoirs. Isotopic ratios in nitrates and supergene iodine minerals are in agreement with previously reported ^{129}I/I ratios in crustal fluids derived from organic material (200-400x10^{-15}). Mesozoic shales are the most probable source for iodine because of the similar ^{129}I/I ratios with rock reservoirs, high organic content and regional occurence.

Origin of felsic microgranular enclaves from Salto Pluton, SE, Brazil

ADRIANA ALVES, VALDECIR DE ASSIS JANASI AND GIOVANA PEREIRA

Instituto de Geociências, Universidade de São Paulo

The 590 Ma Salto Granite Pluton, part of the post-orogenic Itu Rapakivi Province (590-580 Ma), SE Brazil, is mainly composed of coarse-grained hornblende-biotite red granite. This main unit was invaded by a body of zoned rapakivi granite which varies from a porphyritic facies dominated by fine-grained matrix (porphyry granite) to a cumulate granite in the eastern deeper portions. Abundant felsic microgranular enclaves (fme) with ellipsoidal shape and dimensions up to 4 m occur within both the red granite and the rapakivi granite, and are interpreted as products of a recharge event of the chamber by a hotter comparetively more mafic magma.

The fme are modally and chemically similar to their host granites. However, they show a slightly more primitive character with SiO_2 contents of ~ 70% against 72-75% observed for the granites and higher Fe, Mg, Ti and Ca contents. These evidences suggest that the enclaves might represent thoroughly hybridized liquids similar to those that gave origin to the porphyry granites. The hypothesis is also supported by the fact that enclave increase in number and size towards the porphyry unit.

Xenocrysts in textural disequilibrium show LREE patterns different from those observed for the whole rock samples. In general, there is a significant superiority in La/Sm_N ratios and liquids calculated to be in equilibrium with such xenocrysts represent more mafic magmas, depleted in such elements.

A similar scenario is suggested for Ba and Sr contents of liquids. It is noteworthy that analyzed crystals from the porphyry unit also show indicatives of a pre-crystallization story in more mafic liquids. However, the modeled liquids show normalized profiles that are parallel to those of their whole rocks, suggesting that the granite magma was the significantly superior in volume compared to the more mafic endmember.

A MELTS model was designed for the investigation of the origin of the abundant rapakivi texture observed in xenocrysts whitin the fme. The predicted amount of LREE expected to be found in plagioclase rims are considerably superior to the observed values, suggesting that the rapakivi texture was probably developed in the more mafic magma, therefore in a stage previous to the thorough hybridization of the mafic and the felsic endmenbers.

Arsenic dissolution from Japanese paddy soil by a dissimilatory arsenate-reducing bacterium *Geobacter* sp. OR-1

S. AMACHI[1]*, D. T. DONG[1] AND N. YAMAGUCHI[2]

[1]Chiba Univ., 648 Matsudo, Matsudo-shi, Chiba 271-8510, Japan (*corespondence: amachi@faculty.chiba-u.jp)
[2]National Institute for Agro-Environmental Sciences, 3-1-3, Kan-nondai, Tsukuba, Ibaraki 305-8505, Japan (nyamag@affrc.go.jp)

Dissimilatory As(V) (arsenate)-reducing bacteria may play an important role in arsenic release from anoxic sediments in the form of As(III) (arsenite). Although respiratory arsenate reductase genes (*arrA*) closely related with *Geobacter* species have been frequently detected in arsenic-rich sediments, it is still unclear whether they directly participate in arsenic release, mainly due to lack of pure cultures capable of arsenate reduction. In this study, we isolated a novel dissimilatory arsenate-reducing bacterium, strain OR-1, from Japanese paddy soil, and found that it was phylogenetically closely related with *Geobacter pelophilus*. OR-1 also utilized soluble Fe(III), ferrihydrite, nitrate, and fumarate as electron acceptors. OR-1 catalyzed dissolution of arsenic from arsenate-adsorbed ferrihydrite, while *Geobacter metallireducens* GS-15 did not. Furthermore, inoculation of washed cells of OR-1 into sterilized paddy soil successfully restored arsenic release. Arsenic K-edge X-ray absorption near-edge structure (XANES) analysis revealed that strain OR-1 reduced arsenate directly on the soil solid phase. Analysis of putative ArrA sequences from paddy soils suggested that *Geobacter*-related bacteria, including those closely related to OR-1, play an important role in arsenic release from paddy soils. Our results provide direct evidence for arsenic dissolution by *Geobacter* species, and support the hypothesis that *Geobacter* species play a significant role in reduction and mobilization of arsenic in flooded soils and anoxic sediments.

The lost city hydrothermal field: A geochemical analog for Nili Fossae, Mars

ELENA S. AMADOR[1]*, JOSHUA L. BANDFIELD[1], DEBORAH S. KELLEY[2] AND WILLIAM J. BRAZELTON[2]

[1]Earth and Space Sciences Dept., University of Washington (*correspondence: esamador@uw.edu)
[2]School of Oceanography, University of Washington

Nili Fossae, Mars contains a mineralogical suite similar to that found at the Lost City Hydrothermal Field (LC) off the mid-Atlantic ridge. The LC is a zone of active serpentinization where the interaction of seawater with the underlying mafic and ultramafic bedrock drives geochemical reactions producing serpentine, brucite, magnetite, and the release of high pH fluids enriched in H_2 and CH_4 [1]. Dense microbial communities subsequently use the abiotically produced H_2 and CH_4 as an energy source to drive metabolisms such as methanogenesis [e.g. 1].

We have acquired fifteen variably altered gabbros, serpentinites, talc-rich fault rocks and carbonates from the LC and characterized their mineralogical variability and spectroscopic characteristics in the thermal infrared and visible/near-infrared (VNIR). These results have been placed into geochemical and astrobiological context with respect to the mineralogically similar units found in Nili Fossae, Mars.

The mineralogy of LC rock samples were determined by measuring their thermal emission spectra. VNIR reflectance measurements were made to determine the spectral characteristics of mineral phases present in order to compare with similar data collected for Mars.

Data from the CRISM VNIR imaging spectrometer orbiting Mars has shown the presence of serpentine, Mg-carbonates, talc and/or saponite within an olivine-rich basaltic unit in Nili Fossae [2-5]. The comparison of VNIR spectral characteristics of the LC samples to the surfaces found in Nili Fossae has shown that the two field sites have similar mineralogical suites.

Mineralogy provides an indication of the geochemical conditions present during the time of mineral formation, and prior studies at LC have shown that the geochemical conditions associated with serpentinization-associated reactions are amenable to the growth of microbial communities. Given that the mineralogy at Nili Fossae, Mars is similar to that at LC, it is possible that similar geochemical conditions, and therefore energy sources for microbial metabolisms, may have been present in Nili Fossae early in Mars' history.

He and Ar diffusivity in basaltic glasses and melts

JULIEN AMALBERTI[1]*, PETE BURNARD[1] AND DIDIER LAPORTE[2]

[1]CRPG-CNRS, Vandoeuvre-lès-nancy, France, (amalbert@crpg.cnrs-nancy.fr)
[2]MV, Clermont Ferrand, France

Recent models of the relative and absolute noble gases abundance in oceanic basalts have proposed that degassing has occurred out of equilibrium [1-2]. In order to constrain the lack of noble gas diffusion data at magmatic conditions, we measured He and Ar diffusivities in silicate liquids and glasses by inducing diffusion profiles at high temperatures (up to 1550°C), and using classical vacuo stepped heating experiment.

We observe (Fig 1) that He and Ar diffusivities converge at high temperature, as do the Ar isotope diffusivities, such that their diffusivities are equal at T> 750 C, consistent with diffusion compensation.

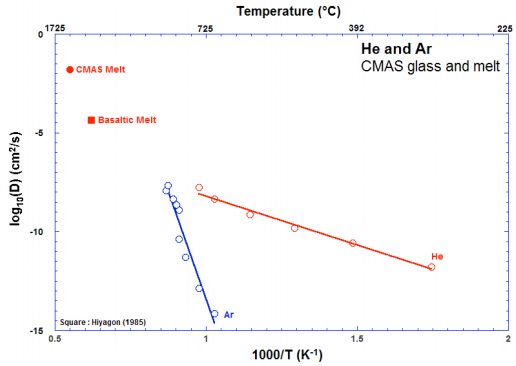

Figure 1: Blue: Ar in glass; Red: He in glass (line) and liquids (circle and square).

Our data suggest that even if disequilibrium degassing occurs during magmatic volatile loss (as suggested from other tracers [3]), this will not significantly fractionate relative noble gas abundances due to similar He and Ar diffusivities at magmatic conditions.

Studies of Air Quality Index of industrial area of Jamshedpur, East India

BALRAM AMBADE

Department of Chemistry, National Institute of Technology, Jamshedpur-831014, Jharkhand, India; (bambade.chem@nitjsr.ac.in)

Air pollution is a major environmental concern in many cities around the world. The major causes of air pollution include rapid industrialization/urbanization and increased none environmentally friendly energy production. The purpose of this paper to highlight the ambient air samples were collected between Jan 2000 to June 2011 in the urban-industrial area of Jamshedpur city, by the high volume sampler, quality of air were monitored. The particulate matter (PM_{10} & $PM_{2.5}$), Sulphur dioxide (SO_2), Nitrogen oxide (NO_x), Ozone (O_3), Suspended particulate matters (SPM) and Mercury (Hg) which give a fair idea of pollution load carried by the air. The monitoring data were collected from two sites randomly selected in Jamshedpur city. The Air Quality Index (AQI) of PM_{10} & $PM_{2.5}$ concentration was found to be moderate, alike results are found in gases like SO_2, NOx and O_3 concentrations were discussed.

Keywords: Urban-industrial area, High volume sampler, Ambient air, Air Quality Index

Performance of Pb Multi Ion Counting array in Triton Plus TIMS

YURI AMELIN AND MAGDALENA HUYSKENS

Research School of Earth Sciences, Australian National University,
(yuri.amelin@anu.edu.au, magda.huyskens@anu.edu.au)

In analysis of picogram quantities of Pb using a single ion counting multiplier, as commonly used in U-Pb dating, precision is limited by the number of Pb atoms of each isotope registered by the multiplier during an analysis. Using an array of ion counters offers substantial increase in the total counts for each isotope and hence potentially better precision.

Here we report performance of an array of five ion counting multipliers: three regular SEMs and two compact discrete-dynode multipliers (CDDs), spaced for simultaneous measurement of Pb isotopes (**Table 1**, below), which is the configuration of the ANU Triton Plus.

	L5 (Plus block)				L4	Dispersion
	IC4	IC3	IC2	IC1	IC5	quadrupole
Step	CDD	SEM	SEM	SEM	CDD	(Volts)
1	205	206	207	208	(209)	-2
2	204	205	206	207	208	0
3	(203)	204	205	206	207	+7
4	202	(203)	204	205	206	+9
5	201	202	(203)	204	205	+16

Cross-calibration by sequential measurements of a single stable ion beam, followed by data acquisition in static mode, relies on the stability of relative yields of the multipliers. In our system, the ratios of multiplier yields drift by 0.05-0.1% per hour (after initial 2-hour settling). This method is thus applicable only to measurements requiring 0.05-0.1% uncertainty, and is impractical if higher precision is required.

An alternative way of using the multiplier array is to treat each channel as an individual detector, and pool the measured isotopic ratios. This approach does not depend on the multiplier yield stability, and can potentially produce precise and accurate results. However, it requires changing the dispersion quadrupole settings between the mass steps (Table 1) to keep the peaks aligned, and to circumvent the effects of imperfect peak flats that are common for CDDs. Our tests have shown that setting the dispersion quadrupole to ±10V changes the signal SEM yields by 0.1-0.3%, and to ±20V by up to 1.2%. No similar effect is observed for Faraday cups.

Our tests indicate that the Pb Multi Ion Counting array in its present form is adequate for measurements at 0.05-0.1% level of precision and accuracy. Achieving a precision level of 0.01-0.02% as required by modern U-Pb geochronology would require either radical improvement in the multiplier yield stability, or a more thorough understanding of the interplay between the zoom optics and the multipliers.

Vulnerability and resilience of soil organic matter to environmental change

WULF AMELUNG[1,2], MICHAEL HERBST[2], ALEXANDRA SANDHAGE-HOFMANN[1], NELE MEYER[1] AND HARRY VEREECKEN[2]

[1]Institute of Crop Science and Resource Conservation, Soil Science and Soil Ecology, University of Bonn, Nussallee 13, 53115 Bonn

[2]Agrosphere Institute (IBG-3), Forschungszentrum Jülich GmbH, 54225 Jülich

Soil organic carbon is one of the largest carbon pools on Earth. Huge amounts of soil C were lost, when soil was converted to cropland in the 18th and 19th Century. However, there is evidence that since the 1950, there is again an increase in carbon storage in the terrestrial biota, with still unclear relations to the contents of soil organic matter (SOM). Yet, different mechanisms contribute to losses and re-accrual of SOM after disturbance.

We will present and discuss some recent knowledge, compiled with own research, on the differential response of SOM to changes in climate, land use and soil attributes across different temporal and spatial scales. We surmise short-term heterotrophic respiration processes to provide a first indication on the vulnerability of soils to environmental change, with different sensitivity of SOM stocks against, e.g., climate induced changes in soil temperature, water content and soil properties. In the medium-term, these processes are increasingly linked to changes in soil structure and material translocations, whereas in the long-term decoupling processes to other element cycles and between surface soil and subsoil appear to contribute to an impaired resilience of soils and their organic matter to environmental change. The degree at which these processes re-couple to climate, management and socio-economy turn future projections into a challenging task. The examples will focus on agricultural systems from temperate and subtropical climates.

High-grade sperrylite zone reveals primitive source in the Sudbury impact structure

DOREEN E. AMES[1], JACOB J. HANLEY[2], GYÖRGYI TUBA[1] AND SIMON JACKSON[1]

[1]Geological Survey of Canada, Ottawa (dames@nrcan.gc.ca)
[2]Saint Mary's University (jacob.hanley@smu.ca)

Earth's largest impact craters had transient craters that penetrated 30-40 km depth and collapsed to form ~200 km impact craters with perturbations of the Moho [1]. The Sudbury impact structure is the eroded remnant of a larger 150-200 km multi-ring crater and uniquely revealing at present-day surface the crustal impact structures in the crater floor below the igneous complex [2].

The Paleoproterozoic Broken Hammer Cu-Ni-PGE deposit, is hosted by impact-induced pseudotachylitic breccias in the crater floor within Neoarchean gneiss and granites. A high-grade PGE-only zone is composed of major coarse epidote-quartz, minor chlorite-sperrylite-merenskyite, with sperrylite crystals up to 4 mm, and trace michenerite. Isolated sperrylite grains in epidote or quartz contain inclusions of gold, petzite, galena and aleskite, whereas complex intergrowths of Pd-, Bi- and Ag-tellurides are associated with specular hematite and cassiterite, suggesting high fO2 conditions. *in situ* trace element analyses of euhedral epidote and chlorite precipitated along growth zones in hydrothermal quartz reveal increasing Mg, Zn, Fe and Ni towards the rims. Late-stage Cpy-millerite penetrates the core of extensional epidote-quartz-sperrylite veins.

Early formed epidote that hosts coarse sperrylite analyzed by TIMS yielded a narrow range of low age corrected $^{86}Sr/^{86}Sr$ ratios from 0.705948 to 0.706457 with a primitive non-radiogenic source supporting a mantle origin [3,4]. This implies that initial impact destabilized the crust-mantle boundary resulting in rapid fluid-gas release and transport of precious metals from the mantle along deep-seated faults to the footwall environment of the SIC.

In situ LA-MC-ICP-MS Sr isotope analysis of epidote and calcite in early syn-PGE ore, later Ni-Cu and Cu-PGE vein ores and post-mineralization phases will be used to trace the evolution of fluids in the Sudbury crater.

Trace elements in olivine characterize the mantle source of subduction-related potassic magmas

E. AMMANNATI*[1,2], S. F. FOLEY[2,3] , R. AVANZINELLI[1], D.E. JACOB[2,3] AND S. CONTICELLI[1]

[1]Dipartimento di Scienze della Terra, Università di Firenze, Italy (* correspondence: edoammo@gmail.com)
[2]Institut für Geowissenschaften, Johannes Gutenberg-Universität Mainz, Germany.
[3]CCFS, Dept. Earth and Planetary Sciences, Macquarie University, North Ryde, NSW 2109, Australia.

Trace elements in olivine have recently been shown to provide useful means to investigate the upper mantle, allowing identification of olivine-free (pyroxenitic) reservoirs in the source of OIBs [1]. But few studies are available of magmatic rocks at destructive plate margins [2]. Here we present the first comprehensive set of major and trace element analyses on olivine from subduction-related Plio-Quaternary magmatism of the Italian Peninsula.

16 rock samples covering the full compositional range from calc-alkaline to ultrapotassic occurring within the Italian magmatic region were selected for their primitive character (Mg# = 60-80) and the presence of olivine at the liquidus. 200 olivine crystals were analyzed for major and trace elements (Ca, Mn, Ni) using EPMA, and more than 100 have been analyzed for trace elements using LA ICP-MS.

Olivine phenocryst cores show a large compositional variability among the different magmatic suites. Olivine from the Lucanian region has the highest Na and Al, whereas most elements have lower concentrations compared to the other Italian regions and fall within typical mantle values. The olivine crystals from the lamproite-like samples (Tuscan Region) bear evidence of an olivine-depleted, pyroxenite-bearing source resulting from Si- and K-rich metasomatism of previously depleted mantle: the olivine crystals are remarkably enriched in Ni (up to 5,000 ppm) with high Cr and low Mn and Ca contents. Olivines from plagio-leucititic rocks of the Roman Region show trace element contents that differ from those of the lamproite-shoshonite suite (extremely low Ni, low Cr and elevated Mn and Ca). This could be explained by a metasomatic reaction in the presence of excess Ca. Li enrichment (up to tens of ppm) in olivine from the Tuscan and the Roman Province indicate the recycling of crustal material into the mantle wedge as a primary cause of the metasomatism [2].

Mineral transformations and bacterial diversity in As-rich waste dumps

F. Y. AMOAKO[1]*, J. MAJZLAN[1] AND E. KOTHE[2]

[1]Friedrich-Schiller-University, Institute of Earth Science, Jena, Germany
(*correspondence: Felix-Yebo.Amoako@uni-jena.de)
(Juraj.Majzlan@uni-jena.de)

[2]Friedrich-Schiller-University, Institute of Microbiology-Microbial Phytopathology, Jena, Germany
(Erika.Kothe@uni-jena.de)

Weathering and mineral transformation of sulphidic waste genenerate Fe-rich secondary phases which retain metals and metalloids in metastable, nano-crystalline, or amorphous phases. Since fate and chemical stability of the pollutants are important factors for their impact on the environment, this research address microbial impact on highly weathered waste materials from the Medieval dumps in the Kaňk deposit, Kutná Hora (Czech Republic), Rotgülden-Salzburger Land (Austria) and a historical mine from Chyžné (Slovakia).

The olive-green and yellow powdery secondary mineral phases were identified using mineralogical methods, such as, powder X-ray diffraction and electron microscopy, and confirm the presence of kaňkite ($FeAsO_4 \cdot 3.5H_2O$), (para)scorodite ($FeAsO_4 \cdot 2H_2O$) bukovskýite [$Fe_2(AsO_4)(SO_4)(OH) \cdot 9H_2O$], and zýkaite [$Fe_4(AsO_4)_3(SO_4)(OH) \cdot 15H_2O$]. These minerals form in a clay-rich matrix which acts as a seal for the weathering eluate solution.

The bacterial diversity was assessed by cultivation to study the role of microorganisms in the weathering processes and their influence on the mineral transformation, thereby leading to the release of the pollutants. So far 25 bacterial and 9 fungal isolates were obtained from the deposits which show low colony forming units and hence low microbiological prevalence. The bacteria are mainly coccoid strains with slow growth rates on arsenate containing media; two aerobic, nine anearobic, ten facultative-anaerobic and the rest are neutral. Nineteen bacterial strains are gram positive and six strains are gram negative. Eighteen bacterial strains are siderophore producers and the rest are neutral. Nineteen bacterial strains are resistant to 5-, 10- and 20 mM arsenate concentrations, with 5 strains resistant to 1 M arsenate. The fungi are high spore producing isolates, and will be categorised as ascomycetes, basidiomycetes, yeasts or zygomycetes.

Establishing a biomarker from trace element incorporation patterns in abiotic and biotic magnetite

M. AMOR[1,2]*, V. BUSIGNY[1], A. GÉLABERT[1], G. ONA-NGUEMA[2], M. THARAUD[1], E. ALPHANDÉRY[2,3], M. DURAND-DUBIEF[3], I. CHEBBI[3] AND F. GUYOT[1]

Magnetite (nominally $Fe^{3+}_2Fe^{2+}O_4$) is a widespread iron oxide found at the Earth surface. It precipitates through either abiotic or biotic processes (magnetotactic bacteria, dissimilatory iron-reducing bacteria, iron-oxidizing bacteria). Magnetite provides part of the magnetic signal in various sediments such as carbonate platforms, paleosols and Banded Iron Formations. Identification of biotic magnetite in ancient sediments remains a key point to trace life evolution over geological times. Although magnetic properties allow identification of recent magnetotactic bacteria fossils, cristallographic characteristics do not appear to be suitable for unambiguous biotic magnetite identification. In this study, we propose to focus on geochemical tools to better understand the origin of fossilized magnetite. Trace elements incorporation in magnetite has been widely studied for enhancing magnetic properties but has never been explored as a potential biomarker. In the present work, we show results of both abiotic and biotic magnetite nanoparticles which were synthetized in presence of multi-elements in the precipitation media. Nanoparticles were then washed to remove adsorbed elements on magnetite surface. Magnetite were characterized using Transmission Electron Microscopy and X-Ray Diffraction. Elements incorporation was quantified with Inductively Coupled Plasma-Atomic Emission Spectroscopy and Inductively Coupled Plasma-Mass Spectrometry. Partition coefficients between solutions and magnetites were finally estimated for each element. Elemental incorporation patterns in abiotic magnetite was quantified and compared with magnetite precipitated by bacteria in order to establish criteria for biomagnetite identification. Elements of the first transition metals series show partition coefficients between mineral and fluid (normalized to Fe) close to 1 in abiotic magnetite but appear more concentrated in biotic magnetite.

Eocene pCO_2 reconstructions using boron isotopes in "glassy" planktonic foraminifera

E. ANAGNOSTOU[1]*, E.H. JOHN[2], K.M. EDGAR[2], P.N. PEARSON[2], C.H. LEAR[2], R.D. PANCOST[3] AND G.L. FOSTER[1]

[1]Ocean and Earth Science, National Oceanography Centre Southampton, UK (*correspondence: e.anagnostou@noc.soton.ac.uk)
[2]School of Earth and Ocean Sciences, Cardiff University, UK.
[3]School of Chemistry, University of Bristol, UK.

The Cenozoic climate transition marks the most recent climatic shift in Earth's history from a greenhouse to an icehouse world (~53-33 Ma). This interval is characterized by a gradual deep-sea [1] and high-latitude [2] cooling of ~10ºC and only moderate cooling of the tropics [2], culminating in Antarctic glaciation at the Eocene/Oligocene transition (EOT).

Although a decline in the CO_2 content of the atmosphere (pCO_2) has been suggested as the trigger for final transition into the ice house [3], currently available early Eocene pCO_2 records are rather variable and appear only weakly correlated with climate variations for this interval. For this reason, using multicollector ICPMS, we generated a new record of boron isotopes ($\delta^{11}B$) in planktonic foraminifera, a proven proxy of seawater pH [e.g. 4]. We utilised multi-species depth profiles from very well preserved "glassy" planktonic foraminifera recovered by the Tanzanian Drilling Project from five time slices spanning 53-37 Ma. We discuss our new reconstructions of seawater pH and derived pCO_2 concentrations, in view of estimates of seawater $\delta^{11}B$ composition and alkalinity.

A common origin for terrestrial and lunar indigeneous water

M. ANAND[1,2]*, R. TARTÈSE[1], J.J. BARNES[1,2], I.A. FRANCHI[1] AND N. A. STARKEY[1]

[1]Planetary and Space Sciences, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK (*correspondence: Mahesh.Anand@open.ac.uk)
[2]Department of Earth Sciences, The Natural History Museum, Cromwell Road, London, SW7 5BD, UK

Variable but significant amounts of "water" have been measured in samples derived from the lunar interior [1-7], challenging the long-standing paradigm of a bone-dry Moon. Based on elevated D/H ratios measured in mare basalt apatites (> 500 ‰), lunar "water" has been inferred to be of cometary origin [3]. In contrast, it has been argued that CI-chondrites ($\delta D \sim 100$ ‰) are also a viable source for lunar H, and that the elevated apatite δD values reflect intense H_2 degassing during magma ascent and emplacement [8].

New OH and D/H analyses in apatites from Apollo basalts and basaltic meteorites, carried out at The Open University using the NanoSIMS 50L, confirm that apatite in Apollo mare basalts have elevated δD values > 400 ‰ and a wide range of OH contents (300-7300 ppm). Apatites in meteorites MIL 05035 and LAP 04841 expand our range for mare basalt δD values down to ~ 200 ‰. These δD variations are consistent with ~ 85 to 99 % degassing of H_2, starting from a CI chondrite-type δD value of 100 ‰. In the ~ 4.3 Ga basaltic lunar meteorite Kalahari 009, 8 out of 9 analyses define an average δD value of -15 ± 47 ‰ for corresponding OH contents of 500 to ~ 4000 ppm. We interpret this D/H ratio as that of an undegassed basalt, directly reflecting the H isotope composition of the lunar mantle. This is in good agreement with recent analyses carried out in melt inclusions in Apollo 17 orange glasses [9]. As this D/H ratio is similar to that of the bulk Earth [10], these new data suggest that terrestrial and lunar hydrogen share a common origin.

Petrology And Geochemistry Of Pyroxene Granulite Of Somvarpet, South Western Dharwar Craton, Karnataka, India

*ANANTHA MURTHY K S[1] , JAYARAM G N[1], LINGADEVARU M[2] AND GOVINDARAJU[1]

[1]Dept. of Applied Geology, Kuvempu University, Jnanasahyadri, Shankaraghatta - 577 451, Karnataka
[2]Dept. of Geology, School of Earth Sciences, Central University of Karnataka, Gulbarga-585 106, Karnataka (Ks.Amurthy@Yahoo.Com)

The Somvarpet area forms a part of high grade granulite terrain in the Western Dharwar Craton. The area mainly consists of peninsular gneiss, Charnokites, pyroxene granulites and mafic enclaves. The Pyroxene granulite, which forms one of the major lithological unit, occurs as large parallel bands with in the peninsular gneiss and exhibit metamorphic textures (Granoblastic and porphyroblastic textures), which are often superimposed on relict mafic igneous textures (ophitic, sub-ophitic and intergrowth textures). Mineralogically, the rock essentially contains Ortho and Clino Pyroxenes, and Plagioclase. Quartz, Garnet and Hornblende occur as accessory minerals, whereas, Illmanite, Rutile, Apatite, Spene and Iron oxides are the minor minerals.

Geochemically, the Pyroxene granulites show tholeiitic affinity with iron enrichment, which is a characteristic feature of Archean tholeiites. Variation in trace element concentrations, particularly, Rb, Th, U and Pb, would indicate their instability during metamorphism. To understand the tectonic setting of pyroxene granulites, the analysis were plotted on various known discriminate diagram, the plots fall well within the basaltic and Island arc tholeiitic fields. The average concentration of Rb (6.60ppm) of pyroxene granulite of Somavarpet is very low compared to the Archean tholeiites (12ppm), probably, due to the loss of Rb during granulite facies metamorphism and it is substantiated by the plot of K Vs Rb, where, the pyroxene granulites follow depleted granulite trend. The Pyroxene granulites of the area exhibit slightly fractionated REE patterns, mainly due to, LREE enrichment rather than the HREE depletion.

Redox-sensitive metals and their isotopes: The Holland legacy of early ocean exploration

ARIEL D. ANBAR[1,2]* AND TIMOTHY W. LYONS[3]

[1]School of Earth & Space Exploration, Arizona State University, Arizona, USA
[2]Department of Chemistry & Biochemistry, Arizona State University, Arizona, USA
[3]Department of Earth Sciences, University of California - Riverside, California, USA

"How lucky I am to have something that makes saying goodbye so hard." – A. A. Milne

In 1984 [1], Dick Holland noted the striking correlation between the abundances of Mo and U on the one hand, and organic carbon on the other, in Devonian black shales. He speculated that the slope of this correlation should scale with the abundances of these elements in ancient oceans, which in turn should scale with environmental redox conditions. These few paragraphs gave rise to a new theme in deep time paleoredox research – trace metals as paleoredox proxies – much of it centered on the question that dominated Dick's interest in his later years: how and when did the Precambrian atmosphere and oceans become rich in O_2?

Over the following ~30 years, and particularly in the last decade, analytical advances turned this speculative vision into a rich and mature field. The development of ICP-MS paved the way for the assembly of large datasets of Mo and U abundances in sedimentary rocks through time. The coupling of multiple dectector arrays to ICP-MS instruments opened the door to exploration of variations in the isotope abundances of these and other redox-sensitive elements, revealing a new and unexpected dimension of paleoenvironmental information.

We will assess the future of this field in light of insights it has yielded. For example, there is now broad confirmation of a Paleoproterozoic "Great Oxidation Event" (GOE), but also evidence of a complex fabric of mild but detectable, possibly variable, "whiffs" of environmental oxygenation preeding this event. Further, it is now documented that widespread oxygen deficiency persisted in the oceans in the wake of the GOE, but the extent of ocean euxinia was apparently of limited extent. And new ideas and insights have emerged about the effects of changes in the abundances of bioessential metals, especially Mo, on ecoystem evolution.

Asian monsoon circulation strength inferred from multicentury tree-ring stable isotope chronologies from southeast Asia

K.J. ANCHUKAITIS[1]*, M.H. GAGEN[2], D. MARTIN-BENITO[3], B.M. BUCKLEY[3], C. UMMENHOFER[1] AND ALLEGRA N. LEGRANDE[4]

[1]Woods Hole Oceanographic Institution, Woods Hole, MA 02540 USA (* correspondence: kja@whoi.edu)
[2]Department of Geography, Swansea University, Swansea, UK
[3]Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY 10964 USA
[4]NASA Goddard Institute for Space Studies, New York, NY 10025 USA

The large-scale dynamic circulation of the Asian monsoon over the last several centuries can be inferred from the oxygen isotope ratios of the annual rings of long-lived tropical conifer species from southeast Asia. Here, we present replicated, multicentury stable isotope series from Fokienia hodginsii growing in the Bidoup Nui Ba National Park site in the southern highlands of Vietnam. This isotope chronology is significantly negatively correlated with summer monsoon surface wind speeds over the Bay of Bengal and the adjacent region, indicating that stronger (weaker) onshore winds are associated with lower (higher) oxygen isotope values. Ring width and isotopes show particular coherence at multidecadal time scales, and together allow past precipitation amount and circulation strength to be disentangled. Estimates of the strength of past monsoon circulation provide data for validating general circulation model simulations of the response of the Asian monsoon to changes in radiative forcing and an independent estimate against which to evaluate long-term changes in the Asian monsoon as reflected in other terrestrial and marine proxies as well as forced last millennium general circulation model simulations.

Duration of prograde metamorphism in the inverted Barrovian sequence, Sikim Himalaya, India

ROBERT ANCZKIEWICZ[1]*, SUMIT CHAKRABORTY[2], SOMNATH DASGUPTA[3] AND DILIP K MUKHOPADHYAY[4]

[1]Polish Academy of Sciences, Kraków, Poland, (ndanczki@cyf-kr.edu.pl)
[2]Ruhr Universität, Bochum, Germany
[3]Indian Institute of Science Education & Research-Kolkata, India
[4]Indian Instituite of Technolohy Roorkee, Roorkee, India

The Lesser Himalaya in Sikkim expose a uniquely well preserved Barrovian metasedimentary sequence that displays little tectonic disturbance and is inverted in terms of both pressure and temperature. The sequence seems to be continous from chlorite-biotite grade until muscovite dehydration reaction with well developed all intermediate zones inbetween.

We determined timing and duration of Barrovian metamorphism by Lu-Hf garnet dating of all individual Barrow zones from garnet isograd up to muscovite out reaction. Garnet is well preserved and shows broad cores with sigmoidal inclusion trails pointing to synkinematic crystallization, which ocassionally are surrounded by narrow, inclusions poor rims. Bulk and single crystal dating resulted in highly precise ages showing progressively older dates with increasing metamorphic grade and higher structural level. The youngest, garnet zone rocks yielded 10.6±0.2 Ma age that is followed by 12.8±0.3 and 13.7±0.2 Ma ages obtained for staurolite and kyanite grades, respectively. Sillimanite zone garnets gave 14.6±0.2 Ma age. Structurally highest rocks, arguably marking the top of the sequence, yielded 16.8±0.1 Ma. All ages are interpreted as reflecting garnet growth on a prograde path, which is indicated by Rayleigh style Lu distribution.

High precision of bulk garnet ages was verified relatively to the duration of single crystal growth by chemically controlled high resolution single garnet dating. Five zones dated from the synkinematically grown core yielded precise analyses, which do not show any resolvable time difference and together define a 13.7±0.2 Ma isochron age. Two fractions from narrow, postkinematically grown rim define a 9.9±3.8 Ma date. Much lower precision of the rim is inevitable consequence of Rayleigh style Lu distribution. These data point to a very fast synkinematic core crystallization, which was followed by a slower phase of rim formation. The data show that age precision is not only analytical but closely resambles the real pace of metamorphic crystallization within the Lesser Himalaya. Lu-Hf dating constraints duration of Barrovian metamorphism from garnet to sillimanite zone as 4.0±0.3 Ma, which compares well with earlier estimates of Baxter *et al* (2002) who determined the duration of metamophism as 2.8±3.7 Ma. for classical (not inverted), Barrovian sequence in Scotland.

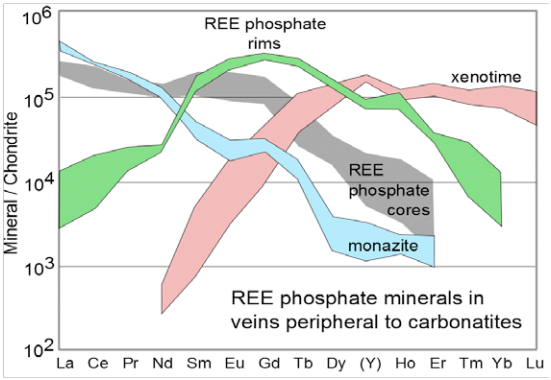
REE fractionation at the Bear Lodge REE+Au deposit, USA: Evidence from mineral chemistry

A.K. ANDERSEN[1]*, P.B.LARSON[1] AND M.C. ROWE[2]

[1]School of the Environment, Washington State University, Pullman, USA (*correspondence: akandersen@wsu.edu)
[2]School of Environment, Univ. of Auckland, Auckland, NZ

The Bear Lodge alkaline intrusive complex hosts one of North America's largest REE deposits. Carbonatites in the central Bear Lodge have REE patterns similar to other carbonatites worldwide, with concentrations decreasing slightly from La to Lu, typical for partial melts from the mantle. Recent exploration reveals zones of HREE- and HFSE-enrichment, much of it hosted by hydrothermal veins peripheral to the LREE-enriched carbonatites. A district-wide zonation from LREE to HREE is reflected by mineralogy. The central carbonatites host REEs in the fluorocarbonate minerals, bastnäsite, synchysite, and parisite, and the carbonate minerals ancylite and carbocerniate. Monazite, xenotime, and hydrated REE-phosphates of the rhabdophane group are common in the peripheral veins. New electron microprobe data show typical REE patterns for monazite and xenotime. Hydrated REE phosphates show a zonation similar to that observed district-wide (LREE to HREE), with rims particularly enriched in Eu-Dy (Figure below).



Recent experimental studies show $HREEF^{2+}$ complexes are less strongly associated than $LREEF^{2+}$ complexes at hydrothermal temperatures (>150°C), suggesting the fluids cooled below 150°C or that a different ligand, such as phosphate or chloride was involved. REE-phosphates (monazite) are known to be highly insoluble, suggesting phosphorous was important during precipitation, but not necessarily during transport. Potential external sources of phosphorous include Paleozoic sedimentary units containing abundant phosphatic microfossils or detrital apatite.

Uranium isotopes in anoxic sediments

M.B ANDERSEN[1,2]*, D. VANCE[1,2], R. HERDSMAN[1], S. LITTLE[1,2], A. MATTHEWS[3], T. LYONS[4] AND S. ROMANIELLO[5]

[5]School of Earth & Space Exploraton, Arizona State University, USA

Elemental and isotopic proxies in marine archives are important tools for reconstructing the chemical evolution of the ocean through time. One sought-after parameter is past ocean redox, for which the Mo isotope tool is relatively mature [e.g., 1]. Uranium's redox sensitive behaviour has also served as a useful indicator for redox conditions in marine sediments [2]. Recent improvements in our ability to measure the 238U/235U ratio has also highlighted the potential for significant redox-induced isotopic variability at the Earth's surface [3.4]. However, the ground-truthing of any such tracer requires knowledge of the singularity of the signal, potential diagenetic overprinting and local vs. global processes, all of which have to be addressed.

To advance our understanding of 238U/235U in marine archives, and its response to ocean chemistry, we have measured U isotopes in anoxic marine sediments from modern euxinic settings (Black Sea and the Cariaco Basin) and in organic-rich Mediterranean sediments (sapropels) formed during the last glacial cycle. The sediments from euxinic settings are characterised by high U enrichment factors and all show 238U/235U moderately heavier than seawater (~0.4 ‰), consistent with published Black Sea data [4]. In contrast, U incorporation into the Holocene Mediterranean sapropel (S1), likely formed under anoxic but non-euxinic conditions, shows lower U enrichment but significantly heavier 238U/235U signatures (~1 ‰) compared to the euxinic sediments.

The 238U/235U signatures suggests different U incorporation into the two types of anoxic sediments likely linked to the specific mechanism of U reduction or the ocean setting. This observation suggest that the 238U/235U in marine archives can potentially fingerprint anoxic versus euxinic water conditions and may provide a paleo-redox proxy to be used in tandem with, for instance, Mo isotopes.

Mantle jets and mantle plumes

DON L. ANDERSON

Seismological Laboratory, Caltech (dla@gps@caltech.edu)

Because of internal heating and effects of viscosity and pressure mantle flow is characterized by large sluggish upwellings. Jets and plumes have been introduced into mantle dynamics and geochemistry because of the perceived need for narrow hot and rapid upwellings to fuel Hawaii and other intraplate volcanoes. These imply a fluid strongly heated from below, no internal heating, non-Stokes law behaviour, flow controlled by external forces and an important role for inertia and momentum. Jets and plumes, as defined in fluid dynamics, and as used in geodynamic and geochemical modeling, are precluded by the equations of fluid dynamics and solid-state physics. The underlying homogeneity, isotropy, adiabatic and thin plate assumptions are ruled out by seismology.

The Morgan plume hypothesis, the McKenzie-Bickle geotherm and mantle jet hypotheses and whole mantle convection scenerios violate fluid dynamic and lattice dynamic scaling relations and the 2nd law of thermodynamics, and do not satisfy well-constrained unsmoothed seismic models that allow for anisotropy. Physics, and geochemical modelling, show that the outer 200 km of the mantle is an appropriate source for intraplate magmas, including their diversity, volumes, compositions and temperatures. The thermal overshoot of boundary layer convection and the subadiabaticity of the deep geotherm explain the relative temperatures of Hawaiian and midocean ridge magmas. Anisotropy shows that the ridge source is in the transition zone.

Top-down processes, driven by secular cooling, fertilize and cool the mantle and create shear boundary layers that are responsible for shear- driven upwellings and intraplate volcanoes. The upper boundary layer of the mantle is a metasomatised, sheared melange that has all the attributes required to explain volcanoes such as Hawaii and the largest igneous provinces.

ca. 1750 Ma arc-related metamorphism in the southern Arunta Complex, central Australia?

J. R. ANDERSON[1]*, D. E. KELSEY[1], M. HAND[1] AND W. J. COLLINS[2]

[1]Centre for Tectonics, Resources and eXploration (TRaX), University of Adelaide, S.A., 5005 (*correspondence: jade.anderson@adelaide.edu.au)

[2]University of Newcastle, N.S.W. 2308

The Arunta Complex, central Australia, is a ~200,000 km^2 poly-metamorphic complex, with a cryptic record of tectonism from the Paleoproterozoic to the Paleozoic. The Arunta Complex records evidence for ~200 Myr of orogenic activity between ca. 1800–1600 Ma, but with the exception of minor magmatism interpreted to have arc-related petrogenesis [1], evidence for subduction-related magmatism and high pressure metamorphism is limited.

This study uses calculated pressure-temperature phase diagrams and *LA-ICP-MS* U–Pb monazite geochronology to investigate a series of granulite facies supracrustal and magmatic rocks from the southern Arunta Complex.

High-grade, regional metamorphism occurred at ca. 1760–1740 Ma. This timeline has previously been interpreted as an igneous event, including magmatism with subduction-related geochemical signatures in the south-eastern Arunta region (Calcalkaline–Trondhjemite Suite). However, recent evidence has highlighted that metamorphism also occurred during this time in the eastern Arunta Complex [2]. If the ca. 1750 Ma magmatism is arc-related, it is possible that we have characterised the thermal structure of the arc (medium pressure, apparent thermal gradient of ~25– 35 °C/km).

The characterisation of the physical conditions of the crust in the southern Arunta Complex at ca. 1760–1740 Ma may provide supporting evidence from a metamorphic standpoint for an active margin in the southern proto-North Australian Craton. If so, the ca. 1760–1740 Ma regional metamorphism is an important constraint for deciphering the Proterozoic tectonic evolution of the Arunta Complex and North Australian Craton.

[5]University of Rhode Island, Narragansett, RI, moran@gso.uri.edu

Radioactive disequlibria within naturally occurring U- and Th-decay series have been exploited to constrain the rates of a variety of processes in the ocean. Here we will illustrate the use of ^{230}Th and ^{232}Th to investigate certain processes that supply and remove trace elements, including:

1) Boundary Scavenging - the enhanced removal of trace elements by scavenging to particles in biologically productive ocean margin regions. Contrasting results from the North Pacific and North Atlantic Oceans reveal some expected findings and some surprises.

2) Bottom Scavenging - the enhanced scavenging of dissolved ^{230}Th by resuspended particles in benthic nepheloid layers. New evidence from the US GEOTRACES program will require reinterpretation of features in certain historical ^{230}Th profiles that were previously attributed to Atlantic overturning circulation. The rapid scavenging in benthic nepheloid layers that is evident in dissolved ^{230}Th profiles may apply to other particle-reactive trace elements as well.

3) Supply of trace elements by mineral aerosols (dust) - a new method employing ^{230}Th and ^{232}Th has gained a great deal of attention recently. We will examine evidence that raises questions about certain assumptions inherent in this approach including, most importantly, the assumption that ^{230}Th and ^{232}Th occur in the same chemical form and, therefore, have equivalent chemical residence times in the upper water column.

Adsorption of natural organic matter at the water/gibbsite interface

K. ANDERSSON[1]*, J. P. L. KENNEY[1], P. PERSSON[1] AND T. KARLSSON[1]

[1]Departemnt of Chemistry, Umeå University, 901 87 Umeå, Sweden (*Correspondence: kristoffer.andersson@chem.umu.se)

Aluminum (Al) is one of the earth's most abundant elements and constitutes about 8% of the earth's crust. It exists mainly as silicates, oxides and hydroxides, combined with other elements or in complexes with natural organic matter (NOM). Speciation is a key factor for understanding the environmental impact of Al. It is therefore important to determine the chemical forms of Al that predominate in different natural media and under varying geochemical conditions. Adsorption of NOM to Al-based mineral surfaces is an important process that can alter the speciation of Al by influencing the rate and extent of dissolution of the mineral and thereby the overall solubility of Al. In this work, aquatic NOM from the Suwannee river (IHSS) has been studied in the presence and absence of an Al mineral surface (Gibbsite), using both *in situ* FT-IR spectroscopic measurements coupled with potentiometric titrations, and wet-chemical methods. These experiments were conducted as a function of time, pH, and concentration in order to follow the adsorption of NOM and the possible dissolution of the mineral surface.

Previous studies have indicated that fulvic and humic acids primarily adsorb to the surface of bohemite in an outer-sphere fashion with only minor formation of inner-sphere complexes **[1, 2]**. Our preliminary results indicate a significant shift in the asymmetric stretch of the carboxylate group in NOM at pH 3.5-5.5, possibly pointing towards a high amount of inner-sphere complexes at the gibbsite surface. Formation of inner-sphere complexes at the surface could promote a ligand-induced dissolution of the minerals. These indications are further suported by batch experiments where a dissolution of the gibbsite mineral are observed. Thus, complexation with NOM could potentially be one of the most important factors, other than pH, for controlling the solubility of Al in environmental systems.

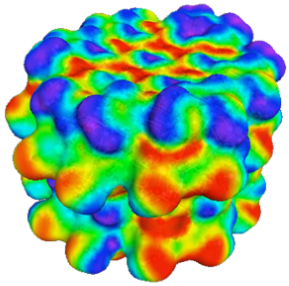
Predicting the protonation behavior of the kaolinite surface

M.P. ANDERSSON AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark, (ma@nano.ku.dk, stipp@nano.ku.dk)

Clay minerals, known for their ion exchange capacity, have an impact on environmental issues such as uptake of contaminants from ground water and retention of oil in reservoirs. Kaolinite is believed to play an important role in enhancing oil recovery by low salinity water flooding, where decreasing Ca^{2+} and Mg^{2+} concentrations in the injected solution increases the amount of oil that can be generated from sandstone reservoirs. The ability of kaolinite to act as an ion exchanger depends on its atomic surface structure, pH and in particular, on its protonation state. This is especially true for metal ions, which compete with protons for bonding sites on surface oxygens.



COSMO surface of the kaolinite cluster model

We have used the implicit solvent model, COSMO-RS, to predict the pK_a values of kaolinite surfaces, using a molecular cluster consisting of 512 atoms, to represent a kaolinite surface. Using a cluster allows us to determine basal plane and edge protonation properties using the same model. We found that the pK_a values could be classified according to surface composition. Al-OH_2 groups had a median pK_a value of 5.5 and were generally more acidic than SiOH groups with a median pK_a value of 10.6. The standard deviation was 2 to 3 pH units for most surface sites. Using our calculated pK_a values, we were able to estimate the point of zero charge (PZC) for kaolinite for the various surface sites, which has been difficult or impossible, using experimental approaches. The kaolinite edge has a PZC of 3.7 and the AlOH basal plane a PZC of 7.7. This has the consequence that the PZC for kaolinite samples ranges between 4 and 6 and is geometry dependent... Higher values are found for flat particles where the basal plane bahavior dominates over edge effects. Our results help explain why the PZC of kaolinite can differ significantly depending on the nature of the kaolinite samples (i.e. the surface to edge ratio, the diameter of particles) used in experiments.

Phase transition in aluminous silica at lowermost mantle P-T conditions

D. ANDRAULT [1], R.G. TRØNNES [2], Z. KONÔPKOVÁ [3], W. MORGENROTH [4] AND H.-P. LIERMANN [3]

[1]LMV-UBP-CNRS-IRD, Clermont-Ferrand, France
[2]Natural History Museum, University of Oslo, Norway
[3]DESY, Hamburg, Germany
[4]Department of Crystallography, Frankfurt, Germany

Using Al-bearing SiO_2 glasses with 4 and 6 wt% Al_2O_3 as starting materials, we investigated the phase transition from the $CaCl_2$-structured to the a-PbO_2-structured phase (seifertite) at pressures and temperatures corresponding to the lowermost mantle. The experiments were conducted with synchrotron-based *in situ* X-ray diffraction in the laser-heated diamond anvil cell. The transition from the $CaCl_2$-structured phase to seifertite occurs between 113 and 119 GPa at 2500 K. Comparison with previous results shows a decrease of the transition pressure with increasing Al-content. A tentative phase diagram reports the minerals compositions as a function of pressure in the SiO_2-Al_2O_3 system. This diagram includes a binary loop compatible with an Al partition coefficient between $CaCl_2$-form and seifertite between 0.55(5) and 1.

Based on the X-ray pattern refinement, our samples show a very small 0.3(2) % volume decrease across the transition. Still, the transition could very well be associated with a more significant change in density if the Al substitution mechanisms are different in $CaCl_2$-form and seifertite. The most likely situation is that Al-substitution occurs via O-vacancies in the $CaCl_2$-form and via extra interstitial Al in seifertite. That would result in a ~1.5-2.0 % density increase at the transition pressure for silica containing 5 wt% Al_2O_3. This value is of the same order of magnitude than the estimated difference in density between peridotitic mantle and basaltic lithologies in the lowermost mantle.

Can Saharan dust explain extensive clay deposits in the Amazon Basin? radiogenic isotopes as tracers of transatlantic transport

M.O. ANDREAE[1]*, W. ABOUCHAMI[1], K. NÄTHE[1], A. KUMAR[1], S.J.G. GALER[1], K.P. JOCHUM[1], E. WILLIAMS[2], A.M.C. HORBE[3], J. W.C. ROSA[4] AND V.H. GARRISON[5]

[1]Biogeochemistry Department, Max Planck Institute for Chemistry, Mainz, Germany (*m.andreae@mpic.de)
[2]Massachusetts Institute of Technology, Cambridge, MA
[3]Departamento de Geociências, Universidade Federal do Amazonas, Manaus, AM, Brasil
[4]Instituto de Geociências - Universidade de Brasília, Brasília, Brazil
[5]U.S. Geological Survey, St. Petersburg, Florida, USA

Previous studies have shown that Saharan dust transport across the Atlantic acts as an important source of mineral nutrients to the Amazon rainforest. The Belterra Clay, which outcrops extensively across the Amazon Basin, has been proposed to result from dry deposition of African dusts. We have investigated this hypothesis by measuring the radiogenic isotopic composition (Sr, Nd and Pb) of a suite of samples from the Belterra Clay, African source regions, dusts deposits from various locations along the airmass transport, and some Caribbean islands to characterize dust in the source and receptor regions.

Our results identify distinct isotopic signatures in the Belterra Clay samples and the African sources. The Belterra Clay displays radiogenic Sr and Pb isotope ratios associated with low ε_{Nd} values. In contrast, Bodélé samples and dusts deposits show lower Pb isotope ratios, variable $^{87}Sr/^{86}Sr$, and relatively homogeneous Nd isotopic compositions, albeit more radiogenic than those of the Belterra Clay.

Our data show unambiguously that the Belterra Clay is not derived from African dust deposition, but results from weathering and erosion under humid tropical conditions. That Saharan dust contributes to the fertilization in the Amazon Basin cannot be ruled out, however, since the African dust isotopic signature is expected to be entirely overprinted by local weathering sources. In contrast, radiogenic isotope data obtained on aerosol filters collected in the US Virgin Islands and Tobago are similar to those of aerosols from Mali, demonstrating that the African dust isotope signal is detectable and transported as far as Central and South America. We conclude that radiogenic isotope systems are powerful tracers of provenance and can be used to fingerprint dust sources and atmospheric transport patterns.

Hymenoptera pollinator effect on environment

O. ANJOS[1,3], O. GONÇALVES[1] AND L. NUNES[1]

[1]IPCB/ESA – Instituto Politécnico de Castelo Branco, Castelo Branco, Portugal. (ofelia@ipcb.pt)
[2]Centro de Estudos Florestais, Instituto Superior de Agronomia, UTL, Lisboa, Portugal

There are several studies reporting the evidence that pollinators are declining as a result of local and global environmental degradation. Operation Pollinator is an international biodiversity program, supported by Syngenta, to boost the number of pollinating insects on commercial farms. It works by creating specific habitats, tailored to local conditions and native insects.

The aim of this work is to increase the ecological suitability of pollinator populations through improves food availability for pollinator employing strategies for surrounding landscape.

Two cherry orchards, located in Fundão, Portugal, were studied: one was installed a patch meadow with flowery prairie with the purpose of increasing pollinator's number; other with poor native biodiversity. It was identified the main groups of insects visiting the cherry blossoms and the surrounding flora, during the flowering cherry trees.

This review was conducted through observation and analysis of pollen in pollinator's nests, artificially placed in the orchards in order to evaluate the visiting flowers.

There was a greater number of pollinating insects in the orchard with higher biodiversity and it was found that insects visited other flora along with the cherry blossoms. The Hymenoptera identified belong to genus: Andrena; Apis; Eucera; Tropinota; Anthophora; Osmia; Xylocopa. The orchard where haven't been installed the patch meadow, shows a lower number of visiting insects as well as lower species variability. The increasing of pollinators protects the environment and increases the fruit production and quality. The findings of the sweeter fruit, with the increased number and diversity of insects leads to the conclusion that the environment benefits from the increase in pollinators with more balanced environment, it's a winning environment for everyone.

The conservation of pollinator habitat can also enrich overall biodiversity and the ecosystem services, protect soil and water quality.

Keywords: pollinators hymenoptera; biodiversity; pollen.
Acknowledge: To Syngenta by the financial support of the project.

Application of geochemistry in shale gas exploration: A case study from Cambay Basin, Gujarat, India

ANNAPURNA BORUAH*, M. A. RASHEED, SYED ZAHEER HASAN, P.H.RAO, AND B. KUMAR

Petroleum Research Wing, Gujarat Energy Research and Management Institute, Gandhinagar, Gujarat, India. (*Correspondence: Annapurna_1910@yahoo.in)

Shale gas is an unconventional hydrocarbon resource as the shale acts both as a source and reservoir for the gas. Gas can be stored in the shale either in the pore spaces or as adsorbed gas on to the organic matter. Characterization and evaluation of the source potential of a rock is made by using parameters like (1) Total Organic Carbon (2) Rock-Eval Pyrolysis (3) Elemental analysis of C, H, N, O and S (4) Vitrinite Reflectance (5) Visual Kerogen Analysis (6) Extract SARA Analysis (7) Gas Chromatograph of extracted bitumen (8) Pyrolysis Gas-Chromatography (9) Gas Chromatograph-Mass Spectrometry of extracted bitumen and (10) Isotope composition of carbon and hydrogen. For commercial shale gas exploration TOC content of the shale should be more than 2%, mature to post mature zone i.e. oil window to gas window (Ro > 0.7%, Tmax >445°C). The kerogen in the shale must be gas prone. At higher temperature zone gas can be generated by insitu cracking of oil. In this study, total 15 shale samples were collected from Broach and Jambusar areas of Cambay Basin, Gujarat, India. The analytical findings reveal that the Shales are found rich in organic matter (1- 5%), maturity (0.7- 1.2VRo), kerogen type II, III marine, hydrogen index <100, thickness is more than 500m and area extent is more than 53000square km. The organic richness attains the oil window at the depth of 2000m and below this depth gas window starts. Finally the laboratory findings highlight the positive prospects for shale gas exploration and exploitation in Cambay Basin.

Keywords: Shale Gas, Geochemical, Exploration.

Quantification of the magma fluxes feeding the growth of a shallow magma reservoir (Soufrière Hills, Montserrat)

C. ANNEN*[1], M. PAULATTO[2], R.S.J SPARKS[1], T.A. MINSHULL[3] AND E. KIDDLE[1]

[1]Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's Road, BS8 1RJ, Bristol, UK (*correspondence: catherine.annen@bristol.ac.uk)

[2] Department of Earth Sciences, University of Oxford, South Parks Road, Oxford OX1 3AN,UK

[3] Ocean and Earth Science, National Oceanography Centre Southampton, University of Southampton, European Way, Southampton SO14 3ZH, UK

Shallow andesite intrusions in arcs participate to the formation of new continental crust. The SEA-CALIPSO experiment revealed a low-seismic-velocity volume beneath Soufrière Hills (Montserrat) extending vertically from 4 to at least 7.5 km depth and attributed to the presence of melt [1]. By simulating the growth of a magma body by accretion of andesitic intrusions we calculated spatial distributions of temperature and melt fraction and the corresponding seismic wave velocities, which were smoothed to be comparable with tomography results.

The size and intensity of the synthetic velocity anomaly are controlled by the diameter of intrusions, the rate at which they are emplaced, i.e. the total duration of the intrusive episode, and the intruded magma initial heat content (including latent heat). We were able to reproduce the tomographically determined velocity anomaly with a relatively wide range of intrusion diameters (4 to 10 km) and magmatic episode durations (6,000 to 150,000 yrs), but, because of a trade off between these two parameters, the corresponding magma fluxes are restricted to 0.7 - 5 x 10^{-3} km^3/yr.

The velocity anomaly can be reproduced with a chamber containing high melt-fraction magma or with a mush of crystals and melts. The range of magma ages in the modelled magma chambers is much wider than the crystal residence time of the erupted andesite [2]. This suggests that eruptions tap small pockets of recently assembled magma and that the velocity anomaly might be mostly due to a non-eruptible mush.

Allergic and Respiratory Health effects of combustion aerosols

ISABELLA ANNESI-MAESANO[1] AND YOUSSOUF HASSANI[2]

[1]EPAR Department, UMR-S 707 INSERM and UPMC Paris VI, Medical School Saint-Antoine 75012 Paris (isabella.annesi-maesano@inserm.fr)
[2]EPAR Department, UMR-S 707 INSERM and UPMC Paris VI, Medical School Saint-Antoine 75012 Paris (youssouf.hassani@gmail.com)

Health effects of combustion aerosols from 3 different aerosols will be dealt with, namely: 1) traffic-related aerosols, 2) indoor combustion aerosol and 3) wildfire aerosol.

1) Traffic-related PM was assessed in the French 6C Study at specific addresses *in situ* ($PM_{2.5}$) and through a dispersion model (PM_{10}) and related to allergic and respiratory health of children living close to the addresses. After adjustment for confounders and NO_2 as a potential modifier, in the 5338 school children of the survey the odds of suffering from EIB and flexural dermatitis at the period of the survey, past year atopic asthma and SPT positivity to indoor allergens were significantly increased in residential settings with $PM_{2.5}$ concentrations exceeding 10 microg/m^3 (WHO air quality limit values). For the 4,907 children who had resided at their current address for the past 3 yrs, asthma (exercise induced, past year and lifetime) was significantly positively associated with $PM_{10.}$ In the same children, PM_{10} were significantly positively associated with eczema (lifetime and past year), lifetime allergic rhinitis and sensitisation to pollens. Among the 2,213 children residing at their current address since birth, the associations persisted for lifetime asthma (1.4 (1.0-2.0)) and for sensitisation to pollens (1.2 (1.0-1.9)).

2) After adjusting for confounders, an increased prevalence of past year asthma was found in the classrooms with high levels of $PM_{2.5}$ (OR 1.21; 95% CI 1.05 to 1.39), compared with others. The relationship was observed mostly for allergic asthma. A significant positive correlation was found between EIA and the levels of $PM_{2.5}$ in the same week.

3) Wildfire combustion aerosols emissions between 2006 and 2010 have been modeled for Europe and will be related to health outcomes.

Determination of REE in carbonaceous geological samples by inductively coupled plasma mass spectrometry

YU.V. ANOSHKINA

Tomsk State University 36 avenue Lenina, Tomsk, 634050, Russia (julianoshkina@gmail.com)

The results of laboratory research on the optimization of sample preparation of carbonaceous rocks are presented. Research were carry out using reference materials of black shales SLG-1, SChS-1, metamorphic shale SSL-1 (Russia), cody shale SCo-1, green river shale SGR-1b, coal CLB-1(USA).

In order to explain the dependence between amount of carbonaceous substances in geological samples and degree of extraction of rare earth elements (REE) precipitates were analyzed after each steps of acid digestion using scanning electron microscope TESCAN Vega LMU with energy-dispersive spectrometer Oxford Instruments INCA Energy 350. The research of element-structural changes in precipitates at each steps of acid digestion was monitored by atomic emission spectrometry Grand and FT-IR stectrometry «Nicolet 6700». The necessity of removal of carbonaceous substances was shown. For determining the temperature range of pre-firing carbonaceous substances was used Simultaneous Thermal Analysis by STA 409 PC Luxx. Following conditions: 800 ºC during 8 hours in ceramic crucibles into muffle furnace were chosen as optimal for pre-firing. Using the oxidative addition ($LiNO_3$) at the stage of pre-firing was suggested as alternative conditions. This step allows to reduce the temperature down to 550 ºC and time to 2 hours.

Optimal conditions for the acid decomposition of carbonaceous rocks with subsequent determination of trace elements by ICP-MS were found. The scheme includes pre-firing with $LiNO_3$, open beaker heating with HF, microwave-digestion program with mixture of HF and HNO_3, open beaker procedure of consecutive evaporation with HCl and HNO_3 sequentially. In was added at a concentration of 10 μg L^{-1} to act as internal standard for correction of matrix effect, signal drift and instrumental instability. Geological reference materials USGS BCR-2, BHVO-2 was analyzed for quality control. All measurements were performed on an Agilent 7500 cx (Agilent Technologies Inc., USA). The results are consistent with published data.

This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.0686, 14.B37.21.1257).

Phosphorus retention in sediments of a eutrophied lake: Role of organic phosphorus

N. ANSEMS*[1], D.W. O'CONNELL[2] J. WIKLUND[2], T. BEHRENDS[1] AND P. VAN CAPPELLEN[2]

[2] University of Waterloo, Ecohydrology Research Group, 200 University Avenue West, Waterloo, ON N2L 3G1, Canada

Phosphorus (P) cycling in aquatic sediments has traditionally been described from an abiotic viewpoint: following Mortimer's classical model, phosphate release from sediments is controlled largely by the oxidation-reduction cycle of iron (Fe). However, biotic processes and organic P (org-P) phases could play an important, if not more important, role. To analyze the fate of P, sediment cores were collected in the oxygenated epilimnion and the anoxic hypolimnion from Lake 227 of the Experimental Lake Areas (ELA) in Ontario, Canada. This experimental lake has been artificially fertilized with P since 1969. Lake 227 is a unique lake, as it has undergone a rapid transition from oligotrophic to eutrophic conditions. ^{210}Pb dating and chemical extractions were complemented by ^{31}P NMR spectroscopy to elucidate sediment P speciation.

The sediment cores contain an historical record of in what extent and in what form P is retained while sediments were subjected to different prevailing conditions. A comparison is made between oxic and anoxic conditions under oligotrophic and eutrophic conditions. The results show that under eutrophic conditions, org-P plus humic-metal-phosphate complexes represent the major pool of reactive sediment P in Lake 227. The formation of the humic complexes is one of the mechanisms accounting for the high retention of P in the sediments since artificial fertilization started. The role of redox dependent Fe-bound P seems to be of secondary importance. Our works highlights the power of whole-lake manipulation to gain a mechanistic understanding of the role of sediment processes in phosphorus cycling.

Oxyanion adsorption on schwertmannite and iron precipitates from acid mine drainage

J. ANTELO[1]*, S. FIOL[2], D. GONDAR[2], R. LOPEZ[2] AND F. ARCE[2]

[1]Dept. Soil Science and Agricultural Chemistry. University of Santiago de Compostela. 15782 Santiago de Compostela. Spain (*correspondence: juan.antelo@usc.es)

[2]Dept. Physical Chemistry. University of Santiago de Compostela. 15782 Santiago de Compostela. Spain

The formation of acid mine drainage implies the weathering and oxidation of the iron sulphide minerals present in mining areas and the formation of large amounts of secondary iron precipitates. The presence of these secondary iron precipitates can be considered of great importance, since they are naturally occurring scavengers for the arsenate and other anionic species found in these highly polluted aquatic systems and their presence controls the mobility and availability of the contaminants[1]. Due to the abundance of arsenate species in AMD environments and the high retention capacity of schwertmannite at acidic pH, many studies have focused on the retention of As(V) or As(III). However, the number of adsorption studies carried out with other oxyanions of environmental interest, such as chromate or molybdate, is limited

The adsorption of different oxyanions has been studied on synthetic schwertmannite and on natural iron precipitates obtained from AMD waters. The adsorption of arsenate, phosphate, chromate and molybdate was examined in relation to pH, and anion exchange between these oxyanions and the sulphate ions present in the crystalline structure of the schwertmannite or the iron precipitates was also analysed. The affinity sequence for the different oxyanions is similar in both the synthetic and natural samples: $AsO_4 \approx PO_4 > MoO_4 > CrO_4$.

Evidence of anion exchange reactions in schwertmannite was obtained, since sulphate ions are released from the iron minerals following oxyanion adsorption. The oxyanion adsorption process for these secondary iron minerals is controlled by two mechanisms: surface complexation with iron hydroxyl groups and anion exchange with the sulphate groups present in the crystalline structure.

Sulfate-oxygen isotope insight into anaerobic methane oxidation in estuarine sediments

GILAD ANTLER[1]*, ALEXANDRA V. TURCHYN[1], ALICIA DAVIES[1], MICHAL ADLER[2], VICTORIA RENNIE[1], BARAK HERUT[3] AND ORIT SIVAN[2]

[1] Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK. (ga307@cam.ac.uk)
[2]Department of Geological and Environmental Sciences, Ben Gurion University, Beer Sheva 84105, Israel.
[3] Israel Oceanographic and Limnological Research, National Institute of Oceanography, Haifa 31080, Israel.

Methane production is driven mostly by microbially mediated methanogenesis. In marine sediments, this naturally produced methane is almost entirely consumed by anaerobic methane oxidation (AOM) coupled to bacterial sulfate reduction (BSR). This coupling between AOM and BSR remains enigmatic. We use the sulfur and oxygen isotope composition of aqueous sulfate ($\delta^{18}O_{SO4}$ and $\delta^{34}S_{SO4}$ respectively) consumed through AOM to further our understanding of this critical microbially-mediated process. We focus on highly stratified estuaries in the coastal area of Israel (the Yarkon and the Qishon). At these sites, sulfate is rapidly consumed and methane concentrations subsequently increase suggesting a coupling between sulfate and methane consumption.

Although the pore fluid geochemistry (e.g. sulfate and dissolved inorganic carbon concentration profiles) are similar at the studied sites, the isotope geochemistry (e.g. the $\delta^{34}S_{SO4}$, $\delta^{18}O_{SO4}$, and $\delta^{13}C_{DIC}$ in the pore fluid and the $\delta^{34}S$ of the sedimentary pyrite) is fundamentally different among the sites. Because the sulfur and oxygen isotopes in pore fluid sulfate are indicative of the relative intracellular fluxes of sulfur intermediates during BSR, we conclude that the isotope geochemistry require that the mechanism of BSR differs among the studied sites and in different sulfate-methane transition zones. We use a model for the various intracellular steps during BSR to explore what may cause these differences. We conclude that the geochemical interpretation of these sites may underrepresent the processes occurring in the subsurface as suggested by the isotope data. This suggests that recycling of sulfur intermediates may be fundamentally different in BSR coupled to AOM than when coupled to standard organic matter oxidation.

Groundwater contamination potential - vulnerability assessment

I.M.H.R. ANTUNES[1], M.T.D. ALBUQUERQUE[1] AND S.F. OLIVEIRA[1]

[1]Polytechnic Institute of Castelo Branco, Portugal, (imantunes@ipcb.pt;teresal@ipcb.pt; sandrinafidalgo@ipcb.pt)

Águeda watershed is a sub-catchement of the Douro river (northern Portugal) and it is distributed on both Spanish and Portuguese territories. The main core of this work is the achievement of a methodological tool able to be used for vulnerability assessment in ttransboudary watersheds.

Groundwaters' vulnerability mapping was carried out by two different methodological approches: DRASTIC and DRASTIC Pesticide [1].

DRASTIC is a numerical index derived from ratings and weights assigned to seven parameters – Deep to water, net Recharge, Aquifer media, Soil media, Topography, Impact of the vadose zone and hidraulic Conductivity. The obtained values raises between 23 (not vulnerable) to 230 (highly vulnerable). Drastic Pesticide uses the same parameters with the reassignment of attributes' weights to stress the importance of agricultural activities.

DRASTIC's map for Águeda watershed shows three spatially distributed vulnerability classes: low (102 - 119), moderate (120 - 139) and moderate to high (140 - 154). The low vulnerable zones occupy almost 78% of the all area while the moderate vulnerable zones correspond to 21% of the remaining area. The moderate to high vulnerable zones represents less than 1% of the total area and it is localized in the central part of the Águeda watershed overlapping the tertiary sedimentary aquifer and the mostly populated area.

DRASTIC Pesticide map shows four spatially distributed vulnerability classes: low (120 - 139), low to moderate (140 - 159), moderate to high (160 - 179) and high (180 - 195). The high proportion increases considerably in the central zone of the Águeda watershed representing more than 20% of the land parceling.

Although similar hydrogeological intrinsic characteristics are observed in the central watershed's area obvious differences can be stressed when anthropogenic activities are taken into consideration. Feasibility studies and the development of specific monitoring activities must be addressed in future work.

Selective Cs sorption in biotite on granite

Y. AOI[1], K. FUKUSHI[1], T. MORISHITA[1] AND A. KAMEI[2]

[1]Kanazawa University, Kanazawa, Japan,
[2]Shimane University, Shimane, Japan
(aoi9856@stu.kanazawa-u. ac.jp presenting author)

The radiocesium released from the Fukushima Daiichi nuclear power plant is ratained at the surface soils around the power plant (Tanaka *et al* 2012). Abukuma granite distributes in the most of the affected areas. Therefore, the contaminated soil minerals has been originated from Abukuma granite(e.g. Kamei *et al* 2003). Mica and/or vermiculite are though to be the one of the candidate for the host phases of radiocesium. It is reported these hardly desorped radiocesium (Qin *et al* 2012). The purpose of the present study is to elucidate of Cs sorption mechanism of biotite in Abukuma granite.

The thin section made from Abukuma granite was soaked in the solution containing 10μM Cs^+ in 0.01 M NaCl solution at pH 4, 5 and 6 for 24 hours. The thin senctions after the reaction with Cs were analyzed by means of electron prove micro analyzer (EPMA).

Abukuma granite was composed of quartz, plagioclace, feldsper, amphibole, biotite and chlorite. Chlorite is alteration products from biotite. Among these minerals, Cs distribution was obserbed only in biotite.

According to the quantitative analys is by EPMA, biotite contains Cs up to 6.7 wt%. biotite accumulated Cs several tens of thousands time than that of Cs in solution. The Cs concentration in biotite was negatively correleated with K concentration in biotite. These observations suggested that Cs selectively sorbs on biotite in granite and the sorption mechasim is considered to be the cation exchange reaction in the inter layer of biotite.

Geology, lithostratigraphy and geochemistry of the oldest Eoarchaean BIFs, Northern Labrador

S. AOKI[1]*, M. SHIMOJO[1], S. SAKATA[2], S. YAMAMOTO[1], A. ISHIKAWA[1], T. HIRATA[2] AND T. KOMIYA[1]

[1]Earth Science and Astronomy, the University of Tokyo, Tokyo, 153-8902, Japan *shogo@ea.c.u-tokyo.ac.jp
[2]Laboratory for Planetary Sciences, Kyoto University, Japan

Banded Iron Formaion (BIF) is chemical sediment, which is a key of deciphering chemical evolution of seawater throughout the Precambrian. However, there are found only few pre-3.6 Ga BIF: the 3.71-3.83 Ga Isua supracrsutal belt and Akilia Island, >3.75 Ga Nuvvuagittuq supracrustal belt and the Nulliak supracrustal belt, respectively. Recently, reassessment of zircon U-Pb dating suggested that the Nulliak supracrustal belts were formed >3.9 Ga[1]. This work presents the geology and geochemistry of the oldest BIF in the earth, in the Nulliak supracrustal belts, Labrador.

Geology and lithostratigraphy shows that there are two types of BIFs in the area: thin BIF layers associated with mafic rocks and BIF layers interlayered with carbonate rocks, respectively. The former is typical Algoma-type BIF, common in the Eoarchean supracrustal belts. The latter is also thin and sporadically distributed in the area, similar to the Algoma-type BIF but its lithostratigraphy is similar to the Superior-Type BIF, uncommon in the Eoarchean BIF. Mineral assemblages of the BIFs are similar each other, and comprises magnetite + quartz + actinolite + cummingtonite, which are typical of amphibolite facies assemblages for BIFs.

PAAS-normalized rare earth elements plus yttrium distribution diagrams (REY_{SN}) of the BIFs exhibit positive La_{SN} + Y_{SN} anomalies, super-chondritic Y/Ho values and LREE, MREE depletion relative to HREE. The geochemical characteristics are shared with modern seawater. In addition, the REY patterns lack negative Ce anomaly whereas display large positive Eu anomaly, suggesting reduced and hydrothermal fluid-influenced seawater. On the other hand, their high abundances of Al2O3 and HFSE contents suggest that detritus input was common in the sedimentary environments of the Nulliak supracrustals. In addition, their high abundances of Ni and Zn contents (>50 ppm) indicate that the >3.9 Ga seawater was enriched in the transitional metals due to high hydrothermal activities or alteration of (ultra)mafic crusts, analogous to the Archaean BIFs[2].

Microbial activity below the Iheya North deep sea vent constrained by quadruple sulfur isotopes

SHINNOSUKE AOYAMA[1]*, MANABU NISHIZAWA[2], KEN TAKAI[2] AND YUICHIRO UENO [123]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology
(*correspondence: aoyama.s.ab@m.titech.ac.jp)

[3]Earth-Life Science Institute, Tokyo Institute of Technology

Sulfate reduction is the predominant microbial metabolisms in the subseafloor environment. The sulfate reduction is generally slow due to the limitation of substrates under the stationary seafloor. On the other hand, hydrothermal system may host active microbial sulfate reduction possibly due to the water circulation. In 2009, a drill ship "CHIKYU" drilled Iheya North hydrothermal system in the Okinawa Trough. For evaluating the sulfate reducing activity, we analysed sulfur isotopes ($^{32}S/^{33}S/^{34}S/^{36}S$) of pore water sulfate and mineralized sulfide extracted from the core samples. The observed ^{34}S-enrichment and decreased sulfate concentration in the upper and intermediate section suggest sulfate reduction took place below the seafloor. On the basis of our model calculation, apparent isotope effect $^{34}\varepsilon$ is estimated to be –21‰ and the occurrence of sulfate reduction is only in the upper part of the subseafloor hydrothermal system, that is the recharge zone of seawater. The observed fractionation together with the slight $\Delta^{33}S$ enrichment all indicate that the sulfate reduction is not thermochemical process but microbial process with high reaction rate. Also, roughly ~50% of mineralized sulfide is estimated to have been deposited from microbial reduction below the seafloor . The rapid seawater circulation in the Iheya North hydrothermal system may be critical to support active microbial sulfate reduction below the seafloor.

A database for calculating geochemical reactions of CO_2 and gas mixtures at high (P, T, salinity)

C.A.J. APPELO[1]* AND D.L. PARKHURST[2]

For calculating gas properties at high pressure an equation of state for gases [1] was programmed in PHREEQC, version 3 [2]. The solubility can be calculated from the fugacity coefficient of the gas and its aqueous molar volume, with accurate results in solutions of various salinities up to 1000 atm and 200°C.

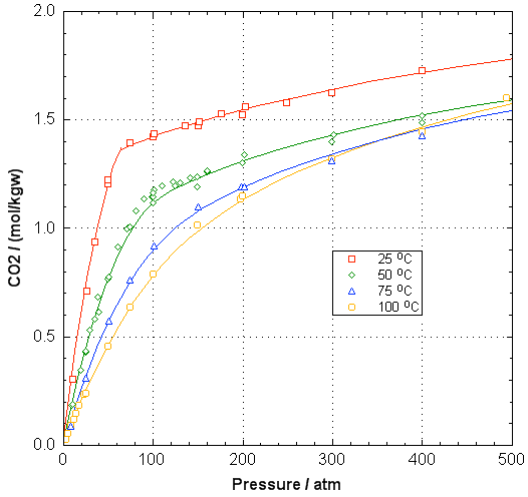

Figure 1. Solubility of CO_2 in pure water as a function of pressure, 25-100°C. Data from literature, lines from PHREEQC.

For modeling gas solubilities and mineral scales at high P-T and saline conditions, Pitzer.dat was adapted [3, 4].

Carbonate mineralisation in the supergiant Olympic Dam deposit

O.B. APUKHTINA[1]*, V.S. KAMENETSKY[1] AND K. EHRIG[2]

[1]CODES, UTAS, Hobart, Tasmania 7001, Australia (*correspondence: olgaa@utas.edu.au)
[2]BHP-Billiton, GPO Box 1777, Adelaide, SA 5001, Australia

The supergiant polymetallic Olympic Dam (OD) deposit is characteristically enriched in carbonate minerals. The relationships between carbonates and other minerals (hematite, magnetite, pyrite, Fe-Cu sulfides, uranium minerals), as well as the source of carbon remain unresolved.

OD is a breccia complex within the Mesoproterozoic granite that was intruded by ultramafic and mafic dykes. The ore minerals are associated with gangue minerals such as barite, fluorite, quartz, apatite and carbonates. Carbonate minerals occur in the association with the sulfides (particularly chalcopyrite) and gangue minerals.

Carbonates in the deposit increase in concentration towards the edges and at depth. REE-fluorocarbonates (e.g. bastnäsite-(Ce), synchysite-(Ce)) postdate the most common Ca-Mg-Fe-Mn carbonate minerals (siderite, calcite, dolomite-ankerite ss).

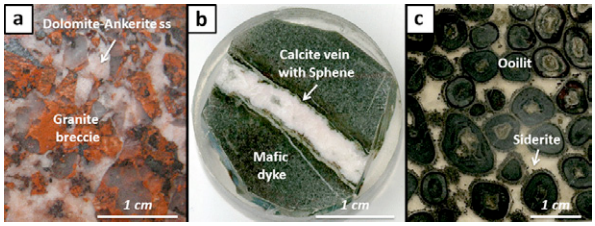

Figure 1: Some examples of carbonate textures.

In most cases carbonates appear as veins in different lithologies (mafic dykes, granite, mineralised breccia, figs. 1a,b) and rarely as oolitic rocks (fig. 1c). In addition, many carbonates occur in brecciated rock both as clasts and breccia cement (fig. 1a), providing evidence for numerous fauling and breccia-forming events. Various textures of carbonate-bearing rocks imply carbonate deposition in several stages.

The relative age of different carbonate generations based on dating of associated minerals (apatite, titanite, rutile, monazite) and $\delta^{13}C$ and $\delta^{18}O$ isotope signatures will be presented at the conference.

Reconstruction of redox conditions during deposition of Jordan oil shale using inorganic geochemical records

S. AQLEH[1]*, S. VAN DEN BOORN[2], O. PODLAHA[2], C. MÄRZ[1], T. WAGNER[1], S. W. POULTON[3] AND S. KOLONIC[4]

[2]Shell Global Solution, Rijswijk, The Netherlands
[3]University of Leeds, School of Earth and Environment, UK
[4]Jordan Oil Shale Company B.V., Amman, Jordam; New adress: SPDC of Nigeria Ltd., Nigeria

With the global rise in petroleum demand the pressure on finding conventional hydrocarbon resources has increased substantially and has led to a shift in focus from conventional to unconventional resources. The situation is particularly precarious for Jordan as it imports ~97% of its current energy needs, which underlines the importance of finding alternative energy resources within Jordan and explains the increased focus on the huge reserves of oil shale in the country which exceed 65 billion tons [1]. Oil shales are characterized as thermally immature packages of fine-grained organic-rich sediments that require artificial heating to generate hydrocarbons [2].

Here we present an inorganic geochemical study of thick sections of oil shale from two neighbouring core-holes in Central Jordan. Bulk geochemical records (total sulphur, total carbon and total organic carbon) along with inorganic geochemical proxies (Fe sequential extraction and trace metals) are used to reconstruct the paleodepositional environment of the oil shale, with special emphasis on understanding the mechanisms behind high-frequency and high-amplitude variations in TOC content that characterize these deposits. The proxy records show that TOC and S_{total} vary in phase but exhibit high amplitude variability, while carbonates contribute the largest fraction to the sediments. Trace metal and Fe speciation data indicate that the depositional environment fluctuated between anoxic and euxinic conditions. The strongest enrichment in redox sensitive trace metals (e.g. Mo and V) and TOC occur in euxinic sediments. The subtle fluctuations in oxygen deficiency at the reducing end of the redox scale are believed to exert an important control on organic matter enrichment and quality.

Diagenetic mobilisation of Fe and Mn in hydrothermal sediments

ALFRED AQUILINA[1], WILLIAM B. HOMOKY[1], LAURA E. HEPBURN[1], SETH G. JOHN[2], TIMOTHY M. CONWAY[2], TIMOTHY LYONS[3] AND RACHEL A. MILLS[1]*

[1]Ocean and Earth Science, National Oceanography Centre Southampton, University of Southampton, SO14 3ZH, UK (*correspondence: rachel.mills@soton.ac.uk, alfred.aquilina@soton.ac.uk, w.homoky@soton.ac.uk, laura.hepburn@soton.ac.uk).

[2]Department of Earth and Ocean Sciences, University of South Carolina, Columbia, SC29208, USA (sjohn@geol.sc.edu, tconway@geol.sc.edu).

[3]Department of Earth Sciences, University of California, Riverside, 900 University Ave. Riverside, CA 92521, USA (timothy.lyons@ucr.edu).

The Bransfield Strait is a tectonically-active marginal basin between the Antarctic Peninsula and the South Shetland Islands. We present data linking diagenetic metal cycles to hydrothermal activity on *Hook Ridge*, a submarine volcanic edifice in the Central Basin. Water column E_h-anomalies, visual observation of fluid flow at the seafloor, and pore-fluid chemistry confirm hydrothermal activity on *Hook Ridge* [1]. Concentration-depth profiles of NO_3^-, Mn^{2+} and Fe^{2+} indicate early stage, suboxic diagenetic reactions. However, compared to a nearby reference site, the sediment surface at *Hook Ridge* is enriched in solid phase Fe (reactive oxides and carbonates) and Mn, and underlain by elevated pore-fluid Fe and Mn content (Fig. 1).

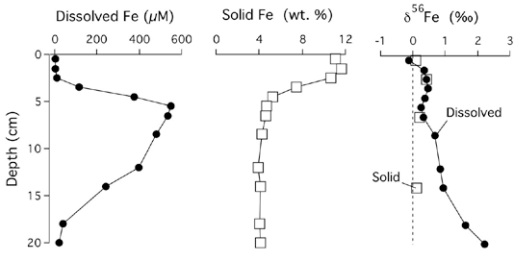

Figure 1. Down-core concentration and isotope composition of Fe in sediments and pore-fluids from *Hook Ridge*.

The isotope composition of dissolved pore-fluid Fe maxima ($\delta^{56}Fe_{dissolved}$ = +0.29 ± 0.05 ‰) is similar to the solid phase isotope composition ($\delta^{56}Fe_{solid}$ = +0.21 ± 0.15 ‰; Fig. 1), and distinct from light values that typify reductive Fe dissolution. Deeper dissolved Fe isotope compositions are consistent with Fe-sulfide reactions. Hydrothermal sediments are routinely overlooked as a significant source of metals to seawater, but *Hook Ridge* sediments indicate vigorous diagenetic mobilisation and enrichment of Fe and Mn with potential to impact Fe-limited primary production in the Southern Ocean.

Distribution, correlation and health risk assessment of heavy metal contamination in surface soils around an industrial area, Hyderabad, India

A. KESHAV KRISHNA[1] AND K. RAMA MOHAN[2]

[1]CSIR-NGRI, Habsiguda, Uppal, Hyderabad-500 007, INDIA (* correspondence: keshav_krishna@ngri.res.in)

[2] CSIR-NGRI, Habsiguda, Uppal, Hyderabad-500 007, INDIA (krngri@rediffmail.com)

Due to rapid industrialisation and urbanisation there has been much concern over the soil contamination with heavy metals. One such example is soils of Kazipalli (Hyderabad), India which has become a serious environmental problem. This region hosts several industrial activities which are the main source for hazardous waste which include pharmaceuticals, drugs, metal, packing, machinery and chemicals. Soil samples from fifty seven (57) sampling sites were collected from this industrial zone and were analyzed for heavy metals (HM) like As, Cr, Cu, Ni, Pb and Zn. Concentrations ranged from 4.4-796.3 mg/kg for As, 9.7-598.6 mg/kg for Cr, 7.9-183.5 mg/kg for Cu, 10.2-129.6 mg/kg for Ni, 25.3-1830 mg/kg for Pb and 23.8-879 mg/kg for Zn.

Application of factor and cluster analysis indicates that heavy metal contamination in soils originates from industrial activities which are of anthropogenic origin. Pearson's correlation analysis showed that there exists close correlations among As-Pb, Cr-Ni, Cu-Zn. Contamination of soils in the study area were further classified for geoaccumulation index (I_{geo}),enrichment factor (EF), contamination factor(CF) and contamination degree (C_{deg}). The values of pollution index (PI) and integrated pollution index (IPI) indicated that metal pollution levels were in order of As>Pb>Cu>Cr>Zn>Ni. Potential ecological risk indices (PERI, RI) showed the area suffered with high As contamination, followed by Cr, Cu, Pb, Ni, and Zn. The health risk assessment based on average daily doses (ADD) of individual elements were calculated using exposure parameters and reference doses from integrated databases of USEPA. Further, the average levels of chronic and carcinogenic risk based on hazard quotient (HQ) and hazard index (HI) are presented in the form of stock plots and tables. These results are important for the development of proper management strategies to decrease point and non-point source of pollution by different remediation methods.

Ancient fragments in the subcontinental lithospheric mantle beneath the Carpathian-Pannonian Region

LÁSZLÓ ELŐD ARADI[1]*, CSABA SZABÓ[1], JOSE MARIA GONZALEZ-JIMENEZ[2], WILLIAM GRIFFIN[2], SUZANNE Y. O'REILLY[2] AND KEIKO HATTORI[3]

[1]Lithosphere Fluid Research Lab, Eötvös University, Hungary
[2]CCFS/GEMOC, Dept. of Earth and Planetary Sciences, Macquarie University, NSW 2109, Australia
[3]Department of Earth Sciences, University of Ottawa, Canada
*correspondance: aradi.laszloelod@gmail.com, http://lrg.elte.hu

The Carpathian-Pannonian region (CPR) was formed by lithospheric extension accompanied by mantle flow and upwelling in the Neogene. Plio-Pleistocene alkali basalts brought fragments of the lithospheric mantle at five places in the CPR: Styrian Basin (Austria, Slovenia), Little Hungarian Plain, Bakony-Balaton-Highland (Hungary), Nógrád-Gömör (Hungary, Slovakia) and Perşani Mountains (Romania).

Several sulfide-bearing lherzolite xenoliths from the CPR were chosen to determine their PGE-distribution and Re-depletion ages (T_{RD}). Both whole-rock and *in situ* analyses show fractionated PGE patterns, which are controlled by partial melting of the upper mantle indicated by the correlation between Al_2O_3 and IPGE/PPGE. This is also supported by the major- and trace- element contents of the rock-forming minerals. *in situ* PGE analyses on sulfide grains show high and variable abundances of Os, Ir, Ru and Rh, with decreasing abundance from Rh to Au and a strong negative Pt anomaly. The total concentrations of PGEs range between 4 and 796 ppm.

The Re-depletion model ages range from near-zero to 1.6 Ga. Most of the T_{RD} ages are older than the oldest (Paleozoic) crustal rocks of the CPR. The main peaks at 0.6-0.8 Ga could be related to the breakup of Rodinia. The remainder of the model ages scatter between 0.95 and 1.35 Ga, which are probably related to the amalgamation of Rodinia. Outliers as old as 1.6 Ga (from Nógrád-Gömör) suggest that the subcontinental lithospheric mantle beneath the region may contain ancient domains dating from the assembly and break-up of the Columbia supercontinent, but these have been overprinted by numerous metasomatic events.

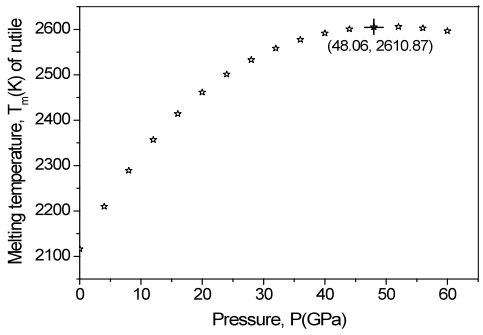
This research was funded by the Hungarian Science Foundation (OTKA, 78425 to Cs. Szabó).

Melting of Rutile under Pressure

S. ARAFIN, R. N. SINGH ,YOUSUF AL-SAIDI AND A.K. GEORGE

Physics Department, College of Science, Sultan Qaboos University, Box:36, Al-Khoudh 123, Oman

Rutile is one of the polymorphs of TiO_2. Out of the total mass of the Earth's crust, amount of rutile found in nature ranges from 0.5% at the upper crust to 0.8% at the bottom crust [1]. It is used in photovoltaic devices, integrated wave guides, gas and humidity sensors, and solar cells. Research on rutile is important to earth scientists because a complete understanding of the composition and thermal state of the Earth's interior depends on information about the elastic properties of this mineral at high pressure and temperature [2].



Information on pressure dependence of the melting temperature of rutile is scanty. Fritz [3] has measured the pressure dependences of the six elastic constants of single-crystalline rutile (TiO_2) by using ultrasonic techniques and a pressure range of 0–2 GPa. We present here pressure dependence of the melting temperature and thermophysical properties such as enthalpy, viscosity and diffusivity of rutile using a semi-empirical approach based on Lindemann's law. The pressure range used in the present study is 0-60GPa. Our preliminary results show that the melting maximum of rutile is 2610 K and it occurs at 48 GPa.

We examine the secular change of properties of podiform chromitites and their host peridotites to understand the evolution of the upper mantle through Earth's history. Podiform chromitites are very rare in the Archean ophiolites. They got gradually abundant in ophiolites from the early Proterozoic to the Phaneorozoic. The size of chromitite pods is mostly small (1 to 20 m x 0.5 to 3 m) in the Precambrian ophiolites, while remarkably larger (up to hundreds meters x several tens of meters) in the Phanerozoic ophiolites. The Archean chromitites show a very restricted and highly refractory composition of chromian spinel: Cr# [Cr/(Cr + Al)] from 0.74 to 0.93 and TiO_2 content less than 0.3 wt%. The Cr# of spinel in the host harzburgite is also high, around 0.7. In the late Proterozoic ophiolites, podiform chromitites are much more abundant than in the Archean and early Proterozoic ones. Al-rich chromitite varieties started to appear in the late Proterozoic ophiolites, although the majority are Cr-rich.

Podiform chromitites are very common and large in size in the Tethyan ophiolites of the late Paleozoic to Mesozoic age. Their host mantle peridotites have a wide range of spinel composition with an intermediate Cr#, around 0.5, serving as the most common host for large podiform chromitites in the Phanerozoic ophiolites. With a few exceptions all known Phanerozoic ophiolites have less refractory peridotites and chromitites than t the Precambrian ophiolites. Diversity in chromian spinel chemistry and PGE contents in podiform chromitites become more distinct in the Phanerozoic ophiolites.

If the tectonic setting of ophiolite formation has been kept the same, the distribution of Cr within the mantle to crust has been changed possibly with time. Larger amounts of Cr were possibly transported to the crust by high-degree partial melts and concentrared as the stratiform chromitite in the Precambrian, and, in contrast, have been stored as the podiform chromitite within the mantle as podi in younger times in the Earth's history.

Archean regional metamorphism of the 3.8-3.7 Ga Isua Greenstone Belt, SW Greenland: Geothermal gradient of the Archean subduction zone and implication for global carbon cycle

T. ARAI[1]*, S. OMORI[2], T. KOMIYA[3] AND S. MARUYAMA[4,1]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, Tokyo 152-8551, Japan (*correspondence: arai.t.am@m.titech.ac.jp)

[4]Earth-Life Science Institute, Tokyo Institute of Technology, Tokyo 152-8551, Japan

The 3.7-3.8 Ga Isua Supracrustal Belt (ISB), southwest Greenland, constitutes the oldest accretionary complex on Earth [1]. Detailed microscopic and microprobe analyses of metabasites in the area revealed that the western ISB underwent regional metamorphism from lower to upper amphibole facies, which record subduction-related progressive metamorphism [1]. Analysis of isochemical phase diagram of the metabasites quantitatively estimated the Archean geothermal gradient along the subducting plates as an intermediate P/T-type metamorphic series. In addition, the correlation of the modal abundance of carbonate minerals in the MORB-related metabasites with its metamorphic grade suggests that the carbonate minerals were formed prior to its subduction at the convergent boundary. Subduction of carbonatized oceanic crusts is considered as one of the main mechanism to reduce the atmospheric CO_2 [2]. Previous works reported that the less metamorphosed 3.1 Ga Archean MORB in Pilbara Craton, Western Australia, contain 30 vol% of carbonate minerals on average, due to the hydrothermal carbonation reaction with the CO_2-rich Archean seawater at the mid-ocean ridge [2], whereas 3.8Ga Archean MORB in the study area rarely contain carbonate minerals. Comparison of the Archean geothermal gradient and stability fields of carbonate minerals of the metabasite suggests that most of carbonate minerals in the oceanic crusts could not have been stably transported into the mantle under the geothermal gradient. The line of evidence indicates that most of the carbonate minerals trapped in the oceanic crusts could have returned to the surface at the subduction zone at least in the Archean 3.8Ga even though the Arcehan oceanic crusts were highly carbonated.

The role of brines in metamorphism and anatexis

L.Y. ARANOVICH

Institute of Geology of Ore Deposits RAS, 119017 Moscow, Russia (lyaranov@igem.ru)

A number of observations point to a potentially wide participation of brines in high grade metamorphic processes. Those are findings of alkali and alkali earth halides as daughter crystals in fluid inclusions; appreciable amount of Cl measured in granite melt inclusions in minerals and direct observations on high temperature halides present in intergranular space in the high grade rocks [1]. Thermodynamic mixing properties of concentrated water-salt fluids at high P-T differ greatly from those of water-non-polar gas mixtures: the former are characterized by a large negative deviation from ideal solutions [2], while the latter exhibit positive deviation from ideality. This difference has two major petrologic implications: unlike water-gas fluids, the presence of brines strongly increases melting temperature of quartzofeldspathic rocks and decreases dehydration of water-bearing minerals. Operation of brines may help to resolve the "granulite paradox": extensive dehydration without hole-sale melting. New experimental results [3] show that there is a large range of P-T space in which subsolidus deep crustal metasomatism may take place at low H2O activity via migrating fluids. Brines may implant K2O and silica into the mid-crust and thus condition it for anatexis. Brine-assisted anatexis differs greatly from rock melting in pure H2O or in CO2-H2O fluids. Large changes in feldspar compositions in equilibrium with melts can result from small shifts in fluid compositions. Contours of constant fluid H2O on the solidus minimum (H2O isopleths) have strongly positive dP/dT slopes. As a consequence, rising accumulations of granitic magma may be fluid saturated and even increase their melting capacity with decreasing depth because of the great pressure dependence of H2O activity in salt solutions. These results offer an explanation for mid-crust migmatization and granite production: rising hot brines may provoke rock melting at some threshold of decreasing depth in the range 15-20 km. Because of their enhanced capacity for metasomatism, leading to eventual melting at appropriate conditions of temperature, pressure and H2O activity, concentrated brines should be considered as possibly important agents in crustal evolution.

The origin of lithium in playas in Nevada, USA: Constraints by lithium isotope ratio

D. ARAOKA[1]*, H. KAWAHATA[1], T. TAKAGI[2], Y. WATANABE[2], K. NISHIMURA[3] AND Y. NISHIO[4]

[1]AORI, The University of Tokyo, Japan (*correspondence: araoka@aori.u-tokyo.ac.jp)

[3]Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Japan

Lithium is an industrially useful element with extremely low reduction potential whose compounds are used in many ways, espeacially in secondary lithium-ion batteries. Highly concentrated lithium resources are often formed in salt crusts and playas by evaporative enrichment, and lithium-rich brine in playas is a major raw material for lithium production. Moreover, lithium isotopic ratios (δ^7Li) have recently been identified as a tool for investigating water–rock interactions [1, 2]. Thus, to determine the origin of lithium in playas, we conducted leaching experiments to evaluate the effect of leaching processes on δ^7Li. Then we determined lithium and strontium isotopic ratios and contents and trace element contents of various lacustrine and evaporite deposit samples collected from playas in Nevada, USA. In samples from the playas, δ^7Li values were much lower than those in river water [3] and groundwater samples [1] from around the world, but they were close to those of upper continental crust [4]. On the basis of temperature dependence of lithium isotope fractionation during water-rock interactions [5], these results indicate that the highly concentrated lithium in playas was supplied mainly through high-temperature water–rock interactions associated with local hydrothermal activity and not directly by low-temperature weathering of surface materials. This study, which is the first to report lithium isotopic compositions in playas, demonstrated that δ^7Li may be a useful tracer for determining the origin of lithium and evaluating its accumulation processes in playas.

[5]GSI Environmental, Houston, Texas, USA

Clayey and silty aquitards are natural barriers that can protect aquifers at sites impacted by DNAPL contamination, with the degree of protection depending on geologic, hydrogeologic and geochemical characteristics. The most effective aquitards are those in which contaminant transport is diffusion controlled, provided the aquitard is sufficiently thick (>20 ft or so) to prevent diffusive breakthrough. If the aquitard is thin but unfractured, upward hydraulic gradients and/or chemical or biological degradation may be required to prevent diffusive breakthrough. The purpose of this presentation is to discuss the state of the art of the science relevant for evaluating processes of contaminant distribution and fate in clay aquitards with emphasis on the application of CSIA.

Two sites contaminated with chlorinated compounds were used in the investigation. A high resolution monitoring network, aquitard cores, microbiological tools and CSIA were used to evaluate the distribution and fate of the contaminants in the aquifer and the aquitards.

VOC's concentration profiles showed the highest concentration of parents and daughter products are observed near the aquitard and difussion was controlling contaminant transport in the aquitards. Much lower concentration or no VOC's were observed in the underlying aquifer at both sites. The isotope data showed that biodegradation was also controlling the VOC's concentration in the aquitard. The microbial data is also in agreement with the isotope data. Results of the detailed investigation confirmed the aquitard at both sites has apparently good integrity, therefore no or minor impact in the underlying aquifer is expected at the study sites.

Tracing perturbations in the oxygenation of the Cenozoic ocean using Molybdenum isotopes

COREY ARCHER[1], SUNE NIELSEN[2], KEVIN BURTON[3] AND JAMES R. HEIN[4]

[1]Institue of Geochemistry and Petrology, Dept. of Earth Sciences, ETH Zurich, Switzerland (corey.archer@erdw.ethz.ch)
[2]Dept. of Geology and Geophysics, Woods Hole Oceanographic Institution, MA, USA
[3]Department of Earth Sciences, Durham University, Science Labs, Durham, UK
[4]US Geological Survey, 400 Natural Bridges Dr., Santa Cruz, CA, USA

In recent years studies of Mo and its isotopes have come to the fore as indicators of palaeoredox conditions of the Earths atmosphere and oceans. Particular interest has focussed on tracing the evolution of the oxygenation of the atmosphere and oceans during key periods of Earths history such as the Great Oxidation event[1], or the resultant changes in ocean chemistry during the Proterozoic Eon[2]. By contrast few studies have focussed on changes in oceanic redox conditions through the Cenozoic, with existing data suggesting that essentially constant, and modern like redox conditions have prevailed for the last 60-70 Myr[3]. This observation is perhaps surprising considering evidence for substantial changes to the ocean-atmosphere system at the start of the Cenozoic[e.g.4].

Here we present new Mo isotope data from a well dated Pacific Ocean ferromanganese crust, potentially unique tracres of ocean chemistry, spanning the entire Cenozoic. Our data shows a small but significant 0.3‰ ($\delta^{98/95}$Mo) positive Mo isotope anomaly from modern ferromanganese crust values starting at the beginning of the Cenozoic, and lasting for much of the Cenozoinc before returning to modern values. These data therefore imply a Cenozoic ocean with a heavier Mo isotope composition than the present day. The Mo isotope anomaly is consistent with the processes inferred to have caused major changes in seawater sulphur and thallium isotopes during the Early Cenozoic[4,5], and indicates that marine ferromanganese precipitation and organic carbon burial rates were significantly higher and lower, respectively, in the Early Cenozoic than present day.

Why wind energy?

CRISTINA L. ARCHER

(carcher@udel.edu)

Wind energy has a relatively minor role in our current energy mix, but it can be one of the most important players in our future energy mix. Humans are extraordinarily effective at transferring carbon from the Earth to the atmosphere, mainly for the purpose of generating useful energy. This carbon-based energy choice has impacts on the Earth's climate, from the carbon cycle to air pollution, but also on other human factors, such as population growth and GDP. Most negative impacts can be eliminated by a green economy in which energy comes from renewable sources, such as wind. Wind will be evaluated in terms of its global potential, variability, effects on climate, and limitations. Preliminary findings also suggest that offshore wind farms can provide the additional benefit of protecting coastal communities during hurricanes.

Geochemistry and mineralogy of Philippine Nickel laterite deposits

CARLO A. ARCILLA, RUSSEL ONG, MERYL CALIBO AND CHERISSE FERRER

National Institute of Geological Sciences, University of the Philippines, Quezon City, Philippines, (caloy.arcilla@gmail.com)

Increased worldwide demand for steel has led into exploitation of nickel coming from Nickel-enriched soils weathered from ultramafic ophiolites. The Philippines is the second largest producer of nickel laterites which are mostly fed into blast furnaces in China. We have conducted extensive mineralogical and geochemical studies on these laterites comprising: 1) XRD and Rietveld refinement to identify mineralogical phases of laterites, 2) sequential extraction studies to delineate phases wherein nickel is enriched preferentially and 3) major and trace element analyses of laterite stratigraphy. We find that iron oxides and hydroxides dominate the limonite phase, not clay minerals, the latter only occurring in the lower "saprolite" phases which are dominated by serpentine-type minerals. While olivine precursors dominate the peridotite bedrock of laterites, we notice that pyroxene-rich horizons give rise to higher-grade nickel laterites. Trace element analyses also reveal surprisingly enriched concentrations of some rare-earth elements and other elements (e.g, Sc, Ti,V) that are not included in payment credits for the ores.

Subduction zones as probes of mantle composition

RICHARD ARCULUS

Research School of Earth Sciences, Australian National University, ACT 0200 (richard.arculus@anu.edu.au)

On a global basis, the genesis of the majority of primitive island arc and backarc magmas is through partial melting of ultramafic parental lithologies in the mantle wedge overlying subducted lithospheric slabs. A combination of slab-derived, fluid-fluxed melting with some decompression melting are assumed to dominate these modes of magma genesis in current convergent margin settings.

The composition of arc-backarc magmas spans a large range, including rare earth- and high field strength element-strongly depleted low-K basalts, to highly enriched high-K basalts, plus a range of high-Mg, intermediate-Si magmas including boninites and high-Mg andesites. Abundant examples of active submarine eruptions of the latter types have been sampled in the past decade in the Tonga-Lau system. Their genesis involves fluid-fluxed partial melting of highly refractory, clinopyroxene-poor parental lithologies, probably at the high temperature end of the spectrum of backarc-arc-mantle wedge thermal regimes.

The addition of fluxing agents serves as a potent probe of the lithogical heterogeneity of the mantle wedge that would not otherwise be subject to partial melting given refractory mineralogical characteristics. A spectrum of basalt-to-boninite magmas with high field strength and rare earth element abundances substantially lower than the majority of primtive mid-ocean ridge basalts, occurs widely in the intra-oceanic arcs of the western Pacific. Mixing of partial melts from refractory lithologies with those generated from more fertile protoliths also appears to be widespread in the western Pacific arc-backarc systems.

Another minor but widespread arc magma type is high-Ca-Mg “ankaramites”, possibly formed through partial melting of mantle wedge orthopyroxene-free wehrlite; this protolith likely originates as sub-Moho cumulates formed during fractional crystallisation of earlier generation hydrous arc magmas.

In contrast, alkali basalt magmas including very high-K types (some are phlogopite-phyric) hosting peridotite xenoliths, with high U/Nb typical of arcs generally, are rare magma types in the western Pacific arcs, but nevertheless indicative of the existence of highly metasomatised mantle wedge sources. The spectrum of mantle lithologies tapped during magma genesis at convergent margins is plausibly an excellent guide to the compositional variability of the upper mantle worldwide.

Aqueous contamination by oxyanions. The use of Zn-Al sulphate layered double hydroxides for waste water treatment

C. ARDAU*[1], A. DAVANTES[2], E. DORE[1], F. FRAU[1] AND P. LATTANZI[1]

[1]Department of Chemical and Geological Sciences, University of Cagliari , Via Trentino 51, 09127 Cagliari, Italy (*correspondence : carla.ardau@tiscali.it)

[2]LECIME, UMR7575 CNRS-Chimie ParisTech, 75005 Paris, France

Sorption is regarded as one of the most promising technologies for the treatment of waste waters, due to its efficacy and cost-effectiveness. Layered double hydroxides (LDHs) is a class of compounds with general formula $[M^{2+}_{1-x}M^{3+}_{x}(OH)_2](A^{n-})_{x/n}.mH_2O$. Possible cationic and anionic associations are widely variable (e.g. M^{2+} = Mg, Zn, Cu; M^{3+} = Al, Fe; A^{n-} = CO_3^{2-}, NO_3^-, SO_4^{2-}). Thanks to their large surface area, and high anionic exchange capacity, LDHs are extensively investigated for their possible use as removers of pollutant oxyanions from waters.

LDHs form spontaneously in a wide range of environments, including mine areas. Zn-Al-sulphate LDHs were found to precipitate from surface waters interacting with mine wastes [1]. Their effectiveness in attenuation of As content in NAMD (Net Alkaline Mine Drainage), observed in natural systems, was the starting point of our investigation.

Synthetic Zn-Al-sulphate LDHs were reproduced in laboratory and tested in several batch sorption experiments, first for the uptake of As and, then, for less conventional environmental oxyanion pollutants (Mo, W and Sb).

The first results in the use of these LDHs as removers of pollutant oxyanions (up to ~90% As(V); up to ~54% Mo; W and Sb work in progress) encourage further investigations. Since the affinity for LDHs strictly depends on the combination of anion charge density and size [2], a key point for sorption efficacy is the anionic form of the investigated pollutant (e.g. $H_2AsO_4^-$, $HAsO_4^{2-}$ or AsO_4^{3-}), and of potential competitors in solution (e.g. HCO_3^- and CO_3^{2-}). For some of elements (Mo), possible polymerisation phenomena must also be considered (see also Davantès *et al*, this issue). Therefore, the optimal pH conditions must be specifically evaluated for any oxyanion and waste water composition in order to enhance the LDHs uptake efficacy.

High-pressure behavior and phase transitions of thaumasite

M. ARDIT[1]*, G. CRUCIANI[1], M. DONDI[2], G.L. GARBARINO[3] AND F. NESTOLA[4]

[1]Dept. of Physics and Earth Sciences, Univ. of Ferrara, 44100, Ferrara, Italy
(*correspondence: rdtmtt@unife.it, cru@unife.it)
[2]ISTEC - CNR, 48018, Faenza, Italy
(michele.dondi@istec.cnr.it)
[3]ESRF, BP 220, 38043, Grenoble Cedex, France
(gaston.garbarino@esrf.fr)
[4]Dept. of Geosciences, Univ. of Padova, 35131, Padova, Italy
(fabrizio.nestola@unipd.it)

Thaumasite, $Ca_3Si(OH)_6(CO_3)(SO_4)\cdot 12H_2O$, is a rare mineral with a hexagonal structure based on cylindrical columns of $[Ca_3Si(OH)_6(H_2O)_{12}]^{4+}$ running parallel to the *c* axis, among which the SO_4^{2-} and the CO_3^{2-} groups are hosted. Thaumasite is unique because i) is the only known mineral stable at ambient *P–T* conditions that possesses silicon hexa-coordinated by hydroxyls; ii) is an indicator of sulphate attack in concretes (deterioration due to thaumasite formation especially occurs at subzero *T*). The thermal behavior of thaumasite has been investigated at *LT* and *HT* [1-3], and it was found that the thaumasite structure collapsed because of a severe dehydration above 417 K [3]. At all events, reports on the *HP* response of the thaumasite structure are lacking.

In this work, the *HP* evolution of the thaumasite structure was investigated using synchrotron XRPD, up to 19.5 GPa. Although during the Rietveld refinements no symmetry changes have been observed, the unit-cell decreasing with *P* is characterized by two strong discontinuities in the 1.38–3.53 GPa and 7.40–15.02 GPa *P*-ranges, respectively. Hence, three distinct compression regimes can be defined, with the thaumasite structure that retains the same $P6_3$ space group. These isosymmetric transitions occur with an increasing of the unit-cell parameters, revealing that the thaumasite structure becomes stiffer after each discontinuity. Comparing the *LT* and *HT* data from literature [1-3] with those collected under *HP* conditions, it is interesting to underline that the variation of the axial ratio *a*/*c* as a function of the normalized cell volume V/V_0 describes an ideal inverse relationship [4].

Trace element composition in a migmatite-granite complex (NW Portugal): Protolith and melting process constraints

M. AREIAS, M. A. RIBEIRO AND A. DÓRIA

CGUP/DGAOT-FCUP, Porto, Portugal
(maria.areias@gmail.com)

In NW Portugal a migmatite massif surrounding a synorogenic granite occurs within the axial zone of the Variscan Orogen. This massif includes: metatexites (patch and stromatic) and diverse granitoid rocks including: (i) diatexites, (ii) leucocratic granites, (iii) and two-mica mesocratic granites. The patch metatexites show anastomosed foliation marked by aligned Bt between grains of Qtz + Pl ± $Grt_{(Alm\text{-}Prp)}$. The Grt can be total or partially replaced by Crd + Qtz + Sil. There are coarser biotite selvedge skirting fibrolytic Sil + Qtz + Pl + Crd + Bt ± Kfs clusters. The stromatic metatexites have micaceous and quartz-feldspathic bands. The former contain Bt + Sil + Crd + Grt + Qtz + Pl. The latter contain large crystals of Qtz + Pl + Kfs+Bt. The diatexites have Qtz + Pl + Kfs + Bt and schlieren with Bt + Sil + Crd ± Grt. The leucocratic granitic bodies have essentially Qtz + Pl + Kfs and Bt and/or Tml clusters. The two-mica granites have Qtz + Pl + Kfs + Bt + Apt and rare schlieren of Bt + Sil ± And ± Grt ± Zrn. In all lithologies $Kfs_{(Or77\text{-}90)}$ is anhedral and replaces plagioclase.

The geochemistry study shows that all granitoid rocks are peraluminous, calc-alkaline with high K. The variation in HSFE is positively related to the content of $FeO_{(t)}$ + MgO and LILE don't show any correlation. The migmatites REE chondrit-normalized patterns are very similar to each other and to NIBAS standard [1]. The leucocratic granites have a REE pattern similar to leucosome, with positive Eu anomaly and variable HREE fractionation. The diatexites show variable REE fractionation and no Eu anomaly.The mesocratic granites show a REE pattern typical of two-mica granites. The enrichment in HREE is related with (i) accessory minerals retention in the melanosome, and (ii) the presence/absence of garnet in granites and leucosomes. This variations in the composition must be related to the input of accessory minerals from the protolith and the degree of melting (Bea,1996), instead of fractional crystallization or magma mixing.

Research integrated in the activities of CGUP, with financial EU funds by FEDER/OPHP and FCT and PETROCHRON project (PTDC/CTE-GIX/112561/2009).

Evolution of subglacial weathering based on multiple isotopic systems

C.A. ARENDT[1]*, S.M. ACIEGO[1], K.W.W. SIMS[2], E.A. HETLAND[1] AND E.I. STEVENSON[1]

[1]EES 1100 N University Ave, Ann Arbor, MI 48109-1005 (*carliana@umich.edu)
[2]GG 1000 E.University Ave. Laramie, WY 82071-2000

Multiple isotope systems with distinct and specific applications provide a comprehensive overview of the evolution of subglacial hydrologic pathways, and thus weathering processes, at the Athabasca Glacier, Canada. Synthesizing traditional stable isotopic analysis of $\delta^{18}O$ and δD, traditional radiogenic analysis of $^{87}Sr/^{86}Sr$ and ε_{Nd}, with a non-traditional application of uranium-series isotopes, allows us to quantify seasonal subglacial evolution and the impacts on weathering processes.

We apply the hydrologic tracers $\delta^{18}O$ and δD to estimate volumes and fractions of water sources to glacial discharge originating as ice, snow, and precipitation. We coupled a $\delta^{18}O$ and δD isotope-mixing model and a Bayesian Monte Carlo estimation scheme to infer the evolving water mass contributions from these three sources. We assess the extent of these water mass interactions and melt pathways with bedrock via heavy isotopes.

The length of time that subglacial water is in contact with underlying bedrock affects hydrological pathways and the magnitude of chemical interactions. Excess ^{234}U and ^{222}Rn from alpha decay depends on this residence time via their radioactive decay. Based on our newly established techniques, we find that the residence time varies by a factor of two through the melt season and is correlated with weathering fluxes. The spatial scale of weathering processes is investigated using radiogenic Sr and Nd isotopes; the age of the bedrock exposed to subglacial weathering varies systematically. The spatial variability in weathering location is revealed by the large variation in $^{87}Sr/^{86}Sr$ and ε_{Nd} (0.712-0.716 and 16-35, respectively). By combining these four isotope systems, we provide a quantifiable evaluation of the meltwater evolution in a polythermal glacier.

Diagnosing petroleum fractionation processes in surface and subsurface environments using GCxGC

J. S. AREY[1,2]*, C. M. REDDY[3], R. K. NELSON[3], R. CAMILLI[3], D. L. VALENTINE[4], G. D. WARDLAW[4], D. NABI[1], P. DIMITRIOU-CHRISTIDIS[1] AND J. GROS[1]

[1] Environmental Chemistry Modeling Laboratory, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland (*correspondence: samuel.arey@epfl.ch)
[2] Eawag, Dübendorf, Switzerland
[3] Woods Hole Oceanographic Institution, Woods Hole, USA
[4] University of California Santa Barbara, Santa Barbara, USA

Petroleum mixtures undergo significant compositional changes when exposed to air or water. This arises when oil is spilled on the sea surface, when deposited on the sea floor, or when extracted using enhanced recovery methods.

Using GCxGC, or Comprehensive Two-Dimensional Gas Chromatography, we can quantify thousands of individual hydrocarbon constituents in oil, including many biomarkers and structural isomers. Further, GCxGC instrument retention times convey information about the phase partitioning properties of each analyzed solute, indicating its tendency to dissolve into water, volatilize into air, or remain in oil phase. Applying GCxGC together with models of environmental behavior, we can differentiate physical fractionation and bio-transformation processes acting on thousands of hydrocarbon constituents in diverse surface and subsurface environments.

In this talk, I will describe diverse examples in which GCxGC allows us to disentangle volatilization, dissolution, and biodegradation processes acting on petroleum mixtures. Case studies include: oil evaporation and dissolution on the open sea; oil weathering on contaminated coastlines; fractionation of oil deposited on the deep ocean floor; and anaerobic oil biodegradation in a subsurface reservoir. An outlook into anticipated future developments is also given.

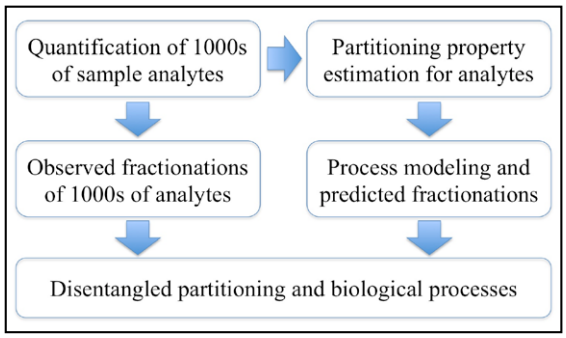

Figure 1: Elucidating fractionation processes using GCxGC.

Sorption of Pb(II) from aqueous solution by Greek attapulgite clay

A. ARGYRAKI[1]* P. MESSINI[1] AND V. ZOTIADIS[2]

[1]University of Athens, Panepistimiopolis Zographou 15784 Athens Greece
(*correspondence: argyraki@geol.uoa.gr)
[2]Edafomichaniki S.A., E. Papadaki 19, 14121 Athens, Greece

Attapulgite clay mined in Grevena, Greece is a readily available material with proven efficiency in the treatment of heavy metal contaminated soil [1]. Here, we present results of laboratory batch experiments aiming to compare raw and heat treated attapulgite clay for the adsorption of Pb(II) from aqueous solution.

Powdered attapulgite clay was supplied by Geohellas S.A. Samples were heat treated in muffle at temperatures of 130, 330, 500 and 800 ºC for 4 hours. P-XRD analysis before and after heating at different temperature revealed that attapulgite crystal lattice gets destructed from 330 ºC -a lower intensity of the main peak is observed. The comparative study of Pb adsorption efficiency of heat treated and non-treated material was performed for adsorbent dose of 2 to 15 g/L, initial Pb(II) concentration 50 mg/L, maximum shaking time 2h and pH 4. The effect of ionic strength was studied by varying the concentration of $NaNO_3$ from 0 to 0.5 mol/L. All experiments were carried out in a chamber set at 22 ºC.

At least 90% of the metal was retained with a dose of adsorbent of 5 g/L for all tested materials while an increase in the amount of dose of adsorbent to 10 g/L reached almost 100% retention for all materials. With the exception of attapulgite clay heated at 800 ºC, maximum adsorption was achieved within the first 5 minutes of reaction. A decrease in adsorption was observed as the concentration of $NaNO_3$ was raised probably due to competition between Na^+ and Pb^{2+} for the adsorption sites.

Complexation and ion exchange are probably the main adsorption mechanisms at the studied pH. Heat treatment induces dehydration (zeolitic H_2O loss) at low temperatures (e.g.<150 ºC) and dehydroxylation at higher temperatures (350- 510 ºC), while the complete destruction of the clay occurs at temperatures over 550 ºC [2]. Our data imply that significant changes in adsorption capacity of the used clay are related to alteration of nanoporosity and reduction of its specific area after calcination in temperatures > 550 ºC.

Temperature determination from speleothems through fluid inclusion and clumped isotope techniques

M. M. ARIENZO[1]*, P. K. SWART[1], S. T. MURRAY[1] AND H. B. VONHOF[2]

[1]Univerisy of Miami, Miami FL 33149, USA
(*correspondence: marienzo@rsmas.miami.edu, pswart@rsmas.miami.edu, smurray@rsmas.miami.edu)
[2]Vrije Universiteit Amsterdam, Amsterdam, The Netherlands
(h.b.vonhof@vu.nl)

Traditionally carbon and oxygen isotope analyses have been used to unravel the paleoclimate history of speleothems. However, the $\delta^{18}O$ of a carbonate is dependent both on the variations in temperature and the $\delta^{18}O$ of the water. In order to solve for the second unknown, an additional proxy is needed and such proxies include fluid inclusions, and/or clumped isotopes. Here we present results from both fluid inclusion and clumped isotope analysis on speleothems from the Bahamas.

Fluid inclusion isotope analysis is the analysis of water filled cavities in speleothems. These cavities preserve drip water at the time of formation and isotopic analysis provides information on the formation water ($\delta^{18}Ow$) and temperature can be calculated. Here we present a new technique utilizing cavity-ring down spectroscopy (CRDS) for $\delta^{18}O$ and δD analysis of fluid inclusions and compare the acquired data to that measured on the Amsterdam Device, a crusher system linked with an IRMS developed at the VU University Amsterdam [1]. Our results demonstrate an average standard deviation on fluid inclusion isotopic analysis of 0.5 ‰ $\delta^{18}O$ and 2.0 ‰ for δD, which is comparable to other IRMS fluid inclusion analytical methods [1].

In addition to fluid inclusions, clumped isotope analysis of the calcite has been conducted. Our results support an offset between the $\delta^{18}Ow$ measured on the fluid inclusions and the $\delta^{18}Ow$ calculated using the temperature calculated from $\Delta 47$. This is similar to the offset observed in the literature for speleothems [2]. To better elucidate the drivers of the $\Delta 47$ offset, cave monitoring has been conducted in the Bahamas, including *in situ* calcite farming. Preliminary results from the cave monitoring support an increasing $\Delta 47$ offset along a growth band for samples which are thought to precipitate in equilibrium.

Systematic understanding of adsorption of oxyanions of Cr, Mo, and W at solid/water interfaces

D. ARIGA,[1] M. TANAKA,[1] T. KASHIWABARA[2] AND Y. TAKAHASHI[1]

[1]Hiroshima University, (m124560@hiroshima-u.ac.jp)
[2]Japan Agency for Marine-Earth Science and Technology

Adsorption of trace elements on iron (oxyhydr)oxides is related to their concentrations and isotopic compositions in natural waters. Among various elements, adsorption of oxyanions of chromium (Cr), molybdenum (Mo), and tungsten (W) which are congeners have been studied here with an emphasis on chromate, because the adsorption mechanism on ferrihydrite is different between molybdate and tungstate which form outer– and inner- sphere complexes, respectively, but not evident for chromate. Therefore, fundamental understanding of the adsorption mechanisms of chromate is essential to discuss these issues. We performed (i) extended X–ray absorption fine structure (EXAFS) analysis for chromate on the three Fe (oxyhydr) oxides (i.e. ferrihydrite, goethite, and hematite), (ii) adsorption experiments of chromate on Fe (oxyhydr) oxides with different conditions of pH and ionic strength, and (iii) quantum chemical (QC) calculations to reveal difference of attachment modes (inner– or outer–sphere complexes) and surface structures such as monodentate–mononuclear, bidentate–binuclear, or bidentate–mononuclear complexes.

EXAFS analysis and adsorption experiments revealed that chromate forms almost outer–sphere complexes with slight amount of inner–sphere complexes on ferrihydrite. In contrast, most of chromate forms inner–sphere complexes on goethite and hematite. Moreover, the chromate forms mainly a bidentate–binuclear complex as inner–sphere complexes based on EXAFS analysis and QC calculations.

In addition, the QC calculation results showed that the stabilities of the hydrated species in aqueous solution and outer–sphere complex on solid surface for oxyanions may govern the determination of attachment modes of oxyanions and the distribution at the solid-water interfaces.

The experimental results of attachment mode for oxyanions will be interpreted by linear free energy relationship (LFER) using $pK_{a\text{-}avg}$ (= (pK_{a1} + pK_{a2})/2) to explain the adsorption behaviors of these divalent oxyanions. We found that the LFER using the $pK_{a\text{-}avg}$ value is essential to explain the adsorption behavior, in particular the preference of outer– and inner–sphere complexes on ferrihydrite, compared with LFER based on either pK_{a1} or pK_{a2} value.

Geological and geochemical features of the Sarıçayır (Yenice/Çanakkale) Skarn deposits

FETULLAH ARIK AND İLKNUR AKIŞ

Selcuk University, Geological Engineering Department, Konya, Turkey
(correspondence: fetullah42@hotmail.com)

The Sariçayir Skarn Deposit is located around the Sarıçayır village and 70 km southwest of Çanakkale. Oligo-Miocene magmatic, metamorphic and volcanic rocks crop out in the study area. The Karakaya complex is the basement of the study area. Structural basement of the Karakaya Complex is represented by the Nilüfer unit that mostly consists of metabasic rocks. Hodul unit which is dominated by arkosic sandstones was emplaces over the Nilufer unit. Both of the Nilufer and Hodul units are metamorphosed to green schist facies. The units of the Karakaya complex are cut by Oligocene Karadoru granitoid and Sarıçayır alkali granites and covered unconformably by the Oligocene Çan volcanics, consist of andesitic pyroclastics and lavas.

Nilüfer and Hodul units were affected by the intrusion of Karadoru granotoid and Sarıçayır alkali granite. Contact metamorphism and skarn zones have been developed between the Karadoru granitoide and the Nilüfer and Hodul units. Contact metamorphism appears to have extended from albit-epidot hornfels to hornblend hornfels facies. Skarn zone, on the other hand, appears to have developed in the type of garnet-epidot skarn.

Skarn type mineralization was developed adjacent to Sarıçayır alkali granite contacts with the limestones belonging to Nilüfer units which are located northwest of Sarıçayır village. Also, epidote and quartz fillings are observed within fractures and faults of the Sarıçayır alkali granite [1].

Garnet, tremolite and epidote were determined in the skarn zone. Also, pyrite, chalcopyrite, sphalerite, galena, digenite and cinnabar were observed as ore minerals. Chemical data obtained from samples indicated that enrichment of the copper, lead, zinc, arsenic and iron-oxide contents. Thus Fe_2O_3 contents reach up to 57.54 % together with 60.6 ppb Au. In addition Cu, Pb, Zn , As and Ag 4656 ppm, 8101 ppm, 3700 ppm, 2500 ppm, and 8.3 ppm respectively.

Igneous sapphirine in Ambatomena, southern Madagascar

M. ARIMA[1]*, K. KIMOTO[1], R. RAKOTONDRAZAFY[2], N. O. T. RAKOTONANDRASANA[1] AND M. A. RANAIVOSON[1]

[1] Yokohama National University, Yokohama 240-8501, Japan (*correspondence: arima@ed.ynu.ac.jp)
[2] University of Antananarivo, Antananarivo, Madagascar (raymondrakoto@gmail.com)

Sapphirine is commonly thought to be metamorphic, and igneous sapphirine is rare [1]. We examined sapphirine-bearing intrusions of early Paleozoic age (~487 Ma) in Ambatomena, southern Madagascar [2]. The Ambatomena rocks intrude highly deformed granulite facies quartofeldspathic gneisses. The rocks consist of sapphirine, spinel, cordierite, plagioclase and orthopyroxene with subordinate amounts of ruby corundum and phlogopite. The anhedral corundum grains show melt-reaction coronas of spinel and sapphirine. The rocks contain abundant sapphirine-orthopyroxene symplectites and in some places cordierite-orthopyroxene symplectites were developed. Sapphirine grains in contact with corundum and spinel are more aluminous than the 7:9:3 composition (up to 68 wt% Al_2O_3). The sapphirine-spinel geothermometry [3] suggests equilibrium temperatures for the sapphirine-spinel paragenesis around 930~1060°C at 5 kb.

The Ambatomena assemblages represent crystallization of sapphirine and associated minerals from aluminous silica undersaturated melts at high temperatures. Petrographic features suggest the following igneous crystallization sequence; (1) crystallization of corundum from melt, (2) sebsequent reaction of corundum with melt to produce spinel and sapphirine, (3) reaction of spinel with melt to form orthopyroxene and sapphirine, and (4) final crystallization of plagioclase, cordierite, and phlogopite from residual melt. This sequence is broadly comparable to the liquidus phase relations in the forsterite–diopside–anorthite–silica system reported by Liu and Presnall [4].

Adsorption of MS2 virus to natural organic matter and model surfaces

ANTONIUS ARMANIOUS[1]*, THÉRÈSE SIGSTAM[2], TAMAR KOHN[2] AND MICHAEL SANDER[1]

[1]Institute of Biogeochemistry and Pollutant Dynamics, Department of Environmental Systems Science, ETH Zurich (antonius.armanious@env.ethz.ch)
[2]Environmental Engineering Institute, School of Architecture, Civil and Environmental Engineering, EPF Lausanne

Previous studies showed that viruses adsorb to natural organic matter (NOM) surfaces with varying affinities. Adsorption to NOM is an important fate process: it may affect the transport of viruses in the environment and it may enhance virus inactivation because NOM-water interfaces are reactive microenvironments. Despite its importance, virus adsorption to NOM remains poorly understood on a mechanistic level. Here, we systematically studied the adsorption of the bacteriophage MS2, a model virus, to different NOM films and to gold surfaces that were uncoated or coated with self-assembled monolayers (SAM) of alkylthiols with -CH_3, -OH, -COO^- and –NH_3^+ end groups. The well-defined chemical properties of the gold and SAM allowed assessing the relative contribution of van der Waals forces, the hydrophobic effect, hydrogen bonding and electrostatic forces to MS2 adsorption. The integrities of the formed NOM and SAM films were verified by ellipsometry and contact angle measurements. MS2 adsorption was studied as a function of solution pH and ionic strength using quartz crystal microbalance with dissipation monitoring that has ng/cm^2 sensitivity. Negatively charged MS2 adsorbed to gold and all tested SAM surfaces except to the negatively charged carboxylate-terminated SAM surface. No virus adsorption was detected to the different NOM films at pH≥ 5 and low ionic strength (I= 10 mM). Adsorption to NOM films increased with increasing ionic strength. These findings suggested that MS2-NOM electrostatic repulsion and possibly steric stabilization forces dominated over attractive interactions arising from the hydrophobic effect, hydrogen bonding, and van der Waals forces. Implications for the interactions of proteins and engineered nanoparticles with NOM will be highlighted.

Rethinking mantle geochemical heterogeneity: New insights into mantle geology

P. ARMIENTI AND D. GASPERINI

[1]Dipartimento di Scienze della Terra, Università di Pisa, via S. Maria, 53, 56126 Pisa, Italy . (armienti@dst.unipi.it)
[2]Departament de Geoquímica, Petrologia i Prospecció Geològica, Universitat de Barcelona, Martí i Franqués s/n, 08028 Barcelona, Spain.

Classical statistical data analysis constrains the upper mantle geochemical and mineralogical complexity introducing the concept of Mantle Resevoirses. This concept is based on the underlying assumption that the mean composition of wide mantle volumes may be attained by significantly smaller representative samples. We argument that this underlying hypothesis needs to be checked and non-linear methods are able to reveal how mantle compositional heterogeneity cannot be conceived as a deviation from a mean value.Non-linear analysis methods reveal that the mutual distribution of isotope and immobile trace element of Ocean Island Basalt mantle sources mirrors the intrinsic spatial organization of the mantle revealing the systematic occurrence of strange attractors in the geochemical signals. This supports the evidence for a chaotic mantle, bridging the discrepancy between geochemical and geophysical views of mantle composition, and overcomes the impasse of the twenty years-old theories on mantle reservoirs. Our results confirm that the vertical scale of mantle heterogeneity is similar to its horizontal organization, as revealed by MORB sampled at ridge axes, and reinforces the conclusion that this structure is inherited from an ancient convection regime, probably affecting the whole mantle scale.

PTt path of rising magmas. An ascent rate meter recorded in lava volatile contents

PIETRO ARMIENTI[1] AND CRISTINA PERINELLI[2]

[1]DST – Pisa University (armienti@dst.unipi.it)
[2]DST – Pisa University (c.perinelli@dst.unipi.it)

Experimental and theoretical investigations prove that the triggers of volcanic eruptions are related to the ascent rates at depth, which control the exolution and expansion of volatile components. Volatile loss (mainly H20 and CO2) has in turn cascade affects on a variety of parameters (crystallinity, viscosity, volume, composition) all able to strongly affect the dynamic of the ascent rate. The complex feedbacks of ascent rate and volatile content may be recorded at shallow levels by the composition of melt inclusions and at depth, by early liquidus phases which are sensible to pressure, temperatue and volatile content.

Among these, pyroxene has been identified as a valid tracef of the PT path of ascent of magma providing dP/dT estimates that may be related to dZ/dt (Z=depth) trough kinetic consideratios on crystal growth and nucleation. The recent introduction of a clinopyroxene hygrometer now opens the possibility to relate the water content to pressure and temperature, extending at considerable depths our record of P,T.t, Xi .

Since degassing of non ideal CO2-H2O mixtures is strongly non-linearly dependent on pressure, the volatile contents of lavas, as revealed by the mineralogical and melt inclusion record, can be matched by a unique PTt path that is coherent with the thermodynamic modelling of gas exsolution.

This new tool to define the PTt path of magmas is here applied to some recent eruptions of Mt Etna.

Simulating the climatic impact of Large Igneous Provinces using a mid-Miocene case-study

DAVID I. ARMSTRONG MCKAY[1], TOBY TYRRELL[1], PAUL A. WILSON[1] AND GAVIN L. FOSTER[1]

[1]Ocean and Earth Science, University of Southampton Waterfront Campus, National Oceanography Centre Southampton, Southampton, SO14 3ZY (correspondence: D.Armstrong-McKay@noc.soton.ac.uk)

Large Igneous Provinces (LIPs) have occurred throughout Earth's history, erupting great quantities (>10^4 km^3) of lava in long-lived (>10^5 y) events that have been linked to major environmental disruptions [1]. While the largest LIP eruptions are widely considered to have had a significant impact on global climate through basalt CO_2 degassing [2–4], the impact of the more numerous smaller LIPs is disputed [5–7]. Here we test the hypothesis that LIPs had a greater impact on Earth's climate history than previously estimated because of the degassing not only of erupted basalts but also intruded, underplated and pyroxenite-enriched magma [1, 4, 8]. We use biogeochemical box models to investigate the potential impact of the Columbia River Basalts (CRB) during the mid-Miocene, as a more rigorous model-data comparison is enabled by the better palaeorecords from this relatively geologically recent event. Comparison of our simulations to palaeorecords [5, 9, 10] of mid-Miocene changes in oceanic carbonate compensation depth (CCD), $\delta^{13}C$ in benthic foraminifera and atmospheric pCO_2 suggests that an emission of ~2000-4000 Pg of carbon between ~16.2 and 15.8 Ma is required to reproduce the palaeorecords, although additional mechanisms are required to match the CCD palaeorecord beyond ~15.8 Ma. This flux is within the estimated range of potential carbon emissions when including non-extrusive sources. Our results indicate that with these additional CO_2 sources the CRB could have played a significant role in the mid-Miocene Climatic Optimum, and implies that other LIPs could have also had a greater climatic impact than currently estimated.

Constraining the history of the Mojavian lithosphere with Sr, Nd, Hf, and Os isotopes of peridotite xenoliths from Dish Hill, California

R.M.G. ARMYTAGE[1]*, A.D. BRANDON[1], A.H. PESLIER[2,3] AND T. J. LAPEN[1]

[1]Earth and Atmospheric Sciences, University of Houston, Houston, TX, 77204, USA, *rarmytage@uh.edu
[2]Jacobs Technology, JETS,, Houston, TX, 77058, USA
[3]Astromaterials Research and Exploration Science, NASA-Johnson Space Center, Houston, TX, 77058, USA

The $^{187}Os/^{188}Os$ ratios in mantle xenoliths have been used to constrain continental growth histories [e.g. 1]. However, there is debate over the degree to which model Os ages reflect large-scale mantle melting linked to continental growth [2], or averaged-out end members after a multi-stage-history of partial melting, melt-rock interaction and metasomatism [3]. Combining different isotopic systematics can help constrain the nature and timing of melt extraction and secondary melt or fluid interactions in subcontinental lithospheric mantle.

A suite of 16 spinel-bearing Cr-diopside peridotite xenoliths from Dish Hill, CA, a Plio-Pleistocene cinder cone in the Mojave Desert were first characterized for major and trace elements (bulk-rock and main phases), then analysed for Os, Hf, Nd and Sr isotopes, with the lithophile isotopic analyses being obtained on cpx separates.

The $^{187}Os/^{188}Os$ ratios fall on two aluminachron [4] trends, with T_{PUM} at 2.12±0.08 Ga and 1.39±0.10 Ga. These two distinct trends are supported in correlations of $^{187}Os/^{188}Os$ versus melt depletion indicies such as Cr# in spinel This signal of two mantle melting events is not present in the Hf isotope data. The correlations between εHf and melt depletion indicies are weak. There is also evidence that Hf is decoupled from Nd as the peridotites that lie off the εHf-εNd terrestrial array of [5] also display LREE enrichments. High Nb/Zr and La/Lu ratios in cpx in one of the peridotites suggest a HFSE-LREE metasomatic component.

The combined isotopic data points to the lithosphere mantle under Dish Hill being formed in two ancient mantle melting events, and overprinted by at least two metasomatic components. There is no evidence in this xenolith suite of underlying Farallon oceanic lithosphere as proposed by [6].

Downward injection of sulfide slurries: their role in the formation of Ni sulfide deposits

N.T. ARNDT[1], S.J. BARNES[2], J. ROBERTSTON[2], C.M. LESHER[2] AND S. CRUDEN[2]

[1]ISTerre, Univ Grenoble, CNRS UMR 5275, Grenoble, France, (arndt@ujf-grenoble.fr)
[2]CSIRO, 6151 Perth, Australia Steve.Barnes@csiro.au
[3]MERC, Laurentian Univ. Sudbury, Canada (mlesher@laurentian.ca)

Magmatic Ni-Cu sulfide deposits form when mafic-ultramafic magma interacts with rocks of the continental crust, which decreases the solubility of sulfide in the magma or adds sulfur to cause the segregation of immiscible sulfide liquid. Strongly chalcophile Ni, Cu and PGE concentrate in the sulfide and if this phase accumulates, an ore deposit is formed. Most models identify gravitative settling of dense sulfide liquid as the cause of sulfide accumulation but inspection of the textures and structures of orebodies indicates that the process is not so simple. Many ores consist of crystal mushes or breccias that are injected in pulses into the host intrusions; layers of massive sulfide commonly penetrate rocks beneath the intrusions.

These features can be explained if sulfide-rich masses of magma migrated from higher in the magmatic plumbing system. As magma ascends, the pressure drops and, particularly if the magma assimilates country rocks, it loses heat. This causes crystallization, which may be accompanied by the appearance of sulfide droplets. The density and the viscosity of the magma increases. Many ore-bearing intrusions are saucer-shaped with flat, sill-like bases and sloping margins. As magma flows up these margins, a dense and viscous sulfide-bearing mush accumulates near the lower border while crystal-free liquid ascends along the upper part. The process differentiates the magma, producing evolved decanted liquids that flows erupts as flood basalt. The magma interacts with the sulfide in the lower part of the conduit, enriching the sulfide in chalcophile metals. The mush layer periodically becomes unstable and slumps down the conduit, to be injected as pulses into the sill-like portions of the intrusions.

Effects of climate change and changes in atmospheric CO_2 levels on sources of terrestrial aerosol precursors

A. ARNETH[1], W. KNORR[2] AND M. WU[2]

[1]Karlsruhe Institute of Technology, Institute for Atmospheric Environmental Research (IMK-IFU) (almut.arneth@kit.edu)
[2]Lund University, Dept. Physical Geography and Ecosystem Analysis (Wolfgang.knorr@nateko.lu.se; Minchao.wu@nateko.lu.se)

The terrestrial biota is a significant source of aerosols and aerosol precursors. Emissions of biogenic volatile organic compounds, for instance, are known to contribute to the growth of secondary organic aerosols and hence exert a negative radiative forcing. Wildfire, as a second example, is a large source of black carbon, with a large positive climate forcing. Hence changes in terrestrial aerosol and aerosol precursor emissions constitute a large and highly uncertain factor in the assessment of future climate-pollution interactions, especially when dealing with the question: to what extent would climate effects of pollution control be counteracted by possibly enhanced biogenic and fire emissions?

From a terrestrial sources perspective, addressing this question requires a consistent, process-based modelling framework, to take into consideration a number of direct and indirect factors that affect emissions collectively. Both fire and BVOC emissions respond rapidly and directly to short-term weather effects, like warm temperatures enhancing BVOC emissions. Fire occurrence directly responds to hot dry conditions immediately. However, over years and decades, climate trends and trends in atmospheric CO_2 concentration also play an important role. For example. wetter conditions and/or higher CO_2 levels can enhance fuel and enhance rather than reduce fires. Vegetation productivity and changing composition must be taken into consideration, both for BVOC emissions and fire regimes. Changes in vegetation composition in response to changing fire regimes can also affect BVOC emissions regionally, while direct human land use is an additional crucial component to be considered for the assessment of future aerosol precursor emissions from terrestrial ecosystems, for both BVOC and fire.

Sneaky sulfate signals: Isotope fingerprints reveal *cryptic* pathways

G.L. ARNOLD* AND B. BRUNNER

Center for Geomicrobiology, Department of Bioscience, Aarhus University, Aarhus, Denmark (*correspondance: gail.arnold@biology.au.dk)

The presence of sulfate in deeply buried methanic marine sediments traditionally considered to be sulfate-free (e.g. Holmkvist *et al* [1]) implies that sulfur (S) cycling is an ongoing process in the deep biosphere, reflecting catabolic pathways where S constituents act as shuttles between compounds that are being oxidized on the one side and reduced on the other side. The pivotal role of the S constituents in such processes often remains hidden or 'cryptic' because while the S compounds are continuously reduced and re-oxidized, the overall inventory of the S constituents remains constant. Exploring cryptic S cycling is of importance for two reasons. First, it provides insight into how microbial processes under energy limitation work, and if/how, specialized microorganisms share the already small amount of available energy to carry out different biochemical reactions. Second, it potentially challenges or at least transforms the paradigm that there is a sequential cascade of electron accepting processes in the environment across redox gradients, with the energetically most favorable electron acceptor consumed first and the least attractive process carried out last. In other words, dissimilatory sulfate reduction could occur in presence of Mn(IV) or Fe(III), or in the methanogenic zone.

We elucidate deep sulfate cycling in the Aarhus Bay sediments and at other sites by looking at both the S and oxygen (O) isotope composition of sulfate, which is affected by sulfate generation and consumption in combination with a numerical model. The combined S and O isotope singature of sulfate allow us to disentangle the processes responsible for sulfate production, such as oxidation of reduced organic and inorganic S and dissolution of barite from processes that consume sulfate, such as sulfate reduction.

Whereas cryptic sulfate generation is evident from the observation of sulfate in the methanic zone, where sulfate has canonically been presumed not to be present, this is not the case for the main sulfate reduction zone in marine sediments. Here, only the analysis of the combination of concentration and S and O isotope composition profiles of sulfate reveals the hidden intricacies of S cycling.

Functional contrasts and functional redundancy in Arctic bacterial communities in the oxic water column and anoxic sediments

C. ARNOSTI[1]*, Z. CARDMAN[1], A.D. STEEN[1], K. ZIERVOGEL[1] AND A. TESKE[1]

[1]UNC Chapel Hill, Dept of Marine Sciences, Chapel Hill, NC 27599, USA (*arnosti@email.unc.edu)

Investigation of enzymatic activities and bacterial community composition in the water column and sediments of an Arctic fjord of Svalbard during two summers captured the transition from a fully oxidized water column to anoxic, sulfate-reducing sediments. In 2008, water column bacterial clone libraries were dominated by members of the phylum *Verrucomicrobia* and the subphylum *Flavobacteria* (Fig. 1), known as aerobic degraders of polysaccharides. Some Svalbard phylotypes were specifically related to single cells attaching to and presumably taking up laminarin and xylan [1]. In addition to these substrates, chondrotin sulfate and fucoidan were hydrolyzed in the water column. In sediments, phylotypes of the anaerobic *Bacteroidetes* and sulfate-reducing *Deltaproteobacteria* were prominent, and a greater range of polysaccharides were hydrolyzed. Despite considerable diffences in water column community composition between 2007 [2] and 2008, patterns of enzyme activities were largely constant. We therefore have evidence of functional redundancy among water column communities of differing composition, which nonetheless use the same comparatively narrow spectrum of substrates relative to their benthic counterparts.

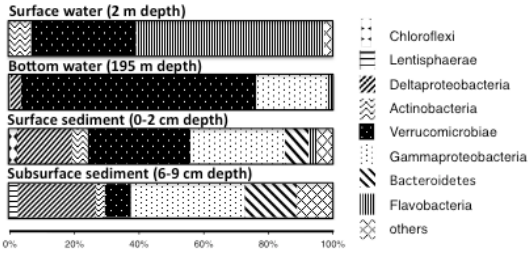

Figure 1. Bacterial 16S rRNA gene clone library composition of water column and sediment samples.

Comparing properties of natural biogenic with biomass burning particles in Amazonia

PAULO ARTAXO[1]*, LUCIANA V. RIZZO[2], JOEL F. BRITO[1], HENRIQUE M. J. BARBOSA[1], ELISA T. SENA[1], GLAUBER G. CIRINO[3], ANDREA ARANA[3] AND ANA M. SERRANO[3]

[1]Instituto de Física, Universidade de São Paulo, Rua do Matão, Travessa R, 187, 05508-090, São Paulo, Brazil. (*correspondence: artaxo@if.usp.br)

[2] Departamento de Ciências Exatas e da Terra, Universidade Federal de São Paulo, Rua Prof. Artur Riedel, 275, 09972-270, Diadema - São Paulo, Brazil.

[3] Instituto Nacional de Pesquisas da Amazonia – INPA. Av André Araújo, 2936, Manaus - AM. 69060-001, Brazil.

The Large Scale Biosphere Atmosphere Experiment in Amazonia (LBA) is a long-term (20 years) research effort aimed at the understanding of the functioning of the Amazonian ecosystem. The strong biosphere-atmosphere interaction is a key component of the ecosystem functioning. Two aerosol components are the most visible: The natural biogenic emissions of particles and VOCs, and the biomass burning emissions.

Two aerosol and trace gases monitoring stations were operated for 4 years in Manaus and Porto Velho, two very distinct sites, with different land use change. Manaus is a very clean and pristine site and Porto Velho is representative of heavy land use change in Amazonia. Aerosol composition, optical properties, size distribution, vertical profiling and optical depth were measured from 2008 to 2012. Aerosol radiative forcing was calculated over large areas. It was observed that the natural biogenic aerosol has significant absorption properties. Organic aerosol dominates the aerosol mass with 80 to 95%. Light scattering and light absorption shows an increase by factor of 10 from Manaus to Porto Velho. Very few new particle formation events were observed. Strong links between aerosols and VOC emissions were observed. Aerosol radiative forcing in Rondonia shows a high -15 watts/m^2 during the dry season of 2010, showing the large impacts of aerosol loading in the Amazonian ecosystem. The increase in diffuse radiation changes the forest carbon uptake by 20 to 35%, a large increase in this important ecosystem.

Compositional heterogeneity of the upper mantle beneath the Siberian craton: Reconciling thermal, seismic and gravity data

IRINA ARTEMIEVA, MATIJA HERCEG, YULIA CHEREPANOVA AND HANS THYBO

IGN, Univ. Copenhagen, Denmark, (irina@geo.ku.dk)

We present a new regional model for the upper mantle structure below the Siberian craton. The model includes (i) thermal model of the lithosphere structure constrained by surface heat flow data, (ii) seismic velocity heterogeneity constrained by global tomography models corrected for temperature variations in the upper mantle, (iii) and a new regional model for the density structure based on the GOCE satellite gravity data. We also present a new regional seismic crustal model SibCrust, which is used to calculate crustal correction to gravity field. Thermal model and seismic tomography models are used as independent constraints on lithosphere thickness, required to convert mantle residual density anomalies to density heterogeneity. New regional upper mantle model is compared with regional and world-wide petrological data on upper mantle velocities and densities constrained by mantle-derived xenoliths. The results indicate a significant compositional heterogeneity of the lithospheric mantle of the region. Seismic velocity and density anomalies cannot be explained by variations in mg# alone. Compared to the adjacent orogenic belts and the West Siberian basin, density structure of the cratonic mantle is in a close agreement with isopicnic condition, although significant regional variations are well correlated with basement topography.

Planning cement materials for a sustainable future

G. ARTIOLI

Dipartimento di Geoscienze, Università di Padova, I-35131 Padova, Italy (gilberto.artioli@unipd.it)

Binders and cements are crucial materials in past and modern human activities. Critical issues to be addressed for a sustainable use of cements include the global generation of CO_2 during mass production of Portland clinkers, the use of recycled materials in the formulations, and the development of alternative, durable and environmentally-compatible binders. Ultimately, the proper life cycle assessment (LCA) of the mass produced cements must be considered in order to save georesources, although this is a rather challenging task [1].

The expanding use of geopolymers [2, 3] and alkali-activated binders [4] for building applications follow this trend, although further progress is urgently needed in determining the chemico-physical, mechanical, and durability properties of alternative materials. Some of the systems currently under investigation will be reviewed, with emphasis on advantages and pitfalls.

The stochastic treatment of mineral surface reaction kinetics

R. S. ARVIDSON[1]*, C. FISCHER[1] AND A. LÜTTGE[1,2]

[1]MARUM / Fachbereich GEO (FB5), Universität Bremen, Klagenfurter Straße, D-28359 Bremen Germany (*correspondence: rsa4046@uni-bremen.de)

[2]Rice University, Houston, TX 77005, USA

There is increasing divergence in approaches describing the geochemical kinetics of mineral surface reactions. The first approach, for which there is long-standing traditional support and a large number of observational data, assumes that the most systems are essentially deterministic, i.e., imposing a given set of initial conditions or a perturbation will always produce the same result at a later time. The well-known mathematical representation of this approach is a set of coupled ordinary differential equations: the change in a given chemical species' concentration as a function of environmental conditions, constrained by heuristically determined parameters (rate constants, overall activation energies, etc.). In contrast, the second approach, supported by more recent work [1], argues that the intrinsic variability of certain mineral-fluid systems preclude such a deterministic treatment. Although well-documented, this intrinsic variability is not well understood. At the moment, neither the presence or absence of significant variations in rate under specific conditions has a consistent explanation. Furthermore, even if deterministic outcomes could be represented by probabilistic functions (by assuming fluctutations are negligible), the deterministic approach provides no explicit defense for this assumption [2].

As an initial step, we wish to assess the amplitude of intrinsic rate variation, and thus need to examine the history of dissolving surfaces over time. We present preliminary results of (1) a large number of direct observations of a fixed area of a dissolving mineral surface at constant undersaturation over time, and (2) model simulations of a similar surface, in which contributions of surface defect density, distance to grain boundaries, and other parameters can be varied. These observations of real mineral surfaces and their virtual equivalents permit comparison of the rate's distribution over the surface and its deviation from an arbitrary mean value. This resulting statistical treatment may be a precursor to a generalized stochastic model of mineral surface reactions, and resolution of otherwise inconsistent observations of reaction rate.

Spherulites in trachytic melts

F. ARZILLI[1]*, M. VOLTOLINI[2], L. MANCINI[1], M.R. CICCONI[3], G. GIULI[3] AND M.R. CARROLL[3]

[1]Elettra-Sincrotrone Trieste S.C.p.A., 34149 Basovizza, Trieste, Italy (*correspondence: fabio.arzilli@elettra.trieste.it)
[2]Lawrence Berkeley National Laboratory, Cyclotron Rd, 94720 Berkeley, California, USA
[3]School of Science and Technology – Geology Division, University of Camerino, Italy

Spherulites are cluster of radiating crystals that occur commonly in rhyolitic melts under highly non-equilibrium conditions [1-2]. Textural data on spherulites of alkali-feldspar and pyroxene are shown in this study. Spherulites grew in trachytic melts during cooling and decompression experiments with water-saturated conditions. The aim of this work is to better understand the growth of spherulites as a function of undercooling (ΔT), P_{H2O}, time and superheating. Experiments were carried out using Cold Seal Pressure Vessel apparatus at pressure range of 30 ÷ 200 MPa, temperature range of 750 ÷ 850 °C and duration of 2 ÷ 16 hours.

This study presents preliminary quantitative data on spherulitic morphologies obtained both by electron microscopy (SEM) and phase-contrast synchrotron X-ray microtomography. Because experiments were performed at different experimental durations, the evolution of spherulites can be studied and furthermore the crystallographic misorientation, the changes in size and the aspect ratio can be measured.

Three kinds of spherulites occured during our experiments: (i) spherulites characterized by widely spaced crystals arranged radially around the nucleus, in agreement with previous observations [3-4]; (ii) spherulites characterized by acicular and tiny fibers radially aggregated; (iii) spherulites characterized by the transition from a single crystal into a polycrystalline spherulite (densely branched spherulitic morphology).

The preliminary results about alkali feldspar spherulites show that their growth rate is about 10^{-7} cm/s. Spherulites were grown between 100 and 200 MPa, thus at high water contents. Moreover, low ΔT along with large superheating can enhance the nucleation and growth of spherulites. Therefore, low ΔT, large superheating and high P_f conditions can trigger the crystallization of spherulitic morphologies.

From death of a glacier to the beginning of life in soil: A case study in the Swiss Alps

J. ASCHER[1]*, C. MAVRIS[2], F. FORNASIER[3], M. CECCHERINI[1], G. PIETRAMELLARA[1] AND M. EGLI[2]

[1]Dept. of Agrifood and Environmental Science, University of Florence, Italy (*correspondence: judith.ascher@unifi.it)
[2]Dept. of Geography, University of Zurich, Switzerland
[3]CRA-RPS Gorizia, Italy

Pedogenesis starts just after deglaciation, with microbial primary succession playing a key role in soil ecosystem development. The progressively exposed moraines of the Morteratsch Glacier (Upper Engadine, Switzerland) offer a full time sequence, from 0 to 150 yrs [1]. We assessed geological, physico-chemical and microbiological parameters (microbial biomass, microbial community structure and selected soil enzyme activities) along the age gradient of the proglacial area. We set up a *double-nested-PCR-DGGE* approach on intracellular DNA extracted from the topsoil (0-10 cm) to monitor bacterial and fungal succession along the chronosequence, capable to detect also low numbers of target sequences occurring in early stage soils.

Increasing soil age was characterized by microbial biomass increase and, as expected, by a dynamic community succession. Both parameters displayed in turn a high positive correlation with SOM content (Ntot and Ctot) and pH decrease (0 yrs: pH 8.11 – 150 yrs: pH 5.64). High correlations with enzymes, biochemical markers reflecting soil activity, were also detected. Numbers of microbial phylotypes were lowest in the youngest soils (0-4 yrs), increased in the intermediate aged soils (4-110 yrs), and decreased again and plateaued in the oldest soils (110-150 yrs).

Our findings confirm that soil microbiota undergo drastic variations both in terms of biomass and community composition according to substrate availability, with interactive adaptation to the differing stages of soil development.

Melt modified mantle lithosphere beneath Dalnyayay pipe

ASHCHEPKOV I.V.[1], NTAFLOS T.[2], SPETSIUS Z.V.[3] AND R.F.SALIKHOV[3]

[1] IGM SD RAS, Novosibirsk, Russia, igora57mail.ru
[2] University of Vienna Althanstr. 14 1090 Wien, Austria
[3] Company "ALROSA", Mirny 678170 Russian

Mantle xenoliths (>100) from Dalnaya pipe (Yakutia) were studieds by EPMA and LAM ICP MS. In deformed and porphyroclastic Cpx is mor Fe- rich and HT and may associate with picroilmenites. The splitted geotherm (33 to 45mwm-2) are traced by course and deformed varieties varieties respectively from 7.5 to 2GPa. Essential inflection and heating detected by PT for OPx ~3GPa referring to Ca-enriched pyroxenitic garnets two more heating intervals are found ~ 7-6 and 5GPa. Continuous branches of growth with decreasing P of Fe# for Gar and low - Fe Cpx Fe# 6 to 12# suggest that primary mantle layering beneath this pipe was smoothed by interaction with melts. The refertilization trend (Fe#9-15% rising upward in two branches refer to the joint crystallization of Ilm - low-Cr Ilm – Cpx - Gar found in intergrowth referring to protokimberlite melts evolution.

In the PFO2 diagrams garnets and Cpx show continuous reduction to the lithosphere base to 4ΔQMF, and a bit higher for Cpx. Ilm - garnet trend is rising upward between -2 -0 ΔQMF. The diamond grade is higher for the porfiric kimberlites containing higher sub Ca garnet from dunites representing melt path veins. Trace elements for olivine show lower Ni and higher Al, Ca, Ti for the deformed veins. Trace elements determined for Gar and Cpx from 13 xenoliths from the middle part of mantle section reveal very similar patterns in the incomatible part in general suggesting reactions with the protokimberlite melts.

Composition and interior structure of the HED Parent Body

HELEN O. ASHCROFT*, BERNARD J. WOOD AND JON WADE

Department of Earth Sciences, University of Oxford, South Parks Road, Oxford OX1 3AN, UK
(*correspondence: helen.ashcroft@earth.ox.ac.uk)

Estimates for the major and trace element compositions of the Howardite-Eucrite-Diogenite (HED) parent body mantle have been derived using geochemical information from the HED meteorites [1] and the observation that refractory lithophile elements occur in chondritic relative proportions [2]. The putative mantle compositions (Table 1) were then used to investigate differentiation processes within Vesta.

	MgO	Al_2O_3	SiO_2	CaO	FeO
PM1	29.7	3.01	42.3	2.40	22.6
PM2	32.8	3.33	46.7	2.65	14.6

Table 1. Major element composition (wt%) of two putative mantle compositions (PM1 and PM2).

These estimates were combined with new information from *DAWN* [3] to model the interior structure of Vesta. Mantle compositions imply a mantle mineralogy of approximately 60% olivine and 40 % pyroxene. We estimate crustal thickness of 10-20 km and a core mass fraction of 15 % for a body with mantle composition PM1, and 20-30 km and 19 % respectively for PM2. Combining this information with experimentally determined crystal-melt and melt-metal partition coefficients (e.g. [4]), the trace element distribution throughout the protoplanet was then calculated, including estimates of Ba/W for Bulk Silicate Vesta of 29-32 for PM1 and 48-67 for PM2.

Initial results from one-atmosphere and piston cylinder experiments confirm that basaltic melts can be derived from these putative mantle compositions with olivine replacing pyroxene as the 1 atm liquidus phase as increasing amounts of mantle are added to eucritic starting compositions. We are currently determining crystal-melt partitioning behaviour for a diverse range of refractory trace elements. The data will be used to further constrain the igneous history of Vesta.

Improved crustal *PTtD* evolution constraints using TitaniQ thermobarometry

KYLE T. ASHLEY*,[1], RICHARD D. LAW[1], DONALD W. STAHR III[1], JAY B. THOMAS[2], MARK J. CADDICK[1], FRANK S. SPEAR[2] AND LAURA E. WEBB[3]

[1]Department of Geosciences, Virginia Tech, Blacksburg, VA 24061, USA (*correspondence: ktashley@vt.edu)
[2]Department of Earth and Environmental Sciences, Rensselaer Polytechnic Institute, Troy NY 12180, USA
[3]Department of Geology, University of Vermont, Burlington, VT 05405, USA

Applications of the Ti-in-quartz (TitaniQ) thermobarometer provide insight into the conditions, timing, mechanisms and rates of metamorphism and deformation. Our work on Vermont metapelites has documented quartz growth with respect to microstructural contexts as resulting from (a) early prograde growth; (b) quartz-producing metamorphic reactions; (c) precipitation from deforming micaceous domains; and (d) retrograde Si-charged fluid influx. In each case, the TitaniQ thermobarometer (with known pressures and activity estimates) reveals temperatures for these events, which all resulted in new quartz growth. However measurements of dynamically recrystallized quartz (notably through subgrain rotation) from Vermont and the Sutlej Valley (NW India) show that new subgrains usually exhibit [Ti] much lower than expected for the temperatures at which deformation occurred. This is an artifact of the mechanisms driving recrystallization in an attempt to minimize internal lattice strain. Defects aligned into subgrain boundaries may provide pathways for Ti to leave the crystal during formation of nearly strain-free subgrains. Increased lattice strain from Ti substitution may be reflected in the systematic increase in uncertainties of lattice refinements with single crystal X-ray diffraction measurements with increasing [Ti]. Therefore application to quartzites where only scarce weak interconnected phases are present to accommodate strain is problematic.

Ti diffusion from garnet porphyroblasts into quartz inclusions has recently been shown to be an effective technique for constraining metamorphic time scales [1]. In Vermont, this diffusion modeling suggests heating after encapsulation and cooling to 450 ºC must have occurred in a short amount of time (<1.2 Myrs). Preliminary application to the Sutlej Valley suggests very similar time scales for metamorphic evolution. Coupled growth and diffusion modeling of large (*ca*. 4–5 mm diameter) garnets attaining low peak temperatures (<600 ºC) have been unable to effectively discriminate *T-t* histories at the resolution of Ti-in-quartz diffusion modeling.

Thermodynamics of melts from shock wave experiments and a simplified speciation model

P. D. ASIMOW, C. W. THOMAS AND A. S. WOLF[1]

[1]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena CA 91125 USA; (asimow@gps.caltech.edu)

Although the thermodynamics of melts nominally falls outside the boundaries of a "thermodynamics of minerals" session, the subjects are intertwined by melting and crystallization and by the critical planetary dynamics that arise from differences between the physical, thermochemical, and transport properties of solids and liquids.

An extensive campaign of shock wave experiments on liquid compositions in the CaO-MgO-Al_2O_3-SiO_2-FeO system now provides constraints on the equations of state (EOS) of multicomponent melts at all terrestrial mantle pressures. The results can be compared to *ab initio* and empirical molecular dynamics (MD) simulations, static experiments, and geophysical observations. Key material property conclusions that have emerged include: (1) a negative temperature dependence to the sound speed, at least for Mg_2SiO_4 melt; (2) clear composition dependence to the effective partial molar volume of the FeO component, presumably related to composition-dependent coordination or spin states; and (3) universal behavior of the Grüneisen parameter, increasing upon compression at a near-uniform rate. Earth science conclusions at this stage include: (4) an absence of cases where mid-mantle magma ocean crystallization can give rise to a neutrally buoyant solid assemblage, at least initially near the liquidus; and (5) the near impossibility of finding a bulk composition in MgO-SiO_2-FeO and an extent of partial melting consistent with phase equilibrium and geophysical constraints for partially molten ultra-low velocity zones at the core-mantle boundary.

Given the expense and limitations of current MD methods for the study of silicate liquids and the challenge of linking microscopic data (e.g. spectroscopy) to mesoscopic data (e.g. EOS) or macroscopic observations (i.e., geophysics), it is helpful to develop simplified models that capture certain key aspects of melt behavior. We have extended the hard-sphere model into a coordination-number dependent, predictive model of speciation and equation of state for silicate liquids, *CHASM*. Currently the model has been calibrated on solid structures for SiO_2, MgO, and MgO-SiO_2 binary systems. It reproduces the pressure-dependence of coordination statistics from MD and allows insight into the natural origins of phenomena (1), (2), and (3) above.

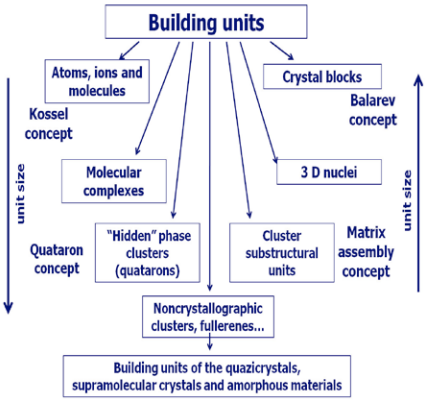
Prenucleation nanoclusters as building units in the crystal growth

A.M. ASKHABOV

Institute of Geology, Komi Science Centre, UralBranch, RAS, Syktyvkar, Russia

The problem of building units is central in the crystal growth theory. Throughout many decades there competed two conceptual ideas.

According to the first, crystals grow by joining to them of already formed in environment crystal blocks (Balarev concept). According to the second, building units are separate ions, atoms and molecules (Kossel concept).



In principle, realization of these two extreme variants does not contradict the general laws of physics and chemistry. As a matter of fact, the majority of modern theoretical models of crystals growth are constructed on their basis. At the same time, for a long time already another idea – on building units as particles larger than separate atoms or molecules, but not being crystalline particles (3 D nuclei) – is discussed. There were suggestions about participation in growth of crystals of intermediate formations (complexes, associates, clusters etc.) of which existence testified the results of numerous experimental (not only spectroscopic) researches of crystal-forming media. However on this basis it was not possible to develop the alternative concept of crystal growth because of arising contradictions with classical theory of nucleation.

We developed a new approach to the analysis of processes of nucleation and growth of crystals which comes from the possibility of formation and existence in supersaturated media of special forms of the connected atoms – nano-size pre-nucleation clusters of "hidden" phase called quatarons [1, 2]. Quatarons owing to their properties are ideal structures as building units. Namely they are the basic growth units and not geometrically and energetically stabilized clusters or another clusters substructural units. Thus an old problem of establishing the nature and sizes of building units in the process of crystals growth is solved.

Timing of Northern Hemisphere climate transitions during the last glacial period from precisely-dated speleothem data

Y. ASMEROM[1]*, V. POLYAK[1] AND M. LACHNIET[2]

[1]Dept. of Earth & Planetary Sciences, Univ. of New Mexico, Albuquerque, NM 87131, USA(*correspondence: (asmerom@unm.edu, polyak@unm.edu)

[2]Department of Geoscience, University of Nevada, Las Vegas, NV 89154, USA(matthew.lachniet@unlv.edu)

Previous $\delta^{18}O$ results of last glacial period precipitation variability in the south western United States from Fort Stanton cave, New Mexico (FS-2) [1], matched changes in Greenland temperatures [2]. We inferred changes in winter precipitation, which were related to changes in the meridional shifts in the position of the position of the polar jet stream, reflecting changes in the polar to equator temperature gradient in the Northern Hemisphere (NH).

We report high-resolution chronology and oxygen and carbon isotope data on another Fort Stanton Cave stalagmite (FS-AH-1), taking advantage of the higher growth rate compared to FS-2 (3 μm/yr vs 11 μm/yr), newer refinements in the half-lifes of ^{234}U and ^{230}Th, a new high purity ^{233}U-^{236}U spike and much improved efficiency from our upgraded Neptune multi-collector ICP-MS. The new chronology, between 48.4 -11.2 kyr B.P., has 2-σ errors in the range of 100 years for most of the segments, including conservative estimate of the uncertainties in the initial $^{230}Th/^{232}Th$ ratios.

Our results show that last glacial stadial (Heinrich Events, HE) and interstadial (Dansgaard/Oeschger Events, D/O) are matched very well in timing, amplitude and duration between the FS-AH-1 and NGRIP [2] with a higher age precision than the ice core data. The lack of systematic pattern in the lead-lag relationships between the ice core and FS-AH-1 D/O and HE chronology suggests that differences are due to chronology and not climatic lags. Thus, FS-AH-1 provides a more precise chronology for the NGRIP record. One significant difference, our record, similar to some North Atlantic records, shows two HE 1 cooling excursions, occurring immediately after two IRD (ice-rafted detritus) events [3] and match temperature sensitive $\delta^{18}O$ marine core data from subtropical Atlantic [4]. The difference between the two records may reflect greater sensitivity of our record to circulation-driven NH temperature gradient variability.

Petrochemical typification of the oolitic iron ores from the Bakchar deposit (Westen Siberia)

E.M. ASOCHAKOVA

Tomsk State University, Russia, ev.asochakova@gmail.com

The Bakchar deposit is confined to the Upper Cretaceous and Paleogene deposits overlapped by a rather thick Neogene-Quaternary rock body (160-200 m). The iron ores are related with several horizons: Narymskian, Kolpashevskian, Tymskian and Bakcharskian. The depth of productive strata varies from 2 to 40 m. The iron ore horizons are traced throughout the entire area of the deposit, as well as outside its borders and are separated by the barren and weakly ferruginous rocks that overlap each other often with washouts.

While researching the ore horizon of the Polinyansk site, we classified the iron ore types, which differ from each other in structural characteristics, a mineral composition of the cementing mass, as well as in the specific locations of these types in the section. There are three main types of ores in the section structure. First type includes goethite-hydrogoethite (oolite) ore, which are brownish-yellow cemented or loose sediments. The second one is glauconite-chlorite; it has a firm weakly cemented composition and greenish-grey color. The third transitional type of ores has characteristics of both goethite-hydrogoethites and glauconite-chlorite formations.

In order to verify validity of ore type classification, we processed statistically all the data of the X-ray fluorescence analysis (Na_2O, MgO, Al_2O_3, SiO_2, P_2O_5, K_2O, CaO, TiO_2, MnO, Fe_2O_3tot) using the software “STATISTICA”.

The group clustered analysis using k-means clustering method allowed us to define one of three classes for each ore sample. The samples of ores are objects for clustering. The number of these classes was chosen according to the amount of ore types in the section described above. Clustering the samples of ore chemical compositions distinguishes clearly locations of different ore types in the ore horizon based on the change of chemical composition.

Using a factor analysis, two main factors were defined, which took more than 70 % of dispersion over. The components of the clastic part (SiO_2, K_2O, MgO, Al_2O_3) and the ore part (Fe_2O_3tot, P_2O_5 and L.O.I.) influenced the variation of chemical composition of the oolite iron ores significantly.

This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.0686, 14.B37.21.1257).

Performance and gas-flow effects of an active 2-volume sampling chamber using a 213 nm laser ablation system for inductively coupled plasma-mass spectrometry

D ASOGAN[1]*, D. A. GREEN[1], S. SHUTTLEWORTH[2] AND J. W. ROY[2]

[1]CETAC Technologies, Omaha, NE 68144, USA (*correspondance: dasogan@cetac.com)

[2]Photon Machines Inc., Bozeman, MT 59715, USA

Laser ablation-ICP-MS technology has been rapidly improving for the past decade. The sampling chamber design of any laser ablation system is vital to ensure minimal elemental fractionation (by minimizing particle condensation/agglomeration), and enhance aerosol transport to improve accuracy, precision and sensitivity.

Improvements in sampling chambers design has led to higher spatial resolution and greater precision, which subsequently improves the quality of data in applications such as (bio-)imaging and geochronology respectively.

This paper discusses for the first time the use of an active 2-volume cell, which uses multiple gas flows to effectively transport laser aerosols for high spatial resolution (fast washout) and stability using a 213 nm laser ablation system. Performance characteristics are presented that highlight its versatility to multiple application types and also the importance of choosing the right gas flows for the particular ICP-MS system in use.

Mineralogical and compositional changes of eclogite and adjacent calcareous metapelite and talc schist from the Eclogite Zone, Austria, were investigated in order to understand fluid-mediated compositional changes during subduction zone metamorphism. Whereas the eclogite in contact to the metapelite shows almost noch change in volume, minor gain of Si, Ca and Na and loss of Mg, the metapelite shows a 30% volume loss, mainly as SiO_2, depletion of Ca and enrichment of K, Mg, Fe and Na – the latter two stemming from an external source. Trace element changes are less spectacular but corroborate changes in the major elements (Sr goes with Ca, Ba with K, etc.)

The eclogite in contact to the talc schist also underwent no significant change in volume, but minor enrichment in Mg and depletion in Na. The talc schist is ultrabasic in composition and of uncertain origin. It experienced more than 30% volume loss towards the contact, where Mg, Fe, Si, Na and Ti are depleted and no major element is enriched.

These changes in bulk composition are expressed in mineralogical, textural and mineral chemical changes of considerable complexity, and are not just limited to the very obvious retrograde interactions. The earliest composition changes are already manifest in the cores of garnets and demonstrate a rather continuous interaction throughout the entire metamorphic history. As the lithological boundaries are planar over distances of tens of metres at least, the volume losses are not induced by folding but rather by (pure or general) shear. Some composition changes cannot be explained by material exchange between the two lithologies (bimetasomatism) alone but must have been caused by advection parallel to the lithological boundaries. Rare garnets and epidotes with oscillatory zoning patterns near the contact indicate local abundance of fluid. The compositional changes are too systematic and complex to be explained as primary (volcano-)sedimentary layering or mixing of clays and ashes.

Characterization of $CaCO_3$ polymorphs grown in silica hydrogel in the presence SO_4^{2-} or CrO_4^{2-} by XAS

J.M. ASTILLEROS[1,2]*, J. GÖTTLICHER[3], N. SÁNCHEZ-PASTOR[12], R. STEININGER[3] AND L. FERNÁNDEZ-DÍAZ[1,2],

[1]Department of Crystallography and Mineralogy, Complutense University , Madrid, Spain. (*correspondence: jmastill@ucm.es)

[3]ANKA Synchrotron Radiation Facility, Karlsruhe Institute of Technology (KIT), Hermann-von-Helmholtz-Platz 1, D76344 Eggenstein Leopoldshafen, Germany

It has been noted that the presence of tetrahedral anions like SO_4^{2-} and CrO_4^{2-} in the medium for synthesis strongly influence $CaCO_3$ crystallization by promoting the formation of vaterite or vaterite/aragonite with respect to calcite. This influence has been related to either interface phenomena, such as preferential adsortion of these ions on particular sites on the surface of a specific polymorph or to changes in the relative free energy of the polymorphs due to differential incorporation of the tetrahedral anions. In order to confirm the incorporation of SO_4^{2-} and CrO_4^{2-} into the structure of the different $CaCO_3$ polymorphs and to study how and to what extent it may occur, crystals of calcite, aragonite and vaterite were grown in the presence of high concentrations of one of these anions using the silica gel method and were studied by X-ray absorption spectroscopy (XAS) at the Cr and S *K* edges in the XANES and EXAFS (only for Cr) regions. Measurements were conducted in the SUL-X beamline of the ANKA synchrotron radiation facility at the KIT (Germany). In all the experiments calcite was the most abundant polymorph in the precipitate, while vaterite and aragonite appeared as minor phase. While calcite grew as elongated single crystals, both aragonite and vaterite appeared as spherulitic aggregates. The incorporation of SO_4^{2-} and CrO_4^{2-} was confirmed in the three polymorphs, with signifcantly higher concentrations in calcite. In the case of calcite XAS spectra were recorded on differently oriented single crystals. Differences are very small and may point to a possible preferential orientation of the tetrahedral SO_4^{2-} anion in the structure. Finally, the comparison between spectra from the three polymorphs evidenced slight differences between those corresponding to calcite and aragonite. Differences are most marked to the spectrum of vaterite for SO_4^{2-} (Cr contents in vaterite were to low for a reliable comparison).

Coupling magnetic and molecular techniques to study microbial-mediated iron and carbon cycling

ESTELLA A. ATEKWANA[1]*, SILVIA ROSSBACH[2], CAROL L. BEAVER[2], FARAG M. MEWAFY[1] AND LEE SLATER[3]

[1]Oklahoma State University, Stillwater, OK, USA (*correspondence: estella.atekwana@okstate.edu)
[2]Western Michigan University, Kalamazoo, MI, USA (silvia.rossbach@wmich.edu)
[3]Rutgers University-Newark, New Jersey, USA (lslater@andromeda.rutgers.edu)

Dissimilatory iron-reducing bacteria are able to reduce iron coupled to organic carbon oxidation, often producing magnetic mineral phases. Magnetic susceptibility (MS) measurements can therefore play an important role in identifying zones where microbial-mediated iron mineral transformation is occurring so that these zones can be studied by microbiological techniques. We investigated the MS and microbial community variations in a hydrocarbon-contaminated aquifer where iron-reduction and methanogenesis are occurring. Our results show two zones of elevated MS at the contaminated locations; one occurred within the zone of water table fluctuation and coincident with high concentrations of Fe(II) and organic carbon. The second was observed in the vadose zone and associated with the methane plume. Using the polymerase chain reaction technique, *Geobacter* species were found to be present in these two zones. At the background location, *Geobacter* species were limited to the upper soil layer. Therefore, *Geobacter* species could be the main drivers of magnetic mineral formation in these zones. Using molecular methods, including denaturing gradient gel electrophoresis and DNA sequencing, we observed that *Smithella* and other syntrophic species were dominant in the zone of peak magnetic susceptibility coinciding with zones of iron reduction and methanogenesis. Our results suggest that the integration of geophysical and microbiological methods will be of value for iron and carbon cycling studies.

Post depositional transformation of Ni-rich birnessite

AMY ATKINS[1]*, CAROLINE L. PEACOCK[2] AND SAMUEL SHAW[3]

[1]School of Earth & Environment, University of Leeds, Leeds, UK. jhs5aa@leeds.ac.uk (* presenting author)
[2]School of Earth & Environment, University of Leeds, Leeds, UK. C.L.Peacock@leeds.ac.uk
[3]School of Earth, Atmospheric and Environmental Sciences, University of Manchester, Manchester, UK. Sam.Shaw@manchester.ac.uk

Birnessite is the dominant Mn oxide in marine sediments. However, under diagenesis and mild hydrothermal conditions the phyllomanganate birnessite transforms to the tectomanganate todorokite [1-3]. Across significant areas of the seafloor birnessite is therefore a transient mineral phase. This is important because scavenging of dissolved trace metals to birnessite exerts a strong control on the concentration of these species in seawater. In particular, in the modern oceans the sorption of Ni to birnessite is the primary control on Ni oceanic concentration [4]. Ni is a bioessential element, required by primary producers and methanogenic bacteria [5]. As such understanding the sequestration of Ni to birnessite, and its fate and mobility during the transformation of birnessite to todorokite, is key to elucidating the feedbacks between Ni abundance, oceanic productivity and ultimately air-sea gas exchange. The presence of Ni in birnessite is traditionally believed to aid recrystallization to todorokite, where Ni is eventually retained in the todorokite structure, providing a potential sink for dissolved Ni [2]. Here we present the results of a novel todorokite synthesis, where we transform Ni-rich birnessite under conditions representative of marine diagenetic and mild hydrothermal settings. We have performed a time resolved study, combining XRD, BET, HR-TEM and XAS to fully characterise the transformation pathway and determine the fate and mobility of Ni during the transformation. Results facilitate our interpretation of recently collected μ-XRF and μ-XAS data, mapping Ni speciation and distribution in natural diagenetic and hydrothermal marine ferromanganese-rich sediments. We find that Ni retards the transformation of birnessite to todorokite under diagenetic and mild hydrothermal conditions, and is ultimately rejected from the neoformed todorokite during a late stage dissolution recrystallization process.

Dynamics of Zn in an urban soil-plant system : Coupling isotopic and EXAFS approaches

A.M. AUCOUR[1], J.P BEDELL[2], M. QUEYRON[2] AND G. SARRET[3]

[1]LGL-TPE, Université Lyon 1, CNRS, F-69622 Villeurbanne Cedex (*correspondence: aucour@univ-lyon1.fr)
[2]LEHNA, ENTPE, F-69518 Vaulx-en-Velin (jean-philippe.bedell@entpe.fr)
[3]ISTerre, Univ. Grenoble 1, CNRS, F-38041 Grenoble Cedex 9 (geraldine.sarret@ujf-grenoble.fr)

Zn isotope compositions can be an effective tool for monitoring Zn cycling in the soil-plant system. Zn isotope fractionations have been reported for model systems (humic acids, oxi-hydroxides, plant and nutrient solution) and in few natural systems. In the soil-plant system, studies combining isotopic and molecular approaches are necessary to identify abiotic and biotic processes controlling Zn isotope cycling.

This study is focused on Zn dynamics in an infiltration basin receiving urban stormwater and colonized by *Phalaris arundinacea* and *Typha latifolia*. The Zn isotope compositions were determined in the various plant organs (root, rhizome, stem, leaves), in fractions of the substrate (bulk sediments, DTPA and $CaCl_2$ sediment extracts, litter), in suspended and dissolved material from the water entry. The Zn speciation was also studied by EXAFS spectroscopy in the same compartments.

The EXAFS spectra were comparable in the various plant organs and indicated mainly an association of Zn with organic acids, with Zn in octohedral coordination. In contrast, the isotopic study evidenced an enrichment in light isotopes of the aerial biomass (δ^{66}Zn of -0.26‰ to -0.03‰) relative to underground biomass (-0.03 to 0.26‰) that is linked to translocation processes. Both Zn speciation and isotope composition of litter differed from that of the plant organs. The EXAFS data indicated that litter Zn was in tetrahedral coordination, corresponding to high affinity sites. The isotopic composition of litter (0.18 to 0.22‰) was enriched in heavy isotopes relative to aerial biomass and got close to that of sediment (0.14 to 0.19‰). Litter formation is thus accompanied by Zn exchange between the decomposing plant and the sediment. The Zn speciation is drastically modified from organic complexes and weakly sorbed species in entry material to phyllosilicates in the sediment. Zn in phyllosilicate is considered as a stable form. Its remobilization by the plant is however indicated by the litter-sediment exchange.

U-Pb ID-TIMS zircon ages and coupled Lu-Hf S-ICP-MS data - A tool for terrane characterisation and determination of paleogeographic affinities: An example from the Caledonides

LARS E. AUGLAND[1], ARILD ANDRESEN[2] AND MARK STELTENPOHL[3]

[1]GEOTOP, UQAM CP 8888, Succ. Centre-Ville, Montréal, Québec, Canada H3C 3P8, (augland.lars_eivind@courrier.uqam.ca)
[2]Department of Geosciences, University of Oslo, P. O.Box 1047 Blindern, 0316 Oslo, (arild.andresen.geo.uio.no)
[3] Department of Geology, 210 Petrie Hall, Auburn University, AL 36849, (steltmg@mail.auburn.edu)

Lu-Hf solution ICP-MS data from zircon fractions that have been dated by U-Pb ID-TIMS provide robust information on the sources of magmatic rocks. When combined, the complementary data sets can be used as a tool for terrane characterisation and source rock identification allowing correlation of spatially separated terranes and providing information on their provenance.

In the Scandinavian Caledonides several suspect/exotic terranes are occuring and here we report U-Pb ages and Lu-Hf isotopic data from a number of magmatic rocks, ranging from tonalites to granites, from the highest tectonostratigraphic levels in the Ofoten-Troms region (Upper and Uppermost Allochthons). Ages range from 484 Ma to 449 Ma with $\varepsilon_{Hf(t)}$ varying from + 9.6 to – 6.2. The combined U-Pb and Lu-Hf data provide a new basis for terrane correlations in the area and supports previous suggestions that all of these terranes are entirely exotic with respect to Baltica. Furthermore, the Lu-Hf isotopic data indicate that the different terranes comprise different crustal segments, from ophiolitic terranes most likely formed during westward subduction east of the Laurentian continent (present day coordinates) to terranes formed on the actual Laurentian margin prior to the Caledonian continent-continent collision. The new data can thus give new constraints on crustal accretionary processes and interactions between the continents during the Caledonian orogen. S-ICP-MS Lu-Hf data from magmatic arc rocks in the North East Greenland Caledonides (Augland *et al* 2012) show a similar $\varepsilon_{Hf(t)}$ range to the granitic rocks analysed in this study and we suggest that the exotic terranes with Laurentian age and Lu-Hf isotope signatures had their pre-collisional provenance in the East Greenalnd segment of the Laurentian margin.

Predictive Bayesian models for risk modeling of geologic carbon capture and storage leaks using natural analogues

CAITLIN AUGUSTIN[1], PETER SWART[2] AND KENNETH BROAD[3]

[1]University of Miami Abess Center for Ecosystem Science and Policy, (c.augustin@umiami.edu)
[2]University of Miami Rosenstiel School of Marine and Atmospheric Science, (p.swart@rsmas.miami.edu)
[3]University of Miami Abess Center for Ecosystem Science and Policy, (kbroad@miami.edu)

Modelling the risks of geologic carbon capture and storage (GCCS) involves many conceptual and quantitative uncertainties. In the development of subsurface carbon dioxide (CO_2) injection as a large-scale greenhouse gas solution, the ability to quantify its uncertainties and risks will play a key role. Published GCCS risk analyses have been based on failure mode and effects analysis, fault-tree analyses, and sensitivity analysis. [1] These analyses have been useful in characterizing risks, but have not yielded quantitative information on the likelihood of a leakage or spill occurring.

Leaked CO_2 is difficult to locate and quantify because monitoring techniques are not widely deployed. Moreover, the released CO_2 may be transported, sequestered or diluted based weather patterns and surrounding ecosystems. Changes in barometric pressure, temperature, and make deterministic fate models nearly impossible to deploy since even the presence of CO_2 is difficult to assess. With GCCS, it will be impractical and impossible to collect comprehensive empirical data regarding geologic reservoir leaks. There is a clear need to introduce statistical technique that integrates limited available data with stochastic modelling. Predictive Bayesian statistical techniques have been developed and demonstrated for exploiting limited information for decision support in many other applications, this paper will adapt and apply them to GCCS. [2]

Natural subsurface CO_2 deposits provide a reasonable analogue for the migration pathways and surface leakage scenarios encountered with GCCS. This paper is concentrated on the development of the conceptual predictive Bayesian model based on theory and literature review. This paper will present predictive leakage scenarios modelled on historic natural subsurface CO_2 leakage data collected from national and international databases.

Sulphides and Ti-Minerals in granulite xenoliths: Tracers of cratonic crust formation

SONJA AULBACH[12], BIBIANA FÖRSTER[1] AND THOMAS CHACKO[2]

[1]Goethe-University, Facheinheit Mineralogie, Frankfurt, Germany, (s.aulbach@em.uni-frankfurt.de)
[2]University of Alberta, Department of Earth and Atmospheric Sciences, Edmonton AB, Canada

The trace-element composition of the common accessory minerals in granulites - sulphides (sf), rutile (rt) and ilmenite (ilm) - contains important petrogenetic information regarding the formation and evolution of the continental crust (CC) [1]. Eclogitic rt and ilm are significant hosts to many high field-strength elements (HFSE), but show contrasting partitioning and therefore fractionate geochemically diagnostic trace-element pairs, such as U-Th, Nb-Ta, Zr-Hf, W-Mo and W-Hf [2,3]. Some of the HFSE (e.g. Cr, Co, Sn, Sb, Mo, W) are chalcophile and siderophile elements (CSE), which are measurable in sulphides. A reconnaissance LAM-ICPMS study of Ti-minerals and sf in four mafic granulite xenoliths (MGX) from the Diavik kimberlites of the central Slave craton (Canada) broadly confirms experimental trace-element systematics - with interesting exceptions - and shows that sf strongly partitions Ni, Co, As and Sb, whereas W, Sn ± Mo concentrate in rt, and Cr, Zn, Ga favour ilm.

Bulk-rock CSE abundances, calculated from concentrations in MGX sf, rt and ilm weighted by modes, balance the abundances of W and Pb in CC [4], but show large excesses for Ni, Cr, Co, Sn, Mo, Sb and As. This suggests a cumulate origin for the MGX and enrichment by (seawater?) fluids. Sf- and rt- ± ilm-saturated melting of such lower CC should generate melts depleted in these elements. Since this is not observed in the upper CC [4], upper CC is probably not related to lower CC by igneous processes.

Segregation of sf-bearing cumulates in the lower CC was recently proposed to explain Cu depletion in the upper CC [5]. Sf in MGX have trace-element concentrations within the range of sf inclusions in diamonds from meta-gabbroic source rocks, which have been shown to control Cu, Se, Te, Mo, Re and PGE in the bulk rock [5]. Since only Cu and Se show complementary depletions in CC, the processes generating the crustal CSE pattern must be more complex.

Cannibalization of previous Na-rich clinopyroxenes by ascending basic magmas of the Garrotxa Volcanic Field (NE, Spain)

M. AULINAS*, G. GISBERT, D. GIMENO AND D. GASPERINI

Dep. Geoquímica, Petrologia i Prospecció Geològica, Universitat de Barcelona. 08028 Barcelona, Spain (*correspondence: meritxellaulinas@ub.edu; ggisbert@hotmail.com; domingo.gimeno@ub.edu; gasperinidaniela@gmail.com)

The Garrotxa Volcanic Field (GVF) is a Quaternary monogenetic volcanic field belonging to the NE Spain volcanic province, recording a Neogene alkaline intraplate magmatic activity consequence of the rift-type extensional tectonics that has affected the eastern margin of Iberia since late Oligocene. The GVF is mainly characterized by alkaline basaltic rocks (basalts and basanites) both potassic and sodic in affinity. In general, mineral assemblage includes olivine and clinopyroxene phenocrysts and microphenocrysts, and a groundmass formed mainly by variable amounts of plagioclase and Fe-Ti oxides. Clinopyroxenes (cpxs) are not petrographically homogeneous and two types are distinguished: (I) Non to normal zoned phenocrysts with beige centres often surrounded by thin brown rims and (II) reversely zoned phenocrysts with green rounded cores wrapped by a beige mantle and an outer brown rim. The green cores (diopsides with Na_2O up to 1% and Al_2O_3 up to 7%) in Type II cpxs show petrographic and chemical evidences in agreement with a xenocrystic nature (e.g. sharp optical and chemical contrast between cores and mantles, rounded shape, high Fe/Mg ratios, or coexistence of type I and type II phenocrysts in a single sample). In this sense, their chemical compositions are in accordance with cpxs crystallized from a more evolved liquid than the primitive ascending basanitic magmas in which they are included. These xenocrysts seem to be petrographically and chemically related to cpxs from clinopyroxenite and gabbroic cumulates which can be found in some of the GVF samples. Therefore, we hypothesize that green cpxs were entrapped or cannibalized by the basic rising magmas. Preliminar cpx-melt calculations indicate that mantles of type II cpxs crystallized at maximum of ca. 30 km depth and consequently, cannibalization occurred at higher depths. This is consistent with the presence of green cpx-bearing mafic and ultramafic cumulates at or near the crust mantle-boundary.

Linking mantle melting and eruption rates at Stromboli volcano: A U-series perspective

R. AVANZINELLI[1,2], A. BRAGAGNI[1], L. FRANCALANCI[1], H. FREYMUTH[2] AND T. ELLIOTT[2]

[1]Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Italy. E-mail, riccardo.avanzinelli@unifi.it
[2]Bristol Isotope Group, University of Bristol, UK

Over the last several hundred years, the steady-state activity of Stromboli volcano has been characterised by persistent mild explosive eruptions, ejecting black scoria bombs. Periodically, lava flows and paroxysms, ejecting also light-coloured pumices, interrupt the 'normal' activity. A degassed and highly porphyritic basaltic-shoshonitic magma (HP-magma), is erupted by the normal activity and lava flows, whereas a slightly more mafic and volatile-rich magma with low phenocryst content (LP-magma) is erupted as pumices only by the paroxysms. Whilst the former is considered as deriving from a shallow level reservoir, the latter has a deeper origin and might resemble the primitive melts generated from the mantle source.

We present new U-series disequilibria measurements on a suite of HP and LP magmas from the present-day activity of Stromboli volcano. Small but significant differences are observed in ($^{238}U/^{232}Th$), ($^{230}Th/^{238}U$) and ($^{226}Ra/^{230}Th$) between HP and LP magmas, testifying and further constraining the complex processes occuring in the shallow level magma chamber (e.g. crystal fractionation, mixing, recycling of material from previous activity).

On the contrary, the variation of ($^{230}Th/^{232}Th$) seems to be little affected by the shallow level processes and can be used to constrain the melting regimes beneath the volcano. This is particularly true for the LP magmas that should reflect the composition of the primitive magma. Indeed, the LP data show an impressive time-related constant variation of ($^{230}Th/^{232}Th$) during the last 15 years that is interpreted as an increase in the melting rate of the mantle source. More importantly this variation can be directly related with the increase in eruption rate that is suggested by both observation (increase of major explosive events and lava flows) and estimates based on the volcano morphology and erupted volumes. This suggests that U-series, and ($^{230}Th/^{232}Th$) in particular, can represent an important tool to estimate the rate of magma production and then possibly forecast the eruption rates in basaltic volcanoes such as Stromboli.

The variation in ($^{230}Th/^{232}Th$) is also discussed with the aim of estimating the turnover times of both the HP and LP systems.

Melt generation in the West Antarctic Rift System: The volatile legacy of Gondwana subduction?

K.B. AVIADO[1], S. RILLING[2], S.B. MUKASA[1], J.G. BRYCE[1] AND J. CABATO[1]

[1]Department of Earth Sciences, University of New Hampshire, Durham, NH 03824, USA

[2]Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI 48105, USA

The West Antarctic Rift System (WARS) represents one of the largest extensional alkali volcanic provinces on Earth, yet the mechanisms responsible for driving rift-related magmatism remain controversial. The failure of both passive and active models of decompression melting to adequately explain the observed volume of volcanism has prompted debate about the relative roles of thermal plume-related melting and ancient subduction-related flux melting. The latter is supported by roughly 500 Ma of subduction along the paleo-Pacific margin of Gondwana prior to the breakup of this supercontinent beginning in the Jurassic, although both processes are capable of producing the broad seismic anomaly imaged beneath most of the Southern Ocean. Olivine-hosted melt inclusions from basanitic lavas provide an unambiguous means to evaluate the volatile budget of the mantle responsible for active rifting beneath the WARS. We present H_2O, C, Cl, F, and S concentrations determined by SIMS for 5 WARS lavas from Northern Victoria Land (NVL) and Marie Byrd Land (MBL). Initial results for the lavas exhibit water contents ranging from 0.5 up to 3 wt % that are positively correlated with Cl and F. Coupling between Cl and H_2O indicates metasomatic enrichment by subduction-related fluids produced during dehydration reactions; coupling between H_2O and F, which is more highly retained in subducting slabs, may be related to partial melting of slab remnants [1]. Application of source lithology filters [2] to major oxide data shows that primitive lavas (MgO wt % >7) from the Terror Rift, considered the locus of on-going tectonomagmatic activity, have transitioned from a pyroxenite source to a volatilized peridotite source over the past ~4 Ma. Integrating the volatile data with the modelled characteristics of source lithologies suggests that partial melting of lithosphere modified by subduction processes is the source of pyroxenite and volatiles in the mantle beneath the present-day rift. The earliest magmatic activity preferentially removed the most readily fusible components from the mantle, resulting in transition to a metasomatized peridotite source over time.

Modeling the evolution of the isotopic composition of atmospheric xenon through time

G. AVICE* AND B. MARTY

CRPG/CNRS, BP 20, 54501, Vandoeuvre-lès-Nancy, France (*correspondence: gavice@crpg.cnrs-nancy.fr)

Even if the isotopic compositions of terrestrial H, N and Ar are clearly chondritic, atmospheric xenon is not chondritic in two ways : it is depleted relative to lighter noble gases, and it is isotopically enriched in its heavy isotopes relative to chondritic or solar components (the so-called xenon paradox). Recently, xenon trapped in Archean samples was found to be isotopically intermediate between Chondritic and Atmospheric [1], which was interpreted as resulting from prolongated loss of atmospheric xenon to space at least until the Archean eon. Such preferential loss could be related to the low ionization potential of Xe and, possibly, to the 10 fold enhanced flux of hard UV light during the first Ga of solar evolution [2].

In order to explore the geochemical consequences of this possibility, we have developped a numerical box model in which atmospheric xenon evolves through time due to degassing from the mantle with no isotopic fractionation, and escapes from the atmosphere to the outer space with enrichment in its heavy isotopes. The model is constrained by the initial conditions (cosmochemical Xe isotopic composition from the literature; Xe initial abundance equivalent to a few % carbonaceous chondrite [3]), the variation in the Xe isotope composition through time [1,4] and the present-day Xe composition of the mantle and of the atmosphere.

The combination of the two processes, permits to reproduce with accuracy (few % difference) the current isotopic composition of the Earth's atmosphere. In particular, the model explains the well known but unexplained atmospheric under-abundance of Xe isotopes from the fission of ^{244}Pu ($T_{1/2}$ = 82 Ma). When corrected for prolongated Xe loss into space, the I-Pu-Xe age of the atmosphere shifts from >100 Ma to 45±5 Ma.

Anaerobic oxidation of methane by sulfate in hypersaline groundwater at the Dead Sea aquifer

N. AVRAHAMOV[1]*, G. ANTLER[1,2], Y. YECHIELI[3,4], I. GAVRIELI[3], S. JOYE [5] AND O. SIVAN[1]

[1]Department of Geological and Environmental Sciences, Ben Gurion University of the Negev, Beer-Sheva
[2]Department of Earth Sciences, University of Cambridge
[3]The Geological Survey of Israel, Jerusalem
[4]Department of Environmental Hydrology & Microbiology, Zuckerberg Institute for Water Research, Blaustein Institutes for Desert Studies, Ben Gurion University of the Negev, Sede Boqer, Israel
[5]Department of Marine Sciences, University of Georgia, Athens, GA (*correspondence: katzavn@bgu.ac.il)

Anaerobic oxidation of methane (AOM) with sulfate as an electron acceptor is not a process that is expected to occur in salt-stressed environments, since the energy yield is extremely low. Still, AOM appears to function even in hypersaline cold seeps sediments in marine environment. Here, we document geochemical evidences for AOM process in the continental hypersaline environment of the Dead Sea aquifer. We explored this process through chemical and isotope measurements of sulfate and methane in groundwater with salinity range of 40-225 Cl $g{\cdot}L^{-1}$ along the Arugot alluvial fan next to the DS. Oxygen values of this groundwater vary from absence to very low (0 to 0.16 $mg{\cdot}L^{-1}$). Sulfate concentrations and isotopes indicates BSR. Mass balance of carbon system parameters as well as the association between methane concentrations to the apparent net sulfate reduction show that methane serves as the main electron-donor. The calculated sulfur isotope enrichment factor might hint high reduction rates of sulfate when methane is used as asubstrate.

Comparison of ^{2}H, ^{18}O, ^{3}H and radionuclides migration in groundwater near the liquid waste injection site (Tomsk-7, Russia)

I.A. AVRAMENKO[1], I.V. BLAZHENNIKOVA[2] AND I.V. TOKAREV [3]

[1](i.a.avramenko@gmail.com)
[2](blazhennikova@mail.ru)
[3](okarevigor@gmail.com)

Groundwater near the site injection of the liquid radioactive waste of the Siberian Chemical Combine (former Tomsk-7, Russia) was studied. There are six (from I to VI) sandy aquifers (the numbers are follow from the crystalline basement to the Earth surface) in this multilayer hydrogeological system. Radioactive solutes (including a high activity waste) are injected into the II and III aquifers on the depth of 270–350 m. Total activity of the buried waste is about 800 millions Curie. The nitrates, gamma radiation, temperature were used for monitoring of the radioactive waste distribution in aquifers for 1963-2000.

Natural water of II and III aquifers has no tritium, because their age is several thousand years according to the helium and radiocarbon dating. The tritium (^{3}H) concentration in radioactive waste is very high, and also the stable isotopes composition (^{2}H and ^{18}O) of natural and man-made water is very different. These isotopes are the best tracers of water, as they form its molecule, whereas the radionuclides of waste are the reactive components, which decay with time and adsorb on the clayey part of sediments. Therefore comparison the behavior of conservative and non-conservative tracers allow to estimate of the retardation factor *in situ*. More than 200 wells have been tested for localization of the boundary between the natural water and man-made solutes. We used the ^{3}H, ^{2}H and ^{18}O monitoring to improve the safety prediction of the waste disposal and also for verification and calibration of the numerical model.

Polyphase evolution of the Eastern Ghats Belt (India) - A multi mineral approach using Rb-Sr and U-Pb ages

EMELIE AXELSSON*, KLAUS MEZGER AND IGOR M. VILLA

Institute of Geological Sciences, University of Bern, Baltzerstrasse 3, 2012 Bern, Swizerland. (*correspondence: axelsson@geo.unibe.ch)

The Eastern Ghats Belt (EGB) is a granulite facies metamorphic belt along the east coast of India. It is a patchwork of discrete crustal segments with distinct geological histories. It records the formation and destruction of at least two earlier supercontinents, namely Colombia (ca 2.1-1.8 Ga) and Rodinia (ca 1.0-0.9 Ga); as a part of the amalgamation of India, east Antarctica, and Australia into the SWEAT (SW United States and East Antarctica) terrane.

Four crustal domains with unique isotopic signatures and ages can be distinguished within the EGB [1]. The highest-grade metamorphism was attained during the regional metamorphism at ca 950 Ma. The subsequent evolution was proposed to be slow cooling at a rate of ca. 1-2°C/Ma [2].

To reconstruct the post-peak evolution after the 950 Ma metamorphic imprint, Rb-Sr biotite ages were determined from biotite-rich metapelitic gneisses. These ages cluster around 500 Ma for most of the Eastern Ghats belt. The anlaysed biotite samples have high Mg content, and the general mineral assemblage is that typical of high temperature granulites: plag + phl + sil + grt and, depending on the protolith, kfs, crn or crd. Common accessory mineral phases are: rt, zrc, spl, ap, spr.

Very young biotite ages like these are unlikely to be the result of slow cooling from the granulite facies conditions at ca 950 Ma. Instead they record a low-grade static thermal overprint of the orogenic belt. This overprint coincides with high-grade meteamorphism in southern India and Sri Lanka (ca 580-550 Ma), corresponding with the Pan-African orogeny. The young ages on a regional scale extend the known area of the pan-African overprint in India significantly.

Petrological and Geochemical Constraints on the origin and evolution of the Early Campanian porphyritic rocks from the Eastern Pontide Magmatic Arc, NE-Turkey

FARUK AYDIN

Department of Geology, Karadeniz Technical Univ., 61080, Trabzon, Turkey (faydin61@gmail.com)

Petrogenesis of the porphyritic rocks in the Eastern Pontides, NE Turkey, play a critical role in determining the nature of the continental crust and mantle dynamics during late Mesozoic subduction processes. In this study, we described, for the first time, the early Campanian (81±0.5 Ma) porphyritic rocks cutting the late Cretaceous volcanic units in the region. The porphyritic rocks were observed as small stocks (< 1km^2) in the study area and they generally contain mafic magmatic enclaves (MMEs). The host porphyritic rocks comprise quartz diorite and tonalite (SiO_2= 64–70 wt%, Mg#= 0.40-0.52) and the MMEs are gabbroic diorite in composition (SiO_2= 51–57 wt%, Mg#= 0.36-0.50). The host rocks have a microgranular porphyritic texture, and they contain 15-25% phenocryst of plagioclase and amphibole with a matrix composing plagioclase ± quartz ± orthoclase ± apatite ± zircon ± Ti-magnetite. Compared to the host rocks, the MMEs are finer grained, and they contain higher proportion of ferromagnesian phases and less feldspar minerals.

Geochemically, the samples usually show a high-K calc-alkaline composition and I-type features with metaluminous character. The host porphyritic rocks and the MMEs are characterized by enrichment of LILE and depletion of HFSE with negative Nb and Ti anomalies. The chondrite-normalized REE patterns are fractionated [$(La/Yb)_N$ = 5-17] and moderately display Eu anomalies (Eu/Eu* = 0.5-1.2). All samples have weak concave-upward REE patterns, suggesting that amphibole and garnet played a significant role in their generation during magma evolution. The host rocks and their enclaves are isotopically indistinguishable. Sr–Nd isotopic data for all of the samples display I_{Sr} = 0.7085–0.7087, ε_{Nd} (81 Ma) = -6.0 to -6.9, with T_{DM} = 1.38–1.63 Ga. Pb isotopic ratios are ($^{206}Pb/^{204}Pb$) = 18.61–18.69, ($^{207}Pb/^{204}Pb$) = 15.66–15.69 and ($^{208}Pb/^{204}Pb$) = 38.78–38.90.

All geochemical results and the Ar–Ar crystallization age, combined with previous regional studies, suggest mixed-origin magma generation in a subduction setting.

Distribution of Cu, Pb and Zn in *Astragalus pycnocephalus Fischer* and *Verbascum euphraticum L.* Plants on Pb-Zn Mining Area in Akdagmadeni, Yozgat, Turkey

NASUH AYDIN[1], GÜLLÜ KIRAT[2] AND CEMAL BÖLÜCEK[3]

[1,3]Balıkesir University, Faculty of Engineering and Architecture. Department of Geological Engineering, BALIKESİR (nasuhaydin@hotmail.com.tr; cbolucek@balikesir.edu.tr)

[2]Bozok University, Faculty of Engineering and Architecture. Department of Geological Engineering, YOZGAT (gullu.kirat @bozok.edu.tr)

The study area is located in Akdagmadeni where 104 km East of Yozgat city and geologically lies within igneous and metamorphic rocks of Akdag Massive. There are several skarn type Pb, Zn deposits which formed by regional contact methamorphism.

Soil and plant samples were collected from both mineralized and unmineralized areas. The plants *Astragalus pycnocephalus Fischer* and *Verbascum euphraticum L.* were examined. Analysis were carried out by Inductively Coupled Plasma-Mass Spectrometry (ICP-MS) method.

Cu, Pb and Zn values of the soil samples were found to be in the range of (A. *pycnocephalus*) 13.1- 418.4 mg kg^{-1}; 29,87- 7839,53 mg kg^{-1}; 48,6- 10000 mg kg^{-1} (V. *euphraticum*) 32.5- 419,4 mg kg^{-1}; 52.96- 9909.13 mg kg^{-1}; 115.1- 10000 mg kg^{-1}, respectively.

Pb and Zn values of most plant samples collected from study area were 10 times higher than the plants from unmineralized areas. Pb and Zn concentration time values were found to be in the range of 463 – 548 mg kg^{-1}; 17.4 – 23.3 mg kg^{-1}, respectively. Translocation factor changed from 0.13 to 4881. Enrichment coefficient of most plant samples were lower than 1. A.*pycnocephalus* and V. *euphraticum* can be used as hyperaccumulator plants for both Pb and Zn. However, these plants cannot be used as hyperaccumulator for Cu.

Keywords: A. *pycnocephalus*, Akdag Massive, Contact Metamorphism, Hyperaccumulator, Pb-Zn Deposit, V. *euphraticum*.

The late Ediacaran (605-580 Ma) anorogenic alkaline magmatism in the Arabian–Nubian Shield: A case study of the Serbal Ring complex, south Sinai, Egypt

MOKHLES K. AZER

Geology Department, National Research Centre, 12622-Dokki, Cairo, Egypt (mokhles72@yahoo.com)

The Serbal pluton is late Neoproterozoic (605-580 Ma) post-collisional A-type granites in southern Sinai, Egypt (northernmost Arabian–Nubian Shield, ANS). It is characterized by discontinues ring-shaped outcrops that was later dislocated by a faults. The Serbal pluton intrudes late Neoproterozoic metamorphic and calc-alkaline rocks. The majority of Serbal pluton is composed of alkali feldspar granite and riebeckite granite with gradational contacts; the former represents the outer zone, while the latter represent the inner zone. The Serbal granites include wide variations of accessory minerals including zircon, apatite, titanite, Fe-Ti oxides, fluorite, allanite, pyrochlore and samarskite. The Serbal granites are highly evolved in composition (75.98-78.52 wt.% SiO_2) and display the typical geochemical characteristics of A-type granites with high SiO_2, Na_2O+K_2O, FeO*/MgO, Ga/Al, Zr, Nb, Ga and Y and low CaO, MgO, Ba, and Sr. They are rich in REE than monzogranite (country rock) and show extreme Eu-negative anomaly (Eu/Eu* = 0.01-0.23). The peralkaline to peraluminous characteristics of the Serbal granites suggested that they have been evolved through different differentiation trends which controlled by varying fluorine contents of the parent magma. The chemical characteristics indicate that the riebeckite granite shares in many features of granites with the tetrad REE effect which manifested by the very low ratios of Eu/Eu*, (La/Yb)n, La/N, Zr/Hf and K/Rb and by the very high K/Ba. The Serbal granites exhibit an alkaline nature of within plate tectonic setting, while the monzogranite of country rocks displays calc-alkaline characteristics of island-arc tectonic settings. The Serbal pluton evolved through fractional crystallization of a parental magma derived through partial melting of juvenile crustal protolith. This crustal protolith has been extracted from a source having geochemical and isotopic data similar to those of the mantle origin. Mineral geothermometry points to the formation of the silicic magma of the Serbal granites at high temperatures, up to 650–850^{O}C at a shallow depth of emplacement (<10 km). This magma erupted after the end of the Pan-African orogeny due to the thinning and extension of continental crust. This stage is characterized by the sudden and radical change from typical subduction-related calc-alkaline magmatism to post-tectonic alkaline (peralkaline) magmatism.

Discovery and characterization of contrasting siderophores produced by related nitrogen fixing bacteria using high resolution LC-MS

OLIVER BAAR, DAVID H. PERLMAN, ANNE M. L. KRAEPIEL AND FRANÇOIS M. M. MOREL*

Princeton University, Princeton, NJ, USA
(*correspondence: morel@princeton.edu)

Azotobacter vinelandii (AV) and *Azotobacter chroococcum* (AC) are closely related N_2 fixing bacteria. Whereas the structures and physiological functions of siderophores produced by AV have been much studied, those of AC remain unidentified beyond a general chemical characterization. Here we have exploited the characteristic iron isotopic fingerprint to identify known and unknown siderophores and characterize them structurally using ultra-sensitive high-resolution nano-flow UPLC-MS on an LTQ-Orbitrap XL platform.

Interrogation of preliminary data for AV revealed many putative Fe-chelators with high abundances, including those previously identified and other, yet unreported compounds.

Siderophores produced by AC were unrelated to those of AV. Many AC siderophores possess aliphatic side chains of variable length with corresponding changes in hydrophobicity. Current work investigates how these chemical differences in siderophore production relate to different metal acquisition strategies and occupation of different ecological niches.

Using isotopic analysis of copper to assess copper transport and partitioning in wetland systems

I. BABCSANYI*, F. CHABAUX, V.M. GRANET AND G. IMFELD*

Laboratory of Hydrology and Geochemistry of Strasbourg (LHyGeS), University of Strasbourg/ENGEES, CNRS, 1, rue Blessig, 67 084 Strasbourg CEDEX
(*correspondence: imfeld@unistra.fr, izabella.babcsanyi@etu.unistra.fr)

Copper isotopes ($^{65}Cu/^{63}Cu$) are potentially powerful new geochemical proxies for transport and oxidation–reduction processes in hydromorphic soils, rivers and lake sediments. However, the integrative signal of $\delta^{65}Cu$ has not been used so far to investigate the transport and partitioning of copper in wetland systems with respect to both hydrological and biogeochemical conditions. Here we used copper isotopes to investigate the copper cycling in a stormwater wetland (as a 'natural laboratory') that regularly received copper-contaminated runoff from a 42 ha vineyard catchment (Rouffach, Alsace, France). Runoff water, suspended solids, sediments and plants were regularly collected throughout the period of copper-based fungicides application (May to July 2011) to establish the copper mass balance and study isotopic fractionations.

60 to 93% of copper in runoff was associated with suspended solids, which were efficiently retained by the wetland (93 to 96%). Copper bound to suspended solids had negative isotope signatures (-0.33 to -0.1 ± 0.1‰), whereas dissolved copper was enriched in ^{65}Cu (0.23 to 1.35 ± 0.06‰). Dissolved copper retention largely varied (68 to 95%) and became depleted in ^{65}Cu when passing through the wetland ($\delta^{65}Cu_{inlet}$-$\delta^{65}Cu_{outlet}$: 0.03 to 0.77 ± 0.08‰). This isotopic shift suggests that copper rapidly sorbed to organic matter or mineral phases of the wetland sediments. Under high-flow conditions, copper was less retained by the wetland and was likely mobilised from the wetland sediments. This was attested by a lower $\delta^{65}Cu$ value of the outflowing dissolved copper, thereby reflecting the contribution of sediment-bound copper (0.02 ± 0.1‰). Copper uptake by the vegetation (*Phragmites australis*, Cav.) was not a significant retention process in the wetland, and accounted for less than 1.5% of the total copper amount in the wetland.

We anticipate our results to be a starting point for using copper isotopes in a comprehensive approach to evaluate processes affecting copper cycling in hydro-biogeochemically dynamic systems, such as wetlands or hyporheic zones.

High-precision Nd isotope and HFSE analysis of Deccan Traps weathering profiles

MICHAEL G. BABECHUK[1]*, MIKE WIDDOWSON[2], MICHAEL MURPHY[3] AND BALZ S. KAMBER[1]

[1]Trinity College Dublin, Dublin, Ireland
[2]The Open University, Milton Keynes, United Kingdom
[3]University College Dublin, Dublin, Ireland

Accurately quantifying the flux of elements from landmasses during pedogenesis necessitates knowledge of the parent rock chemistry and some control on whether allochthonous materials (e.g., dust) have beem added to the profile during exposure. This is important, for instance, in calculating weathering rates from U-series isotopes in young profiles or interpreting stable isotope depth signatures. The Deccan Traps provide an ideal natural laboratory for studying chemical weathering due to the thick succession of mafic flows which have been weathered to varying degrees on different time scales. In addition, the isotopic and elemental composition of the basalt parent rock contrasts significantly with most potential dust sources (e.g., Archean-Proterozoic crust of the Dravidian Shield).

Deeply weathered laterite of the Deccan Traps has experienced significant accumulation of aeolian material during its long exposure history. For example, in a full laterite profile near Bidar, an upward increase in Th concentration and accompanying decrease in the Nb/Th ratio is evident from the base to top. If Nb is assumed to be immobile during pedogenesis and least affected by dust addition, Th is enriched up to 400% relative to the parent rock in the most contaminated samples. Variations in the Nb/Th ratio are well correlated with the $^{143}Nd/^{144}Nd$ ratio, implicating the source of the contaminant as being incompatible element enriched and less radiogenic than the Deccan basalt.

Near Chhindwara, a sub-Recent weathering profile is exposed which spans across two identifiable basalt flows. The individual flows can be fingerprinted with variations in their HFSE composition, highlighting another important consideration in mass balance calculations of a weathering profile. Even more interesting, however, are the uppermost samples of the lower exposed flow with alkali element, HFSE ratios, and subtly less radiogenic Nd isotope values which again suggest contamination with an allochthonous component. This is interpreted to represent the entrainment of sediment in the lava flow top during emplacement or the accumulation of dust during post-eruption volcanic quiescence prior to the emplacement of the overlying flow.

U-Pb dating vs. Sr isotope chemostratigraphy on Neoproterozoic carbonates: Shedding light on blind dating?

M. BABINSKI[1], G.M. PAULA-SANTOS[1]; M. KUCHENBECKER[2], S. CAETANO-FILHO[1], R.I.F. TRINDADE[3] AND A.C. PEDROSA-SOARES[2]

[1]Instituto de Geociências, Universidade de São Paulo, São Paulo, SP, Brazil. (babinski@usp.br)
[2]Instituto de Geociências, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil.
[3]Instituto de Geofísica, Universidade de São Paulo, São Paulo, SP, Brazil.

Sr isotope ratios of carbonate rocks have been extensively used for global correlations especially on Precambrian rocks due to lack of fossils and scarcity of dating targets to constrain their depositional ages. This “blind dating” procedure has been questioned before but it is still commonly used. Here we present a case study on carbonates from the basal units of the Bambuí Group (central Brazil) where Sr, C, and O chemostratigraphy was combined with U-Pb ages from detrital zircons recovered from pelitic intercalations. Our results show a strong incompatibility between $^{87}Sr/^{86}Sr$ ratios and the detrital zircons record.

The Bambuí Group is composed of a carbonatic-pelitic sucession which overlies a glacial diamictite (Jequitaí Fm.) correlated to the Sturtian or Marinoan ice-ages. U-Pb ages from detrital zircons from the diamictite sets the maximum depositional age at 875 Ma. The cap carbonate that overlies this diamictite has $\delta^{13}C$ negative values and was dated at 740 ±22 Ma, indicating a Sturtian age. Limestones and dolostones overlying the cap carbonate show $\delta^{13}C$ values around 0 ‰. Upsection, carbonates are organic-rich limestones displaying highly positive $\delta^{13}C$ values. All carbonates, including those overlying the diamitite, show $^{87}Sr/^{86}Sr$ ratios between 0.7074 to 0.7076. These ratios are compatible with depositional ages as old as 650 Ma according to the global Sr isotope evolution curves available in the literature. However, detrital zircons yielded U-Pb ages as young as 540 Ma, pointing to depositional ages close to the Precambrian-Cambrian boundary or even younger, when more radiogenic Sr isotopes ratios (ca. 0.7085) are expected. This may result from a restricted sea context for the Bambuí carbonate platform; consequently their Sr isotope ratios do not correspond to that of contemporaneous ocens. Several lines of evidence suggest this is not an unusual scenario for Neoproterozoic carbonate platforms. Our work shows that worldwide correlations based only on Sr isotopes must be considered with caution.

Rocky constraints on catabolic energy supply in the subseafloor

W. BACH[1], W.-A. KAHL[1], N. JÖNS[1], A. TÜRKE[1] AND O. PLÜMPER[2]

[1]Geoscience Department, University of Bremen, Klagenfurter Str., 28359 Bremen, Germany (wbach@uni-bremen.de)
[2]Department of Earth Sciences, Utrecht University, Budapestlaan 4, 3584 CD Utrecht, The Netherlands

Reactions between circulating seawater and oceanic basement release reduced components, which can be used as electron donors by chemolithoautotrophs in the subseafloor. High-temperature axial hydrothermal vent systems show a pronounced influence of basement composition on metabolic diversity, with ultramafic hosted systems supporting a greater range of catabolic reactions, including anaerobic ones [1].

We investigate the influence of temperature (2-110°C), rock composition (basalt vs. peridotite), and permeability on energy availability for a subseafloor biosphere away from axial vents where seawater circulation through fractured basement takes place at lower temperatures.

In fresh basalt, oxidation of ferrous iron is the main energy source at low temperatures (<25°C) and under oxic conditions. Increasing extents of alteration of glassy lava will build up palagonite rims as diffusive barriers between the fractures and unaltered glass, which slow down the rates of alteration. Palagonite has little or no ferrous iron and is enriched in U and K. Unless new fractures form and allow circulating seawater to interact with fresh material, the principal source of energy will change to dihydrogen produced radiolytically by U and K. At moderate temperatures (25-60°C), recharge of oxygenated seawater is sluggish and anaerobic metabolic reactions become more important. At high temperatures (60-110°C), the metabolic energy demand has increased relative to the energy supply, making growth more difficult for microbes.

In mantle peridotite, abundantly exposed in rift mountains along slow spreading ridges and commonly strongly serpentinized, oxidation of ferrous iron is also the main energy source at T<25°C. Brucite dissolves in contact with cold seawater, increasing permeability of the rock and pH in the interacting fluid. Serpentinites are often pervasively affected by low-T reactions, indicating that new permeability develops in the course of interaction with seawater. At T>25°C, dihydrogen yields are very high throughout. While the increased energy supply and permeability will facilitate microbial growth, high pH and the dearth of CO_2 in the interstitial solutions may impedete it.

Contaminant geochemistry and migration in three different mine sites in Finland – Comparison of anthropogenic and geogenic contamination for risk assessment

S. BACKNÄS[1]* K. TURUNEN[1] A. PASANEN[1] T. KARLSSON[1] AND L. SOLISMAA[1]

[1]Geological Survey of Finland, P.O.Box 1237, FIN-70211 Kuopio, Finland (*Correspondence: soile.backnas@gtk.fi)

Areas with bedrock abundant in ore minerals have naturally high amount of harmful elements in soil as well as in ground and surface waters. After the beginning of the mining the anthropogenic contamination also tends to increase. Thus, it is important to estimate the effects of mining activity and water treatment methods to the geogenic background when assessing the long term effects to the surrounding environment. In this study, geochemical and anthropogenic contaminant geochemistry and transport in soil at three different mine sites in Finland: Suurikuusikko, Siilinjärvi and Luikonlahti, were characterized by using extraction methods and mineralogical studies. Water samples were analyzed for metal and metalloid concentrations, anions and physico-chemical properties. Also groundwater and geochemical modeling software were used to study the groundwater flow paths and hydrogeochemistry.

The results show that the geogenic background, the hydrogeology of the site and concentrations of harmful elements in mine wastes and waters must be considered in risk assessment of mine sites. When evaluating the risks, the concentration levels must be compared to geochemical background, but also the ratio of available, potentially mobile and total concentrations must be studied, because the mining activities tend to increase the proportion of potentially mobile and available elements. Due to residues of chemicals used in enrichment process and weathering of minerals during the process, the concentration profile of harmful elements in waters can be used to distinguish the anthropogenic and geogenic contamination. Results also indicate that fractures of crystalline bedrock are important pathways for contaminant migration to environment and should be studied using geophysical methods and groundwater flow modeling when assessing the environmental effects of mines.

Surface complexation on birnessite controls Pb distribution in highly contaminated soil and karst groundwater

C.G.D. BACON[12] AND D.M. SHERMAN[2]*

[1]School of Earth Sciences, Univeristy of Bristol, UK, BS8 1RJ (*correspondence: dave.sherman@bristol.ac.uk)
[2]Golder Associates (UK) Ltd, Bourne End, UK, SL8 5AS (cbacon@golder.com)

At the historic mineries of Priddy near Bristol, soils are heavily contaminated with up to 2000 mg/kg Pb. However, porewater concentrations of Pb are undersaturated with respect with natural common Pb minerals such as cerrusite. Scanning electron microscopy and EDX analysis revealed that the Pb in Priddy soil is associated with a poorly-crystalline Mn oxide phase. The Mn oxide phase contains up to 40 wt. % Pb. Using μ-EXAFS spectroscopy, and μ-XRD, we identified the Mn oxide as birnessite, similar to the poorly crystalline microbial δ-MnO_2 described by Villalobos *et al*. [1]. However, the origin of the birnessite in Priddy soil is unclear. Using μ-EXAFS, we find that Pb is complexed on both edge and vacancy sites, as proposed by [2].

The hydrology of the mining area drains into a complex network of caves, with the resurgence at Wookey Hole. Within the caves are extensive coatings of birnessite (as identified using XRD and Raman spectroscopy). We hypothesise that this birnessite is of microbial origin as found elsewhere [3]. The soil birnessite must be reduced to release dissolved Mn(II) which is then oxidized in the dark cave system by chemolithoautrophic bacteria. The secondary birnessite in the cave also contains up to 40 wt. % Pb. μ-EXAFS shows that Pb associated with this birnessite in both edge and vacancy surface complexes.

We hypothesise that the complexation of Pb by birnessite controls the dissolved Pb concentration in soil pore water and groundwater. To test this, we have performed a series of batch sorption edge experiments with synthetic birnessite and fit these to derive equilibrium expressions and constants for the possible surface complexation reactions. Using our surface complexation model, we are predicting the concentration of Pb in soil porewater and groundwater. However, a reactive transport model needs to account for the microbial birnessite recyling.

U-Pb and Hf isotope characteristics of zircon from chromitites at Finero

I.YU. BADANINA[1], K.N. MALITCH[1,2] AND E.A. BELOUSOVA[2]

[1]Institute of Geology and Geochemistry of the Uralian Branch of Russian Academy of Sciences, Ekaterinburg, 620075, Russia (*correspondence: dunite2009@rambler.ru)
[2]GEMOC ARC National Key Centre, Macquarie University, Sydney, NSW 2109, Australia (ebelouso@els.mq.edu.au)

The Finero phlogopite-peridotite represents a metasomatized residual mantle harzburgite, exposed at the base of the lower-crust section in the Ivrea Zone, Western Alps [1]. Previous studies point to one or more Late Paleozoic mantle metasomatic events in the Finero peridotite, although there is little agreement regarding the relative timing of different events or the source of the metasomatizing agents.

Studied chromitite samples derived from the dump in the prospecting trenches of Alpe Polunia and Rio Creves. Dominant zircon population is pale pink and show different shapes (subhedral, subrounded or elongated). In cathodoluminescense (CL), the main set of population is represented by complex grains, which show development of core-rim relationship (most likely recrystallized rim on a preserved core). Subordinate zircon grains are colourless, with a smoky cathodoluminescense and almost no internal pattern. Three main U-Pb age clusters have been identified. The youngest cluster, typical for subordinate zircon population and rims in complex grains from dominant population, yielded two $^{206}Pb/^{238}U$ ages (e.g., 208.6 ± 4.0 Ma, MSWD=2.0, n=8 and 194.9 ± 3.4 Ma, MSWD=0.45, n=3, respectively). The other clusters represent cores and rims in the composite grains, with ages 288.3 ± 7.3 Ma (MSWD=3.3, n=6) and 248.6 ± 3.3 Ma (MSWD=0.13, n=8), respectively. In Lu-Hf systematics, zircons of all age populations show a relatively narrow spread in $^{176}Hf/^{177}Hf(t)$ values, with majority (~90 %) falling between 0.282652 and 0.282533. An increase in $^{176}Hf/^{177}Hf(t)$ ratio from old to young zircon populations defines a trend, which follow CHUR evolution curve.

Our data do not concur with the assumption [2] of a single metasomatic event during chromitite formation. In contrast, a prolonged formation and multistage evolution of zircon growth is considered a feature typical of a metasomatized subcontinental mantle at Finero.

This investigation was supported by the Uralian Branch of Russian Academy of Sciences (grant 12-P-5-1020).

The effect of 1,10-phenanthroline on the oxidative dissolution of iron monosulfide (FeS)

C.E. BADICA* AND P. CHIRITA

University of Craiova, Department of Chemistry, Calea Bucuresti, 107I, Craiova 200512, Romania
(*correspondence: badica.catalina@gmail.com)

The effect of 1,10-phenanthroline (a Fe^{2+} ligand) on the oxidative dissolution of synthetic iron monosulfide (FeS) was tested by using electrochemical methods. The experiments were performed in air-saturated HCl solutions with the concentration of 1,10-phenanthroline in range 0-1 mM, at pH 5 and 25ºC. The corrosion current densities (i_{corr}), corrosion potentials (E_{corr}) and values of the components of equivalent circuit that fits the Electrochemical Impedance Spectroscopy (EIS) data were determined.

i_{corr} values are quasi-constant when the concentration of 1,10-phenanthroline varies between 0 and 0.5 mM. When the concentration of 10-phenanthroline exceeds the value of 0.5 mM, i_{corr} increases from 30.7 μA cm^{-2} up to 38 μA cm^{-2}. E_{corr} increases from -393 mV up to -338 mV when the concentration of 1,10-phenanthroline increases from 0 to 0.5 mM. At higher concentrations of ligand, E_{corr} decreases down to -355 mV. The values of the components of equivalent circuit that fits EIS data were found to be in agreement with the variation of i_{corr} and E_{corr}.

Our conclusion is that the oxidative dissolution of FeS in the presence of 1,10-phenanthroline is the result of two processes with opposite effect: 1) the inhibiting adsorption of 1,10-phenanthroline on the FeS surface and 2) the promoting effect of 1,10-phenanthroline on the breakage of Fe-S bond.

Earth's building blocks: The "Core Spyglass"

JAMES BADRO[1], JOHN BRODHOLT[2], JULIEN SIEBERT[13] AND RICK RYERSON[1,4]

[1]Institut de Physique du Globe de Paris, France
[2]University College London, United Kingdom
[3]Université Pierre et Marie Curie, Paris
[4]Lawrence Livermore National Laboratory, USA

The details of Earth's accretion, and the nature of Earth's building blocks in particular, are still poorly understood. One way to constrain accretionary processes is to understand the major differentiation event that took place during accretion: core formation. Earth's core formed during accretion as a result of melting, phase-separation, and segregation of accretionary building blocks (meteorites, planetesimals, protoplanets). Extensive melting lead to the formation of a Magma Ocean, and the bulk compositions of the core and mantle depend on it evolution (pressure, temperature, composition) during accretion. The entire process left a compositional imprint on both reservoirs: in the silicate Earth, in terms of siderophile trace-element concentrations (a record that is observed in present-day mantle rocks); and on the core, in terms of major element composition and light elements dissolved in the metal (a record that is observed by seismology through the core density-deficit).

Constraining accretionary processes by looking at the core has been studied for almost ten years. Based on partitioning of slightly siderophile elements, the current paradigm is that Earth must have formed under very reducing conditions, followed by a complex oxidation mechanism to reach the present-day redox state. In the light of new partitioning data under extreme conditions, we will show here that Earth can form at a constant redox state (the present-day value), or even form in relatively oxidized conditions (that of carbonaceous or ordinary chondrites). This paradigm shift is strengthened by the fact that oxidizing conditions favour oxygen solubility in the core, which is a requirement both for the inner-core density jump and outer core density deficit.

Advances in instrumentation based on cavity enhanced laser absorption spectroscopy

DOUGLAS BAER, MANISH GUPTA, FENG DONG, ELENA BERMAN, TOM OWANO AND ROBERT PROVENCAL

Los Gatos Research, Mountain View, CA, USA

Novel instrumentation based on high-resolution laser absorption spectroscopy now allows high precision measurements of gas concentration and isotopic ratios continuously, in real time, and without preconcentration. These analyzers employ tunable lasers that operate in the near-infrared and mid-infrared spectral regions and employ an optical cavity as a measurement cell. The simple operation of these instruments allows measurements almost anywhere. The laser wavelength is continuously and repetitively scanned over selected absorption features of target isotopologues to record high-resolution absorption lineshapes at data rates of 1 Hz or faster. The integrated areas of the measured lineshapes enable determination of the respective isotope-specific concentrations directly. No longer constrained to operate in a laboratory, these analyzers offer opportunities to record measurements in remote sites in less-developed areas. This presentation will summarize recent developments at LGR in both hardware and software analysis that enable measurements of isotopic ratios in carbon dioxide (δ13C, δ18O, CO2), methane (δ13C, CH4), nitrous oxide (δ15Nα, δ15Nβ, δ18O, N2O) and water (liquid and vapor; δ2H, δ17O, δ18O, H2O) in ambient air and in complex gas samples. An overview of the current performance of LGR instruments and perspectives on future developments will be presented.

Ca isotope fractionation in a permafrost-dominated boreal ecosystem (Kulingdakan watershed, Central Siberia)

M.-L. BAGARD[1]*, A.-D. SCHMITT[12], F. CHABAUX[1], O.S. POKROVSKY[3], J. VIERS[3], P. STILLE[1], F. LABOLLE[1] AND A.S. PROKUSHKIN[4]

[1]Université de Strasbourg-CNRS LHyGeS, 1 rue Blessig, 67084 Strasbourg Cedex, France (*correspondence: mbagard@unistra.fr)
[2]Université de Franche-Comté-CNRS, 16 route de Gray, 25030 Besançon Cedex, France
[3]Université Paul Sabatier-CNRS, 14 Avenue Edouard Belin, 31400 Toulouse, France
[4]V.N. Sukachev Institute of Forest, Krasnoyarsk, Russia

Ca isotope compositions were measured in different compartments (stream water, soil solutions, rocks, soils and soil leachates and vegetation) of a small permafrost-dominated forested watershed in the Central Siberian Plateau. Our results show that only the processes related to vegetation activity significantly fractionate Ca isotopes within the watershed. These fractionations occur during Ca uptake by roots and along the transpiration stream within the larch trees. Biomass degradation then significantly influences the Ca isotopic compositions of soil solutions and soil leachates via the release of light Ca. Furthermore, organic and organo-mineral colloids originated from organic matter degradation are thought to affect the Ca isotopic composition of soil solutions by preferential scavenging of ^{40}Ca. This imprint of organic matter degradation on the $\delta^{44/40}Ca$ of soil solutions is much more significant for the warmer south-facing slope of the watershed than for the shallow and cold soil active layer of the north-facing slope, indicating that the available stock of biomass and the decomposition rates are critical parameters that regulate the impact of vegetation on the soil-water system. Moreover, the obtained $\delta^{44/40}Ca$ patterns contrast with those described for permafrost-free environments with a much lower $\delta^{44/40}Ca$ fractionation factor between soils and plants, suggesting particular processes related either to the presence of permafrost or to the specific features of organic matter degradation in permafrost environments. Finally, biologically induced Ca fractionation observed at the soil profile scale is not visible in stream and river waters, whose isotopic variability in the course of the year is likely controlled by the lithological heterogeneity of the sources. As such, we suggest a negligible influence of biologically related fractionation on the long-term Ca isotopic signatures of riverine fluxes carried to the ocean.

Effect of Fe(II) ions on the sorption of selenite onto chlorite

MIN HOON BAIK* AND JONG TAE JEONG

Korea Atomic Energy Reseach Insitute, Daejeon, Republic of Korea (mhbaik@kaeri.re.kr)

It has been reported that Fe(II)-bearing minerals or Fe(II) ions can reduce oxoanionic selenite ($Se(IV)O_3^{2-}$) either to Se(0) or Se(-II) and then decrease the mobility of the selenite in subsurface environments [1, 2]. In this study the effect of Fe(II) ions on the sorption of selenite onto chlorite surfaces was investigated as a function of selenite concentration, Fe(II) concentration, and pH.

The sorption of Se(IV) onto chlorite surfaces followed the Langmuir isotherm regardless of the presence of Fe(II) ions. The Se(IV) sorption was enhanced at a pH > 6.5 when the Fe(II) concentration was higher than 5 ppm because of the increased sorption of Fe(II) onto chlorite surfaces. XANES (X-ray absorption near edge structure) spectra of the Se *K*-edge showed that most of the sorbed Se(IV) was reduced to Se(0) by Fe(II) sorbed on the chlorite surfaces, especially at pH > 9. The combined results of field emission scanning electron microscopy and X-ray diffraction also showed that elemental selenium and goethite were formed and precipitated on the chlorite surfaces during the sorption of selenite. Consequently it can be concluded that Se(IV) can be reduced to Se(0) in the presence of Fe(II) ions by the surface catalytic oxidation of Fe(II) into Fe(III) and formation of goethite at neutral and particularly alkaline conditions.

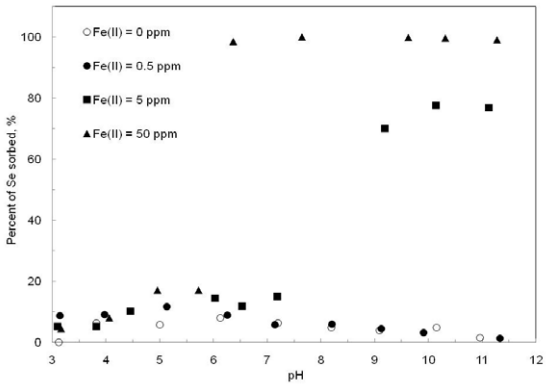

Figure 1: The sorption of Se(IV) onto chlorite surfaces as a function of pH at different concentrations of Fe(II) ions.

Horizontal gene transfer in phylogenetically-distant taxa that induce the formation of modern wrinkle structures: Implications for the interpretation of Earth's earliest microbialites

J.V. BAILEY[1] AND B.E. FLOOD[1]

[1]Dept. of Earth Sci., University of Minnesota, Minneapolis, MN 55455, USA (*correspondance: baileyj@umn.edu)

Wrinkle structures in rocks dating back to the Archean are commonly interpreted to represent the stabilizing influence of cyanobacteria on sediments because the trapping and binding of sediment by these phototrophic microbes is known to produce similar features in modern tidal flat settings [1]. Our observations of modern sediments show that, like cyanobacteria, chemolithotrophic taxa within the Beggiatoaceae can produce features that are reminiscent of those found in the ancient rock record. Despite similarities in cell morphology and division patterns, the Cyanobacteria and the Beggiatoaceae are generally considered to be phylogenetically-distant clades in rRNA-based phylogenies. However, our comparisons of *Beggiatoa* and cyanobacterial genomes show that these organisms share many genes that potentially code for phenotypic traits such as chemotaxis, filament formation, and the production of extracellular polymeric substances. Some of these genes may underlie the similar biostabilizing influences these organisms impart on sediments. Our analyses further suggest that at least some of these genes may have been acquired via horizontal gene transfer. The presence of multiple biostabilizing clades in the modern, as well as the potential for extensive horizontal gene transfer over 3.5 billion years of evolution, complicates the interpretation of ancient sedimentary features using solely morphological criteria.

Overview of the instrument

Ion beam for secondary ion mass spectrometry (SIMS) down to 10 nm can reveal new perspectives for cosmochemistry and material sciences. We have developed LIMAS (Laser Ionization Mass Nanoscope [1]) that is a time-of-flight sputtered neutral mass spectrometer (TOF-SNMS) with non-resonant laser post-ionization system. LIMAS is mainly composed of Ga focused ion beam (FIB) for sputtering, femtosecond laser for post-ionization of the sputtered particles, and high mass resolution multi-turn mass spectrometer of which mass resolving power of $^4He^+$ (m/z=4) is 8,500 (FWHM) after 90 cycles.

One of our goals is to determine micro-distribution of noble gases in solids derived from solar wind (SW) irradiation. An ultra-fine ion probe and post-ionization procedure should reveal the processes of the solar-gases were implanted and the surface layer was lost by space weathering because SW implanted layer is less than 100 nm and high spatial resolution *in situ* He analysis has never been done.

The spatial resolution for ^{4}He was achieved ~50 nm which was evaluated by using ^{4}He implanted Si-wafer (dose: 2×10^{16} ions/cm^2). A detection limit of the present system is about 10^{18} atoms/cm^3 for ^{4}He. The performance of LIMAS should be improved towards higher sensitivity and lower background noises because bulk concentrations of solar-He in gas-rich meteorite are 10^{16}–10^{18} atoms/cm^3 [2] for rocky material (density ~ 3 g/cm^3).

The association between iron and carbon in freshwater colloids

S. BAKEN[1]*, J.P. GUSTAFSSON[23] AND E. SMOLDERS[1]

[1]KU Leuven, Dept of Earth and Environmental Sciences, Kasteelpark Arenberg 20 bus 2459, 3001 Leuven, Belgium (*correspondence: stijn.baken@ees.kuleuven.be)
[2]KTH, Dept of Land and Water Resources Engineering, Teknikringen 76, SE-100 44 Stockholm, Sweden
[3]SLU, Dept of Soil and Environment, Box 7014, SE-750 07 Uppsala, Sweden

Iron and carbon are important constituents of natural colloids, which intimately links the fate of these two elements in riverine systems. Iron may strongly affect the binding of trace metals by organic matter, e.g. through competition for binding sites, which highlights the importance of a correct appreciation of the Fe speciation in surface waters. However, the chemistry of Fe and C in natural colloids is complex and depend on many factors including the pH, the Fe:C ratio, and the redox speciation of Fe [1-3].

Two areas with a contrasting Fe chemistry were studied: a lowland area with widespread seepage of iron-rich groundwater, and an upland peat area. Samples of ten oxic, well-mixed streams were subjected to cascade filtration using conventional filtration (1.2 μm, 0.45 μm, 0.1 μm) and cross-flow ultrafiltration (CFF; 5 kDa). The colloidal fraction, here operationally defined as between 0.45 μm and 5 kDa, was isolated by CFF and subsequently freeze-dried. The speciation of colloidal Fe was determined by EXAFS spectroscopy at the Fe K-edge (MAX-lab, Lund, Sweden).

In the rivers draining upland peat, Fe and C were predominantly recovered in the fraction between 5 kDa and 0.1 μm. Conversely, in the rivers draining the lowland with extensive seepage of iron-rich groundwater, Fe was most abundant in the $>0.1\,\mu$m fraction, whereas C was predominantly present $<0.1\,\mu$m. The EXAFS data reveal that colloidal Fe speciation is different in both study areas. It exists as mononuclear Fe complexed by dissolved organic matter, as colloidal hydrous ferric oxides (likely stabilized by adsorbed organic matter), or as a mixture of these. The colloidal Fe concentrations show considerable seasonal variability. Overall, this study contributes to a better understanding of colloidal Fe speciation and of its interaction with organic C.

Asian Monsoon moisture transport 1999-2005 and its implications for palaeomonsoon reconstructions

ALEXANDER J. BAKER[1], HARALD SODEMANN[2], KATHLEEN R. JOHNSON[3], JAMES U. L. BALDINI[1] AND JEROEN VAN HUNEN[1]

[1]Department of Earth Sciences, Durham University, Science Laboratories, South Road, Durham DH1 3LE, UK.
[2]Institute for Atmospheric and Climate Science, Swiss Federal Institute of Technology, CH-8092 Zurich, Switzerland.
[3]University of California at Irvine, 3206 Croul Hall, Irvine, CA 92697, USA.

The Asian summer monsoons affect the livelihood of the world's most populous regions. Predictions of future monsoonal variability require reliable palaeoclimate reconstructions from proxy data. Speleothem $\delta^{18}O$ records from Chinese cave sites are assumed to provide direct palaeomonsoon intensity records, but recent research suggests $\delta^{18}O$ integrates a more complex climate signal. We detected the sources modern monsoonal precipitation across China using a Lagrangian precipitation source diagnostic and reanalysis data. Our results show that monsoonal precipitation (May-August) in this region is primarily derived from the northern and western Indian Ocean; identification of this signal is consistent with recent GCM results. We also find that recycled moisture over continental Indo-China is an important contributor to west-to-east moisture transport during the monsoon season. These data highlight the importance of proxy site location and improve our ability to isolate the precipitation amount or monsoon intensity signal in palaeomonsoon reconstructions.

Trace element and ^{26}Al–^{26}Mg constraints on silicate differentiation of the HED parent body

J. BAKER[1]*, J. DALLAS[2], M. SCHILLER[3], J. CREECH[2] AND M. BIZZARRO[3]

[1]School of Environment, University of Auckland, New Zealand (*correspondence: j.baker@auckland.ac.nz)
[2]School of Geography, Environment and Earth Sciences, Victoria University of Wellington, New Zealand
[3]Centre for Star and Planet Formation, Natural History Museum of Denmark, Denmark

The howardite–eucrite–diogenite meteorites are considered to originate from the asteroid Vesta. Diogenite meteorites appear to be mafic cumulates with a pyroxene-dominated mineralogy, whereas eucrites are basaltic in mineralogy and composition. However, the relationship(s) between these products of silicate differentiation of their parent asteroid(s) remain enigmatic, if indeed they originated from the same parent body as is suggested by their common three-oxygen isotope compositions.

We have conducted a detailed *in situ* major and trace element study of minerals (pyroxene and plagioclase) in a large number of diogenites and non-cumulate eucrites (n = 44) by LA-ICPMS. We have also analysed to ultra-high precision ($\delta^{26}Mg^* \pm 0.002‰$) the Mg isotopic composition of the same bulk meteorites by MC-ICPMS. Significant variations in $\delta^{26}Mg^*$ related to ^{26}Al decay in the first 5 Myr of the Solar System are evident amongst the suite of diogenites ($\delta^{26}Mg^* = –0.011‰$ to $+0.013‰$) and eucrites ($\delta^{26}Mg^* = +0.004‰$ to $+0.0040‰$). Despite their limited range in mineral major element compositions, mineral trace element concentrations vary widely. For example, moderately incompatible heavy rare earth element concentrations in pyroxene vary by more than two orders of magnitude (e.g., Yb = 0.02 to 3.1 ppm).

Trace elements such as Yb in pyroxene and Sr in plagioclase co-vary with bulk rock $\delta^{26}Mg^*$ values, which potentially implies rapid magmatic differentiation of a magma ocean. However, the large range of trace element abundances is difficult to reconcile with any simple cogenetic model for partial melting or crystallization of diogenites (cumulates) and eucrites (residual liquids) from a common parent body or magma ocean. Stable Mg isotopic compositions ($\delta^{25}Mg$) of eucrites appear to be distinct from those of both diogenites and terrestrial basalts, which might imply that diogenites and eucrites originated from separate parent bodies or that eucrites are the product of a formation process (i.e., residual liquids of extensive fractionation of an ultramafic magma body) that is fundamentally different to the partial melting processes that produces basaltic magmas on Earth.

Environmental fate, transport, and bioavailability of CeO_2 nanoparticles in stream mesocosms

LEANNE F. BAKER[1]*, RYAN S. KING[1], JASON M. UNRINE[2] AND COLE W. MATSON[1]

[1]Baylor University, One Bear Place #97266, Waco, TX, USA 76798-7266 (*correspondence: leanne_baker@baylor.edu)
[2]University of Kentucky, Lexington, KY, USA 40546-0091 (jason.unrine@uky.edu)

Emissions from wastewater treatment facilities ("press"-type exposures) and accidental spills ("pulse"-type exposures) are two possible entry routes of engineered nanomaterials into aquatic environments. Significant uncertainty exists regarding the processes governing transport and environmental fate of these novel materials. Outdoor, 1870L recirculating stream mesocosms were treated with either 1) a one-time addition (pulse) of acetate-coated cerium dioxide nanoparticles (CeO_2 NPs) to achieve aqueous concentration of 10 mg NPs/L or 2) a 25-day continuous exposure (press) of the same amount of CeO_2 NPs as 1), a third stream served as a control. Mesocosms were lined with unglazed ceramic tiles and stocked with fish, invertebrate, plant and microbial species. CeO_2 NPs are known to be insoluble, so total Ce concentrations measured by ICP-MS served as a proxy for CeO_2 concentrations. Results suggested rapid aggregation of CeO_2 NPs in the pulsed dose. Aqueous concentrations were between 0.24-0.37 mg/L 12-76 hours after NP addition, declining to 0.02 mg/L by cessation of the experiment on day 30. Aqueous Ce concentrations in the press-dosed stream averaged 1.2 mg/L on day 15 (12% of target) and 1.1 mg/L (11% of target dose) on day 25. Five days after completion of NP dosing in press mesocosms (day 30 of experiment), aqueous concentrations of Ce had declined to an average of 0.46 mg/L, which was still higher than any Ce concentration measured in the pulse-dosed stream. Consequently, the concentration of Ce in periphyton was lower in the press-dosed stream on day 30 (average of 9.08 μg/g of dry sample) than in the pulse-dosed stream (average of 13.11 μg/g). The press dose resulted in longer-range transport of NPs, such that periphyton concentrations of Ce in the lower reaches of the press-dosed stream were nearly double those observed for the pulse-dosed stream (6.4 μg/g vs. 3.3 μg/g, respectively), likely because of a reduced particle-particle interaction and subsequent aggregation relative to the pulse addition. These results suggest that exposure scenarios may play a significant role in determining the environmental fate, transport, and bioavailability of stable metal oxide nanomaterials.

Development of fertile magma at El Teniente, Chile: Implications for porphyry-style mineralisation

M.J. BAKER[1]*, P.N. HOLLINGS[2] AND D.R. COOKE[1]

[1]CODES, University of Tasmania, Hobart 7001, Australia (*correspondence: bakermj@utas.edu.au)
[2]Dept. of Geology, Lakehead University, Thunder Bay, Ontario, Canada, P7B5E1

El Teniente porphyry Cu-Mo deposit is located in the Andean Cordillera in the central Chilean porphyry belt, which is host to a number of world-class late Miocene-Pliocene porphyry copper deposits. El Teniente is considered one of the world's largest copper deposit in terms of contained metal, with a total identified resource of over 16 billion metric tonnes (Gt) at 0.554 % Cu [1] and 7.8 Gt at 0.018 % Mo [2].

A series of calc-alkaline intermediate to felsic porphyritic sills and dikes, collectively termed the Teniente Plutonic Complex, are spatially associated with magmatic-hydrothermal breccias and veins that host mineralization at El Teniente. They were emplaced between 7.1-4.9 Ma, although previous work has suggested a 7.10 ± 0.41 Ma age for a sample of the porphyry may be inherited [3,4].

Samples from the Teniente Plutonic Complex have been analysed for Rb/Sr and Sm/Nd isotopic compositions. ε_{Nd} values are consistently positive, ranging from 2.4 to 3.2, whereas $^{87}Sr/^{86}Sr_i$ values are between 0.70388 and 0.70421. When compared to other intrusive rocks from Central Chile [5], El Teniente rocks display broadly similar trends, implying that a geologic event led to an abrupt decrease in ε_{Nd} values ca. 5 Ma. The isotopic data reflect localized assimilation of crustal material into the mantle wedge as a result of subduction erosion adjacent to a zone of ridge subduction [5], rather than intra-crustal contamination, consistent with a subduction-erosion model [6]. The data suggest the Teniente Dacite Porphyry and associated mineralization was emplaced as several discrete intrusions over a ca. 1 million year period. This process has implications for the relationships between porphyry emplacement and Cu-Mo mineralization in central Chile.

Cl in magmas: A tool for degassing processes

H. BALCONE-BOISSARD[1]*AND G. BOUDON[2]

[1] ISTeP, Université Pierre et Marie Curie, Paris, France (*correspondence : helene.balcone_boissard@upmc.fr)
[2] Institut de Physique du Globe de Paris, Paris, France

Volatiles are responsible of magma ascent from reservoir to surface. For differentiated melt, H_2O is the main volatile species, the behavior of which control the eruptive style. But H_2O is generally difficult to measure precisely that limits the dataset available. Halogens are interesting to study and particularly Cl that is easier to analyse in volcanic glass (residual glass and melt inclusions) by electronic microprobe at the concentrations that occurred in natural samples.

Cl is generally controlled by its partitioning into the H_2O phase that explains a wide range of behavior. Here we present different results on Cl behavior in magmas, from basic to acid composition, in order to highlight how Cl may be a useful parameter for degassing processes. In rhyolitic melt, Cl follows H_2O behaviour and provides the same information of closed- vs. open-system degassing. In alkali magmas such as phonolitic or trachytic magmas, Cl content in magmatic melt may be buffered in precised (P, T, composition) domain corresponding to magma storage at depth in equilibrium with a two-phase fluid composed of H_2O-rich vapor and a brine. At that conditions, Cl content depends on the pressure at which the magma is stored, and thus acts as a barometer. The pressure at which the magma is deduced from the solubility law corresponding to the melt composition studied. In some cases, Cl may only behaves as a pure incompatible and non-volatile element and images a stratified reservoir. Whatever the composition, effective Cl degassing potentially affecting the environment.

We illustrate these different behaviors with data on glass (melt inclusions and residual glass) from different eruptions from various contexts (Vesuvius, Etna, Azores, Lesser Antilles and Vanuatu arc).

Cyclic dolomitization of limestone at Oker (Germany)

ANDRE BALDERMANN[1], ARTUR P. DEDITIUS[1], CHRISTIAN P. STICKLER[1], ALBRECHT LEIS[2] AND MARTIN DIETZEL[1]

[1]Institute ofApplied Geosciences, Graz University of Technology, Rechbauerstraße 12, 8010 Graz, Austria; (baldermann@tugraz.at)
[2]Institute of Water, Energy and Sustainability, Joanneum Research, Elisabethstraße 18, 8010 Graz, Austria

Magnesium and sulfur are one of the major elements that control dolomitization in marine, low-temperature environments. However, conditions and reaction mechanisms, which are related to dolomitization are poorly understood.

We investigated partly dolomitized limestone (Oker, Langenberg, Germany) of Upper Jurassic age (~153 Ma) that was deposited in a shallow marine, sabkha environment. X-ray diffraction (XRD), $\delta^{18}O$ and $\delta^{13}C$ isotope measurements, and electron microprobe (EMP) analyses were completed on porous dolomite, sandwiched by layers of limestone.

The lower limestone layer consists of micritic calcite (-1.7 to -2.9‰ of $\delta^{18}O$ and 1.3 to -0.7‰ of $\delta^{13}C$, VPDB), which formed under marine conditions. EMP analyses revealed low-Mg calcite (LMC) of $(Ca_{0.96\text{-}0.99}Mg_{0.004\text{-}0.03}Sr_{0\text{-}0.01}Na_{0\text{-}0.01}Fe_{0\text{-}0.002})_{0.99\text{-}1.0}CO_3$. Samples from the contacts between dolomite and limestone layers contain LMC, high-Mg calcite (HMC), and dolomite, which are associated in single grains. The dolomite core, $(Ca_{0.97\text{-}1.14}Na_{0\text{-}0.01})_{0.97\text{-}1.14}(Mg_{0.75\text{-}0.97}Fe_{0\text{-}0.02}Mn_{0\text{-}0.01})_{0.76\text{-}0.99}[(C_{0.998\text{-}1.0}S_{0\text{-}0.002})O_3]_2$, is ~10 µm in diameter, and is surrounded by LMC, $(Ca_{0.86\text{-}0.99}Mg_{0.006\text{-}0.05}Fe_{0\text{-}0.004}Na_{0\text{-}0.002}Mn_{0\text{-}0.001})_{0.96\text{-}0.97}CO_3$, and subsequently deposited HMC, $(Ca_{0.64\text{-}0.78}Mg_{0.19\text{-}0.32}Fe_{0\text{-}0.004}Na_{0\text{-}0.003}Mn_{0\text{-}0.002})_{0.91\text{-}0.99}CO_3$. The "pure" dolomite (2.2 to 1.7‰ of $\delta^{18}O$ and 1.7 to -0.1‰ of $\delta^{13}C$, VPDB) comprises of 2-50 µm sized euhedral crystals of $(Ca_{1.02\text{-}1.12}Na_{0\text{-}0.02})_{1.02\text{-}1.13}(Mg_{0.82\text{-}0.94}Fe_{0\text{-}0.02}Mn_{0\text{-}0.002})_{0.83\text{-}0.97}[(C_{0.994\text{-}1.0}S_{0\text{-}0.006})O_3]_2$, and shows alternate growth zones of S and Fe. XRD data confirm non-stoichiometric dolomite with 51-54 mol% of $CaCO_3$. The degree of order in dolomite, in respect to dolomite super structure, decreases from 83% to 42% with increasing S contents from 0.02 to 0.06 S [a.p.f.u.], respectively. The upper limestone layer contains no dolomite or HMC, and displays marine conditions; i.e., micritic LMC (-1.8 to -3.4‰ of $\delta^{18}O$ and -1.6 to -4.0‰ of $\delta^{13}C$, VPDB).

The euhedral shape and the (Fe, S)-growth zoning of the dolomite crystals, and the alternate zones of dolomite, LMC, and HMC suggest dolomitization via dissolution of primary carbonates and subsequent cyclic and abrupt changes in the chemical (Mg, Fe, and S), and isotopic composition of the interstitial solutions.

A distinct tectono-metamorphic evolution at the southern edge of Tisia Mega-Unit revealed by monazite and xenotime age dating

D. BALEN[1], P. HORVÁTH[2], F. FINGER[3] AND P. KONEČNÝ[4]

[1]Faculty of Science, University of Zagreb, Croatia (*correspondence: drbalen@geol.pmf.hr)
[2]Rhodes University, Grahamstown, Republic of South Africa
[3]Division of Mineralogy, University of Salzburg, Austria
[4]Dionýz Štúr Institute, Bratislava, Slovak Republic

The Slavonian Mountains (Pannonian Basin, Croatia) are the area of particular significance within Tisia Mega-Unit. This large unit, with complex internal structure, encompasses three huge southward dipping Alpine nappe systems that expose characteristic lithologies of south-eastern part of Pannonian Basin basement. Complexes of the central nappe system (i.e. Bihor) outcrop along the 5.5 km long, NNW–SSE trending Kutjevačka Rijeka transect. This transect is one of the most prominent geological cross-sections that reflects a complex history of the metamorphic and igneous evolution, giving insight into crustal evolutionary processes and their relationship to deformation and metamorphism.

Our previous age dating of monazite from the representative rock complexes along Kutjevačka Rijeka transect, combined with geothermobarometric data, revealed complex structure and metamorphic history that includes a pre-Variscan (Ordovician to Silurian; 444±19 and 428±25 Ma) and a Variscan (356±23 Ma) medium-grade metamorphism [1, 2]. The primary focus of this study is on surprisingly large extent of very low- to low-grade Alpine metamorphism recorded in the parametamorphic rocks (chloritoid and chlorite schists) along the transect. The Th–U–Pb age dating on xenotime grains within the chloritoid schist gave an average age of 120±36 Ma, peak metamorphic conditions reaching 3.5–4 kbar and 340–380 °C. The age of 219±81 Ma obtained on Yb-rich xenotime (inherited?) core domain(s), implies a possible existence of older low-grade metamorphic phase(s) [3]. Two distinct penetrative low-grade metamorphic foliations recorded in the chlorite schists are accompanied by existence of two populations of small (~3.5 μm) low-Th monazites, giving an average age 99±15 Ma. Histogram of obtained ages shows two peaks at 120 and 80 Ma while age modelling recognized two peaks at 113±20 and 82±23 Ma. Those ages argue against "stratigraphic doubts" that contradict Alpine metamorphism in the area.

Contribution of fungi and bacteria to the Mg biogeochemical cycle in podzolic soils

C. BALLAND-BOLOU-BI[1]*, E. B. BOLOU-BI[2], S. J. M. HOLMSTRÖM[1] AND N. G. HOLM[1]

Stockholm University, Dept. of Geological Sciences, Stockholm, Sweden (*Clarissebolou-bi@geo.su.se)
Uppsala University, Dept. of Earth Sciences, Air, Water and Landscape sciences, Uppsala, Sweden

Silicate mineral weathering is a key process in soil formation through leaching of essential elements (Mg, Fe, Al), which sustain plant growth and determine the chemistry of soil solutions and exchange complex. Biological role on silicate mineral weathering remain to date a scientific challenge due to the strong relation between plant growth, silicate mineral weathering and CO_2 cycle. However, some constrains, such as microflora associated to plants, are unresolved allowing to quantify biological impact on silicate mineral alteration in the soil and on major cation biogeochemical cycle. Soil microorganisms (fungi and bacteria) play a major role in the availability of nutrients in soils. They participate in weathering of primary materials through the production of low-molecular masses organic acids (LMMOAs). The objective of this study is to quantify the impact of microorganisms (bacteria and fungi) during granite bioweathering and to better understand and quantify the contribution of microflora to Mg biogeochemical cycle.

For this, we lead several experiments of geological material (granite) bioweathering to investigate the impact of fungi and bacteria on the release of Mg from granite during 42 days. The microbial communities were directly isolated in November 2011 from different horizon (O, E, B) of a podzolic soil under 3 different tree species (Scots Pines, Spruce, Birch) in Norunda (Sweden). To characterize mechanisms of dissolution, we monitored low-molecular organic molecules produced by microorganisms, microbial biomass, pH, Mg released and Mg isotope ratio variations.

Result indicates that pH decreases significantly from 6.5 to 4-5 during the first week of the experiments and then roughly stabilizes over time. In contrast, in all experiments, the fraction of released Mg is strong until 30 % at the end of the experiments. There is a positive correlation between the Mg leached from phlogopite and the carbon produced (LMMOAs and biomass) by microbial communities. Whatever the tree species, the microbial communities isolated from the upper part of the organic horizons of the soil are less efficient to weather the granite and don´t produce great quantities of LMMOAs. Preliminary isotope analyses indicate that δ^{26}Mg in the leaching solutions collected at the end of the experiments are close to the initial value of the granite. Only leaching experiments performed with microbial communities isolated from the upper part of the organic horizons induce a high enrichment in the light isotope (~ -1.0‰) in the solution, suggesting a biotic effect that will be investigated.

Combined Halogen (Cl, Br, I) and noble gas mantle geochemistry

C. J. BALLENTINE[1], R. BURGESS[1], H. SUMINO[2], D. HILTON[3], D. GRAHAM[4], P. VAN KEKEN[5], D. CHAVRIT[1], L. RUZIE[1], P.L. CLAY[1], B. JOACHIM[1], B. WESTON[1], L.D.A. JEPSON[1] AND M. BROADLEY[1]

[3]UCSD, (drhilton@ucsd.edu)
[4]OSU, (dgraham@coas.oregonstate.edu)
[5]U. Michigan, (keken@umich.edu)

Not yet two decades ago the community view of the mantle structure had converged on a mantle geochemically layered at 670km depth. This model has passed on, is no more, ceased to be, expired and is now history. Killed, by geophysical observation. Although the layered mantle is now an ex-model the geochemical observations used to support it remain; the formation, location and evolution of a volatile rich mantle reservoir capable of fluxing the mantle beneath mid ocean ridges with accretionary volatiles, such as ^{3}He, still attracts significant attention.

High precision multi-collector noble gas mass spectrometry is providing us with new detail of the mantle system. MORB basalts and mantle-derived CO_2 natural gas fields show a MORB-source mantle with light and heavy noble gases, and therefore associated volatiles, that originate as a trapped component in accreting meteorites [1]. New data from Iceland nevertheless, shows that the Iceland OIB source region is incompatible with this source simply providing the noble gases now in the upper mantle [2]. An additional volatile input into the mantle is today through recycling noble gases with a seawater signature [3], while dry subduction may have operated on the Early Earth to introduce accretionary volatiles into the mantle [4].

Heavy halogens (Cl, Br, I), in combination with noble gases, are a powerful tool to understand the subduction of volatiles and highly incompatible elements in detail [5]. Due to low Br and I concentrations, new techniques only now allow us to determine: accretionary material characteristics; partitioning data; and investigate the different terrestrial reservoir halogen mass balance. We present an overview of progress in this new field and discuss how the combined halogen/noble gas data might be used to reconcile the apparent need for a volatile-rich reservoir that fluxes the shallow mantle with the new Icelandic data [2].

Reconstructing the Rheic: Geochemical analysis of ocean lithosphere from the Variscides

A.R. BAND[1]*, T.L. BARRY [1], A.D. SAUNDERS[1] AND J.B MURPHY [2]

[1]University of Leicester, Leicester, LE1 7RH. (correspondence: arb37@le.ac.uk, tlb2@le.ac.uk & ads@le.ac.uk)
[2] St. Francis Xavier University, Antigonish, B2G 2W5. (bmurphy@stfx.ca)

Although the Rheic Ocean dominates palaeo-geographic reconstructions of central Europe during the Palaeozoic, many factors regarding its general evolution & internal tectonic configuration are inadequately constrained [1]. A major component in aiding a better understanding of these factors is the accurate assessment of suture zones & associated metabasite suites within the internal Variscides. As such this study focuses on the geochemistry of the Lizard- Cornwall, Sudetes-Poland, Acatlan-Mexico & Ossa-Morena, Careon, Morais-Iberian ophiolite complexes. Sampling within these complexes focused on the least deformed mafic members in order to fully assess the geo-tectonic setting of basalt genesis. Major, trace and rare earth element data (XRF & ICP-MS) has been examined and shows general LREE depletion & a lack of significant Ta, Nb or crustal derived element anomalies for all complexes. The new geochemical data enables an accurate discrimination of the geo-tectonic setting for each complex and aids in constraining future palaeo-geographic reconstructions of the enigmatic Rheic basin. The lack of crustal contamination & origins within the upper mantle, facilitates use of some samples for a future Hf-Nd isotope study aimed at fingerprinting the Devonian upper mantle and furthering our understanding of the origin & evolution of the Dupal anomaly [2]. Additionally, we will use the isotope data to investigate models to explain the apparent depleted nature of the source of Rheic Ocean basalts [3].

Clumped isotope thermometry in Belemnite shells from the Early Cretaceous Karai Shale Formation, Trichinopoly, India

YOGARAJ BANERJEE, PROSENJIT GHOSH* AND RAMANANDA CHAKRABARTI

Centre for Earth Sciences, Indian Institute of Science, Bangalore 560012, India (*pghosh@ceas.iisc.ernet.in)

Well-preserved Belemnites fossils are hosted in the upper Albian Karai Shale Formation, India, which represents an offsore high stand depositional environment (1,2). It has been argued that $\delta^{18}O$ variability in these Belemnites – growth bands reflect seasonal –paleo-temperature changes in the sea water (2). We investigate paleo-seawater temperatures by analyzing clumped isotopes (Δ_{47}) in 15 petrographically and chemically well-characterized unaltered samples of Belemnite guard shells. Sample powders were drilled from the exterior growth bands, avoiding the outermost portion. $\delta^{18}O$ and $\delta^{13}C$ were also determined. Our Δ_{47} measurements yield a temperature range of 20°C (Δ_{47} = 0.667±0.005) to 42°C (Δ_{47} =0.624± 0.005) using the Ghosh *et al*., (2006) thermometry equation. The spread in Δ_{47} values together with $\delta^{13}C$ and $\delta^{18}O$ and inferred salinity values allowed characterization of the 15 samples into three suites with distinct temperature and salinity ranges. Considering the nektonic behaviour of Belemnites (3), we propose an alternative mechanism to explain the spread in our paleo-temperature data by invoking the role of thermohaline circulation during Early Cretaceous, similar to modern mid-latitude modern oceanic conditions.

Major and trace element geochemistry in groundwater of Patancheru Industrial Area, Andhra Pradesh, India

B. DASARAM*

CSIR-NGRI, Habsiguda AND Uppal, Hyderabad-500 007, India (*correspondence: bdram11@gmail.com)

Patancheru Industrial Development Area is located about 40 km from Hyderabad City, A.P. This is one of the contaminated areas identified by the Central Pollution Control Board (CPCB) New Delhi. More than 200 small and large-scale industries manufacture pharmaceuticals, paints, pesticides and chemicals and metallic products in this region. All effluents drain through the area to join the main Nakkavagu stream, which merges into Manjira River, and is one of the major drinking water sources to some parts of Hyderabad and adjoining areas.

During pre- and post-monsoon seasons the ground water samples were collected from open and bore wells. The samples were analysed for major, minor and trace constituents. Several heavy and toxic trace elements were estimated by Inductively Coupled Plasma Mass Spectrometry (ICP-MS). The geochemical data obtained was utilized to assess the extent of pollution and its impact on human health. Some of the toxic and trace elements (As, Se, Pb, Cr, Cu and Mn) were found to be more than the desirable levels in drinking water (WHO guidelines). The Contour maps for these trace elements were prepared to know their spatial and temporal distribution and to identify the point source and transport of the contaminant. These studies would emphasis the need to adopt some remedial measures and combat pollution.

Geochemical characteristics and correlation of oil-source in Minfeng area for Dongying depression, Bohai Bay Basin, Eastern China

BAO DONGMEI[1]* AND JIANG YOULU[2] AND JIANGLIN[1]

[1]PetroChina Research Institute of Petroleum Exploration & Development,Beijing 100083,China (bdmei@petrochina.com.cn)

[2]Earth Resource College, China University of Petroleum, Dongying, Shandong 257061, China

The Minfeng area is located in the northeast of Dongying Depression. The characteristics of the gas chromatography of saturated hydrocarbons and the steroid terpane biomarkers show that there are three sets of source rocks with obvious differences including the upper part of the fourth member of the Shahejie Formation (simplified as Es4s) , the middle part of the third member of the Shahejie Formation(simplified as Es3z), and the lower part of the third member of the Shahejie Formation(simplified as Es3x). There are four types of oil.

Further studies focus on oil-source correlation. Based on the techniques of fingerprint indetification, scatter diagram analysis and mathermatical statistics, the results indicate that oils in reservoirs of the second member of the Shahejie Formation(simplified as Es2) (from7 to 10 sand units) of Yong3 fault-block , Es2(No.4 sand unit) of Yong51 fault-block and Yanjia area came from Es4s source rock. Oils in reservoirs of Minfeng sag came from Es3z and Es3x souce rocks. Oils in reservoirs of Es2 (No.3 and No.5 sand units) of Yong3 fault-block, Yong66 fault-block, Yong12 fault-block, Yong51 fault-block are mixed by oils coming from Es4s and Es3x. Oils in reservoirs of Es2 (No.3 and No.5 sand units) of Yong2 fault-block, Yong63 fault-block came from Es3z source rock.

It is possible to infer that oils from Es4s source rock, which were main along the favorable sandbodies and uncomformity, migrated lateraly from sag to Yanjia area and eventually filled in the sandy conglomerate bodies of Es3 and Es4 because of lack of oil-source faults. Oils are diverse types because of many oil-source faults in Yong Anzhen area. It implies that traps in Yonganzhen area formed in the same period according to the distribution of the types of oils on the plane. Early generated oil accumulated in the reservoir which was near to the source rocks. With the further burial depth of the source rocks, overlying source rocks gradually entered the hydrocarbon generation period, the oil began to accumulate in traps which were further distance from the source rocks.

Direct atmospheric O_3 and O_2 signatures from the deep past and their first-order pattern

HUIMING BAO

Department of Geology and Geophysics, Louisiana State University, Baton Rouge, LA 70803 (bao@lsu.edu)

The isotope compositions of atmospheric O_3 and O_2, two of the most important molecules in the atmosphere, offer us windows to the deep history and evolution of the Earth. Sulfate is an oxyanion capable of recording direct O_3 and/or O_2 signatures from the distant past. Recently, an improved understanding of the triple oxygen isotope systematics of various sulfur oxidation processes has demonstrated that secondary atmospheric sulfate bears O_3 signature ($\Delta^{17}O$ positive), while sulfate of oxidative weathering origin bears O_2 signature ($\Delta^{17}O$ negative). The ultimate source of the ^{17}O anomalies in O_3 and O_2 is the Chapman reaction in the stratosphere, which via stratosphere-troposphere exchange links the concentrations and triple oxygen isotope compositions of atmospheric O_2, CO_2, and O_3 to the rates of bioproductivity, weathering, and organic burial on the Earth surface.

Despite many unfilled gaps in its record, I propose here that, from existing data, a first-order temporal pattern for sulfate $\Delta^{17}O$ for the last 3.5 billion years has emerged. There are three outstanding features. (1) The Marinoan O-17 Depletion (MOSD) event at 635 Ma is a clear anomaly in which the $\Delta^{17}O$ of sulfate reached as negative as –1.64‰. The most viable explanation for this event is a post-glacial, ultra-high pCO_2 world, which is consistent with the "snowball" Earth hypothesis. Data for other alleged "snowball" Earth periods are lacking at this time, and other secondary "depletion" events are predicted. (2) The Archean sulfate has an average $\Delta^{17}O$ value of –0.05 ± 0.05‰, while the post-Archean sulfate has an average $\Delta^{17}O$ at –0.12 ±0.05‰ (MOSD data excluded), a pattern that is consistent with the lack of O_3 shield, i.e. the absence of Chapman reaction, in the Archean. However, the role of thermal alteration has yet to be examined. (3) The oldest sulfate with distinct positive $\Delta^{17}O$ values has been traced back to the Eocene (~35 Ma). However, if O_3 became essential in atmospheric oxidation of SO_2 as soon the ^{33}S anomaly ceased to exist in rock records, $\Delta^{17}O$-positive sulfate should have been produced since the Early Proterozoic Era. Bear in mind that any geological record is the net result of production and destruction. By understanding the geologic context of sulfate records, and by exploring diverse and continental deposits in particular, we shall piece together a first-order, direct geological record of atmospheric O_2, O_3, and CO_2 for the last 3.8 billion years.

U-Pb dating of hydrothermal zircon and its implications for the metallogeny of the Donping gold deposit in North China

ZHIWEI BAO[1], WEIDONG SUN[1] AND CHUANGJIU LI[2]

[1] CAS Key Laboratory for Mineralogy and Metallogeny, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, 510640, China
[2]Guangdong Nonferrous Metals Geological Exploration Institution, Guangzhou, 510080, China

The large Dongping gold deposit is located in the northern margin of the North China Craton, northwestern Hebei province, China. The ores are hosted by the Shuiquangou syenite complex and consist mainly of auriferous quartz veins and K-feldspar altered and silicified disseminated ores, both of which are characterized by low sulfide volumes, Te-rich and As-poor. U-Pb dating of zircons from the hornblende syenite on the western margin of the complex yields an age of crystallization of 400±3.5Ma. The close spatial relation of the gold mineralization with the syenite complex, and S, Si, and Pb isotope compositions of the ore-related mienrals, suggest that the ore deposit might be genetically related to the syenite complex. However, almost all of the published age of ore-formation vary in range of 157~177 Ma (^{40}Ar-^{39}Ar ages of hydrothermal K-feldspar[1-2]), which caused considerable controversy over the metallogeny of the Dongping gold deposit. Morphology, cathodoluminescence image and rare earth element concentrations of zircons from the first stage disseminated ore and grey auriferous quartz vein, and late stage low grade quartz vein suggest that the zircons are neocrystallized hydrothermal. The hydrothermal zircons from the disseminated ore and auriferous grey quartz vein are dated at 389±1.0Ma and 385±5.7Ma, respectively, which are close to the crystallization age of the syenite complex and might have been formed during post-magmatic hydrothermal processes. Considering the two type of ores are dominant parts of the ore deposit, we argue that the pervasive post-magmatic hydrothermal alteration is the main ore forming stage. U-Pb dating of the hydrothermal zircon from the low grade auriferous quartz vein yields an age of ~140Ma, which represents Yanshannian hydrothermal superimposition. Thus, the Dongping gold mine is a post-magmatic hydrothermal ore deposit with later stage hydrothernal overprint.

Distribution of rare earth elements in marine Co-rich ferromanganese crusts of the South Atlantic

A.P.M.G. BARANDAS[12], M.A.I. DUARTE[1] AND J. ENZWEILER[2]*

[1] LAMIN (Laboratório de Análises Minerais) - Geological Survey of Brazil (CPRM) (ana.barandas@cprm.gov.br)
[2] University of Campinas, P.O. Box 6152, CEP13083-970, Brazil, (*correspondence:jacinta@ige.unicamp.br)

Rare earth elements (REE) are of great geological, technological, economic and strategic interest. The increasing use of REE in high-tech products and the restrictive politics of some countries for commercialization of some REE raw products resulted in search for new deposits of these elements as well as the feasibility of unexplored reserves. One of the possible sources of REE are cobalt-rich seamount ferromanganese crusts. These are unconventional ores abundant in the deep ocean. Co-rich crusts are enriched in metals such as Co, Pt, REE, Ti, Ni, Tl, Te, Zr, W, Mo and Bi. The chemical and mineralogical characterization of Co-rich crusts occurrences has been carried out in several oceans [1,2]. In the South Atlantic, they are well known in the Rio Grande Seamount [3]. Ferruginous vernadite is a common phase in Co-rich crusts and moderate amounts of carbonate-fluorapatite (CFA) are found in thick crusts, as weel as low amounts of quartz and feldspar[4].

In this work, samples of cobalt-rich crusts from the Rio Grande Seamount, South Atlantic were chemically characterized. Trueness of analytical data was checked by analysis Co-rich seamount crust reference materials GSMC-1 and GSMC-3 [5]. The content of REE in the analysed samples is variable (ΣREY 320-3,100 mg/kg) and only 5-10% of these totals it is of heavy REE. Almost all samples show strong enrichment in Ce, as evidenced by PAAS normalized REE patterns. Such type of finding was previously interpreted as related to hydrogenetic Fe–Mn crusts [6]. Their formation is ascribed to the oxidative scavenging of Ce and its preferential removal from seawater by hydrous Fe–Mn oxides.

On regularities in accumulation and distribution of elements in living matter of natural and technogenic ecosystems

NATALIA BARANOVSKAYA

Tomsk Polytechnic University, Tomsk, 634050, Russian Federation
(*correspondence: natalya.baranovs@mail.ru)

The task of gaining information on element composition of living matter was set by V.I. Vernadskiy at the beginning of the last century. In spite of the long history of study in this problem, there is still a number of questions to be answered.

For this purpose we have revealed the regularities in accumulation and distribution of elements in living matter on the sites with various rates of natural-technogenic ecosystem transformations. The research is based on the results of up-to-date high-sensitivity analytical methods – instrumental neutron activation and inductively coupled mass-spectrometric plasma (ICP-MS).

Living matter is not homogeneous in its composition. The analysis of materials obtained by us attests the fact that in regularities of element mean content distribution in living matter the conformities of their accumulation are observed that correspond to general distribution laws for material objects: that of Mendeleyev-Clark on element distribution in different masses and Oddo-Harkins rule on element interchange with even and uneven numbers. It was revealed that in the zones of geochemical abnormities conditioned by geologic and metallogenetic features there is an increase in concentration of specific elements in composition of living organisms against the background of observing geochemical regularities. Element composition of living matter is subjected to significant transformation in the zones of technogenesis. In such zones the disruption in basic element accumulation regularities is observed. As a result it was stated that technogenic factor has an effect on organism of modern urban residents in the form of intensive accumulation of such elements as lead, gold and cadmium.

The results of research in living matter from different sites shows that the indicators of its internal changes under the influence of the environment are mostly the element relationships. The most informative is Th/U, as well as the relationship of rare-earth elements and some others.

Geochemistry of mineral springs ecosystems of Baikal region

NATALIA BARANOVSKAYA, BULAT SOKTOEV*, LEONID RIKHVANOV AND TATIANA PERMINOVA

Tomsk Polytechnic University, Tomsk, 634050, Russian Federation
(*correspondence: bulatsoktoev@gmail.com)

The Baikal rift area is characterized by a rich variety of mineral springs. The research of microbial communities has been started quite recently, but there is a lot of information showing the important role of microbial communities of hot springs in the evolution of life in the Precambrian [1].

The complex studies in thermal springs have shown that severe environmental conditions (high temperature, alkaline pH and high sulfide content) contribute to the development of specific microbial communities, having significant biodiversity and high intensity of biogeochemical processes, comparable to the microbial communities of neutral thermal spring. The main feature of these communities is the formation of microbial mats, often in collaboration with travertines [1].

The objective of our study is to identify geochemical features of different springs in the Baikal rift area. Thus, the mat samples were taken in several springs of the Baikal region in the summer of 2012. The chemical composition was determined by multi-element neutron activation analysis (Department of Geoecology and Geochemistry of Tomsk Polytechnic University, Russia).

The data shows that the mats of different mineral springs are characterized by absolutely different content of elements. Thus, mats of the tonic spring are characterized by the largest content of Na, the mats of methane spring – that of Ca. The mats of some springs are characterized by higher content of some elements. For instance, the mats of cold Arangatuy stream have higher content of Ba, Ce, Nd, Th, Tb, Yb, Ta, Sm. We should bear in mind the higher accumulation of the mats in the stream of U (177 mg/kg).

All this suggests that the mats help to assess biogeochemical role of microorganisms in ecosystems, shows an important role of microbial communities in hot springs in the evolution of life on the Earth, as well as taking an active part in the formation of travertine.

Petrological constraints on formation of the martian crust

D. BARATOUX*[1], M. MONNEREAU[1], M.J. TOPLIS[1], K. KURITA[2], H. SAMUEL[1], R. F. GARCIA[1] AND M. WIECZOREK[3]

[1]Institut de Recherche en Astrophysique et Planétologie, CNRS & Université Paul Sabatier, Toulouse III, 14. Av. Edouard Belin, 31 400 Toulouse. (*correspondance: david.baratoux@irap.omp.eu)

[3]CNRS, Institut de Physique du Globe de Paris, 5, rue Thomas Mann. Université Paris Diderot, 75205 Paris Cedex 13, France.

The 4 Ga-record of Martian volcanic activity has been characterized over the last decade by various remote sensing instruments, including gamma ray spectroscopy and visible/near-infrared spectroscopy. Based on these data, the martian crust is viewed as a basalt-dominated world with limited crustal differentiation. This relatively simple situation (when compared to the Earth) may be responsible for observed trends in surface chemistry and mineralogy with age, such as an increase with time of the abundance of high-calcium pyroxene relative to that of low-calcium pyroxene. Indeed, petrogenetic modeling suggests that these trends can be explained in terms of variable degrees of partial melting of a martian mantle of constant composition [3,4], providing a quantitative estimate of the average cooling rate of the martian interior. On the other hand, further work is needed to reconcile this model with the existence of distinct geochemical mantle reservoirs inferred from the analysis of the SNC meteorites. The idea that the martian mantle has been cooling for at least the last 4 Ga, as constrained from data spanning the entire Noachian-Hesperian-Amazonian periods, has several petrological, geochemical and geophysical implications. For example, mineralogical transitions observed around 3.7 Ga may be related to minor changes in mantle temperature. Furthermore, even the oldest exposed surface rocks could be an expression of this ancient volcanism rather than being associated with a mantle overturn following the crystallization of a magma ocean. In light of these results, we also argue that the density of the martian crust should be revised to higher values, in agreement with [5]. A lower density contrast with the mantle implies a thicker crust for which a basalt-eclogite transition would appear to be very likely (at least in some regions), providing a motivation to explore mechanisms of crustal recycling and implications for the fate of heat-producing elements.

Hydrogeochemical and isotopic characterization of the Saturnia thermal aquifer

A. BARBAGLI[1]*, F. BROGNA[1], E. GUASTALDI[1], G. LIALI[1], C. REZZA[2] AND M. TROTTA[1]

[1]CGT Center for GeoTechnologies, University of Siena, Via Vetri Vecchi, 34 - 52027 S. GiovanniValdarno, Italy. (*correspondence: barbagli.alessio@gmail.com)

[2]Corso Italia n 16,80011, Acerra, Naples Italy. (carmelarezza@yahoo.it)

The thermal area of Saturnia was discovered and visited for several centuries before the Roman Empire and is still one of the most visited thermal springs in the world. It is located in central Tuscany between the Monte Amiata and the Tuscan volcanic area to the south. Herein, we study the thermal aquifer by chemical and isotopic analyses.

At first time, chemical-physical analyses have been used to a preliminary choose between all the sampled waters. Later, some elements and compounds (Na, Ca, Mg, K, Cl, SO_4^{2-}, NO_3^-, total alkalinity, Li, Sr, B, F^-, SiO_2, CO_2, Sb, As, Se, Fe, Mn, Hg e Pb) have been analyzed ad used to classified the previously chosen samples. In particular, Lithium (according to [1]), Boron and Strotium shows that the main important host of the studied thermal water is the calcareous geological formation of "Calcare Cavernoso"; high values of Selenium, according to [2, 3], also shows the influence of volcanic fluids in the thermal anomalies of the Saturnia thermal area.

Finally, some isotopes have been analyzed (^{2}H; ^{3}H, ^{3}He,^{4}He, ^{13}C, ^{18}O, ^{86}Sr, ^{87}Sr) to obtain others important information. The isotopes in the water molecule show that the recharge area of the thermal aquifer is located some km towards north regarding to the Saturnia spring, and his residence time is greater than 30 years. The ^{87}Sr/^{86}Sr ratio, measured in the Saturnia thermal water, allowed distinguish the aquifer (according to [4]) from the other host of the near thermal aquifer of Mt. Amiata, sampled in Bagni San Filippo. The isolation from the surface infiltration during the underground flow of the thermal water of Saturnia has been checked by the values of δ^{13}C. And by the analysis of ^{3}He/^{4}He, sampled in a larger area, the influences of the mantle in the Saturnia thermal area has been excluded, in according to [5].

Probing the interactions between iron oxides and sediment organic matter using X-ray absorption spectroscopy

ANDREW BARBER[1]*, KARINE LALONDE[1] AND YVES GÉLINAS[1]

[1]GEOTOP and Concordia University, 7141 Sherbrooke West, Montreal, Quebec, H4B 1R6 (*correspondence andrew.jack.barber@gmail.com; k_lalonde@hotmail.com; yves.gelinas@concordia.ca)

Sediments and sedimentary rocks make up the largest sink for organic carbon one the planet while approximately 20% of the organic carbon found within marine sediments is bound to reducible iron oxide species [1]. Here we use Scanning Transmition X-ray Microscopy (STXM) as well as X-ray Absorption Near Edge Spectroscopy (XANES) in order to probe the local envrionment of iron oxide-bound organic matter within a variety of marine surface sediments and water column suspended particles. STXM data was collected on beamline 10ID-1 (SM) at the Canadian Light Source, where we analyzed regions with iron co-localized organic carbon, and then obtained spatially relevent NEXAFS images and spectra for these regions at both the carbon K-edge and iron $L_{2,3}$ edge. From these we are able to determine the speciation of both carbon and iron with a spatial resolution of 40 nm. We see important contributions from aromatic and carboxyl functionalities independent of the presence of iron but see an increase in the relative proporation of aliphatic functionalities in the presence of iron-organic mineral phases.

XANES spectra at the iron K-edge were collected at beamline X26a at the Brookhaven National Synchrotron Light Source and were used to probe the effect bound organic matter has on the X-ray absorption spectra of iron. A shift towards lower energies was seen at the iron edge for synthetic iron oxides precipitated in the presence of organic matter, demonstrating that we can distinguish between iron oxide-bound organic matter and pure iron oxide minerals. XANES spectra were also collected on a variety of surface sediment samples; using linear combination fitting and well-defined end-members, we were able to determine the proportion of sediment iron which is bound to organic matter based on the effect of organic matter on the synthetic iron co-precipitates.

The role of iron in the diagenesis of organic carbon and nitrogen in sediments: A long-term incubation experiment

ANDREW BARBER,[1] KARINE LALONDE,[1] ALFONSO MUCCI[2] AND YVES GELINAS[1]*

[1]Concordia University, Montreal, Quebec, Canada (*correspondence: Yves.Gelinas@concordia.ca)

[2] McGill University, Montreal, Quebec, Canada

The burial and preservation of organic matter (OM) in marine sediments is tightly coupled to the diagenetic cycles of iron and manganese. These strong iron-OC complexes, formed within the oxic layer of the sediment, are transferred to the deeper anoxic sediment layers through sedimentation, physical reworking and bioturbation; and are metastable over geological timescales [1]. Using a long-term (400-day) incubation, we examined the effect of iron on the early diagenetic transformations of OM in marine sediments. The fate of fresh, algal-derived DOM was monitored by tracking its stable carbon isotopic signature ($\delta^{13}C$). We demonstrate the incorporation of the ^{13}C-depleted tracer into the sediment through sorption (adsorption and co-precipitation with iron oxides). In the presence of iron oxides, we observed increased transfer of the dissolved algal material to the solid phase, revealing the role of iron in shuttling OM from sediment porewaters to sediment particles. Furthermore, we show that the presence of iron has a differential effect on OC and organic nitrogen (ON), with preferential preservation of OC and accelerated degradation of ON in the presence of reactive iron oxide surfaces. Hence, we propose that redox-sensitive metals may play a crucial role in regulating the global redox balance through increased carbon preservation as well as controlling the concentration of reactive nitrogen species in the open ocean.

U behaviour under acid mine drainage conditions: Preliminary results from an experimental approach in Río Tinto area (Spain)

L. BARBERO[1], M. KETTERER[2], M. BASKARAN[3], A. HIERRO[4], J.P. BOLÍVAR[4] AND M. CASAS-RUIZ[1]

[1]Universidad de Cádiz, Spain, (luis.barbero@uca.es)
[2]Northern Arizona University, USA
[3]Wayne State University, USA
[4]Universidad de Huelva, Spain

Preliminary results show that dissolved U and Th concentrations in water samples collected from río Tinto area is 2-3 orders of magnitude higher than that in the environmental base-levels in undisturbed areas with 234U/238U activity ratios (UAR) much higher than 1, thus indicating a strong disequilibria. Taking into account that under low pH conditions, congruent dissolution rates are high, this disequilibrium is surprising. Different waste pile rocks that include bedrock Fe oxi-hydroxides, gossans and country rocks have been used for conducting a set of leaching experiments. Results indicate that: 1) Distilled water leaching, although creating an acidic media very rapidly, do not generate leachates with UAR higher than 1.8 in most cases UAR being close to unity; 2) Leaching with different mixtures of acetic acid and ammonium oxalate lead to very high UAR ratios in leachates from Fe-bearing ochre bedrock sediments; 3) Sulphuric acid leaching experiments also generate leachates with high UAR ratios in Fe-rich materials, this not being dependent on acid concentration; and 4) Sulfuric acid leaching after annealing of Fe-oxi-hydroxides at 800ºC during several hours results in leachates with UAR close to unity. All these results indicate that not only the leachant but also the extent (?) of radiation damage in Fe-oxi-hydroxides play an important role in the origin of U isotope disequilibrium under acidic conditions.

Melting of an hybryd source below the Danakil Region

E. BARBIERI[1], A.CIPRIANI[1,2], D. BRUNELLI[1,3] AND E. PAGANELLI[1]

[1]Dipartimento di Scienze Chimiche e Geologiche, Universita` degli Studi di Modena e Reggio Emilia, 41100 Modena, Italy
[2]Lamont-Doherty Earth Observatory of Columbia University, 10964 Palisades , NY, USA
[3]Istituto di Scienze Marine, Geologia Marina, CNR, Via Gobetti 101, 40129 Bologna, Italy

The Danakil region is a modern example of rifting located atop a mantle plume. Along the rift system, a large number of shield volcanoes erupted large volumes of tholeiitic magmas with a wide compositional range, generally enriched in incompatible and trace elements, reflecting the source heterogeneity and the variability of melting processes that contributed to their generation. The Danakil lavas represent the combined product of continental rifting and ascending mantle plume processes.

Major and trace elements were analyzed in modern lavas sampled from the Erta Ale Chain and the Asal region and compared to literature data. Although highly enriched in trace elements, our lavas are significantly different when compared to the Oligocene main lava suites generated in the earliest stages of mantle plume activity. Based on La/Sm, Rb/Sr and Zr/Nb ratios and REE abundances they are intermediate between the high-Ti primitive lavas and the low-Ti tholeiitic basalts erupted 30 Ma ago due to the arrival of the plume-head. Trace elements abundances and geochemical modelling indicate that our lavas derive from a “hybrid” source characterized by a great complexity, possibly a metasomatized sublitospheric-mantle component that includes hydrous phases and melting at depths lower than those that generated the Oligocene lavas.

The wide compositional range of the Afar lavas suggests that those modern lavas erupted along the rift are not simply the product of melting of a deep mantle plume but derive from a composite source resulting from the interaction between the plume tail and the surrounding sublithospheric mantle previously metasomatized by the plume activity. As a consequence, this very complex and heterogeneous source undergoes extremely variable melting processes as testified by the characteristic chemistry of each volcanic complex.

Further geochemical and isotopic investigations will help to better constrain the signature and contribution of each of the reservoirs and to what extent the mantle is metasomatized by hydrous phases below the Afar region.

[3]SLAC , National Accelerator Laboratory, Linac Coherent Light Source, Menlo Park, CA 94025, USA

[4]Department of Earth and Environmental Sciences, University of Pennsylvania, Philadelphia, PA 19104, USA

The enigmatic fossil calcareous algae *Solenopora jurassica* is known for its distinctive pink and white banding. Though widely accepted as an algae, there has been some debate over its taxonomic affinity, as well as the derivation of its visible banding pattern which thougth to be seasonal. Despite these hypotheses little geochemical work has been carried out to test them. This study represents the first in depth geochemical analysis of this fossil in order to study its affinity and the possible seasonal origin of its banding pattern. Seasonal growth is shown by differences in calcite density, and increased Mg/Ca molar ratios and chlorine levels indicate higher temperatures during the time that white bands were deposited when compared to the pink bands. Pyrolysis gas chromatography mass spectrometry and infrared spectroscopy show the presence of tetramethyl pyrrole, protein moieties and carboxylic acid groups, indicative of the red algal pigment phycoerythrin. This supports the identification of *S. jurassica* as an algae, given that the pigment is only known to occur in cyanobacteria and algae. There is no evidence that the fossil is bacterial and no other taxonomically indicative biomarkers were identified.

Serpentinites as catalysts for vapor conversion of methane in the Earth crust

VICTOR BARELKO [1], OLEG SAFONOV [2], NATALIA BYKOVA [1], VICTOR DOROKHOV [1] AND LEONID BYKOV [1]

[1]Institute of Problems of Chemical Physics, Russian Academy of Science, Chernogolovka, Russia (barelko@icp.ac.ru)

[2]Institute of Experimental Mineralogy, Russian Academy of Science, Chernogolovka, Russia (oleg@iem.ac.ru)

Serpentinites of the oceanic lithosphere are an active source of reduced gases, such as H_2, CH_4, as well as an abiogenic source of complex hydrocarbons. Appearance of H_2 is related to the serpentinization of ultrabasic rocks of the oceanic floor. However, production of H_2 in the CH_4 and H_2O-bearing fluids is possible according to the catalytical reaction knows as «vapor conversion of methane», since serpentinite composition and structure can serve as close analogy of the artificial catalysts. We performed an experimental study of the reaction of the methane conversion by vapor using massive lizardite-antigorite serepentinite, which in addition to serpentine contains chromite, magnetite and few chlorite. The sample has not crushed to the fraction 0.5-0.71 mm before experiment. The volume ratio H_2O/CH_4 in the reaction zone was 8-10/1, filtration rate through the rock 1 cm-thick layer was 0.5-0.6 cm/s, while the time of the contact of the vapor-methane mixture with serpentinite was 1.5-2 s. During interaction with the vapor-methane mixture, serpentinite was partially dehydrated with presumable formation of olivine and silica-rich aqueous solution. Chromatography shows that the conversion of CH_4 to H_2 increases with temperature and reaches 14 % at 825^{O}C. The conversion of CH_4 to CO and CO_2 at 825^{O}C is 3 % for both components. Along with H_2, CO and CO_2 the reaction products include ethanol and methanol, which do not form on standard catalysts. The present experimental results support the conclusion on the high catalytical effectiveness of serpentinite: at short time of contacts of the vapor-methane flux with this rock resulted in relatively high degree of conversion. Experiments inspire testing of the catalytical properties of other crustal rocks.

Spatially resolved fully simultaneous determination of large numbers of isotope concentrations and isotope ratios by LA-MH-ICP-MS

D. ARDELT, W. BARGER*, M. REIJNEN AND O. PRIMM

SPECTRO Analytical Instruments GmbH, Boschstr. 10, 47533 Kleve, Germany
(*correspondence: willi.barger@ametek.com)

Laser Ablation-ICP-MS has developed into a powerful tool for the determination of elements, element ratios and isotope ratios in solid samples. The analysis of more and more elements with high spatial resolution and from ever smaller sample sizes is a challenge for this technology.

The development of a fully simultaneous ICP-MS brings several advantages for resolving this challenge: 'all' elements and isotopes can be determined in the same analytical run without sacrifying analysis time for any isotope. The simultaneous measurement also allows elimination of correlated noise, like flicker noise from the plasma or noise generated by the ablation process itself.

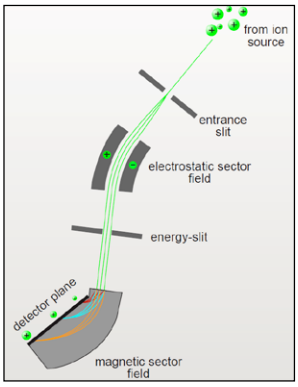

Figure 1: Mattauch-Herzog MS with Solid State Detector.

A double focussing sector field mass spectrometer in Mattauch-Herzog (MH) geometry (Figure 1) was combined with a 4800-channel, large CMOS based semiconductor direct ion detector, placed in the focal plane of the magnet. Each of the channels operates fully simultaneously, using two different amplifications, covering the mass range from ~5 to 240 amu.

The use of this new technology with laser ablation, for simultaneous chemical imaging of large numbers of isotopes, and analytical results for relevant samples, will be presented, with special emphasis on the expected advantages of the fully simultaneous detection.

Microstructures and compositions of melt inclusions from Jubrique (S Spain): Implications for anatexis

AMEL BARICH[1], ANTONIO ACOSTA-VIGIL[1], CARLOS J. GARRIDO[1], BERNARDO CESARE[2] AND OMAR BARTOLI[2]

[1]Instituto Andaluz de Ciencias de la Tierra, CSIC, Univ. Granada, Spain
(amelbarich@iact.ugr-csic.es)
[2]Dipartimento di Geoscienze, Univ. Padova, Italy
(bernardo.cesare@unipd.it)

Melt inclusions (MI) are small droplets of silicate liquid trapped by minerals growing either with or from the melt [1]. Most MI in anatectic terranes appear partially or totally crystallized due to slow cooling at depth, and have been named "nanogranites" [2]. MI represent a new and powerful method to study anatexis, because they can give information about melt compositions at the source region of crustal granites, including concentrations of H_2O [3].

There are very few studies of nanogranites, and only one has reported the presence of MI along a prograde metamorphic sequence from metatexites to diatexites [4]. We present a new occurrence of nanogranites along the prograde metamorphic sequence of Jubrique, located on top of the Ronda peridotites (S Spain). Jubrique represents a complete though strongly thinned (≤5 km) section of upper to middle-lower continental crust, ranging from carbonates and low-grade phyllites at the top to felsic Grt-bearing metatexites and granulites at the bottom and in contact with the peridotites.

MI show partially irregular to well facetted negative crystal shapes and occur in cores and rims of Grt porphyroblasts. They show a variable size, from ~5-10μm to several tens of μm in diameter; some of them reach up to ~200-300μm. Because of the large size, nanogranites at Jubrique have the potential to be remelted and analyzed by EMP but also by LA-ICP-MS. Nanogranites are composed of rare glass, daughter phases Qtz, Pl, Kfs, Bt and Ms, and solid inclusions of Ky and less frequently Gr, Hc, Rt, Ilm, Zrn, and Mnz. Ky was the main solid phase that favored the trapping of MI by poisoning crystal surfaces during Grt growth.

Previous studies concluded that anatexis in the granulites occurred in the Sil field during decompression and thining. The presence of Ky+Rt within MI, and their occurrence in the high-P cores of Grt, indicate that partial melting in granulites and migmatites initiated at high P conditions, and that most Grt in these rocks crystallized in the presence of melt.

Study of Zsolnay building ceramics in aspect of deterioration by environmental factors

ÁGNES BARICZA[1]*, BERNADETT BAJNÓCZI[2], MÁRIA TÓTH[2] AND CSABA SZABÓ[1]

[1]Lithosphere Fluid Research Lab, Institute of Geography and Earth Sciences, Eötvös University, H-1117, Budapest Pázmány Péter sétány 1/c, Hungary

[2]Institute for Geological and Geochemical Research, Research Centre for Astronomy and Earth Sciences, Hungarian Academy of Science, H-1112 Budapest, Budaörsi u. 45, Hungary

(*correspondance: baricza.agnes@gmail.com)

The Zsolnay products are the one of the most famous Hungarian ceramics. The glazed building ceramics produced by the Zsolnay Factory were often applied to decorate the buildings, mainly around the turn of the 19th-20th century and since their outplacements the ceramics have suffered numerous environmental and human influences. Our purpose is to observe the alterations by environmental factors considering that these ceramics have never been studied in this aspect before. The studied objects were used on two buildings in Budapest. We have examined the major characteristics of the glaze and the ceramic body on two buildings in Budapest, the depositions on the surface of the glazed and the unglazed sides of some selected ceramics. Several types of Zsolnay ceramics were used as building materials on these buildings. We distinguished different kinds of damage, black deposition layer and alterations. Natural and artificial particles (e.g. carbonaceous and Fe-rich), spherules and a characteristic gypsum layer frequently cover the studied objects. Traces of biological activity (hyphaes) were also found and connected to these organic residues calcium-oxalate (weddellite) was identified. On some samples the glaze has started to weather and the lead leached from the thin surface layer of glaze by rainfall and, if this phenomenon continues for a long period, it will result in the deterioration of the whole glaze.

Trends in urban biogeochemistry at the Anthropocene

S. BARLES*

Université Paris 1 Panthéon-Sorbonne, 191 rue Saint-Jacques, 75005, Paris, France

(*correspondence: sabine.barles@univ-paris1.fr)

As socio-natural sites [1], cities *create* a specific biogeochemistry [2], mainly because they attract huge amounts of materials concentrated in very small areas. This *urban metabolism* is the result of two intertwinned phenomema: the natural processes on one hand, the technical ones on the other. Its study calls for an interdisciplinary approach as illustrated in [3]. In order to better characterise urban metabolism, we chose Paris urban area as a case study. By crossing historical methods and material/substance flow analysis, we were able to describe long term trends and changes. These results, together with other ones for other cities, allow to give a general insight into urban key issues in terms of biogeochemistry.

The very characteristic of cities is the externalisation of a great (and up to now growing) part of their metabolism. Cities were borne from a specialisation that made possible for some people to not produce their food and then to develop other activities in specific places – cities. This externalisation peacks with industrial revolution(s) with, for instance the partial externalisation of water cycle, the one of urban by-products transformation, etc. The shift of cities from sink (up to the end of the 19th century) to source of emission to air and water for substances like N or P is another characteristic of cities metabolism. This is due to changes in waste management and to the devalorisation of urban fertilisers (especially human manure) that occurred at the beginning of the 20th century together with the increase in fossil fuel consumption (for N).

As a result, urban metabolism goes far beyond the urban limits and cities can be considered as one of the main drivers of biogeochemical cycles, considering both their direct and indirect impacts on them. Today, one of the great challenges faced by urban managers and biogeochemists is the improvement of urban metabolism (its *re-internalisation*?), its transformation from a constraint to an asset – for the provision of nutrients, the reduction of urban heat island, etc.

Investigating instrumental mass bias in MC-ICP-MS using isotope ratio plasma profiles

J. BARLING[1], N. S. BELSHAW[1] AND A. N. HALLIDAY[1]

[1] Department of Earth Sciences, University of Oxford, South Parks Road, OX1 3AN, UK (jiey@earth.ox.ac.uk)

In multi-collector inductively-coupled-plasma mass spectrometry (MC-ICP-MS) heavy/light isotope ratios are fractionated to high values relative to the true value. Accurate and precise correction of this instrumental mass bias is a prerequisite for accurate MC-ICP-MS isotope ratio data. However, understanding of this phenomenon is limited.

As a step towards gaining insight into the processes involved in generating instrumental mass bias we have measured the variation of heavy/light isotope ratios as sampling depth in the plasma is varied. These axial plasma profiles were measured at ~250μm intervals over a sampling depth of ~3.5 mm. Each experiment consisted of 6 profiles sampled over the same sampling depth range but tuned at different sampling depths.

Pb and Mg were chosen as the analytes. These elements though very different in mass have similar first and second ionisation potentials, therefore any differences in heavy/light isotope ratios variation with sampling depth should be mass dependent. All profiles were curvilinear. For Pb the heavy/light isotope ratio ($^{208}Pb/^{206}Pb$) increased with decreasing sampling depth, whereas for Mg ($^{26}Mg/^{24}Mg$) it decreased. $^{208}Pb/^{206}Pb$ values on individual profiles varied by 0.56 – 0.70% of the average value measured on the profile and the magnitude of variation increased as the tuned sampling depth decreased. Variation in $^{26}Mg/^{24}Mg$ was much greater, 1.1 – 1.3% of the average value measured on each profile and increased dramatically to 7.1% for the profile tuned at the shallowest sampling depth. If only ratios measured at the tuned sampling depth on each profile are considered, the trends are reversed e.g. $^{208}Pb/^{206}Pb$ generally decreases with decreasing sampling depth.

These apparent variations in instrumental mass bias with sampling depth in the plasma result from a combination of processes occurring during transport of the analyte through the plasma (e.g. radial mass dependent dispersion of ions and attoms and ionisation potential effects) and additional mass dependent effects produced during sampling and transport through the interface. The contrast in apparent mass bias response between Mg and Pb allows us to speculate on the relative significance of plasma versus interface processes in producing the instrumental mass bias.

Subduction channel or fossil rifted margin? Serpentinite geochemistry of the Punta Rosa Unit, Western Alps

JAIME D. BARNES[1], MARCO BELTRANDO[2], CIN-TY A. LEE[3], STACI LOEWY[1] AND EMILY CHIN[3]

[1]Department of Geological Sciences, University of Texas, Austin, Texas, USA 78712, (jdbarnes@jsg.utexas.edu)
[2]Dipartimento di Scienze della Terra, Università di Torino, Via Valperga Caluso 35, 10125 Torino, Italy
[3]Department of Earth Science, MS-126, Rice University, Houston, Texas 77005, USA

The Punta Rosa unit (PR), now stacked in the Valaisan domain (Western Alps) preserves evidence of Mesozoic mantle exhumation at the seafloor, despite having undergone pervasive Alpine deformation/metamorphism. Serpentinites are overlain by slivers of continental basement or meta-sedimentary breccia and have been interpreted as an ocean-continent transition (OCT) based on structural data [1]. However, similar lithological associations throughout Alpine-type orogens are often interpreted as subduction-related "tectonic mélanges" [e.g., 2]. Here we present the first geochemical study of PR serpentinites to further test the interpretation of their tectonic setting.

Stable isotope and major and trace element compositions of PR serpentinites with varying distances from the contact with meta-sedimentary material were determined. $\delta^{37}Cl$, $\delta^{18}O$, and δD values range from +1.1 to +2.7‰, +7.0 to +8.5‰, and -50 to -73‰, respectively. $\delta^{37}Cl$ values are some of the highest reported for serpentinites and increase towards the contact with the metasediments, indicating interaction with metasediments/altered oceanic crust during Alpine subduction/exhumation. O and H isotope data are consistent with low-T interaction with seawater (with partial resetting of H by meteoric fluids) or slab-derived fluids. Bulk serpentinite samples have high REE concentrations, compared to typical mid-ocean ridge serpentinites, with nearly flat to slightly convex up REE patterns (La_N/Sm_N = 0.38 – 0.62; La_N/Yb_N = 0.20 – 0.47; Sm_N/Yb_N = 0.41 – 0.89). These high REE concentrations are similar to those observed in OCTs (Iberia Abyssal Plain; Newfoundland) [3] and the Malenco and Platta peridotites (Switzerland), which are the type localities for preserved OCTs [4]. Serpentinite geochemistry supports stratigraphic and structural evidence for an abyssal origin of the PR serpentinites, providing a powerful tool to determine tectonic setting in poorly exposed/highly deformed metamorphic units.

Archean andesites as products of plume/crust interaction?

STEPHEN J. BARNES[1], CARISSA ISAAC[2] AND MARCO L. FIORENTINI[2]

[1]CSIRO, Perth, Western Australia, (steve.barnes@csiro.au)
[2]University of Western Australia, Perth, WA, (20685898@student.uwa.edu.au)

A key line of evidence for Archean plate tectonics rests on the presence of andesites, the signature rock type of modern subduction zones. This study considers the petrogenesis of andesites from the 2.7 Ga East Yilgarn Craton (EYC) in Western Australia, a richly mineral-endowed terrane that has been a prime focus of debate between proponents of a uniformitarian, plate-tectonic driven interpretation, and advocates of an alternative plume-driven model. While EYC andesites have incompatible trace element characteristics similar to those of modern island arc andesites, they have unusually high Ni, Cr and MgO contents. This suggests the possibility that they contain a substantial mantle plume component. To test this hypothesis, we consider the major and trace element compositions of these rocks in relation to the entire assemblage of EYC volcanic rocks with ages between 2690 and 2710 Ma, including komatiites, plume-derived basalts and dominantly dacitic felsic rocks. The dacite component occurs as part of a bimodal association with simultaneously erupted komatiites, has characteristic TTG-like trace element chemistry, and chondritic to slightly depleted Nd and Hf isotopic characteritics. This component is interpreted as the partial melting product of underplated juvenile or near-juvenile mantle-derived mafic material. Numerical modelling of fractionation of plume-related tholeiitic basalts coupled with contamination by the TTG-like dacite component provides a good fit to all of the essential major and trace element characteristics of the EYC andesites, and is also consistent with the chondritic to slightly depleted Nd and Hf isotopic characteristics of the andesites[1]. Thus, a rock type previously taken as a key line of evidence for plate tectonic processes can be explained just as well by an alternative plume-driven mechanism, consistent with the overwhelmingly plume-derived character of basalts and komatiites across the entire craton[2]. This explains a paradox, noted in a number of Archean volcanic rock sequences, that apparently subduction-related rocks are interleaved with voluminous basaltic magmatism derived from 1000 km-scale plume-head arrival events. The problem is moot if Archean andesites are products of plume, not subduction zone, magmatism.

Isotopic tracing of ancient metal production using geological and mining archaeological research – Gaul mining from Limousin and Morvan (France). A case study

S. BARON*[1], B. CAUUET[1] AND C.G. TAMAS[2]

[1]TRACES-CNRS, 5, allées A. Machado, 31058 Toulouse Cedex 09, France. (*correspondence: sbaron@univ-tlse2.fr)
[2]University Babes-Bolyai, 1, M. Kogalniceanu str., 400084 Cluj-Napoca, Romania

The isotopic tracing from mines/ore bodies to archaeological materials (slags, metals, objects) constitutes a powerful tool in metal provenance studies. The progress of high resolution mass spectrometers (MC-ICP-MS) during the last decade currently facilitates accurate analyses of traditional and non-traditional isotopes, allowing thus precise and consequently more accurate interpretation [1]. Nevertheless, these high precision isotope analyses on ores are often carried out in an elusive way ignoring the geological approach as well as the mining archaeology background. The currently used lead isotope ores database is not completly relevant for the tracing of the ancient metals for several reasons: i) the isotopic composition of the analysed ores is usually not linked with their mineral paragenesis, and ii) the analysed ores are not those really exploited by the ancient miners. Futhermore, the ancient *chaîne opératoire* from ores to metal(s)/objects is not systematically considered [2].

Through an example of metal production in Gaul (France) during Protohistoric times, we demonstrate the importance of establishing a geochemical tracing based on geological and chronological/archaeological samples.

Our aim is to characterize the mining activity and the metal production at regional scale (Limousin and Morvan) and in a second stage to acquire the isotopic and trace element signature of the exploited ores and the produced metals (Au, Ag and Sn). This approach based on geological, mining archaeological and geochemical studies will refine the tracing of the metals at least for Limousin (5^{th} to 1^{st} centuries BC) and Morvan (2^{nd} to 1^{st} centuries BC) and will allow to obtain isotopic data bases needed for relevant metal provenance studies.

Acknowledgments: Research carried out in the frame of ANR MINEMET project (France).

Silica and germanium cycling in a coastal shelf environment: Insights from northern Gulf of Mexico

JOTAUTAS J. BARONAS[1]*, DOUGLAS E. HAMMOND[2], WILLIAM M. BERELSON[3], JAMES MCMANUS[4] AND SILKE SEVERMANN[5]

[1]Department of Earth Sciences, Univeristy of Southern California, 3651 Trousdale Pkwy, Los Angeles, CA 90089, USA (correpondence: baronas@usc.edu)

[2]College of Earth, Ocean, and Atmospheric Sciences, Oregon State University, 104 CEOAS Admin Bldg, Corvallis, OR 97331-5503, USA

[3]Institute of Marine & Coastal Science, Rutgers University, 71 Dudley Road, New Brunswick, NJ 08901-8521, USA

The Ge/Si ratio recorded in sedimentary opal covaries with glacial-interglacial cycles as far back as the Mid-Miocene [1], demonstrating its potential as a proxy for Si cycling. However, there are multiple mechanisms potentially influencing the Ge/Si recorded. These include the intensity of terrestrial rock weathering, variations in the size of the diagenetic Ge sink, and biological fractionation by marine silicifiers.

We have measured Ge and Si concentrations in the water column and sediment pore waters in the Gulf of Mexico (GOM). Results indicate extensive fractionation, enriching the shelf surface water Ge/Si to 2.3 (all Ge/Si ratios are in μmol/mol), significantly higher than the main Si source - the Mississippi River (Ge/Si = 1.5). Preliminary box model calculations predict a fractionation factor of $R_{biogenic\ silica}/R_{water}$ = 0.5-0.6, where R is Ge/Si ratio. GOM deep water (500-2100 m Ge/Si = 0.82-0.86) is also enriched relative to the published global ocean values (Ge/Si = 0.70-0.76). Porewater observations in coastal sediments (Ge/Si = 0.3-0.7) and modelling suggest that 10-30% of Ge is diagenetically sequestered into an unidentified (possibly iron-rich) authigenic precipitate.

Ferrian chromite formation in podiform chromitites from south-central Chile

F. BARRA[1,2]*, F. GERVILLA[3] AND M. REICH[1,2]

[1]Dept. of Geology, University of Chile, Santiago, Chile (*correspondence: fbarrapantoja@ing.uchile.cl)

[2]Andean Geothermal Center of Excellence (CEGA), University of Chile, Santiago, Chile

[3]Dept.of Mineralogy and Petrology, University of Granada, Granada, Spain

The metamorphic basement of the Coastal Cordillera in south-central Chile comprises two units with constrasting characteristics. The Eastern series is characterized by high T/low P conditions, whereas the Western Series represent high P/low T metamorphic conditions [1]. These units have been interpreted as an accrecionary prism, where the Eastern series formed by frontal accretion and the Western series was produced by basal accretion [2]. The Western series comprises mainly metapsammopelitic rocks, metabasites and minor serpentinized ultramafic rocks. The serpentinite bodies are scattered within the Western series and show variable degrees of serpentinization. Although most of these serpentinites have accesory chromian spinels, only in one locality podiform chromitites have been found. Here we present the chemical composition of these chromitites determined using electron microprobe analysis (EMPA) in order to provide some insights on the formation of ferritchromite as an alteration product of chromite.

Chromitites are highly brecciated with a matrix completely altered to Cr-rich chlorite. Chromite spinel grain cores are high-Al in content, whereas ferrian chromite (i.e., ferritchromite) is Fe^{+3} rich and usually formed along cracks and margins. The observed pattern of alteration is similar to that described for other locations [3] with volume reduction associated with dissolution of chromite and formation of porous chromite. Unaltered chromite cores show Cr# [Cr/(Cr + Al) atomic ratio] = 0.65–0.70, Mg# [Mg/(Mg + Fe^{+2}) atomic ratio] = 0.50–0.70, and $Fe^{+3}/(Fe^{+3} + Fe^{+2})$ <0.15. The chemical composition of chromites evolved towards higher #Cr (0.75-0.95), lower #Mg (0.40-0.10), and higher #Fe (0.20-0.40). The observed trend is consistent with a reaction of chromite with olivine to produce chlorite. The alteration process is concomitant with mass loss and development of a porous texture in chromite.

Reconstructing past hydrology from annual cycles in trace elements in a Moroccan Stalagmite

J.J. BARROTT*, C.C. DAY AND G.M. HENDERSON

Department of Earth Sciences, University of Oxford, UK
(*correspondance: julia.barrott@earth.ox.ac.uk)

We present annually resolved trace element and stable isotope data from a laminated Mid-Holocene north Moroccan stalagmite. All reported analyses were performed on the same 200-µm micro-milled calcite samples, yielding an entirely inter-comparable dataset. In addition to $\delta^{18}O$, $\delta^{13}C$, Mg, Sr, Ba, U and P, we present the first measurements of Cd in speleothem carbonate. Recent cave-analogue experiments [1] demonstrate that Cd/Ca is highly sensitive to variation in the amount of calcite precipitated from solution, with high Cd/Ca particularly indicative of low degrees of prior calcite precipitation. We employ a multi-proxy approach, using Cd alongside other trace elements and stable isotopes to reconstruct changes in hydrology at this site.

With the exception of $\delta^{18}O$, highly distinct annual cycles occur in all reported proxies and correspond closely to changes in laminae colour. The observed annual cycle in Cd/Ca implies that % calcite precipitated is a major driver of annual trace element cycles in this sample. The agreement between the trace elements, laminae colour and $\delta^{13}C$ agrees well with that expected in calcite precipitated in a site where rainfall is highly seasonal. Weaker correlations with $\delta^{18}O$ reflect the more integrated nature of the information recorded by oxygen isotopes, indicating that some regional signal is being captured.

Despite differences in seasonal cave ventilation these observations show remarkable agreement with annual trace element cycles from a modern speleothem at St Michael's Cave, Gibraltar [2], which lies 27 km northwest of our site. Such a parallel between sites gives confidence that trace element geochemistry can potentially be used for robust regional palaeoclimate reconstruction, and perhaps also for the careful extrapolation of monitoring studies between sites.

Ancient recycled nitrogen isotope signatures in Siberian xenoliths

P. H. BARRY[1]*, D. R. HILTON[2] AND L.A. TAYLOR[1]

[1]Planetary Geosciences Institute, Dept. of Earth and Planetary Sciences, University of Tennessee, Knoxville, TN 37996 (*Correspondence: peter.barry@utk.edu)
[2]Scripps Institution of Oceanography, La Jolla, CA 92093

Siberian xenoliths display compelling evidence for a recycled crustal origin. In order to assess if nitrogen is also recycled in ancient subducted-oceanic crust we have measured N-isotopes ($\delta^{15}N$) and elemental (N_2/Ar) ratios for a suite of peridotitic and eclogitic xenoliths (n=10) from two petrologically-distinct kimberlite pipes (i.e., Udachnaya and Obnazhennaya). Additionally, all samples have been well-characterized, mineralogically, petrographically, and for major and trace element chemistry.

Crustally-derived xenoliths (Gt, Cpx and Ol) of Siberia are believed to originally be derived from subducted oceanic crust which has since amalgamated to form the Siberian craton. The occurrence of non-mantle-like oxygen isotope signatures in Siberian xenoliths suggests that these lithologies are artifacts of partially-melted subducted ocean crust [1, 2]. Subsequently, this material was transported to Earth's surface via kimberlitic volcanism. The age of Siberian xenoliths have been constrained to be within 2.7 - 3.1 Ga using Re-Os and Sm-Nd isotope dating techniques [3]. $Mg\#_{Gt}$ ranges from 86 - 96, suggesting relatively primitive magmas. Major and trace element chemistry indicates that these samples have been subjected to varying degrees of metasomatism. Due to the antiquity of these particular xenoliths, they represent prime targets for N-isotopes, which have been previously suggested to show a secular variation throughout Earth history [4].

N-isotopes ($\delta^{15}N$) of Siberian xenoliths range from -0.7 to -10.8 ‰ and are consistent with both upper mantle (MORB = -5 ± 2 ‰) and recycled contributions (modern sediments = +6 ± 2 ‰). N_2/Ar values range from 32 to 178, spanning both atmospheric (84) and typical mantle values (84-164). Cpx mineral separates retained the most nitrogen gas. Notably, all Obnazhennaya samples display N-isotope values above the MORB range, indicating a larger contribution from a recycled component vs. Udachnaya samples, which span the MORB range. These results suggest xenoliths of different kimberlite pipes sample isotopically-distinct parts of the mantle, and may preserve varying mantle/crustal contributions throughout Earth history.

Tracking Indian-type mantle at its western limit during the closure of Neo-Tethys and opening of the Indian Ocean

T.L. BARRY[1]*, J.H. DAVIES[2] AND I.L. MILLAR[3]

[1]Dept. of Geology, University of Leicester, Leicester, UK (correspondence: tlb2@le.ac.uk)
[2]School of Earth & Ocean Sci., Cardiff University, Cardiff, UK (daviesjh2@cf.ac.uk)
[3]NERC Isotope Geosciences Lab., Keyworth, Notts, UK. (i.l.millar@bgs.ac.uk)

Since the work of Mahoney *et al*. [1] on old west Indian Ocean and east Tethyan MORBs, we have known that Indian-type (DUPAL) mantle resided beneath at least parts of Neo-Tethys at the time of opening of the Indian Ocean. Furthermore, work on a ~350 Ma ophiolite from China [2] demonstrates that Indian-type mantle must have contributed, in some places, to MORB genesis during the formation of Paleo-Tethys. Together, this evidence suggests that Indian-type mantle has at least to some extent remained within the shallowmost asthenosphere during multiple Wilson cycles, over 100's millions of years.

In the western Pacific the margins of the Indian-type mantle have been recognised and, in places, mapped adjacent to Pacific-type mantle [e.g. 3-5]. Detailed work along this boundary has shown that very little mixing has taken place, but what happened to the Indian-type mantle at its western limit during the diachronous closure of Neo-Tethys?

Using robust Hf-Nd isotopes on an extensive suite of MORB rocks from Neo-Tethyan ophiolites, extending from the Himalayas, through the Mediterranean and Europe, to earliest central Atlantic and proto Caribbean ocean crust, we assess where Indian-type mantle occurred beneath Neo-Tethys. Inferences from these results are then linked to 3D numerical spherical geodynamic models (run using mantle circulation code TERRA) and used to investigate models of how this isotopically distinct Indian-type mantle may have been preserved in the upper mantle during successive events of ocean closure and re-opening, with little apparent tendency to mix laterally.

[4] Dipartimento di Scienze della Terra, Univ. Milano, Italy; email: stefano.poli@unimi.it

Formation, extraction and ascent of hydrous anatectic melts to upper crustal levels represent the most important mechanisms for the reworking of the Earth's continental crust [1, 2]. In this scenario, the water content of melts is of prime importance in the formation and evolution of the continental crustal and so far the experimental approach has been largely applied for obtaining constraints on the water content of anatectic melts.

The study of melt inclusions hosted in peritectic phases of partially melted rocks represents a recent, small-scale powerful approach to a better understanding of melting in the continental crust [e.g. 3-5]. Successful experimental rehomogenization of the inclusions to a glass allows the direct analysis of the natural anantectic melts produced in the source region of crustal magmas [5]. This approach provides the precise melt composition for the specific anatectic rock under study.

We report the results of NanoSIMS analyses on melt inclusions hosted in peritectic garnet of partially melted metasedimentary rocks. Data are discussed in order to i) combine information from classical petrology and melt inclusions, ii) compare them with previous estimations from experiments and thermodynamic calculations and iii) deal with new questions, such as the water content heterogeneities of natural anatectic melts in the source region.

[5]University Aix-Marseille, France: nicolas.roche@univ-amu.fr

Widespread use of Engineered Nanomaterials (ENMs) in a myriad of consumer products and technologies has lead to release of ENMs to the environment. A likely first route of environmental exposure of ENMs is thrugh the waste stream. Within wastewater treatment plants (WWTPs) ENMs undergo transport and transformation processes different from traditional organic contaminants. Understanding ENM-specific fate and transport is thus a critical void in current nanomaterial research.

In this study, we tracked the mobility and transformations of a common ENM, CeO_2 to determine releastic concentrations and the nature of the ENMs released from WWTPs in solid and effluent. An aerobic bioreactor seeded with sampled activated sludge was dosed with pristine and citrate coated CeO_2 chronically at enviornmentally relevant concentrations for a six week period. Two samples of CeO_2 were employed to observe the impact of surface chemistry on fate. During the lifetime of the reactor, affinity of the ENM for the solid versus liquid phase was measured and it was observed that > 90% of the added CeO_2 associated with the solid phase regardless of the surface coating. In addition, Ce speciation was monitored with XANES to explore the CeO_2 transformations. It was found that after 5 weeks in the reactor environment, strong reduction of the Ce(IV) in the ENM to Ce(III) occurred. Reduced Ce(III) was only measured in association with the solid phase indicating the key role of the microbial communities in promoting this reduction. In addition, it was seen that the citrate coating altered the kinetics of this reduction by preventing it until consumption of the coating by the bacteria. Determination of the interaction with the biomass and nature of the Ce(III) complexes is ongoing. Studies such as these can help inform the modeling community attempting to predict exposure and risk of ENMs released to the enviornment.

New interpretation of kinematics and morphogenesis of block structures of the Black Sea-central transcaucasian terrane

LEVAN BASHELEISHVILI

[1]Javakhishvili Tbilisi State University A.Djanelidze geology institute, Georgia, levanbash@yahoo.com

Modern structure of the Black Sea-Central Transcaucasian Terrane is mainly conditioned both by meridional and latitudinal fault systems. They encompass different depth of the Earth's crust crystalline basement. They as a whole make a mosaic-block pattern. The analysis of lithofacies and thicknesses of sedimentary cover sometimes establishes their autonomous and inverse nature of development as well as differentiated kinematics. The research data enables to make the following conclusions: The Caucasian molasse depression (within the territory of Georgia) is divided into eastern and western subsiding zones by the Dzirula (crystalline basement) salient; they are also divided by faults into separate restricted blocks. Westwards and eastwards of the central uplift zone, along the faults is outlined a gradual "stepwise" submergence and tilting of blocks of the crystalline substrate. In the modern literature the analogous structures are known as the so called "tilt" blocks and kinematically they are related to tensile strains.

Thus, in contemporary structure of the pre-Alpine crystalline basement of the South Caucasian molassics depression (along the latitudinal profile) is marked the existence of tension structure mainly in condition of stepped-inclined blocks, which subsequently turn into the so-called listric faults. The appearance of this one is bound up, on the one hand, with uplift of the mantle masses in some parts of the region and on the other hand, with advance of the Arabian plate to the north and connected with them lateral squeezing out of masses both to the west and the east especially at the late-orogenic (collision) stage of development.

Effects of heating on the leaching of U-Th series radionuclides in a suite of natural minerals

BASKARAN, M[1] AND GARVER, E[1]

[1]Department of Geology, Wayne State University, Detroit, MI-48202, USA; Baskaran@wayne.edu

The differences in the extent of leaching (with 0.1 N HNO_3 for ~25 days) and recoil of U-Th series radionuclides [U (^{234}U), Th (^{230,234}Th), Ra (^{224,226,228}Ra), Pb (^{210,212}Pb), ^{210}Po, ^{228}Ac and ^{222}Rn] from a suite of natural minerals (zircon, monazite, thorite and cerite) were assessed at room temperature and after heating these minerals at 200°C and 600°C. Our results indicate the following: i) The concentrations of U-Th series radionuclides in the leachate depend on the amount of the accumulated radiation dose in the minerals; ii) The amount of radionuclides leached from annealed (200°C or 600°C) minerals is lower by 3 orders of magnitude compared to unannealed minerals; and iii) The differences in the daughter/parent ratios of a number of pairs in the ^{238}U and ^{232}Th series (^{210}Po/^{210}Pb, ^{228}Ac/^{228}Ra, ^{234}Th/^{238}U, ^{212}Pb/^{224}Ra, ^{224}Ra/^{228}Th and ^{222}Rn/^{226}Ra) between the heated and heated minerals range over several orders of magnitude.

This study provides insight on the location of ^{238}U and ^{232}Th and possibly their daughter products in mineral grains (in paritcular, if they are located in grain boundaries), the effects of track density on the leaching of U-Th series radionuclides from mineral grains, the effects of the internal radiation damage on the escape of radon and the leaching of other non-gaseous daughter products in the U-Th series. This study has implications on the assessment of the performance of nuclear wasteforms in groundwater environment. This study has also bearing on the mobility of U-Th series radionuclides in rocks/minerals that are in contact with erupting magma.

We will present possible mechanisms for the differences in the extent of leaching of radionuclides between the heated and unheated minerals in our presentation.

Internal Lu-Hf isotope systematics of the quenched angrite D'Orbigny and two plutonic angrites

R. BAST[1]*, E. E. SCHERER[1], K. MEZGER[2], M. FISCHER-GÖDDE[3] AND P. SPRUNG[3]

[1]Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, D-48149 Münster, Germany (*correspondence: Rebecca.Bast@uni-muenster.de)
[2]Institut für Geologie, Universität Bern, CH-3012, Switzerland
[3]Institut für Planetologie, Westfälische Wilhelms-Universität Münster, D-48149 Münster, Germany

The long-lived radioactive decay of ^{176}Lu to ^{176}Hf potentially provides a precise and disturbance-resistant chronometer for dating early Solar System processes. However, some meteorites (e.g., the quenched angrite Sah 99555 [1]) show excess ^{176}Hf [1-3], resulting in Lu-Hf dates significantly older than the Solar System. One possible explanation for this is that irradiation in the early Solar System produced the short-lived isomer ^{176m}Lu ($t_{1/2}$ = 3.7 hr) and thus accelerated the ^{176}Lu-decay [4-5].

In contrast to the results of Sanborn *et al*. [6], we found excess ^{176}Hf in the quenched angrite D'Orbigny and the plutonic angrite NWA 4801. Our internal Lu-Hf isochrons yield dates of 4760 ±64 Ma for D'Orbigny (8 fractions) and 4635 ±19 Ma for NWA 4801 (10 fractions). The initial ^{176}Hf/^{177}Hf values are 0.279736 (37) and 0.279788 (89), respectively, which are in the same range as the CHUR values of [7-8] back-calculated to 4567 Ma, and 3-6 ε-units higher than the initial Hf isotope composition of the Solar System suggested by Bizzarro *et al*. [1].

Our new data do not preclude irradiation on the angrite parent body as a possible cause for the old apparent ages. However, not all Lu-Hf dates are too old: our 8-point Lu-Hf isochron for the plutonic angrite NWA 4590 yields 4580 ±46 Ma, which is in agreement with the Pb-Pb age reported by [9-10]. Its initial ^{176}Hf/^{177}Hf value of 0.279794 (16) agrees with the CHUR values of [7-8] back-calculated to 4567 Ma.

Zeolites and mafic phyllosilicates in Livingston Island, Antarctica

J. BASTIAS[1], F. FUENTES[2], L. AGUIRRE[1], F. HERVÉ [1,2], F. FERNANDOY[2] AND A. DEMANT[3]

[1]Departamento de Geología, Universidad de Chile, Plaza Ercilla 803 8370450, Chile (joaquinbastias@ug.uchile.cl)
[2]Escuela de Ciencias de la Tierra, Facultad de Ingenieria, Universidad Andres Bello, Abate Molina 140 8370116, Chile (ffuentes@unab.cl)
[3]Laboratoire de Pétrologie Magmatique, Université Aix Marseille III, 13397 Marseille Cedex 20, France

The present work is a report on the geochemistry and petrology of the very low-grade alteration minerals developed in the volcanic successions from Punta Hannah (PH) and Shirreff Cape (SC), Livingston Island, Antarctica.

The outcrops consist of andesitic-basaltic rocks from volcanic successions assigned to the Upper Cretaceous [1]. These rocks are one of the most extensive volcanic exposures in the South Shetland Islands.

The alteration minerals occur in amygdules, veins, veinlets, groundmass, or patches. This replacement of the phenocrysts can be partial, affecting the crystal edges and fractures or total. Primary plagliocases have been strongly altered to albite, zeolites and calcite, and clinopyroxenes to mafic phyllosilicates and celadonite.

Petrographic, XRD and EMP analyses show the occurrence of the zeolites: laumontite, stilbite, faujasite and heulandite in PH, and natrolite and analcime in SC. Mafic phyllosilicates correspond to interstratifications between chlorite and trioctahedral smectite. Chlorite layer percentages range between 57% and 84%, and display diabantite compositions [2]. Equilibrium temperatures of mafic phyllosilicates from PH, calculated using two geothermometers [3, 4], range between 160 and 190°C for those with chlorite layer percentages above 75%. This range is in agreement with temperature estimates for zeolites of 150-230°C. Zeolites from SC suggest temperatures below 150°C.

The characteristics of these rock successions indicate a Ca-Na remobilization in the light of albitization and the widespread occurrence of Ca-rich zeolites. Hydrothermalism and burial processes would account for the genesis of the secondary minerals.

Project Anillo CONICYT ACT 105 financed the research.

FreeGs thermodynamic database project: implementation, lessons, and future?

E. N. BASTRAKOV[1]*, L. A. I. WYBORN[1], T.P. MERNAGH[1] AND A. CHALNEV[2]

[1]Geoscience Australia, Canberra, ACT 2601, Australia (*correspondence: Evgeniy.Bastrakov@ga.gov.au)
[2]DIISR, Canberra, ACT 2601, Australia

Increasing demand in reactive-transport modelling for the purposes of CO_2 sequestration, use of geothermal energy, and nuclear waste disposal requires ready access to standardised thermodynamic data. These must be adopted for multiple formats for ever increasing number of modelling applications.

FreeGs [1, 2] is a web-enabled database developed at Geoscience Australia by the Predictive mineral discovery Cooperative Research Centre (2001-2007). It was intended as a unified Australian hub of thermodynamic data for geochemical modelling for economic geologists. The database was complemented by integrated software to calculate thermodynamic properties of species and chemical reactions at elevated temperatures and pressures. The end users had put a critical emphasis on the following decisive features:

- High end-user usability in an interactive mode
- Transparency of the compiled data
- Extendibility (data formats & incorporated models)
- Options for remote access and maintenance

In the interactive mode, FreeGs readily facilitates (1) comparison of TD data compiled from different sources, (2) their model presentation via alternative algorithms (equations of state), and, (3) output of data in alternative formats (e.g., $\Delta g(T,P)$ *vs* log $Kr(T,P)$).

Despite these features and a friendly web GUI, practical usage of the database system by the scientific community was rather limited. As we see it, the development of a human interface and integration with calculation algorithms were over-emphasised at the expense of the implementation of the data delivery web service. That hindered efficient access to data by external parties and created avoidable development and maintenance overheads.

The future of a similar database will lie in the realm of a database located on a cloud server with (1) HTML access ("find and read") for simple and infrequent ineractions, and (2) web service for the delivery of plain standardised data that can be further processed by users applications as needed.

A new strategy for identifying shales with high gas retention using noble gas, nitrogen and carbon

S. BASU[1]*, A. P. JONES[1] AND A.B. VERCHOVSKY[2]

[1]Dept Earth Sciences, University College London, Gower S., London WC1E 6BT, UK (*correspondence: sudeshnabg@yahoo.com, adrian.jones@ucl.ac.uk)

[2]PSSRI, Open University, Milton Keynes, MK7 6AA, UK (a.verchovsky@open.ac.uk)

Noble gases have been used to distinguish between hydrocarbon maturities, and evaluate the fracture network in a shale [1]. Carbon and nitrogen isotopic ratios, and noble gases, have the potential to identify the origin of shale gas. A combined study using all three simultaneously can strengthen previous applications, and have the potential of further utilizations. But such studies on shale gas cuttings are non-existent.

The preferential adsorption of Xe and Kr is higher for kerogen than shales [2]. So, distinct fractionation pattern should set apart organic-rich shales. In conjunction with carbon and nitrogen isotopes, C/N and N/Ar ratios, they can provide useful insights on the type of sedimentary organic matter. A combination of stepwise combustion and vacuum crushing can be used to decouple the free and bound gases.

A new analytical protocol for high precision EPMA of olivine

V.G.BATANOVA[1,2] AND A.V.SOBOLEV[1,2]

[1]ISTerre, University J. Fourier, Grenoble, France, valentina.batanova@ujf-grenoble.fr

[2]Vernadsky Institute of Geochemistry RAS, Moscow, Russia

Composition of olivine provides critical information on the composition and origin of primary mantle derived melts and their sources. Especially informative are minor and trace elements Ni, Mn, Ca, Al, Cr, Co, Ti, Zn, P, Na [1, 2], which being in the concentration range over 10 ppm are assessable by EPMA.

Long counting times (up to 300 sec) on WDS at high beam current (300 nA) reported in [1] yield precision of individual analysis around 30 ppm (2 standard errors) for Ni, Mn, Ca, Al, Cr and 300 ppm for Fo content of olivine. Here we report 2-3 fold improvement of EPMA precision for larger range of trace elements in olivine (Ni, Mn, Ca, Al, Cr, Co, Ti, Zn, P, Na).

The analytical protocol built up on brand new JEOL JXA 8230 EPMA in ISTerre, UJF, Grenoble, France. Facility has tungsten source gun, is equipped by five WDS and one SDD EDS and placed in the environment with controlled temperature (22+/-0.3 degrees C) and humidity (50+/-3%).

The analytical conditions are the following: acceleration voltage 25kV, 900 nA beam current, WDS recording for trace elements (Ni, Mn, Ca, Al, Cr, Co, Ti, Zn, P, Na) and EDS recording for Si, Mg, Fe, total counting time 12 minutes, ZAF correction. Instrumental drift during analytical sessions is monitored by repeated measurements of olivine standards. For trace elements this protocol yields detection limits from 3 to 10 ppm and average precision of individual analysis of 10 ppm (2 standard errors). For Fo of olivine precision is 300 ppm (2 standard errors).

Comparison of EPMA and LA ICP-MS data for the large range of olivine compositions suggests that accuracy of EPMA is similar to precision noted above. For elements with concentration over 100 ppm the obtained EPMA precision and accuracy are better than these of LA ICP-MS. For the concentration of elements between 50-100 ppm both methods show similar precision and accuracy; and for concentration between 10-50 ppm LA ICP-MS yields better precision and accuracy. Spatial resolution of EPMA, however, is significantly better: 3-5 micrometres compared to 30-50 for LA ICP-MS. This makes our new EPMA protocol of great advantage for measurement of zoned or small olivine grains.

Delineation of groundwater zones using weighted overlay analysis of hydrochemical and multiple isotopic data, Ulaanbaatar, Mongoila

BATSAIKHAN BAYARTUNGALAG[1], SEONG-TAEK YUN[1]*, KYOUNG-HO KIM[1], BERNHARD MAYER[2] AND SANG-TAE KIM[3]

[1]Korea University, Department of Earth and Environmental Sciences, Seoul, South Korea (*correspondence: styun@korea.ac.kr)
[2]University of Calgary, Geoscience, Canada
[3]McMaster University, School of Geography and Earth Sciences, Hamilton, Canada

The water demand in Ulaanbaatar (UB), the capital of Mongolia, is quickly increasing due to significant population growth. Municipal water supply in UB depends solely on groundwater withdrawn from alluvial aquifer that is developed along and near the Tuul River. To overall understand the status of groundwater in UB, we performed a hydrochemical and environmental isotopic survey. Concentrations of cations and anions, $\delta^{13}C$ of dissolved inorganic carbon, $\delta^{15}N$ and $\delta^{18}O$ of nitrate, and $\delta^{34}S$ and $\delta^{18}O$ of sulphate were analysed. Three major hydrochemical types of groundwater occur in UB: 1) Ca-HCO_3 type, 2) Ca(-Mg)-HCO_3 type, and 3) Ca(-Na)-Cl(-NO_3) type. Types 1 and 2 mainly occur in forest and grassland areas at outskirts of UB and represent the natural water chemistry without anthropogenic contamination. Type 3 occurs predominantly in urbanized areas and is characterized by increased concentrations of TDS, Cl+NO_3 (and NO_2)+SO_4 due to significant contamination. The $\delta^{15}N$ and $\delta^{18}O$ values of nitrate in type 3 groundwater indicate the main source of contamination from latrines (manure) and sewage. To delineate several groundwater zones under contamination risks, we conducted digital image processing techniques of remote sensing and GIS. Then, multi thematic maps on lithology, slope, land-use, lineament, drainage, soil and rainfall were integrated in a raster based GIS (i.e., weighted overlay analysis) to identify the weighted factors of groundwater contamination and to classify and map the groundwater zones as very poor, poor, good, and very good in relation to contamination susceptibility. The results of this study will be helpful for planning schemes for sustainable groundwater management in UB.

Raman spectroscopy and powder diffraction study of synthetic Coffinite ($USiO_4$) at high pressures

J. D. BAUER[1], S. LABS[2], S. WEISS[3], L. BAYARJARGAL[1], H. CURTIUS[2], W. MORGENROTH[1], D. BOSBACH[2], C. HENNIG[3] AND B. WINKLER[1]

[2]Forschungszentrum Jülich GmbH, Inst. f. Energie- und Klimaforschung – Nukleare Entsorgung (IEK-6), 52425 Jülich, Germany
[3]Helmholz-Zentrum Dresden Rossendorf, Inst. f. Ressourcenökologie, 01314 Dresden-Rossendorf, Germany

Coffinite, $USiO_4$, can form under reducing conditions from UO_2 in contact with silica-rich waters (Langmuir's criterion) [1]. Spent nuclear fuel (SNF) consists to > 90% of UO_2, therefore the safety assessment for a final repository in deep geological formation will benefit greatly if coffinite is taken into account as a potential secondary phase. While high pressures are not of specific relevance for a final repository for SNF, its structural behaviour at high pressures is of general interest to understand the phase stabilities and to benchmark model calculations. The high pressure behaviour of coffinite has been studied before on natural and synthetic samples [2,3]. A pressure-induced irreversible phase transformation from the zircon- to the scheelite-type structure was found at about 15 GPa using an alcohol-water mixture as a pressure medium [3].

Here, synthetic coffinite was studied under high pressure conditions in the diamond anvil cell with neon as quasi-hydrostatic pressure medium up to pressures of 35 GPa. The samples are free of impurities of UO_2, as characterized by XRD and HRTEM. Powder diffraction experiments with synchrotron radiation indicate a pressure-induced phase transformation at 18-20 GPa. In contrast to the earlier high pressure study [3], this transformation is reversible on pressure release and no UO_2 is formed during the process. A detailed data analysis is currently in progress.

Raman spectra were obtained up to a pressure of 18 GPa. Further measurements at higher pressures are on-going.

Financial support from the German Federal Ministry of Education and Research (BMBF) under grants 02NUK019C and 02NUK019E is gratefully acknowledged.

Oxygen and hydrogen stable isotopes in Alpine waters and fine-grained soils near Saas Fee, Switzerland

KERSTIN K. BAUER[1]*, THIERRY ADATTE[1] AND TORSTEN W. VENNEMANN[1]

[1]Institut des sciences de la Terre, Géopolis, Université de Lausanne, CH-1015 Lausanne, Switzerland (*correspondence: kbauer@unil.ch)

Samples of soil and surface water were collected along a transect of 30 km with 1600 m of difference in altitude in the valleys of Saas Fee and Visp in the Swiss Alps. Mineralogical, chemical, and isotopic (O and H) compositions were measured to study the water-rock interactions, clay mineral formation, and the influence of altitude on the isotopic composition of soils during weathering of the parent rock, in order to draw conclusions for the usability of hydrous minerals derived from alpine soils for paleoelevation studies.

Waters have a range of $\delta^{18}O$ and δD values typical of those for precipitation and glacial melt water, decreasing with altitude of the catchments. The major dissolved ions characterize the composition of the substrate lithologies by elevated contents of Ca, sulphate, K, and Mg ions. This is also the case for the mineralogical composition of the soils that corresponds to the occurrence of ophiolitic material in higher elevations and granitic gneisses and schists in lower regions. While phyllosilicates from early-stage weathering and transformation of illite and chlorite to interstratified minerals (vermiculite, illite-vermiculite, chlorite-vermiculite and illite-smectite) are present, their abundance is relatively low. The isotopic composition of the fine earth fraction and the < 2 μm clay component in the soil was in average identical, and corresponds to the range of values of the host rock material. This suggests that the present climate and this environment do not allow for the neoformation of larger quantities of clay minerals in contact with ambient water.

Pore scale visualization of chemical gradients at biogeochemical interfaces using micromodels and Raman microspectroscopy

T. BAUMANN*, C.METZ, N. P. IVLEVA AND R. NIESSNER

Institute of Hydrochemistry, Technische Universität München, 81377 München, Germany (*correspondence: tbaumann@tum.de)

Biogeochemical interfaces (BGI) are controlling the fate of organic chemicals at the interface between the terrestrial and the aquatic environment. BGI are highly dynamic in the spatial and temporal domain. One of the key features of BGI is their limited temporal and spatial accessibility which is hard to imitate in conventional laboratory test designs.

Processes at BGI can be visualized and quantified using microfluidic structures mimicking the pore topology of the soil, so called micromodels. In combination with Raman microspectroscopy chemical information can be retrieved from a micromodel experiment with a spatial resolution on the order of 1 μm^2 and a temporal resolution in the s-range. To increase the sensitivity, silver nanoparticles have been added to the water phase flowing through the micromodel to make use of the amplifying surface-enhanced Raman effect. Currently chemical gradients of moderately lipophilic substances have been acquired with a limit of detection of 10^{-8} mol/L. Challenges to overcome include the interactions between silver nanoparticles and target analytes which might alter the mass transfer rates, and the settling of nanoparticles in the channel.

As high resolution acquisition comes with a limited field-of- view (FoV) and, e.g., the growth of a biofilm outside of the FoV alters the flow pattern, the flow velocity has to be monitored using fluorescent latex beads and single particle tracking. For a fast measurement of well-defined variables, like the pH-value or the oxygen concentration, thin film polymers with encapsulated sensor dyes are chosen.

When looking at microbial growth in porous media, not only the development of a biofilm changes the flow paths and the accessibility to the microbes, but also the development of locally confined gas bubbles, as with *P. denitrificans*. Here, the growth rate is correlated with bacterial activity and the results indicate different bacterial densities in pore bodies and pore throats.

Diverse hydrothermal venting at the Jan Mayen vent fields, AMOR

T. BAUMBERGER[1]*, M.D. LILLEY[2], R.B. PEDERSEN[1], I.H. THORSETH[1] AND A. STENSLAND[1]

[1]Centre for Geobiology, University of Bergen, 5007 Bergen, Norway (*correspondence: tamara.baumberger@geo.uib.no)

[2]School of Oceanography, University of Washington, Seattle, WA 98195, USA (lilley@u.washington.edu)

The basalt-hosted Jan Mayen vent fields (JMVF) are located at 71° N on the southern end of the ultra-slow spreading Mohns Ridge (AMOR). Over the past few years, scientific cruises have repeatedly visited and extensively sampled these vent fields. Researchers have identified several types of hydrothermal venting and have noted significant differences in hydrothermal fluid compositions within relatively short distances. The types of venting range from focused high-temperature fluid venting from numerous chimney structures, to low-temperature diffuse fluid flow areas. In addition free gas bubbles were observed being released from the seafloor. The chemical composition of the high-temperature endmember vent fluids is primarily characterized by high concentrations of carbon dioxide together with low hydrogen and methane concentrations. Fluids from the diffuse flow areas are characterized by an increased concentration of methane, which is strongly reflected in the hydrothermal plume observed above these diffuse systems. High concentrations of dissolved methane together with low concentrations of dissolved hydrogen were measured in the water column close to the seafloor for the diffuse flow hydrothermal plume, while high hydrogen/low methane concentrations were found in the high-rising non-buoyant plume. The main constituent of the gas bubbles, however, was carbon dioxide. In addition, at 560 m water depth along the flank of a high-temperature venting chimney, formations of gas hydrate were observed. A few tens of meters away, a ridge segment with several small chimneys with a flame-like discharge was observed, suggesting subcritical phase separation through boiling at relatively low pressures. Here we present a study on the diverse geochemical fluid and gas characteristics of the Jan Mayen hydrothermal systems located on the ultra-slow spreading Arctic Mid-Ocean Ridge and compare the results with the fluid composition of other mid-ocean ridge hydrothermal systems.

The SwissSIMS ion probe facility

L. BAUMGARTNER[1,] AND A.-S. BOUVIER[1]

[1]ISTE, University of Lausanne, Lausanne, Switzerland, (lukas.baumgartner@unil.ch)

A new ion probe laboratory, housing a CAMECA IMS 1280-HR has been established at the University of Lausanne, Switzerland in the Institute of Earth Sciences. The SIMS facility was obtained through funding from the Swiss National Science foundation, the universities of Bern, Geneva, Lausanne, and the ETHZ. It is organized as a Swiss National Facility, with a scientific steering committee. The instrument was installed in the second half of 2012, and it passed specification late 2012. The NanoSIMS facility of the EPFL under the direction of Dr. Anders Meibom is housed in the same building. The combination of facilities offers the users a unique opportunity for *in situ* surface analysis.

We will focus on basic and applied research in all domains of earth science. The IMS 1280-HR is equipped with high-density cesium and oxygen primary ion sources, 5 interchangeable electron-multiplier spectrometers (EMS) or Faraday cup and 2 fixed Faraday cups for multi-collection and one electron multiplier and two Faraday cups for mono-collection. The magnetic sector is stabilized with a Hall probe to improve reproducibility of isotopic ratios; transmission is optimized for IMS sensitivity.

So far we have tested and adapted existing methods on using NIST or MPI-DING standards and we improved existing method for *Cl* isotope measurements [1]. We are currently developing and establishing various carbonate standards for *O* and *C* isotopes, in house quartz standards for *O* and *Si* isotopes, as well as standards for oxygen isotopic composition for olivine, titanite, biotite for *O* isotopes. We are now ready to start the first scientific projects.

Geochemical mapping in urban area of an old mercury mining town (Idrija, Slovenia)

Š. BAVEC[1], M.GOSAR[1]*, H. BIESTER[2] AND H. GRČMAN[3]

[1] Geological survey of Slovenia, Dimičeva ulica 14, SI-1000 Ljubljana, Slovenia (spela.bavec@geo-zs.si, correspondence: mateja.gosar@geo-zs.si)

[2] Technical University Braunschweig, 38106 Braunschweig, Germany (h.biester@tu-bs.de)

[3] Agronomy Department, Centre for Soil and Environmental Science, Biotechnical Faculty, University of Ljubljana, Jamnikarjeva 101, 1000 Ljubljana, Slovenia (helena.grcman@bf.uni-lj.si)

Detailed soil geochemical survey tackles the urban area of Idrija, which is the oldest mining town in Slovenia with about 7000 population. Strong legacy of 500 years of mercury mining and ore processing in Idrija have resulted in widespread contamination. Environmental impacts on a regional scale caused by atmospheric emissions from the Idrija ore roasting plant were established in investigations of mercury spatial distribution in soil on regional scale [1, 2].

This study is part of the URGE project (Urban Geochemistry) and brings into focus urban area of Idrija town. Soil was systematically sampled (45 sampling sites) in 4 km^2 of Idrija urban area. Two soil horizons (0-10 cm and 10-20 cm) were sampled in order to distinguish between different metal sources. Samples were prepared and analysed according to URGE project. A sampling model grid was developed for collection of 9 soil samples per km^2. Due to higher population density, the density of samples was increased in the town centre. Contents of potential harmful elements were determined using aqua regia digestion. As expected, Hg contents were extremely elevated and ranged from 8 to 1210 mg/kg with a median of 60 mg/kg for upper soil horizon and from 7 to 1550 mg/kg with a median of 50 mg/kg for lower soil horizon. Spatial distribution analysis shows that higher contents appear along river banks, where ore residues were dumped in the past and in the part of the studied area, where soils overly rocks containing mercury ore. Other potential harmful elements didn't show critical elevations according to legislation. so the study was further directed into analysis of mercury species and their water-soluble and bio-accessible portions using different extraction methods.

The Chronology of Dehydration

ETHAN F. BAXTER[1], BESIM DRAGOVIC[1,2] AND MARK J. CADDICK[2]

[1]Department of Earth and Environment, Boston University, 685 Commonwealth Ave, Boston MA, 02215 USA

[2]Department of Geosciences, Virginia Tech, 5060 Derring Hall, Blacksburg, Virginia 24061 USA

The global geologic water cycle including the hydration and dehydration of the lithosphere during tectonic and metamorphic processes plays a first order role in shaping our planet. In subduction zones, dehydration is responsible for mantle melting, arc magmatism, seismic triggering, slab densification, and more. It is challenging to constrain the rate and timing of paleo-dehydration unless a passive mineral marker of the dehydration process can be identified and dated in the dehydrated rock residue. We use thermodynamic modeling to show that the growth of garnet may be used as a proxy for dehydration in diverse bulk rock compositions and tectonic contexts. Generally, as garnet grows in a subducting rock, fluid is produced due to metamorphic dehydration of hydrous precursor phases including chlorite, lawsonite, epidote, and amphibole. We quantify the proportional relationship between garnet and water production in common lithologies along three representative subduction geotherms [1]. Over the garnet growth interval ~400 to 700 ˚C (and corresponding depths for each geotherm) the average production ratio for altered MORB compositions is 0.52 (wt % water per vol % garnet) in cooler geotherms (Honshu and Nicaragua) and 0.27 in hotter (Cascadia) geotherms, with predictably lower ratios if the input basalt previously experienced less hydrous alteration. Over the same interval the water production ratios are approximately 50 % lower for pelitic sediment (0.24 and 0.13, respectively). Garnets can also be dated at high precision (<±1 Myr) with the Sm-Nd (or Lu-Hf) system, thus constraining the timing of dehydration by proxy. With large single crystals (>5mm diameter), concentrically growth zoned garnets may be microsampled and dated from core-to-rim, thus constraining the duration of dehydration. When coupled with thermodynamic analysis, a complete P-T-H_2O chronology can be extracted. Example P-T-H_2O chronologies from Sifnos, Greece reveal rapid, focused dehydration around 46 Ma spanning just hundreds of thousands of years [2].

Precise U-Pb (ID-TIMS) and SHRIMP ages on single zircon for Achaean TTG rocks on Baltic Shield

BAYANOVA T., MITROFANOV F., MOROZOVA L., NITKINA E., SEROV P., FEDOTOV D. AND LARIONOV A.

bayanova@geoksc.apatity.ru felix@geoksc.apatity.ru morozova@geoksc.apatity.ru nitkina@geoksc.apatity.ru serov@geoksc.apatity.ru fedotov@geoksc.apatity.ru larionov@mail.wplus.net

Voche-Lambina polygon lies on the boundary between Belomorian mobile block and Central –Kola domain (Morozova *et al*, 2011). New neoarhaean U-Pb data on single zircon from TTG of international polygon named of the Voche-Lambina yielded 3158.2±8.2, which are situated on Central-Kola block in the Baltic Shield. Zircon are characterized by low concentration U and Pb, low U/Th ratio with 0.2. REE diagrams of grey gneisses reflect high fractionation La/Yb>30,encriched by light REE and depleted by heavy Yb<0.6 ppm. Model Sm-Ng ages on the rocks have protolith from with the ages 3.4 to 3.2 Ga, positive εNd from +1.29 to +3.3, ISr equals 0.702. Precise age of amphibolites metamorphism has been dated on single zircon with 2704.3±5.9 Ma. In the frame of the Central-Kola domain there is an Ingosersky TTG complex. Firstly U-Pb dating on single zircon from Bt-gneisses reflects 3149±49 Ma. Metamorphic alterations were in 2725.2±2.5 Ma and connected with origin of Amf-Bt gneisses and 2733.6±6.6 with Bt-Amf gneisses. (NItkina at all, 2012). Achaean gneisses in Monchegorsk ore region were firstly dated in the Central-Kola domain and near Murmansk. Single zircon from gneisses in Monchegorsk region which are the basement for Paleoproterozoic PGE layered intrusions with U-Pb ages on zircon and baddeleyite from 2.4-to 2.5 Ga (Bayanova *et al*, 2009) has 3.16 Ga and single zircon with 2776±3 Ma is considered as amphibolites metamorphism. New U-Pb (ID-TIMS) data on single zircon from high alimunia gneisses near Murmansk in the Central-Kola domain gave 3.17 Ga, core from these zircon population has the age 3695±5 Ma by SHRIMP. Time of amphibolites metamorphism was dated with 2753±3 Ma. Therefore based on the new data on single zircon from TTG and gneisses from Central-Kola domain leads to the long history of continental crust origin in the Baltic Shield from 3.16 to 3.7 Ga.

We thank to D. Wasserburg for 205 Pb artificial spike, J. Ludden for 91500 and Temora standards, F. Corfu, V. Todt and U. Poller for assistance in the establishing of the U-Pb method for single zircon and baddeleyite grains. The study is contributed and supported by IGCP 599 and Department of Earth Sciences RAS, program 4.

Improvements of the coherent and precise ice core dating tool Datice: new data and parameterization

L. BAZIN[1]*, A. LANDAIS[1], G. DURAND[2], C. RITZ[2], M. MONTAGNAT[2], B. LEMIEUX-DUDON[3] AND D. RAYNAUD[2]

[3]LJK, Grenoble, France

Recently, we published the new ice core reference chronology AICC2012 common for 5 ice cores (EDC, EDML, Vostok, TALDICE and NorthGRIP) back to 800 ka (thousand of years before 1950) [1, 2]. To construct this optimized chronology we used the "Datice" Bayesian tool [3], using a background chronology and data constraints (absolute and orbital age markers, stratigraphic links between the ice cores) for both the ice and gas phases.

One of the limitations of AICC2012 was the lack of a good characterization of variance associated with the thinning background scenario respecting the deformation history. We thus propose a new definition of this variance using numerous data of microstructure and fabric for the EDC ice core [4].

A second limitation of AICC2012 was the lack of orbital constraints on the long EDC ice core. We present a new high-resolution record of $\delta^{18}O_{atm}$ and $\delta O_2/N_2$ between 100-800 ka obtained on EDC ice of high quality exempt of gas loss. Together with the complete record of air content [5], another orbital dating tool, we provide an important step for improving the reference ice core chronology for Antarctic ice cores.

High- to low- pressure features of compound xenoliths: implications from Fe-Ti-Ca metasomatism and glass formation

BAZIOTIS, I.[1,4], ASIMOW, P.D.[2], NTAFLOS, T.[3], KORONEOS, A.[1] AND POLI, G.[4]

[1]Department of Mineralogy, Petrology and Economic Geology, Aristotle University of Thessaloniki, 54124, Thessaloniki, Greece, baziotis@metal.ntua.gr

[3]Department of Lithospheric Research, University of Vienna, 1090, Vienna, Austria
[4]Department of Earth Sciences, University of Perugia, 06100, Perugia, Italy

Mantle xenoliths preserve invaluable information on chemical and thermal events in the earth's mantle and on the ages and rates of such events. The presence of Fe-Ti oxides such as ilmenite or armalcolite in areas affected by mantle metasomatism, for example, could contstrain the oxidation state of the metasomatic event and provide information about the metasomatic agent(s). Here we focus on lherzolite- and clinopyroxenite- rich xenoliths from Cima Dome (California) and Chino Valley (Arizona), their unusual mineral assemblages, and their formation.

Fe-Ti minerals identified in the selected xenoliths include armalcolite and ilmenite. In the Chino Valley clinopyroxenite, Nb-rich and Nb-free rutile both occur, either included in or included by ilmenite. Moreover, ilmenite is initially replaced by Fe-oxide + kassite (a rare hydrous Ca-Ti oxide). Both ilmenite and rutile are rimmed by titanite. These successions imply a change from Fe-Ti to Ca-rich silicate metasomatic agents percolating through the host rock. In the amphibole-bearing lherzolite from Cima Dome, Ti-rich pargasite is surrounded by glass-1, spinel, plagioclase, clinopyroxene, olivine and armalcolite. The latter is entrained within the glass pocket and has a skeletal crystal shape suggesting rapid growth at high pressures ~1.0 GPa and low oxygen fugacity at mantle depths. The presence of glass-1 is associated with rapid melting and breakdown of pargasite to Ol+Cpx+Spl+Gl-1) en route to the surface. Glass-2 is observed along grain boundaries of pyroxenes and olivine, however is Si-enriched and depleted in Ca, Mg, Al, Ti compared to glass-1. Both samples suggest extended multi-stage histories involving partial melting to form primary minerals, a period of metasomatic alteration, and a short timescale of decompression upon eruption.

Storage of Initially Organic Nitrogen in Silicate Minerals and Volcanic Glasses

G. E. BEBOUT[1]*, K. E. LAZZERI[1], A. P. PALYA[1], L. D. ANDERSON-SMITH[1], M. R. M. IZAWA[2], N. R. BANERJEE[2] AND C. A. GEIGER[3]

[3]Material Sciences, Universität Salzburg, Salzburg, Austria.

We are investigating pathways by which initially organic N can be incorporated and stored in silicate minerals and glasses, focusing on phases other than the clays and micas, the latter known to house N as NH_4^+. Despite its volatility, N is surprisingly compatible in various silicates, largely as NH_4^+, but also as molecular N_2 in microporous phases (e.g., beryl, cordierite, zeolites, melanophlogite). These species can provide a record of ancient organic processes.

Along relatively warm prograde P-T paths, a significant fraction of the organic, mica-bound N in metasedimentary rocks can be lost at lower grades, due to partitioning into H_2O-rich fluids generated by breakdown of layer silicates such as chlorite. This N loss could affect the degree to which ancient (e.g., Archean) low-grade suites can be used to extract paleo-environmental information. However, at higher grades, the remaining N is retained to a surprising degree, even in rocks that experience partial melting, in phases such as K-feldspar and cordierite. Thus uptake and long-term storage of atmospheric/organic N in early-formed continental crust is possible (Goldblatt *et al*., 2006). $\Delta^{15}N$ values for coexisting cyclosilicates (N_2) and micas (NH_4^+) in some pegmatites and metasedimentary rocks indicate preservation of N isotope fractionations like those predicted by theoretical studies.

Incorporation of N with organic $\delta^{15}N$ in seafloor basalts can result in a seafloor N budget rivalling that in overlying sediments, strongly influencing the N subduction budget (Li *et al*., 2007). Our work on palagonitized volcanic glasses on the modern seafloor and in Mesozoic basalts, some of the glasses bearing microbial ichnofossils, demonstrates this uptake and that analyses of such glasses could be useful in the search for signs of ancient life on Mars. Low-grade metabasalts in the Abitibi Complex (2.7 Ga) contain small amounts of N, now in mica, with organic $\delta^{15}N$ that could reflect Archean seafloor incorporation of sedimentary/organic N, likely via a pore fluid. Melanophlogite, a silica clathrate found in low-T hydrothermal settings, contains up to 1700 ppm of N_2 also with organic $\delta^{15}N$. Our ongoing work considers the extent to which such phases can store N without isotopic change for geologically significant time periods.

Thermal conductivity of (Mg,Fe)O from ambient to deep mantle conditions

M.M. BECK[1,2], V. HAIGIS[3], F.R. SCHILLING[2] AND S. JAHN[1]*

[1]GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany (*correspondence: jahn@gfz-potsdam.de)

The thermal conductivity $\varkappa$ is one important physical property that controls the structure and the dynamics of the Earth's mantle [1,2]. Furthermore, $\varkappa$ influences the heat flux at the core-mantle-boundary and thus the generation of the Earth's magnetic field [3]. In spite of its significance, this parameter is insufficiently constrained due to the great technical challenges to measure thermal transport properties at pressure and temperature conditions relevant for the lower mantle. Here, we use an alternative approach and predict the thermal conductivity of model (Mg,Fe)O by equilibrium molecular dynamics simulations. We first investigate the effect of isotope disorder on $\varkappa$ in pure MgO with natural isotopic composition by randomly distributing the three most abundant Mg isotopes in the simulation cell. At ambient conditions we find that earlier simulations of Haigis *et al*. [5], which used an average isotope mass for all Mg ions, overestimate the thermal conductivity by about 32%. This overestimation is comparable to the predicted 46% from phonon lifetime calculations [4]. With rising temperature, the influence of isotope disorder on $\varkappa$ decreases and becomes almost insignificant at deep mantle conditions. Next, we analyse how the substitution of 10% or 20% of Mg by Fe masses affects $\varkappa$. Due to the larger mass difference between Fe and Mg ions compared to that between Mg isotopes, the reduction is now much larger at ambient conditions and still relevant at pressures and temperatures of the lower mantle. Combining our new results with those of Manthilake *et al*. for $(Mg,Fe)SiO_3$ perovskite [6], an aggregate mantle of 20% $(Mg_{0.80}Fe_{0.20})O$ and 80% $(Mg_{0.97}Fe_{0.03})SiO_3$ perovskite has a thermal conductivity of 10±2 W/(m K) at 3000 K and 138 GPa.

Composition of the oceanic crust: where have all the noble metals gone?

H. BECKER[1]* AND C. MEYER[2]

[1]* Institut für Geologische Wissenschaften, Freie Universität Berlin, Germany, hbecker@zedat.fu-berlin.de
[2]Institut für Geologische Wissenschaften, Freie Universität Berlin, Germany, chmeyer@zedat.fu-berlin.de

It has been speculated that the low noble metal abundances of many evolved MORBs may reflect sulfide fractionation, either during melting, or, as a consequence of fractional crystallization in the oceanic crust [e.g., 1].

The depletion of incompatible noble metals and Re in lherzolitic fractional melting residues from the depleted mantle [2] can be used to estimate bulk peridotite-silicate melt partition coefficients for these elements at the specific P-T-f_{O2}-f_{S2} conditions of melt extraction (D_{Pd}≈0.7, D_{Au}≈0.12, D_{Re}≈0.08). The data for Re are in good agreement with bulk partition coefficients calculated from experimental data at suitable upper mantle f_{O2}. Calculated abundances of these elements in primitive melts at 5-10 % melting are 10 ppb for Pd, 10 to 6 ppb for Au, and 2 to 1 ppb for Re. This contrasts with typical abundances in MORB of 0.05-2 ppb Pd and 0.1-3 ppb Au, whereas Re shows good agreement [e. g., 1,3,4]. Because partial melting of depleted mantle lherzolite cannot explain noble metal abundances in "primitive" MORBs, fractional crystallization in the crust is commonly invoked [1,3]. New data for the PGE+Re in different lithologies of the lower oceanic crust at hole 735B (crust formed by very slow spreading at the SW Indian ridge), indicate even lower abundances of Pd, Au and Re than in many MORBs. Clearly, the main site of fractionation of the PGE must be deeper than the drilled section. Recent data from lower crust of the Wadi Tayin section of the Oman ophiolite suggests significantly higher PGE abundances in fast spreading oceanic crust [5]. However, even these higher abundances fall short of expected concentrations in the oceanic crust. We conclude from this that most of the noble metal fractionation in MORB magma likely occurs during magma transport in the uppermost mantle. Dunites and harzburgites from the mantle section of the Oman ophiolite are strongly enriched in Pt, Pd and Re, thus providing hints for such fractionation processes [6, 7].

Component specific Hf-W dating of Allende and Vigarano CV3 chondrites

BECKER[1]*, M., KRAHNER[1], K., HEZEL, D.C[1]., SCHULZ, T.[2] AND MÜNKER, C.[1]

[1] Institut für Geologie und Mineralogie, Universität zu Köln, Germany, (*correspondence: maike.becker1@gmx.net)
[2] Department of Lithospheric Research, University of Vienna

The formation of chondrules, matrix and other components of chondrites is not yet fully understood. Knowing their relative formation ages and genetic relationships can provide crucial information on their formation conditions. Short lived radionuclides can provide new insights into the chronology of the formation of early solar system materials. In the past, the ^{26}Al-^{26}Mg system has been mainly used for this purpose, but recently the ^{182}Hf-^{182}W system emerged as a promising tool to date chondrule formation. Thus, components of chondrites that never underwent high temperature metamorphism, like CV3 chondrites, are well suited candidates for Hf-W investigations. Earlier studies of Allende chondrules with the Al-Mg und Pb-Pb systems indicate that they formed up to 3.2 Ma after CAI formation[1-4].

We prepared 23 Allende and 13 Vigarano separates for Hf and W isotope measurements, covering both reduced and oxidized CV chondrites. These include pure handpicked chondrule and matrix fractions as well as magnetic separates and bulk aliquots. The separates all define isochrons which indicates a contemporaneous formation of all components. The ages defined by the isochrons suggest formation of Allende and Vigarano components within 3 Ma after CAI formation. These ages are consistent with chondrule formation ages obtained from other isotopic systems.

Notably, W and Hf concentrations in chondrule and matrix fractions from Allende and Vigarano vary considerably. Chondrules from Allende exhibit high Hf/W ratios (2.5 to 3.0), whereas matrix and strong magnetic fractions exhibit low Hf/W ratios (0.5 to 0.9). Unlike in Allende, Vigarano contains chondrules with extremly low Hf/W ratios. As suggested from petrological observations, these low ratios can be attributed to the presence of metal inclusions within the reduced Vigarano chondrules.

Actinide redox processes on iron sulfides: an electrochemical, microscopic, and computational approach

UDO BECKER[1]*, KE YUAN[1] AND DEVON RENOCK[2]

[1]Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI 48109, USA, [2]Department of Earth Sciences, Dartmouth College, Hanover NH, 03755 (*correspondence: ubecker@umich.edu)

Little is known about the reaction mechanism of actinyl complexes on mineral surfaces, i.e. the role of the redox potential, the nature of the reductant, the importance of minerals in terms of providing catalytic surfaces, the role of anions in solution that polarize a mineral surface to promote or inhibit electron transfer, and the activated states that may slow down the kinetics of the redox process.

In order to resolve these, electrochemical studies using a micropowder electrode technique were performed in combination with a quantum-mechanical and microscopic (AFM) approach. The electrochemical approach allows us to determine the specific redox potential of actinide reduction on a given mineral surface. For example, uranyl reduction takes place at -0.22 V on hematite, -0.17 V on magnetite, and at -0.14 V on pyrite. Further electrochemistry experiments were performed on machinawite, in order to be able to compare these with quantum-mechanical calculations on the thermodynamics, charge and spin transfer, and electrochemical potential for reduction and oxidation to occur. The calculations show that the energy gain of the co-adsorption of hydroquinone (as an analogue for microbial reduction) and uranyl is on the order of 0.5 eV (≈50 kJ/mol) as compared to the separate adsorption of uranyl and hydroquinone. Similar co-adsorption on FeS (mackinawite) reveals that Fe(II) cations in the mineral surface become high spin (Fe(II) in bulk mackinawite is low spin), thereby increasing its potential for electron transfer.

Atmospheric CO_2 starvation of trees arrests mycorrhizal-driven silicate weathering

DAVID BEERLING[1], JOE QUIRK[1], LYLA TAYLOR[1], STEVE BANWART[2] AND JONATHAN LEAKE[1]

[1]Department of Animal and Plant Sciences, University of Sheffield, Sheffield S10 2TN, UK. Email: d.j.beerling@sheffield.ac.uk
[2]Kroto Research Institute, North Campus, University of Sheffield S3 7HQ, UK

Trees dominate terrestrial silicate mineral weathering by converting solar energy into chemical energy that fuels roots and their ubiquitous nutrient-mobilizing fungal symbionts. These biological activities regulate atmospheric CO_2 over geological timescales by driving calcium and magnesium fluvial ion export and marine carbonate formation. However, the important stabilizing feedbacks between CO_2 and biotic weathering anticipated by geochemical carbon cycle models remain untested. This presentation will show experimental evidence for a non-linear feedback across a Cenozoic CO_2 range from 1500ppm to 200ppm, whereby low CO_2 curtails mineral surface alteration via trenching and etch pitting by arbuscular mycorrhizal and ectomycorrhizal fungal partners of tree roots. Integrating our experimental findings into a process-based model revealed a CO_2 drop from 1500ppm to 200ppm caused the flux of calcium and magnesium weathered from silicate rocks to drop three-fold. It is proposed that 'low' CO_2 effectively acts as a 'carbon starvation' brake on tree-driven weathering. These findings have implications for the role of forests and fungi in regulating Earth's minimum atmospheric CO_2 concentration over the Cenozoic.

Ore deposits and lithosphere evolution in the early Earth

*G. C. BEGG[1,2], W.L. GRIFFIN[1], SUZANNE Y. O'REILLY[1], AND J. M.A. HRONSKY[1,3].

[1]CCFS/GEMOC, Macquarie University, Sydney, Australia
[2]Minerals Targeting Intl., 17 Prowse St., W. Perth, WA 6005, Australia
[3]Western Mining Services (Aust.) Pty Ltd, 17 Prowse Street, W. Perth, WA 6005, Australia
(*correspondence: graham.begg@bigpond.com)

Plate tectonic processes, including subduction-related magmatism, rifting and collision are critical for the formation of many types of magmatic and hydrothermal ore deposits. Given the evidence for the existence of plate tectonic processes from as early as 3.9Ga, the absence of significant mineral deposits older than about 3Ga is attributed to either of a failure to survive, or the absence of another key ore-forming environment. Subcontinental Lithospheric Mantle (SCLM), which appeared between ca 3.6-3.0 Ga, provides the solution to understanding both of these issues. Pristine SCLM, formed as a residue of high temperature plume melting, is depleted (Fe-poor), buoyant, refractory, and has very high viscosity. These traits make for a durable lithosphere, a home for mineral deposits, in contrast to the easily removed (subducted, delaminated) dense oceanic lithospheric mantle. Integration of geological, geophysical and geochemical data from the crust and mantle, indicates that Archean SCLM underlies the majority of today's continental crust. Plate tectonics (forces, fluids, magmas) has resulted in metasomatism, fracturing, melting and suturing of the SCLM. These processes, along with the impact of mantle plumes and the rise of atmospheric oxygen, have provided the metals, energy and focus for ore systems in a range of associated crustal environments.

Seismic anisotropy changes across upper mantle phase transitions

CAROLINE BEGHEIN[1]* AND KAIQING YUAN[1]

[1] Dpt. of Earth and Space Sciences, UCLA, Los Angeles, CA 90095-1567, USA (*correspondence: cbeghein@ucla.edu)

Constraining mantle flow near the mantle transition zone (MTZ) can help better understand its role in Earth's thermochemical evolution and mantle dynamics. Using a higher mode surface wave seismic dataset [1] we modeled global 3-D azimuthal anisotropy in the top 1000km of the mantle, thereby providing constraints on mantle deformation to much greater depths than in previous studies.

Our model unravels significant seismic anisotropy in the MTZ, challenging common views of mantle deformation, and reveals a striking correlation between minima in anisotropy amplitudes, changes in the fast axes of propagation, and the location of phase transitions. This relation between anisotropy changes and phase transformations suggests lattice preferred orientation of anisotropic material in the deep upper mantle.

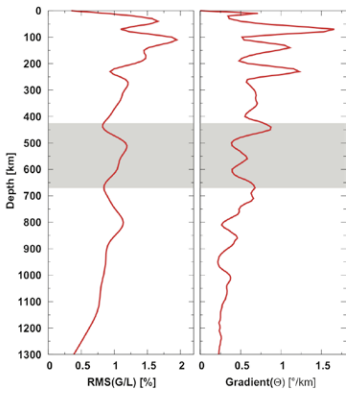

Figure 1**: Root mean square anisotropy amplitude (left) and average vertical gradient of fast axis (right)**

The detected global changes in the fast axes could indicate mantle flow layering, consistent with mantle geochemistry. The interpretation of our results in terms of convection style and therefore in terms of heat transport is however non-unique due to a lack of laboratory data on MTZ mantle anisotropy. Seismic anisotropy might not be a good proxy for mantle flow at these depths, in which case whole mantle convection cannot be ruled out.

Nevertheless, our model provides unique new constraints on mantle deformation and advances toward a better understanding of Earth's convective pattern and heat transport will require stronger constraints on the effects of pressure, temperature, melting, and water content on the deformation mechanisms and slip systems of MTZ materials.

Volatile distribution in the Taupo Volcanic Zone, New Zealand

FLORENCE BÉGUÉ[1]*, DARREN GRAVLEY[1], ISABELLE CHAMBEFORT[2], CHAD DEERING[3] AND BEN KENNEDY[1]

[1]University of Canterbury, Christchurch, New Zealand, (florence.begue@pg.canterbury.ac.nz * presenting author)
[2]GNS Sciences, Wairakei Research Centre, Taupo, New Zealand,
[3]University of Wisconsin-Oshkosh, Oshkosh, USA,

The central Taupo Volcanic Zone (TVZ) is an actively rifting continental arc where more than 6000 km^3 of rhyolitic magma has erupted from at least eight caldera centres over the past 1.6 Ma. The extensive magmatism in the TVZ is intimately associated with the high heat flux and active geothermal systems. These geothermal systems have previously been subdivided into two groups: 1) low-gas (i.e. CO_2), high Cl, low B and Li/Cs ratio systems suggested to have chemical affinities with basaltic (and rhyolitic) magmas, and 2) high-gas, low Cl, high B and Li/Cs ratio systems having chemical affinities with andesitic magmas.

Here we present new trace and volatile data on quartz-hosted melt inclusions from eight large, rhyolitic eruptions to examine the relationship between slab-derived fluid input and the geographic distribution of the two chemical groups observed in the present-day hydrothermal systems.

Based on trace element and volatile content, the rhyolites can also be subdivided into two distinct groups; R1 which is enriched in Li, Ba and B, and has Cl contents of ~0.2 wt%; and R2, which has lower content of these fluid-mobile elements, but higher Cl contents (0.25 to 0.35 wt%) than R1.

These differences in volatile contents are related to distinct parental magmas (i.e. two distinct sources), with "wetter" R1 having a higher slab-fluid component compared with the "dryer" R2. The difference in chlorine content between R1 and R2 magmas is related to the Cl solubility, which increases with decreasing H_2O content (i.e. higher Cl content in the dryer R2 melts).

A comparison between the new volatile data on the rhyolites and these present-day geothermal systems reveals that the observed differences in the fluid composition of surface springs are correlated with the distribution of the two rhyolite types. We, therefore, suggest that the variation in geothermal fluids does not necessitate a separate andesitic magma as a source, but is a continuation of different slab-derived fluid contributions producing slightly different rhyolite types. While the correlation observed here is strong, we do not rule out the influence of fluid-rock interaction as a possible contributor and this remains to be explored.

Constraints on the Composition of the Lower Continental Crust from Joint Inversion of P- and S-wave Seismic Velocity Data

MARK D. BEHN[1]*, OLIVER E. JAGOUTZ[2], DONNA J. SHILLINGTON[3] AND PETER B. KELEMEN[4]

[1]*WHOI, Woods Hole MA, USA, mbehn@whoi.edu
[2]MIT, Cambridge MA, USA, jagoutz@MIT.EDU
[3]LDEO, Palisades NY, USA, djs@ldeo.columbia.edu
[4]LDEO, Palisades NY, USA, peterk@ldeo.columbia.edu

Seismic velocity data constitute one of the primary constraints on the bulk composition of the lower continental crust. P-wave velocity data are frequently used to infer the composition of the deep crust and to support petrologic models for the origin of the continental crust. Unfortunately, recent work has demonstrated that a large range of compositions can be associated with the same P-wave velocity, rendering the interpretation of these crustal velocity models to be highly non-unique. Alternatively, the ratio between P- and S-wave velocity (Vp/Vs) can be directly inferred from receiver function studies (though not the absolute P- or S-wave velocity). However, Vp/Vs ratios alone also lead to highly non-unique estimates for lower crustal composition.

In order to provide more robust constraints on lower crustal compositions, we calculate elastic properties for an expansive suite of crustal compositions (anhydrous and hydrous) and invert for major element chemistry as a function of P- and S-wave velocity over a range of pressure and temperature conditions. We show that the combination of P- and S-wave data significantly improves compositional resolution, particularly when *a priori* pressure and temperature constraints can be used to determine whether the lower crust resides in the alpha- or beta-quartz stability field.

We apply this inversion technique to a range of geologic settings with high quality P-wave S-wave data (e.g., cratonic North America, the African and Indian shields, and the Aleutian arc crust—which may represent a building block for continental crust). Compositional models for each region are derived based on expected crustal geotherms, along with complementary estimates for lower crustal physical properties including density and viscosity. These data are then used to test different models for crustal evolution.

Geodynamic implications from element fluxes in the Tonga-Lau system

CHRISTOPH BEIER[1], MARCEL REGELOUS[1] AND KARSTEN M. HAASE[1]

[1]GeoZentrum Nordbayern, Universität Erlangen-Nürnberg, Schlossgarten 5, D-91054 Erlangen, Germany, christoph.beier@fau.de

It is well known that lavas from active back-arc spreading centres contain a 'subduction component' (e.g. high Pb/Ce, U/Nb), the strength of which decreases with increasing distance of the spreading axis from the volcanic arc. However, it is not well understood how the Ba-, Pb- and U-rich subduction component is transported from the subducting plate to the shallow melting zone underneath the ridge axis. Many tectonic models for subduction zones assume vertical transport of fluid or aqueous melt from the surface of the subducting slab to shallower levels beneath the back-arc spreading axis, and the decreasing subduction signal with distance from the arc is thought to result from a decreasing fluid release from the subducting slab at greater depths. To test these hypotheses, we present new data from the Tonga-Kermadec arc, a 3000 km long arc in the southwestern Pacific, along with new and published data from the Valu Fa, Central and Eastern Lau back-arc basin spreading centres. The distance between the arc and back-arc increases from less than 10 km at ~23°S to ~150 km at 19°30'S, allowing the interaction between the arc and back-arc melting regimes to be constrained. Assuming that Nb is immobile in fluids, and that Ba/Nb, Th/Nb ratios are not fractionated during melting, we map out the subduction-related enrichment of Ba and Th underneath the Tonga Arc-Lau Basin system, and show using mass-balance arguments that the simplistic model of vertically rising fluids or melts is unrealistic. We suggest that the overlap in melting zones beneath the arc and beneath the back-arc spreading centre allows horizontal flow of melt from beneath the arc towards the back-arc (i.e. in the opposite direction to the flow of solid mantle induced by plate subduction) at shallow levels in the mantle, and this best explains a subduction zone signature underneath the back-arc. Our work demonstrates for the first time that melt can be focussed from the extreme edges of the melting zone underlying an active spreading ridge to the ridge axis, over distances of up to 200 km. Our model provides an alternative explanation for $(^{238}U/^{230}Th) > 1$ in back-arc lavas, and indicates horizontal melt flow velocities of 0.4-1 m/y.

Contrasting style of Iron formations deposited before and after the GOE

BEKKER ANDREY[1]

[1] Dept. of Geological Sciences, University of Manitoba, Winnipeg, Manitoba R3T 2N2, Canada; bekker@cc.umanitoba.ca

Iron Formations are typically interpreted to indicate anoxic deep-water conditions before the rise of atmospheric oxygen and ocean ventilation. However, deposition of iron formations continued after the Great Oxidation Event (GOE) in shallow-marine conditions above the fairweather wavebase. Their deposition on several continents at ca. 1.89 Ga has been linked to a mantle plume breakout event and indicates development of the shallow-water redoxcline in the global ocean separating deep-water, anoxic and ferruginous conditions from shallow-water oxic and well-mixed environments. Iron oxidation at the dynamic redoxcline has been linked to iron-oxidizing microbial ecosystems, oxygenic photosynthesizers, and abiotic iron oxidation. In contrast, Archean iron formations were typically deposited below the storm wavebase and lack indicators of wave or storm activity. Conspicuous absence of Archean iron formations with granular structures and Fe-coated grains might indicate lack of mechanisms for quantitative iron oxidation in Archean shallow-marine settings, suggesting that oxidizing conditions and a strong redoxcline were lacking even in highly productive shallow-marine settings. Iron isotope values of Archean and Paleoproterozoic iron formations are also consistent with non-quantitative Fe-oxidation in the Archean oceans arguing against a significant role of oxygenic photosynthesis in deposition of Archean iron formations. It seems therefore likely that anoxygenic photosynthesis in depositional settings with low sedimentation rates is responsible for deposition of Archean iron formations. The prediction from the contrasting style of deposition of iron formations before and after the GOE is that deposition of iron formations occurred at lower sedimentation rates before the rise of atmospheric oxygen. If this is the case, it has implications for scavenging capacity of iron oxyhydroxides and thus interpretation of geochemical records of iron formations.

Ge, related trace elements, and Ge isotopes in sphalerite from the Saint-Salvy deposit (France) by LA-ICP-MS and MC-ICP-MS.

BELISSONT, R.[12]., BOIRON, M.-C.[1], LUAIS, B.[2], AND CATHELINEAU M.[1]

[1]GeoRessources, Université de Lorraine, Vandoeuvre-les-Nancy, France

[2]CRPG, CNRS, Vandoeuvre-les-Nancy, France remi.belissont@univ-lorraine.fr

The recent increasing worldwide demand in germanium (Ge) encourages research for the understanding its geological cycles and the factors controlling its concentration in minerals. Ge occurs in a wide variety of geologic environments and though it averages 1.6 ppm in the Earth's crust, high Ge contents may occur in both oxide and sulphide minerals (up to 100–3000 ppm), especially sphalerite so that Zn ores represent a major source of Ge, with coal. The Ge-bearing sphalerite of the Saint-Salvy Zn-Ge-Ag-(Pb-Cd) vein-type deposit was subjected to an integrated mineralogical, geochemical and Ge isotopic study in order to understand the mechanisms and processes that conduct Ge and related minor/trace elements (e.g. Cu, In, Ga, Ag, Sb, Sn) to be enriched in sphalerite regarding source, transport, and deposition conditions.

In situ analyses of trace elements using LA-ICP-MS, coupled with optical and electron microscopy and multivariate statistics, pointed out an opposite distribution of Ge between compositional zoning types in sphalerite, with contents ranging from 15 to 2580 ppm. In *rhythmic bandings,* Ge anticorrelates with Fe, Cd, In and Sn, and averages 500 and 200 ppm within light brown and dark brown bands, respectively. In *sector zonings*, Ge is enriched and correlates with Cu, Ga, Sb, Ag and As, and averages 1100 ppm. Cu would enhance the incorporation of trace elements, beeing involved in many coupled substitution mechanisms, among which the most notable: $2Zn^{2+} \leftrightarrow Cu^{+} + Sb^{3+}$. In addition, the main coupled substitutions $3Zn^{2+} \leftrightarrow Ge^{4+} + 2Ag^{+}$ and $3Zn^{2+} \leftrightarrow In^{3+} + Sn^{3+} +$ also occur. Trace element features of the sphalerite from Saint-Salvy compared with those of other deposits worldwide revealed to be efficient to discriminate among genetic types of ores, which may find interests in exploration guidance. Bulk Ge isotope analyses by MC-ICP-MS showed $\delta^{74}Ge_{NIST3120a}$ ranging from -1.97 to +1.01‰ (±0.25‰ 2σ SD) that positively correlate with Ge content and highlight large sub-surface fractionation processes during sulphide precipitation in low temperature hydrothermal open system.

Photophysical studies of biologically produced macromolecules

E. BELKASEM[1], L. SWANSON[1], A. ELAYATT[2] AND M.E. ROMERO-GONZÁLEZ[2]*

[1]Department of Chemistry. The University of Sheffield. Sheffield S3 7HF, UK (chp08esb@shef.ac.uk)
[2]Kroto Research Institute. The University of Sheffield. Sheffield S3 7HQ, UK (m.e.romero-gonzalez@shef.ac.uk)

The attachment of microbes to solid surfaces is controlled by the macromolecular structure of the cell wall as much as driven by functional genes that are induced to produce cell wall macromolecules. We present here a quantification of the molecular conformation and sorption forces involved in the attachment of cell wall macromolecules such as lipopolysaccharides (LPS), alginates and extracellular polymeric compounds (EPS) extracted from bacteria. Our hypothesis is that the molecule-surface interfacial forces mediate the physicochemical interactions of bacteria cell wall, and its adaptation to the host environment. Photophysics techniques were used to investigate adsorption of biopolymer onto mineral surfaces which should act as model systems for bacterial growth. Adsorption of dilute aqueous solution of macromolecules was studied as a function of pH in the presence of alumina and silica using Time resolved anisotropy studies (TRAMS), fluorescence and ICP-MS. The alumina and silica particles were used to mimic active sites existing on the surface of kaolin-like particles. It was found that LPS for example, had a high adsorption affinity for Al_2O_3 and in contrast adsorbs weakly to SiO_2 surface. Strong adsorption was observed at low pH for both minerals. The dependence of adsorption on the mineral concentration was also examined at different pH conditions: the adsorption amount was observed to increase by increasing the mineral concentration. Macromolecular folding and conformation of the LPS, alginate and EPS at the solid-solution interface was also quantified using TRAMS. The results showed a high pH and ionic strength dependence demonstrating that macromolecule adhesion is favoured and mediated by ions such as H^+ and Ca^{+2} in solution. These findings indicate that proton bridges and van der Waal forces are responsible for interactions at the interface. A model for macromolecule adhesion at the interface including the role of ions in solution and folding was proposed. This model is representative of the behaviour of biological macromolecules at the aqueous-surface interface in natural environments. The processes described here have a direct implication on bacteria mediated mineralisation via concentration of ions from solution.

Magmas, solutions and metals

AARON BELL[1], ADAM SIMON[2]*, ELIZABETH TANIS[2] AND LAURA BILENKER[2]

[1]Institute of Meteoritics, University of New Mexico
[2]Earth & Environmental Sciences, University of Michigan [*simonac@umich.edu]

Holland[1] demonstrated experimentally that Cl-bearing magmatic-hydrothermal aqueous fluids can scavenge metals from silicate melt and transport the metals into the surrounding crustal environment where fluid-rock reactions and decompression may cause metal precipitation and form ore deposits. Specifically, the abundance of Cl in the fluid phase was demonstrated to be a master variable that controls the total mobilized quantity of metal. Holland[1] stated: "It remains to be seen just how useful these criteria will turn out to be; the results of preliminary tests are encouraging". This was a prescient statement indeed. Over the ensuing four decades, scientists have constructed a wonderful house of experimental knowledge on the scaffolding that Holland built, and these data guide our undersanding of the incredible role of aqueous fluids in magmatic-hydrothermal systems.

Our research group continues to investigate experimentally the mobility of transition row metals, high field strength, and rare earth elements in aqueous fluids ranging from those exsolved from silicate melt in shallow-level magma chambers to fluids evolved during the blueschist to eclogite transition in subduction zones. Specifically, we are investigating how the complexity of aqueous fluid, i.e., dissolved chloride salts, fluorine, albite, etc., affects element mobility.

Data for the mobility of iron in a silcate melt – aqueous fluid – magnetite – sulfide assemblage indicate that the mass transfer of iron can moderate oxygen fugacity, sulfide stability, the composition of ferromagnesian silicates, and the fractionation of stable iron isotopes. These data have important implications for using iron as a geochemical fingerprint for processes that form porphyry, high-sulfidation, iron-oxide-copper-gold (IOCG), and iron-oxide-apatite (IOA) deposits. New data for the mobility of Y (a proxy for the heavy-REE) and Nb (a proxy for all HFSE) in xenotime- and rutile-saturated aqueous fluids, respectively, indicate that these elements are orders of magnitude more soluble at the moderate temperature and high pressure conditions where fluids evolve in subduction zone environments. These new data have significant implications for element recycling during the high-pressure metamorphism that accompies subduction, and ultimately for evolution of continental crust.

Solubility of Nickel Ferrite ($NiFe_2O_4$) from 100 to 200°C

ALEXANDRE BELLEFLEUR[1], MARTIN BACHET[1], PASCALE BENEZETH[2] AND JACQUES SCHOTT[2]

[1] EDF R&D Site des Renardières, Avenue des Renardières 77818 Moret Sur Loing, (alexandre.bellefleur@edf.fr)
[2] GET Toulouse University, 14 Avenue Edouard Belin 31400 Toulouse (benezeth@get.obs-mip.fr)

Nickel ferrite is one of the oxides present on surfaces of the components of the primary circuit of pressurized water reactors (PWR). Its dissolution contributes to the release of nickel in the primary water, at the origin of the contamination phenomenon. A complete understanding of the behavior of nickel in the primary circuit must include solubility measurements of nickel oxides, including mixed oxides such as nickel ferrite.

The solubility of nickel ferrite was measured in a Hydrogen-Electrode Concentration Cell (HECC), which has been described in [1], at temperatures of 100°C, 150°C and 200°C and measured *in situ* pH between 4 and 5.25. The experimental solution was composed of HCl and NaCl (0.1 $mol.L^{-1}$). Based on previous studies ([2,3]), pure nickel ferrite was experimentally synthesized by calcination of a mixture of hematite Fe_2O_3 and bunsenite NiO in molten salts at 1000°C for 15 hours in air. The so obtained powder was fully characterized. After the experiment, the powder showed no significant XRD evidence of Ni(II) reduction. Nickel concentration was measured by atomic absorption spectroscopy and iron concentration was measured by UV spectroscopy. The protocol has been designed to enable the measurement of both dissolved Fe(II) and total iron [4].

The solution was slightly undersaturated relative to nickel oxide [1] and to both hematite and magnetite. The nickel/iron ratio indicated a non stoichiometric dissolution. The solubility measurements were compared with equilibrium calculations using the MULTEQ database. The solubility of nickel ferrite in a reducing acidic solution is reasonably well described by the available thermodynamic data.

Alternative nitrogenases in terrestrial ecosystems?

JEAN-PHILIPPE BELLENGER, YAN XU, XINNING ZHANG, AND ANNE KRAEPIEL[1234]

[1]Chemistry department, Sherbrooke University, Sherbrooke, Quebec, J1K2R1, Canada

Recent studies have shown that molybdenum (Mo), which is used in the Mo-nitrogenase, can limit N_2 fixation in temperate and tropical ecosystems. This suggests that alternative nitrogenases, which use V or Fe in place of Mo, may contribute to N_2 fixation. The acetylene reduction assay (ARA) is commonly used to estimate N_2 fixation rates but requires the use of an adequate conversion ratio (R ratio = acetylene reduction/N_2 fixation). The theoretical value for R is 3-4, but measured values in the field range from less than 1 to more than 10. In this study, we show that even in pure cultures, the R ratio is variable and dependent on the culture growth phase. Nonetheless, low R values (below 2) can be consistently attributed to N_2 fixation by alternative nitrogenases. Interestingly, an analysis of the literature shows that low R ratios are measured almost exclusively in soils, and are not found in the surface oceans (where Mo is abundant, and alternative nitrogenases are unlikely to be important) or in plant symbions (which do not possess the genes for the alternative nitrogenases). The low R ratios may thus be indicative of alternative nitrogenases in soils. In a series of microcosm experiments with temperate soils from New Jersey, we were able to confirm that alternative nitrogenase genes were present, and expressed, even though N_2 fixation did not appear to be Mo-limited. The R ratios were low at the beginning of the incubations, suggesting that alternative nitrogenases contribute to the bulk to N_2 fixation in these samples. The R ratios also tended to increase over time, possibly reflecting depletion of the fixed carbon pool, or increased contribution from the Mo-nitrogenase. The possibility that alternative nitrogenases may contribute to N_2 fixation in systems that are not Mo limited is intriguing and deserves further investigation.

Development of the La-Ce systematics : application to arc magmas

N. BELLOT[1], M. BOYET[1], C. PIN[1], C. CHAUVEL[2], R. DOUCELANCE[1] AND D. AUCLAIR[1]

[1] Laboratoire Magmas et Volcans, Université Blaise Pascal, CNRS UMR 6524, 5 rue Kessler, 63038 Clermont-Ferrand, France
correspondance : n.bellot@opgc.univ-bpclermont.fr
[2] ISTERRE, Maison des Géosciences, CNRS, 1381 rue de la piscine 38400 Saint Martin d'Hères, France.

In the 1980's, the ^{138}La-^{138}Ce systematics ($T_{1/2}$= 302 Ga) has been developed [1,2]. Since La/Ce fractionation is strong in some supergene conditions (due to the occurrence of Ce^{4+}), this isotope system is able to offer new information on the material involved in the genesis of magma in subduction zones. Here, we present Ce isotope data measured on Martinique lavas that have been thoroughly characterized in a previous study [3].

The Ce purification involves 3 steps: 1) REE isolation in HCl medium on cationic resin; 2) La-Ce-Pr-Nd separation using 2MLA acid; 3) purification of the Ce fraction using LnSpec resin. The Ce isotopic compositions were measured as the oxide species by TIMS, (Triton). In order to increase the signal size of the two minor isotopes (^{136}Ce and ^{138}Ce), ^{140}Ce was not measured. The oxygen isotope composition is determined *in situ* following the method developed by [4]. ^{138}Ce/^{142}Ce ratios are normalized to ^{136}Ce/^{142}Ce=0.01688. ^{138}Ce/^{136}Ce ratio measured in the AMES standard is equal to 1.33745±4 (n=10, or ^{138}Ce/^{142}Ce=0.0225761±7) in agreement with previous measurements [4]. The ^{138}Ce/^{142}Ce ratios measured on the standard basalts BHVO-2 and BCR-2 are 0.0225662±15 (n=13) and 0.0225684±13 (n=3), respectively. The ^{138}Ce/^{142}Ce ratios of the Martinique lavas define a large range (0.0225660 – 0.0225706) showing that the Ce isotopic system can be a powerful tool to trace heterogeneities in the source of arc lavas.

The Ce isotopic tracer applied to 30 Martinique lavas shows a clear correlation with Nd, Sr and Pb isotopes suggesting a varying contribution from sedimentary material. Complementary data on sediments located in front of the arc should provide further constraints on the mixing relationships between sedimentary components and the mantle wedge underlying the Lesser Antilles arc.

Rb and Sr adsorption at the Quartz(101) – water interface

F. BELLUCCI[1]*, S.S. LEE[1], Z. ZHANG[1], P. FENTER[1] AND D.J.WESOLOWSKI[2]

[1]Argonne National Laboratory, Argonne, IL, 60439, USA
[2]Oak Ridge National Laboratory, Oak Ridge, TN, 37831, USA

Quartz is an abundant and ubiquitous rock-forming mineral in Earth's continental crust, and influences the chemistry of numerous aqueous systems [1]. The sorptive property of quartz changes the mobility of ions in water while its dissolution process controls long-term silica cycling through the earth system. Batch experiments [2, 3] showed that the dissolution rate of quartz at near-neutral pH increases substantially in the presence of cations while the degree of enhancement depends on the choice of cation. However, the detailed understanding on the mechanism remains unclear mainly because of the lack of atomic-scale information on the processes to explain the complexity of the interface chemistry. Molecular-scale investigation of the quartz surface-cation interaction is the first step in understanding this cation-induced mechanism. Here, we report on Rb^+ and Sr^{2+} cation adsorption at the quartz(101)-water interface observed in 10mM salt solutions at pH 10 using x-ray reflectivity (XR) and resonant anomalous XR measurements.

The best fit models of the experimental data suggest that Rb^+ adsorbs at an average height of 2.7 Å above the surface (defined as the average position of the two terminal oxygens), which may be a mixture of inner- and outer-sphere species. Adsorbed Sr^{2+} is prevalently located at 4.6 Å above the surface, suggesting the formation of an outher sphere complex. The occupancies of these complexes with respect to the unit cell area (UC) are 0.19 Rb^+/UC, and 0.07 Sr^{2+}/UC. The smaller coverage of Sr^{2+} compared to that of Rb^+ is likely due to the difference in cation valency. The charge of the quartz(101) surface calculated based on the coverages at pH 10 is approximately 0.14 to 0.21 e^-/UC or ~1 e^- for 5 to 7 UC.

Pyroxenites from mantle section of Voykar Ophiolite (Polar Urals) – pathways for melt and fluid migration

I.A.BELOUSOV[1,2], V.G.BATANOVA[2,3], A.V.SOBOLEV[2,3] AND G.N.SAVELIEVA[4]

[1]CODES, Hobart, Australia, ivan.belousov@utas.edu.au
[2]Vernadsky Institute of Geochemistry RAS, Moscow, Russia
[3]ISTerre, University J. Fourier, Grenoble 1, France
[4]Geological Institute RAS, Moscow, Russia

Late stages of formation of rocks from mantle section of Voykar Ophiolite were shown to take place in SSZ environment [1,2]. Dunite bodies and pyroxenite veins mark different stages of melt migration [2]. Best evidence for SSZ environment is preserved in mineral compositions from pyroxenite veins – high #Cr of spinel and LILE enrichments in Cpx and high-Al amphibole. Pyroxenite compositions display variability which is a function of their modal compositions, morphological features and spatial location.

Minerals from orthopyroxenites usually have high mineral #Mg, are most depleted in incompatible elements, show low Al in pyroxenes and spinel ($\#Cr^{Spl}$ >0.6). Other group of pyroxenites with high mineral #Mg is represented by thin (cm-scale) clinopyroxenites and websterites and complex dunite-pyroxenite veins. Their major element compositions were equilibrated with adjacent harzburgites. Minerals from thicker websterites and clinopyroxenites have lower #Mg and subparallel boninite-like trace element patterns of Cpx [1]. Cpx compositions across harzburgite-pyroxenite contacts show depletion in HREE (opposite to harzburgite-dunite contacts) and Zr and enrichment in LREE and Sr. High-Al amphibole from websterites display trace element patterns with different LREE/HREE and MREE/HREE ratios, which could reflect their formation from melt to fluid-like agent.

Therefore, Voykar mantle section pyroxenite veins represent pathways for melts variously depleted in incompatible elements or in some cases fluids with boninite-like trace element patterns and elevated silica contents. Those melts were produced by melting of hybridized mantle source formed as a result of transformation of mantle olivine to orthopyroxene under the influence of slab-derived fluids/melts [2]. Different areas of massif could be arranged in order of increasing HREE contents in Cpx from dominated type of pyroxenite which could reflect relative depth or degree of melt fractionation.

New insights into the history of an ophiolite from zircons

E.A. BELOUSOVA[1]*, J. M. GONZÁLEZ-JIMÉNEZ[1], I.T. GRAHAM[2], W.L. GRIFFIN[1] AND SUZANNE Y. O'REILLY[1]

[1]GEMOC/CCFS, Macquarie University, Sydney, Australia (elena.belousova@mq.edu.au)
[2]School of Biological, Earth and Environmental Sciences, University of NSW, Sydney, Australia

The Coolac Serpentinite Belt is part of the Tumut ophiolitic complex in the Lachlan Fold Belt, southeastern Australia. The 63 km belt contains a high proportion of massive (unfoliated) ultramafic rocks that have undergone only lower greenschist-facies metamorphism [1]. New U-Pb, Hf- and O-isotope and trace-element data have been obtained for zircons from the rocks of the belt. These include zircons separated from two (high-Al and high-Cr) massive chromitites and rodingites and grains recovered from gullies draining mainly weakly serpentinised massive porphyroclastic harzburgite. The Belt is either faulted against, or intruded by, the S-type Young Granodiorite. Zircons from the Young Granodiorite collected at the contact with the serpentinite belt were also studied to refine the tectonic relation and timing of the granitic magmatism,

The U-Pb age obtained on the zircons from the serpentinite belt display a wide range of ages, from Silurian to Paleo-Proterozoic, with the main age population clustering around 430 Ma. This main peak coincides within the analytical error with the age obtained for the Young Granodiorite (427.6 ± 3.2 Ma) and inherited zircon ages for plagiogranites from the Belt [1]. The ages for the inherited zircon populations in the granodiorite correlate well with the older zircon populations from the Coolac ultramafic rocks.

Most of the Coolac zircons have negative εHf and heavy (>6) $\delta^{18}O$ indicative of a crustal origin. Combined with U-Pb age information, this implies that the zircons in the peridotites are xenocrystic. One possibility is that zircons derived from subducted sediments were incorporated into the ophiolitic rocks (as in the Luobusa (Tibet) ophiolite [2]). However, the similarity of the Coolac ophiolite-derived zircons with those from the Young Granodiorite may indicate that they were introduced into the Coolac peridotitic complex during the granitoid magmatism and thus may carry no information on the origin of the Tumut ophiolitic rocks. In the latter case, the Coolac rocks should be older than the granitic magmatism of the 420–390 Ma age of the Lachlan Fold Belt.

Monomeric and polymeric silica sorption on calcite

D.A. BELOVA[1]*, O.N. KARASEVA[2], L.Z. LAKSHTANOV[1,2] AND S.L.S. STIPP[1]

[1]Nano-Science Center, Department of Chemistry, University of Copenhagen, Copenhagen, Denmark (db@nano.ku.dk)
[2]Institute of Experimental Mineralogy RAS, Chernogolovka, Russia (olga@iem.ac.ru)

Literature data about sorption of dissolved silica by calcite is fairly sparse and contradictive. Klein and Walter [1] investigated silica uptake at pH 6-8.3 and reported adsorption to be strongly pH dependant, with a maximum at pH 6. On the other hand, in flotation studies where sodium silicate was used as a depressant to suppress the flotation tendency of calcite, the experiments were mostly performed at pH > 8 and silica adsorption by calcite was reported to reach maximum at pH 9 to 10 [2, 3, 4]. In addition, the role of silica polymer adsorption in suppressing calcite flotation is unclear. Some authors [2] did not find any relationship with polymeric silica while others [3, 4] reported polymer adsorption to be responsible for suppression. Our study aimed to clarify the pH dependence of silica uptake by calcite and the importance of silica polymers in the process.

We investigated sorption of dissolved silica on calcite at 25 ºC in calcite equilibrated solutions with pH ranging from 6 to 11, with varying initial silica concentration (≤ 2 mM) and surface area to liquid ratio (≤ 480 m^2/L). The experimental conditions were designed such that polymeric silica introduced with the concentrated stock solution is stable at pH > 9 but unstable at lower pH.

Silica uptake was observed to increase with pH. At pH 11, almost 50% of the dissolved silica was removed from the solution, while no silica sorption was found at pH 6.1. The presence of stable silica polymers at pH > 9, is at least partly responsible for this pH dependence. At pH 8.3, we observed a significant, but temporary uptake of silica. It was released again to solution after several hours. This is consistent with silica being dominantly adsorbed as polymeric species and desorbed in response to depolymerisation.

Melt evolution from the mantle wedge to the crust: insights from South Kamchatka and West Bismarck arc xenoliths

A. BÉNARD[1]*, S.R.B. MCALPINE[1], O. NEBEL[1], P.M.E. TOLLAN[2], R.J. ARCULUS[1] AND D.A. IONOV[3]

[1]Research School of Earth Sciences, Australian National University, ACT Australia 0200
[2]Department of Earth Sciences, Durham University, Durham, UK
[3]PRES-Lyon & UMR6524-CNRS, Saint-Etienne, France (*correspondence: antoine.benard@anu.edu.au)

Rare xenoliths carried by recent andesites or arc tholeiites are the only direct witnesses of active sub-arc processes. We present a detailed study on such xenoliths from Avacha volcano in southern Kamchatka (Russia) and Ritter volcano, West Bismarck Arc (Papua New-Guinea Region). Avacha is located on a 'mature' subduction zone (~120 km Pacific slab depth, ~40 km crustal thickness). Harzburgites cut by websteritic veins, as well as massive olivine- and hornblende-clinopyroxenites and hornblendites occur in Avacha andesitic deposits (≤7000 yrs. BP). Based on the compositions of minerals, melt inclusions and interstitial glass, we infer that the websteric veins formed from high-Ca boninites (HCB). Unlike a previous study [1], this inference is consistent with recent reports of complementary low-Ca boninites (LCB) in these rocks [2]. Similar datasets show that clinopyroxenites and hornblendites crystallized respectively at Moho and mid-crustal depth, producing residual liquids similar to Avacha andesites. Modelling suggests that these 'cumulate' rocks can form from an ascending HCB melt, modified by fractionation and melt-rock reactions in the lithospheric sub-arc mantle.

Ritter is part of an active and complex subduction zone (~120 km depth for the Solomon Sea Plate slab and ~20 km crustal thickness). Harzburgites, pyroxenites and dunites are found in picritic arc tholeiites (≤125 yrs. BP) from Ritter. We show with the same toolbox, that pyroxenites and dunites are former primitive sub-arc melt channels. Evidence for LCB percolation in veins through these samples supports the current generation of boninitic mantle melts, like for Avacha.

In line with literature datasets on exhumed arc sections, we propose that boninites are common primary mantle wedge liquids in various types of subduction zones. Supported by our dataset on harzburgites, this puts direct constraints on mantle wedge melting beneath arcs. The possible HCB-andesite liquid line of evolution leads us to re-examine melt ascent and element flux models for subduction zones.

Non-traditional stable isotopes and surface complexation models for ion binding to humic substances (NICA-Donnan) and oxide mineral surfaces (CD-MUSIC)

M.F. BENEDETTI[1]

[1]Université Paris Diderot –Sorbonne Paris Cité - IPGP – UMR CNRS 7154, Paris France ; benedetti@ipgp.fr

Non-traditional stable isotopes (i.e. Zn, Fe, Ni and Cu) are increasingly used for environmental studies [1]. Considering the wide range of possible sorbents (Mn or Al oxides, phyllosilicates, carbonates, biologic surfaces…), the importance of the reactions at the sorbent/water interface for these numerous studies emphasized the importance of modelling approaches that are needed to quantify the isotopic fractionation of these elements caused by their sorption at mineral/water, organic moieties/water interfaces.

The present work will show how the use of EXAFS spectroscopy and CD MUSIC and NICA Donnan modelling can help to better understand the changes in isotopic ratio. Zn isotopic fractionation upon sorption onto Hydrous Feric Oxide (HFO) and goethite will be discussed to assess the influence of reactions at the Fe-(hydr)oxide/water interface on the isotopic distribution of Zn [1]. The Zinc isotopic fractionation during interaction onto natural organic matter will be discussed. The Donnan Membrane device was successfully adapted for isotopic measurements and used to separate Zn bound to the PHA from free Zn^{2+} ions in solution and allowed the measurement of isotopic ratios of free Zn^{2+}. The NICA-Donnan model, is used to simulate the corresponding isotopic fractionation and the composition of free Zn in the Seine river, France and allows a better understanding of Zn isotope fractionation mechanisms associated with organic matter binding [2].

Capturing and storing CO_2 in basaltic formations is one of the most promising options for reducing the effects of energy production from fossil fuel on the Earth. These geologic reservoirs have high reactive potential for CO_2-mineral trapping due to an abundance of divalent-cation containing silicates, such as forsterite (Mg_2SiO_4). Recent studies [1-4] have shown that carbonation of these silicates is more effective in wet scCO_2 conditions, encountered near a CO_2 injection well, than in dry and/or CO_2-saturated aqueous fluids. More interestingly, formation of magnesite under supercritical fluid conditions has been reported in some of these previous studies at temperatures as low as 35°C [3], in spite of its known sluggish formation under aqueous scenarios.

In this study, we used high pressure IR spectroscopy to investigate the carbonation of nanometer-sized forsterite at 35 and 50°C by systematically titrating water that subsequently dissolves in scCO_2 at 90 bar. The results show that at low total dissolved water concentrations, only highly structured adsorbed water and bicarbonate are detected at the forsterite surface. However, as the water concentration increases up to a critical value, but below H_2O-saturated scCO_2, a more liquid-like water film is detected on the forsterite particles, the bicarbonate concentration decreases and magnesite precipitates, as shown in our *in situ* IR spectra, as well as from *ex-situ* XRD, TGA and SEM analyses.

The results of these studies provide important insights into metal silicate carbonation mechanisms in low water scCO_2 environments. They reinforced the concept of a water threshold for carbonation to occur, which has also been demonstrated for steel corrosion in the presence of wet scCO_2 [5]. These results will also constrain thermodynamic models and molecular dynamic simulations used to predict mineral trapping extent in basaltic host rocks.

Mantle Potential Temperature Trend for the Central Atlantic Magmatic Province

ALAN BENIMOFF AND JOHN H. PUFFER J

[1]Dept.of Engineering Science and Physics, College of Staten Island/CUNY, Staten Island, NY 10314
[2]Dept.of Earth and Environmental Sciences, Rutgers University, Newark, NJ 07102,

Recently published high precision geochronology by Blackburn *et al*. [1] dates each of eight basaltic magmatic events intruded and extruded during the Central Atlantic Magmatic Province (CAMP) over a 0.6 Ma time span. Each of the four major CAMP magma compositions including High titanium quartz normative, High Iron quartz normative, Low titanium quartz normative, and Olivine normative are represented. Geochemical data from a variety of sources are available for each of the eight basaltic units and being applied to PRIMELT2 software developed by Herzberg and Asimow [2] that will enable the determination of mantle potential temperatures. These data will enable us to calculate temperature trends that will have a direct bearing on the petrogenesis of CAMP magmatism. Preliminary data yield mantle potential temperatures for the mean High titanium quartz normative and Olivine normative primary compositions determined by Salters *et al*. [3] of 1394°C and 1449°C respectively. These temperatures are lower than the > 1500°C melting range generally applied to the mantle plume model but are consistent with decompression melting of a subduction enriched subduction metasomatised sub-continental lithospheric mantle source (SCLM). The temperature trend that we establish will allow us to further evaluate the application of mantle plume and SCLM source models to CAMP.

Planets, Minerals and Life's Origin

STEVEN A. BENNER[1,2]

[1]Foundation for Applied Molecular Evolution, PO Box 13174, Gainesville FL 32604
[2]The Westheimer Institute for Science and Technology, 720 SW 2nd Ave., Gainesville FL 32601

Four paradoxes stand astride any effort to understand how life originated on Earth:

(a) The Tar Paradox. Organic molecules, given energy and left to themselves, devolve into complex mixtures, "asphalts" better suited for paving roads than supporting Darwinian evolution. Any scenario for origins requires a way to allow organic material to escape this devolution into a Darwinian existence, where replication with imperfections, where the imperfections are themselves heritable, allows natural selection to avoid a tarry fate.

(b) The Water Paradox: Water is commonly believed to be essential for life. So are biopolymers, like RNA, DNA, and proteins. However, the biopolymers that we know find water corrosive. Any scenario for origins must manage the apparent need of life for a substance (water) this is inherently toxic to life.

(c) The Single Biopolymer Paradox. Even if we can make biopolymers prebioically, it is hard to imaging making two or three (DNA, RNA, proteins) at the same time. At the same time, genetics versus catalysis place different demands on the behavior of a single biopolymer intended to support life. Catalytic biopolymers should fold, for example, while genetic biopolymers should not fold. Catalytic biopolymers should contain many building blocks; genetic biopolymers should contain few.

(d) The Probability Paradox. Some biopolymers, like RNA, strike a reasonable compromise between the needs of genetics and the needs of catalysis. However, emerging data suggests that RNA is more likely to deliver catalytic power that destroys RNA than catalytic power that makes RNA.

This talk will review experimental data that makes suggestions about early planetary environments and mineralogy that might avoid, mitigate, and possibly resolve certain of these paradoxes. Key are the presence of minerals, including borates and molybdates, that interact with organic species that are intermediates between atmospheric carbon dioxide and dinitrogen and RNA. Productive interaction requires as well a subaerial environment having only intermittent interaction with water. Recent data suggests that such environments might even be found today on Mars.

An integrated isotopic-geologic view of early continental crust formation from the oldest rock record

VICKIE C. BENNETT[1]* AND ALLEN P. NUTMAN[2]

[1]*Research School of Earth Sciences, The Australian National University, Canberra, Australia; vickie.bennett@au.edu.au

[2]GeoQuest Research Centre, School of Earth and Environmental Sciences, University of Wollongong; allen.nutman@gmail.com

A cornerstone of Earth sciences for many years was the assumed complementary of mantle and crustal chemical evolution, with extraction and recycling of continental crust through time thought to be the main processes controlling the composition of the upper mantle. This view has been brought into question following discoveries of extinct nuclide signatures in Archean rocks (e.g. ^{142}Nd, ^{182}W) requiring early differentiation and/or a non-chondritic Earth. Linked to this are questions of which isotopic and geochemical monitors of continental crust formation processes and continental mass are most reliable.

Here we present an integrated geochemical and geologic examination of Archean continent formation with an emphasis on the patterns of ^{176}Hf and ^{143}Nd isotopic variations. Focus is on the largest extent of early crust located within the 3000 km^2 Eoarchean Itsaq Gneiss Complex of SW Greenland. This complex preserves evidence of several temporally and spatially distinct episodes of juvenile crust formation between ~3.89 Ga and 3.66 Ga, which are dominated by TTG rocks. In each event, TTG suites were emplaced into slightly older gabbros, basalts and andesites, which have geochemical signatures consistent with fluid-fluxing of upper mantle sources. The TTG suites are characterized by magmatic zircon with initial εHf of ~0 and positive whole rock initial εNd of +4 to +2. The most likely geodynamic settings for generation of this early crust were convergent plate boundary environments analogous with, but not identical to, modern island arcs. The pattern of near constant εHf values in primitive granitoids for >300 m.y. argues against derivation of these magmas by repeated sampling of a mafic crustal source, from reworking of older crustal material, or from a mantle source previously experiencing large amounts of Hadean crustal extraction. Starting at 3.66 Ga, granitic rocks first begin to show Hf isotopic evidence for reworking of older crust. Varying ^{143}Nd isotopic compositions of Eoarchean rocks likely reflect early Sm/Nd fractionation unrelated to crustal extraction. We propose that the shift to correlated ^{176}Hf-^{143}Nd isotopic temporal trends, as typify Phanerozoic style arc accretion processes, began as early as ~3.5 Ga.

Geochemistry and Carbon Management

SALLY M. BENSON

Energy Resource Engineering Department, Stanford University, Stanford, California

Without a doubt, meeting human energy needs while dramatically reducing greenhouse has emmissions is one of the grand challenges of our time. Geochemistry plays a critical role in assessing both the impacts of changing the chemical composition of the atmosphere due to emission of greenhouse gases and designing solutions. Over the coming decades, a radical transformation of our energy system is needed to reduce global greenhouse gas emissions by over 80%. Solutions for achieving needed emission reductions include improving enegy efficiency, shifting to renewable energy resources for producing electricity, reducing emissions from fossil fuel by capturing and storing CO_2, switching from coal to natural gas for power generation, and sustaining use of nuclear power, In this paper, the critical role that geochemistry plays in developing and evaluating solutions is highlighted. Examples from carbon dioxide capture and storage, nuclear waste disposal, shale gas development, and providing the critical materials for renewable energy and storage systems are provided. Over the coming decades, Earth's resources will be taxed in new and unforseen ways. The discipine of geochemisty will play a crucial role in anticipating and responding to these challenges.

Intracellular calcification by cyanobacteria: a significant controlled biomineralization process

KARIM BENZERARA*[1], FERIEL SKOURI-PANET[1], MARIE RAGON[1], NITHAVONG CAM[1,3], JINHUA LI[1], CELINE FERARD[1], JEAN-FRANÇOIS LAMBERT[3], THOMAS GEORGELIN[3], MAGUY JABER[3], DAVID MOREIRA[2] AND PURIFICACION LOPEZ-GARCIA[2]

[1]IMPMC - ERC Calcyan, CNRS & UPMC, 75005 Paris, France, *correspondence: karim.benzerara@upmc.fr

[2]3Ecologie, Systématique et Evolution, UMR 8079 CNRS & Université Paris-Sud, France

[3] Laboratoire de Réactivité de Surface, UPMC & CNRS, Ivry-sur-Seine, France.

Cyanobacteria had a pivotal role on several global geochemical cycles throughout Earth's history in particular, by biomineralizing $CaCO_3$. Calcification by cyanobacteria has so far been considered exclusively as an induced extracellular biomineralization process. However, we recently discovered deep-branching cyanobacteria that form intracellular amorphous Ca-Mg-Sr-Ba carbonates [1]. The existence of such intracellularly calcifying cyanobacteria may modify significantly our view on the past and modern role of cyanobacteria in the formation of carbonate deposits and the degree of control they achieve on this geochemically important process. However, several questions remain open: is this biomineralization process widespread phylogenetically or restricted to one single species? Does it occur under specific or diverse environmental conditions? To what extent do phases formed intracellularly by these cyanobacteria differ from abiotically-formed carbonates?

We will address these questions using diverse approaches including high spatial and spectral resolution spectromicroscoscopies and molecular biology.

Polysulfides as intermediates in the bacterial metabolism of stored sulfur

J.S. BERG*, J. MILUCKA, A. SCHWEDT, A.-C. KREUTZMANN AND M.M.M. KUYPERS

Max Planck Institute for Marine Microbiology, 28359 Bremen, Germany (*correspondence: jberg@mpi-bremen.de)

Zero-valent sulfur is a key intermediate in the microbial oxidation of sulfide to sulfate. Many sulfide-oxidizing bacteria therefore produce and store large amounts of sulfur intra- or extracellularly. It is still not well understood how the stored sulfur is metabolized as the most stable form of S^0 under standard biological conditions – orthorhombic α-sulfur – can most likely not be utilized by bacterial enzymes.

In this study, the speciation of sulfur in single cells of living bacteria was investigated by Raman spectroscopy. Four different strains of *Beggiatoa* were used to compare the chemical nature of sulfur under various ecological and physiological conditions. Results showed that in microaerobic cultures at circumneutral pH, stored intracellular sulfur consisted of S_8 rings and inorganic polysulfides (S_n^{2-}). Linear sulfur chains were detected during both the oxidation and reduction of stored sulfur suggesting that S_n^{2-} species comprise a pool of activated sulfur utilized by bacteria. The formation of S_n^{2-} results from the cleavage of sulfur rings, either biologically by membrane-bound thiol groups and glutathione or chemically by the strong nucleophile HS^-. It is likely that *Beggiatoa* in the environment utilize both of these mechanisms to generate S_n^{2-} intermediates as they migrate vertically between oxic and sulfidic sediment zones.

With Raman spectroscopy it was possible to further track the fate of sulfur during its oxidation to sulfate. Unexpectedly high concentrations (up to ~2 M) of internal sulfate were detected in *Beggiatoa* sp. Although the reason for the intracellular accumulation of sulfate remains unknown we could show for the first time that *Beggiatoa* contain sulfate in concentrations 100-1,000-fold higher than that of the external environment.

Non-classical nucleation of minerals and the multiple roles of additives

JOHN K. BERG*, MATTHIAS KELLERMEIER, ASHIT RAO, HELMUT CÖLFEN AND DENIS GEBAUER

Physical Chemistry, University of Konstanz, D-78457 Konstanz, Germany, [*correspondence: john.berg@uni-konstanz.de, denis.gebauer@uni-konstanz.de]

Recent reports have demonstrated the existence of stable clusters of calcium carbonate ($CaCO_3$) prior to nucleation through various experimental methods and also computer simulations [1, 2, 3, 4]. In contrast to classical notions, it appears cluster aggregation, not the assembly of their constituent ions, plays the significant role in nucleation of amorphous calcium carbonate (ACC), which later transforms into crystalline polymorphs.

This multi-stage process can be influenced by additives in several ways, which is of particular interest for biomineralization, as various additives, *e.g.* proteins, polysaccharides, and inorganic salts, are present throughout the nucleation processes. Though many systems have been investigated [5, 6, 7], the exact roles of additives are yet unknown, especially when it comes to mechanistic insights.

In the current contribution, we summarize the concept of non-classical nucleation of $CaCO_3$ by means of pre-nucleation clusters and recent advancements, including other mineral systems. Moreover, through potentiometric titration assays in the presence of additives, we exemplify the role of additives from simple salts to complex proteins on the early stages of precipitation, *e.g.* pre-nucleation cluster stability, time of nucleation, solubilities of the subsequently-formed phases, and on further phase transformations to the various crystalline polymorphs. Beyond insight into the fundamentals of biomineralization, understanding of the effect of additives on crystallization is also crucial in the creation of biomimetic materials and the formulation of novel anti-scalant methods of industrial importance.

3D visualisation of core formation in deforming planetesimals

M. BERG*[1], I.B.BUTLER[1], S.REDFERN[2], Y.LEGODEC[3] AND G.D. BROMILEY[1,4]

[1]School of Geosciences, Grant Institute, University of Edinburgh, Edinburgh, UK maddy.berg@ed.ac.uk*
[2]Dept. Earth Sciences, University of Cambridge, UK
[3]Inst. de minéralogie et de phisique condensés, Université Pierre et Marie Curie, Paris, France
[4]Centre for Science at Extreme Conditions, University of Edinburgh, Edinburgh, UK

Deformation may significantly enhance permeability of small fractions of metallic melt in a solid silicate [1]. This is an important factor in constraining processes of core formation, as a permeable network in solid silicate could have led to segregation of a core and mantle much earlier than previously thought, importantly long before the onset of a molten silicate 'Magma Ocean'. Few experiments examine effects of low strain-rate deformation at realistic conditions of core formation in small planetary bodies. In addition, 3D melt geometry and permeability is usually inferred indirectly from 2D textural analysis of polished sample slices.

We have conducted experiments on a synthetic solid olivine – liquid FeS system at extreme P-T conditions using the rotational Paris-Edinburgh Cell (roPEC), and have analysed 3D melt geometry of quenched samples have using micro- and nano-tomographic imaging techniques. Deformation at strain rates as low as 10^{-6} s^{-1} aids grain boundary wetting and the formation of melt veins that appear to locally 'drain' certain areas of the sample. Results support theories of complex, multi-stage core formation in which pre-differentiated planetary bodies collided to form the Earth. These proto-cores may have sunk directly to the Earth's centre without re-equilibration with the Earth's mantle, which has major implications for the inferred geochemical composition of the lower mantle [2].

Voluminous outburst of silicic low $\delta^{18}O$ magma in NE-Iceland inferred from zircon $\delta^{18}O$ and U-Pb geochronology

BERG S. E.[12]*, TROLL, V. R.[2], RIISHUUS, M. S.[1], BURCHARDT, S.[2], DEEGAN, F. M.[23] AND HARRIS, C.[4]

[1] Nordic Volcanological Center, Reykjavik, Iceland (*sylvia@hi.is)

[2]Dept. of Earth Science, CEMPEG, Uppsala University, Sweden

[3]Laboratory for Isotope Geology, Swedish Museum of Natural History, SE-104 05 Stockholm, Sweden

[4]Dept. of Geological Sciences, University of Cape Town, Rondebosch, South Africa

The Borgarfjörður Eystri area in NE-Iceland represents the second-most voluminous outcrop of silicic eruptive rocks in Iceland and is a superb locality to unravel bimodal volcanism (c.f. "Bunsen-Daly" compositional gap), which has struck petrologists as abnormal for this tectonic setting for decades. Several explanations have been proposed; closed system fractional crystallisation, partial melting of hydrothermally altered crust, or partial melting of an underlying fragment of old continental or oceanic crust. To contribute to a solution to this issue we focus on zircon to unravel the origin, timing and evolution of voluminous evolved rhyolites in the Neogene silicic volcano complexes in the greater Borgarfjörður Eystri area. We report zircon U-Pb geochronology and $\delta^{18}O$ values measured by SIMS, and on whole rock $\delta^{18}O$ values of felsic and intermediate units from Dyrfjöll and Breiðavik central volcanoes. With this new dataset we are able to decipher timing, primary magmatic processes, as well as contamination and/or post emplacement alteration. Zircon U-Pb ages of key units reveal prolonged silicic activity represented by several rhyolite flows as the systems were gradually building up (from 13.42 ± 0.15 to 12.79 ± 0.15 Ma), followed by explosive caldera forming volcanism in the Breiðavik and Dyrfjöll centres (12.44 ± 0.27 and 12.40 ± 0.19 Ma). The lifetime of these volcanic centres ended abruptly with eruption of a dacite flow at 12.26 ± 0.33 Ma and younger basaltic volcanism. Zircon $\delta^{18}O$ values range from 1.1 to 4.7 ‰ (n = 179), corresponding to $\delta^{18}O_{(magma)}$ values of 3.3 to 6.0 ‰. These data imply significant contamination by hydrothermally altered crust. Whole rock $\delta^{18}O$ values ranging from 2.9 to 18.5, confirm contamination by hydrothermally altered material but also indicate the influence of low-temperature alteration in some samples. We propose a relatively short, though violent, eruptive episode of the Borgarfjörður Eystri volcanoes, with voluminous and explosive outbursts of felsic volcanics from a low $\delta^{18}O$ magma source, likely spanning 1 M.yrs. in total duration.

Pyroxenites and the construction of oceanic arc roots

J. BERGER[1], R. CABY[2] AND J-P. BURG[1]

[1]Geological Institute, ETH Zurich, 8092 Zurich, Switzerland (julien.berger@erdw.ethz.ch)

[2]Géosciences Montpellier, Université de Montpellier II, 34095 Montpellier, France

Pyroxenites are a major component of arc roots. They bear important information on the igneous and metamorphic evolution of arcs. In the Jijal and Sapat complexes of the Cretaceous Kohistan oceanic arc (Himalaya, Pakistan), pyroxenites formed by reactive flow of basalts within residual mantle peridotites [1,2]. In the Talkeetna Jurassic arc (Alaska), pyroxenites are high-pressure fractionation products of primitive hydrous basalts [3].

The Neoproterozoic Amalaoulaou oceanic arc root (Gourma belt, West Africa) exposes dykes of spinel and garnet pyroxenites cutting across interlayered garnet granulites and plagioclase pyroxenites [4]. Spinel pyroxenites were crystallized at about 1.0 GPa. Isobaric cooling down to 850-900 ºC induced the formation of garnet around spinel. In the vicinty of the pyroxenite dykes, lower crustal gabbros were partially molten leading to the formation of garnet granulites and garnet-clinopyroxene-rutile residues.

Spinel pyroxenites were fractionated from a primitive hydrous basalt (Mg# ~ 60-70). Calculated equilibrium liquids are similar to melt-like hornblende gabbros forming the middle to lower crust of the Amalaoulaou arc. One peculiar orthopyroxene-rich spinel pyroxenite found as a xenolith within the garnet granulites shows high Mg# and Cr content but high incompatible elements contents (LREE, Zr, Nb). It is interpreted as a product of melt-peridotite reaction before the intrusion of the garnet granulite precursor.

The strong planar-linear, high-temperature fabric of spinel pyroxenites in dykes is oblique to layering and metamorphic foliation of garnet granulites. These dykes are representing magma paths where the primitive mantle-derived basalt differentiated en-route by segregation of pyroxene and spinel. The Kohistan and Amalaoulaou complexes do not display a thick sequence of cumulate pyroxenites. Instead, scattered cumulate pyroxenites resulted from fractionation and/or melt-rock reaction in dykes or channels.

Fluoride in groundwaters of regolith and bedrock (0-900 meters depth) in a granitoidic setting, SE Sweden

T. BERGER[1]*, F. MATHURIN[1], H. DRAKE[1] AND M.ÅSTRÖM[1]

[1] School of Natural Sciences, Linnaeus University, 39233 SE-Kalmar
(*correspondence: tobias.berger@lnu.se)

Parts of Scandinavia show elevated fluoride in groundwaters which can be linked to the igneous host bedrocks of the Baltic Schield [1]. We investigated fluoride in groundwaters down to 900 meters depth in a small area located in southeastern Sweden. Just north and south of the study area intrusions of fluorine-rich (average 0.43 wt%) 1.45 Ga old granites are situated [2, 3]. Fluoride in private excavated wells are approximately five times higher here compared to Sweden in general [4]. Groundwaters in regolith (boreholes with plastic-casings; 0.3 mm slot screens) and fractures in the bedrock (boreholes with packed-off sections) were monitored for several years and were evaluated with respect to fluoride hydrogeochemistry. In addition, fluorine content in the host rock minerals have been investigated using wavelength dispersive spectrometry.

Fluoride in the regolith groundwaters ranged from below level of detection (LOD, <0.2 mg/L) to 5.1 mg/L (median 1.4 mg/L) and were overall stable over time. In the bedrock groundwaters, concentrations ranged from below LOD to 7.4 mg/L (median 2.7 mg/L). The area closest to the Götemar granite showed the highest fluoride concentrations in both water types, which suggests presence of F-rich secondary mineral coatings on fracture walls (fluorite is overrepresented here) and F-rich glacial deposits originating from the intrusion of the Götemar granite as major sources.

This granite and associated greisen contain higher amounts of F-rich fluorite and apatite, than surrounding rocks and in addition, biotite, muscovite and apatite are much more F-rich. Further on, the fluoride concentrations in the bedrock groundwaters increased closer to the surface in waters classified as of meteoric origin [5]. This pattern may indicate a downward transport of fluoride from the regolith into the bedrock fracture system.

Carbonate clumped isotope thermometry in the subsurface

KRISTIN D. BERGMANN*[1], SAID AL-BALUSHI[2], JOHN P. GROTZINGER[1] AND JOHN M. EILER[1]

[1]California Institute of Techonology, 1200 E California Blvd Pasadena, CA 91125
(*correspondence: bergmann@caltech.edu)
[2]Petroleum Development Oman, Muscat, Sultanate of Oman

The carbonate clumped isotope thermometer potentially can be used to reconstruct the temperature and d18O of the ocean in the distant past. However, there is considerable uncertainty regarding how the thermodynamically controlled, temperature dependent abundance of carbonate groups containing both ^{13}C and ^{18}O, is affected during burial. There is evidence that both recrystallization and solid state diffusion within the crystal lattice are important processes. There is likely a time-depth dependence to these processes, though the details of these dependencies are currently poorly constrained. This study explores how the burial and exhumation history modifies the primary distribution of isotopes in host carbonates from the subsurface and surface of Oman. The study includes rocks of Eocene to Neoproterozoic age that sit at current burial depths of 360 m to 5850 m. Additionally, we analyzed exhumed carbonates from the same formations, estimated to have been buried from 1-2 km up to 8-10 km.

Results from this work suggest two dominant modes of diagenesis: 1) Texturally well preserved carbonates measured from the subsurface yield seawater compositions similar to today of around 0‰ with Phanerozoic samples yielding temperatures <40°C and Neoproterozoic samples yielding temperatures <60°C. 2) Highly recrystallized carbonates affected by low-water-to-rock diagenesis sit close to the current geothermal gradient. Samples exhumed from depths >8km yield higher temperatures (120-150°C) and very enriched fluid compositions (~8‰) and also indicate low water-to-rock diagenesis.

From shale oil to shale gas: mineralogical and geochemical evolution of Barnett Shales

S. BERNARD[1], R. WIRTH[2], A. SCHREIBER[2], H-M. SCHULZ[2] AND B. HORSFIELD[2]

[1]LMCM, UMR 7202, MNHN and CNRS, Paris, France (sbernard@mnhn.fr)

[2]GFZ German Research Centre for Geosciences, Telegrafenberg 14473 Potsdam, Germany. (wirth@gfz-potsdam.de, schreiber@gfz-potsdam.de, schulzhm@gfz-potsdam.de, horsf@gfz-potsdam.de)

Tight oil is a rapidly growing unconventional energy resource that is increasingly viewed as an abundant global commodity. An issue is that tight oil reservoirs are highly heterogenous. As a result, fluid production assignments and mixing, drainage zone definition and reservoir performance remain poorly constrained. Here, we report the characterization of samples from the organic-rich Mississippian Barnett shale gas system (Fort Worth Basin, Texas, USA) at varying stages of thermal maturation. Using a combination of compositional organic geochemistry and spectromicroscopy techniques, including transmission electron microscopy (TEM) and scanning transmission X-ray microscopy (STXM - 5.3.2.2. ALS STXM Polymer beamline [1] - 10ID-1 CLS SM beamline [2]), we document the mineralogical and geochemical evolution of the investigated samples and evidence the net increase in sample geochemical heterogeneity with increasing maturity [3]. We distinguish kerogen from bitumen in samples of oil window maturity from the estimation of aromaticity and polarity using STXM-based XANES spectroscopy. The formation of nanoporous pyrobitumen has been inferred for samples of gas window maturity, likely resulting from the formation of gaseous hydrocarbons by secondary cracking of precursor bitumens. By providing *in situ* insights into the origin and fate of organic fluids as a response to the thermal evolution of the macromolecular structure of kerogen, the present contribution constitutes an important step towards better constraining reservoiring within unconventional systems.

[4]Sibelco, Group Central Laboratory, Moneystone Quarry, Whiston, Stoke on Trent ST10, 2DZ, United Kingdom

A combination of three industrial flux compositions (sodium fedspar > 67 wt.%, potassium feldspar > 69 wt.% and a 1:1 mix of them) and two particle size distributions (d50 ≈ 45 and 75 μm) have been used to prepare sanitary-ware slips (flux amount about 25 wt.%). Samples have been fired up to 1200 °C, and then characterized in terms of water absorption, density, X-ray diffraction (at ambient and HT conditions) and micro-structure occurrence by Scanning Electron Microscopy.

Despite of the small differences in the samples, some trends have been observed. Water absorption and interconnected porosity (obtained by density measurements) are minimized if sodium feldspar is used, suggesting a better densification, in agreement with [1]. The same effect is achieved by decreasing the flux particle size, which leads to a higher reactivity of the starting slip, in keeping with [2]. The application of RIR-Rietveld method [3] to powder diffraction patterns shows that also differences in phase composition are present: in particular, the highest glass content has been observed if the smallest flux particle size is used, in combination with a sodium bearing feldspar. Moreover, observations from HT-powder diffraction experiments (thermal range 900-1100°C) do not yield significant differences in the feldspar thermal decomposition as a function of flux composition and particle size.

Microbial extracellular polymeric substances modulate the product of uranium biomineralization

R. BERNIER-LATMANI[1], P.P. SHAO[1], L.R. COMOLLI[2], M. STYLO[1], D.S. ALESSI[1] AND J.R. BARGAR[3]

[1] École Polytechnique Fédérale de Lausanne, CH-1015 Lausanne, Switzerland (* correspondence: rizlan.bernier-latmani@epfl.ch)
[2] Lawrence Berkeley National Laboratory, Berkeley, CA 94720, USA
[3]Stanford Synchrotron Radiation Lightsource, SLAC National Accelerator Laboratory, Menlo Park, CA 94025, USA

Microbial biomineralization influences the cycling and sequestration of a variety of metals and metalloids in the environment. Uranium biomineralization by *Shewanella oneidensis* MR-1 was shown to produce two distinct U(IV) products under different chemical conditions. Here, we report that the uranium product is modulated by the formation of extracellular polymeric substances (EPS), a biological response that improves cellular resistance to U toxicity. When imaged by cryo-electron microscopy and analyzed by X-ray absorption spectroscopy, the two uranium products have distinct morphologies and atomic environments. This difference is shown to be due to the presence or absence of EPS using a spectro-microscopy method –scanning transmission X-ray microscopy (STXM)– that can differentiate amongst carbon biomolecules and localize U. When EPS is present, U is largely associated with it instead of the cell surface. Furthermore, we show that when the suspected U reductases are removed by mutation, EPS production and cellular viability decrease. Hence, the structure of the product of uranium biomineralization is intricately linked to the formation of EPS. We posit that a single U(IV) product is favored in the subsurface due to the prevalence of biofilms and because EPS are major component of those structures.

Hydromagnesite reactivity in aqueous solutions

U.-N. BERNINGER[12,*], V. MAVROMATIS[1], G. JORDAN[2], J. SCHOTT[1] AND E.H. OELKERS[1]

[1]GET, CNRS, UMR 5563, Toulouse, France (* corresponding author, berninger@get.obs-mip.fr)
[2] Dept. f. Geo- u. Umweltwiss., LMU, München, Germany

Hydromagnesite ($Mg_5(CO_3)_4(OH)_2*4H_2O$) is the most common hydrous Mg-carbonate occurring at Earth's surface environments. It usually forms as a secondary phase in alkaline and Mg-rich natural waters where magnesite ($MgCO_3$) formation is inhibited by the strong hydration of aqueous Mg [1]. Formation of hydromagnesite is commonly mediated by microbiological activity [2], so that its dissolution and growth may be closely coupled to promoting primary productivity in aquatic environments.

A critical factor defining the role of minerals in natural processes is the link between their dissolution and precipitation rates. In accord with transition state theory, precipitation rates should be readily calculated from corresponding dissolution rates using simple functions of chemical affinity. This possibility has proven to be challenging to validate due to the difficulty in measuring the precipitation rates of most minerals in the laboratory. The relative ease to which hydromagnesite precipitates at ambient conditions makes it ideally suited to assess the link between dissolution and precipitation rates.

Hydromagnesite dissolution and precipitation rates have been measured in closed-system reactors from far to near to equilibrium conditions in $NaHCO_3/Na_2CO_3$ bearing aqueous solutions at pH from 8.5 to 11.2 and temperatures from 25 to 75 °C. Resulting rates (r) have been modeled using:

$$r = k(1-\Omega^{\sigma})^{n}$$

where k is the surface area normalized rate constant, Ω the saturation degree of hydromagnesite, σ the Temkin's coefficient [3] (σ = 0.2), and n the reaction order (n = 1). Preliminary data interpertation suggests that the rate constants describing dissolution are from one to two orders of magnitude faster than those describing precipitation. For example, at 25 °C and pH 8.5 dissolution and precipitation rate constants were determined to be $3.0x10^{-9}$ and $5.4x10^{-11}$ mol/m^2/s, respectively. Such differences could be attributable to the changing density of reactive sites on the mineral surface as a function of fluid saturation state.

Recovering and refurbishing of the SILNUC code, a tool to mitigate and prevent amorphous silica scaling

FERNANDO L. BERRO JIMÉNEZ[1], GIORGIO VIRGILI[1], ILARIA MINARDI[1] AND LUIGI MARINI[2]

[1] West Systems, www.westsystems.com (f.berro@westsystems.com; g.virgili@westsystems.com; i.minardi@westsystems.com)

[2] Consultant in Applied Geochemistry, I-55049, Viareggio (LU), Italy (luigimarini@appliedgeochemistry.it)

Modelling the fate of silica in geothermal brines is of utmost importance to prevent and mitigate amorphous silica scaling both in surface installations and in the geothermal reservoir upon reinjection of spent fluids.

In principle, these theoretical predictions can be done using the software code SILNUC which was written by Weres and coworkers over thirty years ago. In practice, as far as we know, only the listing of this software is presently available in their report [1]. Thus, we decided to try to recover and refurbish this code.

SILNUC models the homogeneous nucleation and growth of colloidal particles of amorphous silica. It comprises three major algorithms.

The first one is the molecular deposition or particle growth algorithm. The Runge-Kutta approach is used to compute the particle radii and the dissolved silica concentration, both as a function of time. The second one is the nucleation algorithm, which simulates the generation of classes of colloidal particles. The third one specifies the temperature, pH, and fraction of water lost through steam separation as functions of time. Review of the recent literature is also planned during refurbishing of the SILNUC code.

The oxidation states of cerium and europium in silicate melts as a function of oxygen fugacity, composition and temperature

Ce and Eu are the only rare earth elements (REE) to occur in oxidation states other than REE^{3+} under terrestrial magmatic conditions. The stability of Ce^{4+} and Eu^{2+} results in anomalous, chondrite normalised, abundances of these elements relative to the other REE due to the effect of oxidation state on trace element partitioning [1]. The link between oxidation state and oxygen fugacity (fO_2) means that fO_2 may be determined if Ce^{4+}/Ce^{3+} or Eu^{2+}/Eu^{3+} can be evaluated directly or inferred from the magnitude of an anomaly.

Ce and Eu L_{III}-edge XANES spectra were used to determine Ce^{4+}/Ce^{3+} and Eu^{2+}/Eu^{3+} in melts *in situ* [2], and quenched to glasses, as a function of fO_2 (from -14 to +6 log units relative to the quartz-fayalite-magnetite, QFM, buffer), composition (MORB plus ten Fe-free systems), temperature (1200-1500 °C) and pressure (1 atm and 1 GPa). Ce^{4+}/Ce^{3+} and Eu^{2+}/Eu^{3+} vary systematically with the thermodynamically predicted dependence on fO_2. For both elements higher oxidation states are favoured by less polymerised compositions (large values of optical basicity and NBO/T) and lower temperatures. Pressure appears to have a negligible effect. A general expression for Eu^{2+}/Eu^{3+} in geological melts has been derived. An fO_2 window, beginning near QFM, exists where both Ce^{4+} and Eu^{2+} are stable. Coexisting Ce and Eu anomalies in minerals such as zircon are thus not necessarily related to plagioclase fractionation. In Fe-bearing compositions, neither Ce^{4+}/Ce^{3+} nor Eu^{2+}/Eu^{3+} are preserved on quenching from a melt to a glass due to electron exchange reactions between Ce^{4+} and Fe^{2+} and Eu^{2+} and Fe^{3+}. This limits oxybarometry to estimates of Ce^{4+}/Ce^{3+} and Eu^{2+}/Eu^{3+} determined from partitioning derived anomalies.

Experimental investigation of K incorporation into tourmaline at high temperature and pressure

ELEANOR J. BERRYMAN[1]*, BERND WUNDER[2] AND GERHARD FRANZ[1]

[1]Technische Universität Berlin, Ackerstr. 75, 13355 Berlin, Germany (*correspondence: eleanor.berryman@mailbox.tu-berlin.de)

[2]GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany

Tourmaline's extensive stability in pressure-temperature space and ability to incorporate a multitude of elements in its structure have motivated investigation into its potential as a recorder of its formation conditions, especially in terms of temperature and composition [1]. However, the discovery of microdiamond-bearing K-dominant dravitic tourmaline, with up to 0.576 apfu K (2.76 wt.% K_2O), in the Kokchetav Massif, Kazakhstan, [2] has increased interest in the relationship between formation pressure and tourmaline's composition, particularly with respect to the incorporation of K. Indeed, a comparison of tourmaline's composition with its inclusion mineralogy has revealed a correlation between K incorporation and increasing pressure [3]. However, whether or not the presence of microdiamond inclusions is sufficient evidence for high pressure formation of K-dominant tourmaline has been questioned [4].

A series of piston-cylinder and hydrothermal synthesis experiments was conducted to begin addressing the absence of experimental data on K-bearing tourmaline and to investigate the effect of pressure and fluid composition on the Na/K ratio of hydrothermal dravitic tourmaline ($NaMg_3Al_6Si_6O_{18}(BO_3)_3(OH)_3OH$). Approximate unit cell dimensions were determined by Rietveld refinement of X-ray diffraction patterns and chemical formulae were calculated from electron microprobe analyses. To date, the highest pressure and temperature conditions investigated (40 kbar, 700°C) have yielded dravitic tourmaline with up to 0.7 apfu K when exposed to a pure KCl fluid. This is the first time Na-absent "potassium dravite" has been synthesized experimentally.

Deconstructing the dissimilatory sulfate reduction pathway: Isotope fractionation of a mutant unable to grow on sulfate

EMMA BERTRAN[1], WILLAM D. LEAVITT[2], ANDRÉ PELLERIN[1], GRANT M. ZANE[3], JUDY D. WALL[3], DAVID T. JOHNSTON[2] AND BOSWELL A. WING[14]

[4]Department of Environmental Sciences, Weizman Institute of Science

Dissimilatory sulfate reduction plays a significant role in shaping the sulfur isotope composition of sedimentary sulfides, which are, in turn, a record of Earth's surface redox history. The fractionation produced by this microbial metabolism is controlled by the flux of sulfur through the respiratory reaction network and the isotopic effect associated with each reaction. Although the net isotope fractionations of this metabolism have been well studied, unravelling the isotopic influence of each component of its pathway is still a challenge. The sulfite to sulfide reduction step is a particularly complicated one. Its full biochemistry is not fully understood and the associated isotope effect is inferred from fractionations associated with the entire metabolic pathway. Here, we investigated a mutant strain of *Desulfovibrio vulgaris* Hildenborough in batch and continous culture to address these issues. This deletion mutant is missing its QmoABC complex, a principal enzyme in the reduction of adenosine phosphosulfate (APS) to sulfite. Thus, this strain is incapable of using sulfate as a terminal electron acceptor. By hindering APS reduction, this mutation also eliminates sulfite disproportionation. In all experiments, lactate and sulfite consumption are concomitant with sulfide and thiosulfate production. Rates of thiosulfate production were one order of magnitude larger in batch than continuous culture experiments. Results from batch culture show a $\delta^{34}S$ between sulfite and sulfide of ≈ -9 ‰. The two components of the thiosulfate pool (sulfonate and sulfane moieties) present a large $^{34}S/^{32}S$ fractionation, with sulfonate more ^{34}S enriched than sulfane by 30 ‰. However, the net fractionation between thiosulfate and sulfite is ≈ +1 ‰. This is inconsistent with isotopic observations of abiotic thiosulfate formation. Steady-state models are presented to understand the mechanism of fractionation during sulfite reduction and incorporate this step into the overall metabolism of sulfate reduction.

In-Situ Monitoring Of Water-Rock Interaction By Micro FT-IR- An Example Of Calcium Silicate Hydrate Formation-

HIROKI BESSHO[1]*, SATORU NAKASHIMA[1], MAI HAMAMOTO[1], NAOKI NISHIYAMA[1], RYOTA TONOUE[1], YUSUKE KIRINO[1], TADASHI YOKOYAMA[1] AND HIROSHI SASAMOTO[2]

[1]1Department of Earth and Space Science, Graduate School of Science, Osaka University, Toyonaka 560-0043, Japan (*Corresponding author: hbessho@ess.sci.osaka-u.ac.jp)
[2]Japan Atomic Energy Agency. Tokai 319-1194, Japan

In the geological disposal of high level radioactive wastes, cementitous grout materials are planned to be used and Calcium Silicate Hydrates (C-S-Hs) are supposed to be formed by water-rock interactions. The current study presents a new methodology of monitoring the C-S-H formation *in situ* by micro Fourier transform infrared (FT-IR) spectroscopy.

An *in situ* hydrothermal cell was constructed from titanium alloy with a diamond window to allow the transmission of an IR beam (Fig.1). In this study, thin sections of quartz were placed in the cell, with the remaining space filled with saturated $Ca(OH)_2$ solution. The *in situ* hydrothermal cell was then sealed and heated at 140 °C at a pressure of 3 MPa. IR spectra were collected every 5 minutes for 24 hours using an IR microspectrometer.

Fig.1

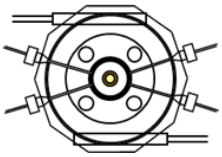

Fig.2

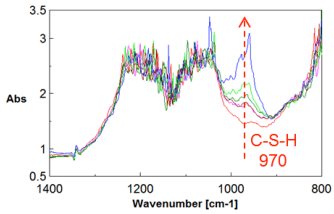

Fig.1 The schematic figure of the *in situ* hydrothermal cell
Fig.2 Infrared spectral changes with time for 5 hours at 140 °C. The absorption band around 970 cm^{-1} (C-S-H) increased with time.

An IR absorption band around 970 cm^{-1} due to stretching vibration of Si-OH increased with time indicating the increasing formation of C-S-H (Fig.2). The temporal changes with 5 minute intervals of the peak heights in the first 240 minutes can be used to determine apparent formation rate constants of the C-S-H. Based on these experimentally determined kinetic parameters, mechanisms and rates of the C-S-H formation processes can be discussed.

Water in Na montmorillonite - A neutron scattering study

M. BESTEL[14]*, F. JURANYI[1], T. GIMMI[24], M. A. GLAUS[2], L. R. VAN LOON[2], M. ZAMPONI[3] AND L. W. DIAMOND[4]

[1]Laboratory for Neutron Scattering, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland (*correspondance: martina.bestel@psi.ch)
[2]Laboratory for Waste Management, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland
[3]Forschungszentrum Jülich, Centre for Neutron Science at FRM II, 85747 Garching, Germany
[4]Institute of Geological Sciences, University of Bern, 3012 Bern, Switzerland

Swelling clays, like Na montmorillonite, are important sealing materials for radioactive waste repositories. The negative charge of crystalline layers is compensated by cations surrounded by water in interlayers. At low hydration, all water is located in interlayers in up to 2 molecular water layers; at higher hydration, interparticle pores between clay particles also contain water.

To model and understand transport properties, e.g. water diffusion, it is important to know the water distribution at different hydrations and densities. Relative fractions of water in the two pore environments were measured directly and for the first time using Fixed Window scans on a neutron backscattering spectrometer. The decisive parameter was found to be the water content (total water / dry clay). In the range from 0 to 0.7 g/g the obtained water amount in the interparticle pores increases monotonically, but not linearly from 0 to 64%. These results were compared with values obtained based on surface area measurements.

They were also used to derive local diffusion coefficients from quasielastic neutron scattering. In the literature local diffusion coefficients can be found only for low hydrations (1 or 2 water layer) because of the difficulties in interpretation of the spectra when more than one water population exists. Here, from our combination of methods (quasielastic neutron scattering and fixed window scans) we can present local diffusion coefficients for up to 4 water layer in the interlayers.

Carbon flow from volcanic CO_2 into soil microbial communities of a wetland mofette

F. BEULIG*[1], D. M. AKOB[2], B. VIEHWEGER[3], M. ELVERT[3], V. HEUER[3], K.-U. HINRICHS[3] AND K. KÜSEL[1]

[1] Friedrich Schiller University Jena, 07743 Jena, Germany (*Correspondence: felix.beulig@uni-jena.de)
[2] U.S. Geological Survey, 430 Reston, Virginia
[3] University of Bremen, 28359 Bremen, Germany

We investigated mofettes, i.e., cold Volcanic CO_2 exhausts, in a wetland area in the NW Czech Republic. Here, continous emanations of CO_2 lead to lower pH and anoxic conditions. Recent findings suggest that such alteration might cause a shift of the microbial community towards anaerobic and acidophilic organisms.

In this study we i) analyzed differences in the active archaeal and bacterial community structure in different depths of a mofette compared to the surrounding wetland soil by 16S rRNA pyrosequencing and ii) used DNA- and lipid-based ^{13}C-CO_2 Stable Isotope Probing (SIP) to identfy microbial communities which can incorporate the emanating CO_2.

16S rRNA pyrosequencing revealed that the overall active bacterial community composition was similar for the mofette and reference soil in all sampled depths. However, in the mofette soil *Acidobacteria* showed a higher relative contribution (55% to 70%) compared to the wetland reference (17% to 22%) primarily consisting of sequences closely related to Cand. *Koribacter* sp. and isolate „Ellin 624“ of Subdivision 1. The active archaeal community of the mofette soil was dominated by methanogens in all depths which were not represented in the wetland reference soil.

Analysis of incorporation of ^{13}C-labeled CO_2 into PLFAs and ether-lipid derived hydrocarbons in the mofette soil showed continuous enrichment over 28 days in almost all bacterial and archaeal biomarkers. Archaeal CO_2 utilization was restricted to the first 10 cm of the soil, while a depth-independent labeling pattern was found for bacterial biomarkers. Archaeal 16S rRNA and formyl tetrahydrofolate synthetase (*fhs*) gene labeling analysis of the first 10 cm suggested that $^{13}CO_2$ was potentially utilized chemolithoautotrophically by two novel groups of acetogens and methanogens, with the latter primarily being affiliated with the family *Methanoregulaceae*. On the other hand, bacterial 16S rRNA gene labeling analysis indicated a non-obligate autotrophic utilization of $^{13}CO_2$ by bacterial families of the *Anaerolineaceae*, unclassified *Bacteroidetes* and *Syntrophaceae*.

Characterization of hydrocarbon and functionalized silica nanoparticle adsorption on mineral surfaces through advanced First Principles techniques

ROCHELE C.A. BEVILAQUA[1], V. A. RIGO[1] AND CAETANO R. MIRANDA[1]*

[1] Universidade Federal do ABC – UFABC - Santo André-SP – Brazil – caetano.miranda@ufabc.edu.br

Atomistic simulations have come to play an increasingly important role in advancing understanding of the fundamental properties related to the hydrocarbon and nanoparticles interaction with mineral surfaces. In this work, we will present an integrated methodology based on First Principles methods to characterize the surface properties (structural, energetic and electronic) and the adsorption of hydrocarbons and funcionalized (hydroxylated, sulphonic acid and pegylated) SiO_2 nanoparticles within mineral surfaces (Carbonate and Silicates). The simulations were based on the Density Functional Theory (DFT) with solid state Nuclear Magnetic Resonance calculations (1) and simulation of noncontact Atomic Force Microscopy (nc-AFM) (2) including van der Waals corrections (3). It was possible to assign the peaks in the NMR spectra for all structures studied and determine the force distance models based on simulated AFM. Our results show a chemical shift differentiation for atoms located on different sites (bulk and surface) for calcite and silicate systems as well as the differences on force versus distance curves. Interestingly, the presence of hydrocarbon molecules also modifies the chemical shift of adsorbed the Ca and Si sites with respect to the pristine and isolated surfaces. Calculated AFM forces allow us the differentiation between the different chemical sites and a clear understanding of the adsorption processes. Within the combining theoretical AFM and NMR simulations with DFT with van de Waals, it should be possible to elucidate the coordination environment of chemical species in many important complex materials in the context of geochemical phenomena.

Strata-specific bacterial diversity in aquifers of the Thuringian Basin/Germany

A. BEYER[12]*, K. BUROW[1], E. KOTHE[1] AND G. BÜCHEL[2]

[1] Institute of Microbiology – Microbial Communication, Friedrich Schiller Univ., Jena, D 07743, Germany (*correspondence: andrea.beyer@uni-jena.de,
[2] Institute of Applied Geology, Friedrich Schiller Univ., Jena, D 07743, Germany

The INFLUINS (Integrated fluid dynamics in sedimentary basins) project investigates coupled dynamics of near surface and deep flow patterns of fluids, transported materials and component substances in the Thuringian Basin. The extensive basin landscape is located in eastern Germany and belongs to the Triassic period of Bunter sandstone (Buntsandstein), shell limestone (Muschelkalk) and Keuper, which crop out at the surface. Older sediments and Permian (Zechstein) can be found at the edges of the basin.

With microbial investigations, we are analyzing the bacterial diversity of groundwater at different locations to see whether there are special patterns in bacterial distributions originating from the different rock strata. Furthermore, we are interested in the bacterial diversity of drilling cores and salt formations from the same locations. This will facilitate understanding fluid movement in the Thuringian Basin. We determined bacterial community from water samples out of nine natural springs and sixteen groundwater wells by cultivation and subsequent morphological, physiological and molecular identification.

First results show that the largest proportions were found to be members of Bacilli and γ- proteobacteria, including the genera *Pseudomonas*, *Marinomonas, Bacillus, Marinobacter* and *Pseudoalteromonas*.

Next steps will be a comparison of cultivation-dependent and cultivation-independent methods to gain further information on bacterial strains which where uncultivable or suppressed by other bacteria strains.

Experimental Calibration of a Garnet-Clinopyroxene Geobarometer for Mantle Eclogites

BEYER, C[1]* AND FROST, DJ[1]

[1]Bayerisches Geoinsitut, University of Bayreuth, 95440 Bayreuth, Germany (*christopher.beyer@uni-bayreuth.de)

We present a geobarometer applicable to eclogitic mantle xenoliths based on the exchange reaction involving the incorporation of Al in 4-fold coordination present as Ca-Tschermak in omphacitic clinopyroxene coexisting with garnet solid solutions. The barometer is calibrated with piston cylinder and multi-anvil experiments between pressures of 3 to 7 GPa and temperatures from 1200 to 1542 °C. Starting materials are synthetic mixtures of varying basalt compositions (hydrous N-MORB), yielding a homogeneous bimineralic garnet-clinopyroxene phase assemblage. We expand our own data set by implementing additional experimental studies conducted in eclogitic systems granting the applicability to a wider range of eclogitic compositions. All experiments are buffered in terms of Al with garnet as the Al-bearing phase. Our calibration reproduces the experimental pressures with 0.4 GPa within the 95% confidence interval. The barometer was then tested with natural eclogites from various mantle xenolith locations covering a wide P-T-X regime. The herein presented barometer opens up the possibility to determine pressures of formation for bimineralic eclogite xenoliths without requiring additional accessory phases. With this barometer we provide an additional tool to investigate the P-T state of upper mantle heterogeneities.

Organic carbon export in Taiwan: insights from marine sediments

OLIVIER BEYSSAC[1], VALIER GALY[2] AND CHIH-CHIEH SU[3]

[3] National Taiwan University, Taiwan.

Terrestrial organic C (OC) delivered to the ocean by rivers is a mix of recent OC and fossil OC derived from erosion of rocks. Burial of fossil OC in marine sediments is a simple recycling of reduced carbon and has no effect on atmospheric CO_2 and O_2 levels. Conversely, its oxidation consumes atmospheric O_2 and returns CO_2 to the atmosphere. In large-scale erosion systems (Himalaya), only graphite resists to oxidation during river transport and/or transient storage in floodplains. In contrast, disordered fossil OC observed in mountainous bedrocks and mountain rivers disappear during transport in large rivers, and are not observed in marine sediments [1]. In addition, such large scale systems may act like a CO_2 pump as a huge amount of modern OC is delivered and buried in the Bengal Fan marine sediments [2].

Here, we investigate the isotopic composition (^{14}C, ^{13}C), organic geochemistry and structure (Raman spectroscopy) of OC in recent turbidite deposits all around Taiwan. We show that the bulk OC is primarily composed by terrestrial modern and fossil OC, but also includes marine OC. We discuss the geochemistry of OC in marine sediments with respect to the modern and fossil OC sources on the Taiwan island. We quantify the respective contributions of these three end-members to the total OC, and discuss the sediments provenance based on the structure and geochemistry of fossil OC. Comparison of the OC in marine sediments with data existing for Taiwanese rivers [3] allows for discussing the carbon budget of erosion. In particular, unlike large-scale systems, fossil OC is massively transfered to marine sediments during erosion in Taiwan. Globally, such small-scale systems with very active erosion and short transfer to the ocean may act as an important sink for OC in the long-term carbon cycle.

Assimilation of sediments embedded in the oceanic arc crust: myth or reality?

R. BEZARD[12]*, J.P. DAVIDSON[1], S. TURNER[2], C.G. MACPHERSON[1], J.M. LINDSAY[3] AND A.J. BOYCE[4]

*rachel.bezard@mq.edu.au

Volcanic products from oceanic arcs afford a unique opportunity to study the subduction factory. Although most of these products are not primitive, the impact of assimilation of the arc crust is often ignored with the consequence that trace element and isotopic compositions are commonly attributed only to varying contributions from different source components. This jeopardises the integrity of recycling mass balance calculations. Here we use Sr and O isotope mineral data from a suite of volcanic rocks from the Lesser Antilles arc to show that assimilation can be significant in oceanic arc basement. Analysis of $^{87}Sr/^{86}Sr$ in single plagioclase phenocrysts from the Soufrière Volcanic Complex (St Lucia) reveal isotopic heterogeneity within and among hand samples ranging from 0.7083 to 0.7094. $\delta^{18}O$ measurements show extreme variation beyond the mantle range: up to +10.9‰ for plagioclase, +11.8‰ for quartz, +9.8‰ for amphibole and +9.5‰ for pyroxene. Such $^{87}Sr/^{86}Sr$ isotope disequilibrium and extreme $\delta^{18}O$ values strongly argue for assimilation of material located within the arc crust. A positive correlation between mineral $\delta^{18}O$ and the whole rock radiogenic isotopes shows that assimilation seems to be responsible for the isotopic heterogeneity observed in St Lucia but also in the whole Lesser Antilles since St Lucia covers almost the whole-arc range of isotopic composition. This highlights the need for detailed mineral-scale investigation of oceanic arcs suites to quantify differentiation that could lead to misinterpretation of source composition and subduction processes.

Constraining the Thermal History of an Ultra-hot Orogen from Metamorphic Reaction History and Garnet-Orthopyroxene Diffusion Modelling Studies

S.K.BHOWMIK[1]*AND S. CHAKRABORTY[2]

[1]Department of Geology & Geophysics, Indian Institute of Technology, Kharagpur 721 302, India (*correspondence: santanu@gg.iitkgp.ernet.in)
[2] Institut fuer Geologie, Mineralogie und Geophysik Ruhr-Universitaet Bochum, D-44780, Germany (Sumit.Chakraborty@rub.de)

The southern margin of the Central Indian Tectonic Zone experienced a history of metamorphism at different sets of conditions during the Proterozoic. A primary, high temperature assemblage of aluminous orthopyroxene (X_{Mg}= 0.585) + calcic plagioclase (An_{49-52}) + magnesian ilmenite (X_{MgTiO3} = 0.06-0.07) experienced three recrystallization events (M_1 with a T_{Max} of ~1000 °C at 9.5 kbar and M_2 at 900°C, 6.7 kbar and M3 at 770°C, 7.5 kbar) to produce two generations of garnet, orthopyroxene and biotite. We have integrated observations on metamorphic reaction textures, mineral compositional zonation, calculated pseudosections, available geochronological data, and diffusion modelling of compositional profiles in garnet and orthopyroxene to constrain the timescale of thermal evolution for this complex sequence. We find that at least a three stage thermal history is necessary to account for all observations consistently. Cooling rates on the order of 10's of °C/ my indicate that high temperatures of M_{1-3} metamorphism were sustained for tens of million years, providing evidence of a long lasting (i.e. > 60 my) regional metamorphic event.

The origins of detrital clays on the East China Sea shelf

L. BI[1], S. Y. YANG[1]*, C. LI[1], Q. WANG[1] AND J.T. LIU[2]

[1] State Key Lab. of Marine Geology, Tongji Uni., Shanghai 200092, China (*correspondence: syyang@tongji.edu.cn)
[2]Institute of Marine Geology and Chemistry, National Sun Yat-sen University, Kaohsiung, Taiwan 80424

There are two kinds of sediment source-to-sink (S2S) systems on the East China Sea shelf. One is "large river/delta – wide shelf – huge input – slower sediment transfer – strong anthropogenic impact" represented by the Changjiang (Yangtze) River; another is "mountainous river – narrow shelf – huge input – rapid sediment transfer – extreme climate event" represented by the rivers in Taiwan Island. To study the contributions of these two S2S systems to clayey sediments accumulated on the shelf, a total of 66 clay samples were selected from the shelf, the Changjiang and mountainous rivers entering the East China Sea. A multivariate analysis technique (EOF) was used to process elemental geochemical data.

The covariance between elements explained by the first two eigenmodes is about 76%. The first mode can explain about 62% of the data variability, in which elements are divided into two groups according to the sign of their eigenvectors. One group is dominated by Ca, Fe, Mg, Mn, P, Co and another by Al, Si, K, Na, Ti and REE. We interpret Mode 1 to be different clay mineral assemblages in the source areas. The second mode can explain about 14% of the data variability. One group consists of K, Na, Rb and LREE while the other elements belong to another group. Mode 2 probably indicates the proportion of non-clay minerals in the clay sediments. Based on the corresponding eigenweights of each sample, the spatial distribution patterns of the clays were revealed. The clay from the Changjiang River was primarily transported southeastward and formed an inner shelf mud belt that mixes with the Taiwan-derived clays in northern Taiwan Strait. Some clay from the Changjiang River may disperse eastward and mix with the clay sourced from the old Yellow River delta in the southwestern Yellow Sea. The oceanic circulation in the East China Sea predominately controls the dispersal and deposition of detrital clays on the shelf.

Enhanced stability and inhibited dissolution of uraninite by nanoparticulate iron sulfide under oxic conditions

YUQIANG BI AND KIM HAYES*

University of Michigan, Ann Arbor, Michigan 48109, USA
(*correspondence: ford@umich.edu)

Redox transition of uranium from dissolved U(VI) species to insoluble U(IV) precipitates can result in successful sequestration of uranium in contaminated soils and sediments. Recent studies have shown that naturally-occuring mackinawite (FeS) can provide an electron source for U(VI) reduction and retard uraninite reoxidation upon oxygen intrusion[1]. However, few studies have provided mechanistic and kinetic information on the interactions of uraninite with FeS solid under oxic conditions. The present study investigated the mechanism(s) and reaction kinetics of inhibited U(IV) reoxidation and transport by nanoparticulate FeS. The oxidative dissolution of uraninite by dissolved oxygen (DO) in FeS-bearing groundwater were conducted using batch and flow-through reactors as a function of pH, FeS content, DO and calcium concentrations, to assess the impact of critical geochemical factors on UO_2 dissolution kinetics. The results indicated that the dissolution rate of UO_2 decreased by an order of magnitude when FeS was present relative to control. The rate decreased rapidly with decreasing DO levels and increasing FeS content. In the presence of Ca^{2+}, the rate was even lowered owing to the formation of Ca-containing passivation layer on uraninite surfaces. Until the depletion of FeS, DO concentration remained at significantly low levels, suggesting FeS was an effective oxygen scavenger. During the inhibition period, dissolved Fe(II), Fe(III) hydroxides, and elemental sulfur were produced from FeS oxidation. In contrast, uraninte remained as U(IV) solid as verified by X-ray absorption spectroscopy (XAS) and X-ray photoelectron spectroscopy (XPS). Although dissolved Fe(II) was not shown to reduce U(VI) under oxic conditions, residue FeS particles was responsible for inhibiting UO_2 dissolution by reducing soluble U(VI). This study suggests that naturally-occuring FeS may serve as an oxygen scavenger and a U(VI) reductant for effective uranium sequestration. These findings have direct implications for our understanding of uranium redox transition and long-term stability in the subsurface.

The Mesozoic dolomites of the Levant margin - evaluating dolomitization style and mechanism from configuration and stable isotope geochemistry

O.M. BIALIK[1]*, I. HALEVY[1] AND J.A. HIGGINS[2]

[1]Weizmann Institute of Science, Rehovot 76100, Israel
or.bialik@weizmann.ac.il (*correspondence)
[2]Princeton University, Princeton, NJ 08544, USA.

The record of the Levantine margin provides a unique window into dolomitization through the Mesozoic [1] and dolomitization in general. Ample carbonate sediments have accumulated through the Triassic, Jurassic and Cretaceous in this region, maintained at relatively shallow burial depth [2], and currently exposed at the surface. We examined the depositional configuration, and the geochemical and stable isotope compositions across several limestone-dolostone transitions, with the intention of inferring the paleoenvironmental trends leading to these transitions and the style of dolomitization in these rocks.

Sequences where selected based on the presence of repeated interchanges between limestone and dolostone, in settings where the occurrence of the dolomite is likely to be derived from early diagenetic processes and interaction with marine or evaporated marine water. Three different settings were targeted: *i)* sub-tidal, open marine, evaporite-free (Cretaceous), *ii)* intertidal, open marine, evaporite-free (Jurassic), and *iii)* restricted lagoon, in association with sulphate evaporites (Triassic). In each case, a cross-section was sampled at a spatial resolution of about 50 cm to evaluate lithological changes and variability in stable isotope ratios. Following the identification of transitions of interest, these were sampled at a spatial resolution of 1-3 cm.

Mineralogy and Ca to Mg ratios in the carbonates were determined by X-ray diffractometry, and the isotopic ratios of carbon and oxygen ($\delta^{13}C$ and $\delta^{18}O$) were measured by mass spectrometry. Sedimentary textures were investigated in hand samples and in some cases by petrographic microscopy. The results of these analyses will be presented and their implications for mechanisms of dolomite genesis discussed. Future work will include analysis of Ca and Mg isotope ratios in the samples to further illuminate dolomitization mechanisms.

Links between diel vertical migrations and ocean oxygen

D. BIANCHI, E.D. GALBRAITH, K.A.S. MISLAN, C. STOCK, J.L. SARMIENTO AND D. CAROZZA

Diel vertical migration of zooplankton and micronekton - the largest migration on Earth, is a major but poorly quantified component of the ocean's biological pump. The impact of this migration on oceanic oxygen has received relatively little attention, partly due to the lack of a predictive framework. By using a global synthesis of acoustic data we show that diel vertical migrations are characterized by coherent large-scale patterns, which are strongly correlated with the distribution of subsurface oxygen. Open ocean oxygen minima, when present, emerge as potential refuges for vertical migrators. Including a representation of the respiratory needs of migrating populations in a three-dimensional ocean model suggests that, by focusing respiration in poorly-ventilated regions of the upper ocean, diel vertical migrations intensify oxygen depletion at the upper margin of oxygen minimum zones. This coupling between migrating animals and marine oxygen may have important implications for fisheries and oxygen minimum zone chemistry in a changing ocean.

The river Po: geochemical fluxes and related insights on weathering processes and erosion rates

BIANCHINI G.[1], MARCHINA C.[1] *, KNOELLER K.[2] AND PENNISI M.[3]

[1] Dip. Fisica e Scienze della Terra, Università di Ferrara, Italy (correspondece: *mrcchr@unife.it)
[2] Dep. Catchment Hydrology, Helmholtz Centre for Environmental Research – UFZ, Halle, Germany
[3]Istituto di Geoscienze e Georisorse, CNR, Pisa, Italy

The Alps and the Apennines both convey water and sediments to the Po river that is the most important fluvial system of the Italian Peninsula, characterized by a length of 650 Km, an hydrological basin of 74000 km^2 and an average discharge of 47 Km^3/yr. Major and trace elements, stable isotope composition of water and radiogenic strontium isotopes were used to characterize the sources and fluxes of solutes. Compared with the local meteoric isotopic signature, stable isotopes ($\delta^{18}O$ between -10.8 and -9.2; δD between -70.0 and -65.4) reveal that most of the recharge occurs in the north-western part of the basin, i.e. conveyed mainly from the highlands. Although subordinate, carbonatic lithologies are preferentially involved in the weathering processes inducing the typical Ca-HCO_3 hydrochemical facies and a specific strontium isotopic signature ($^{87}Sr/^{86}Sr$ 0.7090-0.7092) that is intermediate between that of Mesozoic carbonates (0.707-0.708) and felsic igneous and metamorphic rocks (> 0.701). The data also provide insights on the erosion and denudation rates of the orogens bordering the basin. The observed TDS (average and median of 39 measurements are 268 and 292 mg/l, respectively) suggest that a solute flux in the order of $13*10^6$ t/yr is transferred from the Po River toward the Adriatic Sea. A total erosion of $68*10^6$ t/yr is estimated within the Po River drainage basin, assuming that solute represent a fraction (of ca 20%) of the weathering products. This estimation conforms to other recent investigations [1].

CO_2 Dissolution rates during CO_2 injection: a consequence and measure of reservoir heterogeneities

M.J. BICKLE[1]*, K. DANIELS[1], J. NEUFELD[1], N. KAMPMAN[1], A. GALY[1], H.J. CHAPMAN[1], Z. ZHOU[2], B. DUBACQ[1], M. WIGLEY[1], O. WARR[2] AND C.J. BALLENTINE[2]

CO_2 dissolution during and after injection into geological storage sites is potentially an important mechanism for stabilising and securing the storage but may lead to enhanced fluid-mineral reactions with both positive and negative consequences for the security of storage. Important questions are how does reservoir heterogeneity influence CO_2 dissolution rates and does the tendency of the low-viscosity CO_2 to finger during injection increase dissolution rates? Here we evaluate the rates of possible CO_2 dissolution in an injection setting by simple pseudo-1D flow modelling with diffusion in the orthogonal direction and compare this with numerical modelling of flow and diffusion in 2D. The results show that the magnitude of CO_2 dissolved is strongly controlled by the rapid flow of brines determined by reservoir heterogeneities. The consequences for fluid-mineral reactions are that these may be strongly localised and this could have important implications for feedbacks between flow and permeability changes in reservoirs.

The results are tested against an injection experiment which utilised CO_2 injection for enhanced oil recovery (EOR) in which we monitored sampled fluid chemistries for 6 months after initiation of CO_2 injection into a five-spot pattern. Interpreting the results required 1) identifying the various water masses present in the reservoir as a consequence of a long history of water injection and then 2) modelling changes in fluid chemistry in terms of CO_2 injection and fluid mineral reactions. The results show a surprisingly rapid increase of dissolved CO_2 in the extracted brines and that this rise was accompanied by initial rapid dissolution of carbonate minerals but longer term dissolution of silicate minerals. The rates of carbonate dissolution are sufficient to cause small increases in formation porosities but these would cause significant increases in the permeability of sandstones which exhibit power law permeability-porosity relations with an exponent of ~9.

Fluid geochemistry of the deep CO_2-rich Caprese Reservoir (Northern Apennines, Italy)

G. BICOCCHI[1]. F. TASSI[12], M. BONINI[2], F. CAPECCHIACCI[2], G. RUGGIERI[2], G. CHIODINI[3], A. BUCCIANTI[1] AND O. VASELLI[1,2]

[3]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Napoli, OV, via Diocleziano 328, 80124 Napoli, Italy

The chemical and isotopic composition of (i) CO_2–rich fluids exploited from Caprese Reservoir (CR) by the ~5,000 m deep Pieve Santo Stefano 1 (PSS1) borehole located in the Upper Tiber Basin (Northern Apennines, Italy) and (ii) natural gas discharges located in the surrounding of the Mt. Fungaia ophiolitic-bearing complex (Ligurian Units), are presented and discussed.

The CR fluids are hosted in fractured dolostones layers of Burano Fm. [1] and consist of CO_2-, N_2-rich gas phase and saline (~82 g/L) NaCl brine. The $\delta^{13}C$-CO_2 and $\delta^{15}N$-N_2 values are interpreted as produced by mixing of deep fluids originated by mantle degassing and thermometamorphic processes involving Mesozoic limestones. Water isotopes and ^3H values indicate that the CR brine is recharged by a long (>50 yr) hydrologic circuit fed by meteoric precipitations.

The naturally discharging gases from the study area are fed by CR, likely due to the fact that the steep Arbia Val Marecchia Line transverse tectonic elements provide preferential paths for these deep-seated fluids, favoring their uprising up to the surface gas vents [2]. The interaction of the ascending CR gas with ophiolite-bearing Ligurian Units and Cervarola-Falterona Unit produces secondary H_2, H_2S and light hydrocarbons in Mt. Fungaia gases.

Precise U–Pb zircon CA-ID-TIMS ages and Sr isotopes for the Plana pluton, Srednogorie, Bulgaria

BIDZHOVA, L.[1]*, NEDIALKOV, R.[1], OVTCHAROVA, M.[2] AND VON QUADT, A.[3]

[1] Sofia University "St. Kliment Ohridski", Sofia, Bulgaria (*correspondence: lora.bidzhova@colostate.edu)
[2] University of Geneva (maria.ovtcharova@unige.ch)
[3] IGP, ETH, Zurich (albrecht.vonquadt@erdw.ethz.ch)

We report new, high precision CA-ID-TIMS U–Pb single zircon ages for the Plana pluton, a part of the ABTS belt in SE Europe. The pluton is located at the Central Srednogorie - Rhodopes border, ~60km SE of Sofia. *in situ* differentiation of high potassium calc alkaline magmas produced gradually varying rock compositions [1]. We analyzed a granite from the central parts of the pluton (A); and a monzogabbro-diorite from the periphery of the pluton (B).

The three youngest grains in (A) overlap and yield a weighted mean 206Pb/238U age of 77.87±0.07 Ma (2σ, MSWD=1.01), our best estimate for the crystallization age of the granite. Two zircons, interpreted as antecrysts, are concordant at ~78 Ma. The remaining two grains, interpreted as xenocrysts, are concordant at ~440 Ma. In (B), two of five grains are concordant at ~440 Ma; the remaining three zircons are discordant and older. Ages of ~440 Ma, are also reported for inherited zircons in other Upper Cretaceous intrusives and Variscan granitoids from Central and Eastern Srednogorie [2, 3, 4]. The presence of inherited zircons provides direct evidence for wall-rock assimilation.

Comparison of our data with published U-Pb ages [3, 5] suggests that the Plana pluton crystallized in the late stages of Upper Cretaceous magmatism in Srednogorie. Initial Sr isotopes of seven studied rocks are between 0.7043 and 0.7050, within the range of the least radiogenic Upper Cretaceous rocks in the Srednogorie region. Studies from Central Srednogorie show a trend toward younger and more mantle-influenced magmatism from north to south [5]. Our high precision 77.87 Ma age, and the mantle-dominated Sr isotope signature of the rocks, correlate the Plana pluton with the magmatic activity of southern Central Srednogorie.

We thank Momchil Dyulgerov and Svetoslav Georgiev for analytical help, and Judy Hannah and Holly Stein for support

Microbial selenium (Se) bioremediation is based on conversion of water soluble, toxic Se oxyanions to water insoluble, biogenic pure elemental Se of particle sizes in the nanometer range (bioNSe). The colloidal stability of the bioNSe suspensions hamper a straightforward removal and recovery by gravitational settling. BioNSe that is not removed from suspension may leave bioremediation reactors with the effluent and is subject to transport and re-oxidation to the original toxic oxyanions. For the first time, colloidal stability fields of pure bioNPSe were determined by electrophoretic mobility (ζ-potential) measurements[1] and column settling experiments (ICP-MS). It was demonstrated that circumneutral pH, commonly applied in bioremediation, prevents settling of bioNPSe, since the particles are strongly negatively charged. Counter cations and protons were used to screen efficiently this intrinsic negative charge. In this manner, settling could be significantly accelerated (up to 86.2 ± 3.5% within 0.5 h) at cation concentrations that would only increase overall treatment costs to minor extents. The ζ-potential measurements showed furthermore, that significantly dissimilar transport behaviour is to be expected in different natural waters (salt, dissolved organic matter rich), which can result in accumulation of Se in certain environments, if bioNPSe leaves bioremediation reactors.

Even though our geochemical proxy toolbox is ever increasing and our analytical techniques are getting more sophisticated, our fidelity at reading past ocean climate information has only slightly improved. This is mainly due to the fact that most relationships are still empirical and controlled by more than just the target parameter. The outstanding challenge is to open the black box and develop a mechanistic understanding of proxy incorporation and preservation. We have carried out a whole suite of laboratory experiments to better understand the calcification processes and the pathways of Mg, Sr, Ba, U and B using confocal laser microscopy, TEM, AFM and simultaneous analyses of B/Ca and $\delta^{11}B$ using femtosecond laser ablation and MC-ICP-MS. Together, the results show a high degree of biological control during calcification and proxy incorporation. We have used the benthic foraminifers *Ammonia aomoriensis*, *Amphistegina lessonii*, *Heterostegina depressa* and the planktonic foraminifer *Orbulina universa*. Lessons learned and a tentative model will be presented.

Experimental constraints on Fe isotope fractionation in fluid-melt-oxide-sulfide assemblages

LAURA BILENKER*[1], ADAM SIMON[1], CRAIG C. LUNDSTROM[2], NORBERT GAJOS[2] AND ZOLTAN ZAJACZ[3]

[1]University of Michigan, Ann Arbor, MI, USA (*bilenker@umich.edu)
[2]University of Illinois, Urbana-Champaign, IL, USA
[3]Institute of Geochemistry and Petrology, ETH Zürich

We report the first experimental data that quantify directly the effect of a fluid phase on stable iron isotope fractionation at magmatic conditions. Our investigation was stimulated by the hypothesis that degassing causes the heavy iron isotope signature measured in degassed rhyolites [1,2], but published experimental studies of iron isotope fractionation lacked a fluid phase.

We used a rhyolite melt, NaCl-bearing aqueous fluid, and magnetite or pyrrhotite. Charges were run at 400, 600, or 800°C, 150 MPa for mineral–fluid, and 800°C and 100 MPa for mineral–melt–fluid; f_{O2} was buffered at ~NNO. Isotopic compositions of starting and quenched phases were obtained by MC-ICP-MS. Time-series runs and the three-isotope method were used to assess equilibrium

Our data indicate that rhyolite melt at 800°C is isotopically lighter than co-existing fluid ($\Delta_{melt\text{-}fluid}$ ~ -0.20‰ ± 0.07 1SD).Magnetite behaves as predicted ($\Delta_{fluid\text{-}magnetite}$ ~ +0.75‰ ±0.07 1SD at 800°C), becoming isotopically heavier relative to both fluid and melt. An andesite-fluid experiment (FMQ+0.5, 1000°C, 150 MPa) yielded an isotopically lighter melt relative to the starting glass, consistent with the coexisting fluid being isotopically heavier than andesite melt. These data suggest that fluid exsolution from silica-rich melts is not the cause for the increased $^{56}Fe/^{54}Fe$ ratio in degassed rhyolites. Interestingly, magmatic and hydrothermal magnetite show distinct iron isotope signatures, suggesting that the iron isotope values of minerals deposited by these processes may serve as geochemical fingerprints of the source reservoir for iron. Additional data from sulfide runs support the observation that individual minerals can fractionate iron differently and that pyrrhotite preferentially incorporates ^{54}Fe into its structure ($\Delta_{melt\text{-}pyrrhotite}$ ~ -0.75‰ ±0.01 SD at 800°C).

These data corroborate the hypotheses that both fluid exsolution and crystal fractionation could influence the isotopic composition of a melt, but perhaps not as predicted. Owing to the importance of melt degassing as a critical process for the formation of ore deposits, our data may also help resolve debates regarding the origin of deposits that may have formed by either magmatic or hydrothermal processes.

Magmas going through Icelandic crustal filter

ILYA N. BINDEMAN[1] , ANDREY GURENKO[2], OLEG MELNIK[3] AND ALEXANDER SOBOLEV[4]

[1]Dept. of Geological Sciences, University of Oregon, Eugene, USA;
(bindeman@uoregon.edu)

[3]Univ J. Fourier, Grenoble, France
[4]Univ J. Fourier, Grenoble, France

Eruption of large-volume basalts in large igneous provinces and hotspots occurs throughout areas of preexisting thick crust and crust overloaded by early eruptions from the same plume. Iceland represents a good testing ground for estimating the amounts of upper crustal contamination of mantle-derived magma in long-lived propagating rifts - magmatic pipelines going through the isotopically fingerprinted low-$\delta^{18}O$ thick crust affected by rain and glacial meltwaters. We report analyses of individual primitive olivines across Iceland and demonstrate that the Icelandic plume is not severely depleted in ^{18}O neither contains higher than mantle values (5.2-4.6‰ for Ol >Fo_{86}). We observe a positive correlation of Fo and $\delta^{18}O$(olivine) down to Fo_{75} suggesting that crustal differentiation and assimilation is responsible for low-$\delta^{18}O$ evolved olivines and host basalts. We report new data and interpretation of oxygen isotope diversity in olivines from large volume rift basaltic eruptions and investigate in detail olivine-basalt oxygen isotopic equilibria. Up to 3‰ variations of Fo_{75} to Fo_{86} olivines suggest rapid transformation of mantle-derived magmas in the magma plumbing systems. Low- $\delta^{18}O$ values of large volume basalts (e.g. Laki, Veidivotn), with MgO <5wt%, require that tens of percent of a low-$\delta^{18}O$ mafic component was added to normal-$\delta^{18}O$ mantle derived basalt. Only limited $\delta^{18}O$ whole rock heterogeneity is present in large volume basalts suggesting effective mixing and homogenization prior to eruption. Diffusive reequilibraion of disequiibrium olivines and plagioclase require hundreds of years, and their longest residence is in the semi-frozen cumulates underneath volcanoes. Rapid transport along a bifurcating network of dikes and sills inside of the hyaloclastitic upper crust provide a viable mechanism for crystal entrainment and basalt mixing by forced convection. We provide a simple numerical model of this process. We further discuss the effect of flowing basalt in upper crustal lithologies leading to crustal melting and generation of low- $\delta^{18}O$ silicic melts with heterogeneous crystal cargos.

Rhyolites-Hard to Produce, Easy to Recycle: Isotopic diversity in zircons as petrogenetic tool

I. BINDEMAN[1], A. SIMAKIN[2], D. DREW[1] AND D. COLON[1]

[1] Dept Geological Sciences, University of Oregon, Eugene, OR, 97403, USA;
(bindeman@uoregon.edu)
[2]Inst Physics of the Earth, RAS, Moscow, Russia

Rapid pace of discovery of oxygen isotope diversity in zircons and other minerals in large volume ignimbrites worldwide suggests that this phenomenon characterize many silicic units studied so far by *in situ* methods. We report new results from calderas in the Snake River Plain: Picabo, early Bruneau, in addition to previously reported Yellowstone and Heise), Kamchatka, and rhyolites from rifts of Iceland (Askja, Hekla, Torfajokull). As low-$\delta^{18}O$ oxygen values fingerprint petrogenesis to the upper crust, these observations lead to a model of silicic magma by "double-recycling" of zircon-saturated, silicic to intermediate rocks. Initial melts are produced slowly in diverse batches and the isotopic signature of zircons record their immediate environment of growth. Next, magma batches with diverse zircons merge into larger-volume magma bodies, which mix crystals together and erupt quickly. Concave-up crystal size distributions of zircons and quartz in studied voluminous ignimbrites can be explained by just two episodes of reprecipitation.

Following the melting simulation of [1] we use visco-plastic rheology for surrounding rocks to explain the formation of magma batches generated side by side and merging them together. We observe: 1) Fast convective melting with low heat dissipation. 2) Efficient mixing on large (kilometers) horizontal scales, due to the vigorous flow field induced by compositional convective melting of silicic predecessors by superheated rhyolites. Chaotic, meter-scale vortexes of altering directions cause disintegration of the liquid parcels to diminishing size. The marker method allows us to track particle mixing (i.e., how zircons with diverse isotopic values brought together). 3) Mechanical interaction of the closely-spaced sills in hot visco-plastic upper crust with low yield stress (<100 MPas) leads to mechanical failure (both brittle and plastic) of separating screens leading to the coalescence of sills into a single body. We suggest that analogous processes of rapid two-stage segregation may characterize granitic batholith, and large supervolcanic magma bodies formed by remelting.

Space-Time Kriging of Precipitation Reconstructed at 12-km Grid Intervals from Tree-Ring Records

FRANCO BIONDI[123]

[1]DendroLab, University of Nevada, Reno, USA; franco.biondi@gmail.com
[2]CIRES, University of Colorado at Boulder, USA; Franco.Biondi@Colorado.EDU
[3]Graduate Program of Hydrologic Sciences, University of Nevada, Reno, USA; fbiondi@unr.edu

Understanding and preparing for future hydroclimatic variability greatly benefits from long (i.e., multi-century) records at seasonal to annual time steps that have been gridded at km-scale spatial intervals over a geographic region. Kriging is a geostatistical technique commonly used for optimal interpolation of environmental data, and space-time geostatistical models can improve kriging estimates when long temporal sequences of observations exist at relatively few points on the landscape. Here I present how a network of 22 tree-ring chronologies from single-leaf pinyon (Pinus monophylla) in the central Great Basin of North America was used to extend hydroclimatic records both temporally and spatially. First, the Line of Organic Correlation (LOC) method was used to reconstruct October-May total precipitation anomalies at each tree-ring site, as these ecotonal environments at the lower forest border are typically moisture limited. Individual site reconstructions were then combined using a hierarchical model of spatio-temporal kriging that produced annual anomaly maps on a 12x12 km grid during the period in common among all chronologies (1650-1976). Hydro-climatic episodes were numerically identified and modeled using their duration, magnitude, and peak. Spatial patterns were more variable during wet years than during dry years, and the evolution of drought episodes over space and time could be visualized and quantified. The most remarkable episode in the entire reconstruction was the early 1900s pluvial, followed by the late 1800s drought. The 1930s 'Dust Bowl' drought was among the top ten hydroclimatic episodes in the past few centuries. These results directly address the needs of water and natural resource managers with respect to planning for 'worst case' scenarios of drought duration and magnitude at the watershed level.

The absolute Cr isotopic ratios of the components of carbonaceous chondrites

J.L. BIRCK* AND C. GÖPEL

IPGP, 75238 Paris, France
(*correspondance: birck@ipgp.fr), (gopel@ipgp.fr)

Non linear isotopic anomalies are common for Cr in carbonaceous chondrites at the mineral scale where percent level variations are common for ^{54}Cr [1,2]. When these anomalies are small relative to the dispersion of mass discrimination during TIMS measurements, the identity of the anomalous isotope(s) is not unambiguous. For the stepwise dissolution fraction of C1 and C2 carbonaceous chondrites former experiments designate ^{54}Cr as the major varying isotope and ^{53}Cr as varying only according to ^{53}Mn decay. Nevertheless below about 10 ε variations some effects can still be present on the two normalizing isotopes ^{52}Cr and ^{50}Cr. As evaporation and condensation in the forming solar system is a credible possibility, significant fractionation can also be present between the components that constitute carbonaceous chondrites. We address this issue in this presentation.

In Orgueil, Tagish Lake, Tafassasset and Paris, dissolution fractions in which non-mass-dependent ^{54}Cr effects can spread up to close to 2% [1-3] were investigated. A Neptune MC-ICPMS was used in the medium resolution mode (M/ΔM~5000) to avoid interferences from Ar compounds in the Cr mass range. ^{53}Cr/^{52}Cr ratios are measured within a 0.05 δ (permil deviation relative to NIST 979). Radiogenic contributions on ^{53}Cr can be substracted using the TIMS data obtained on the same Cr fractions.

^{53}Cr/^{52}Cr ratios in fractions from stepwise dissolution in C1 and C2 chondrites [1-3] are identical to their respective whole rocks within 0.1 δ. This implies that despite large differences in ^{54}Cr the other three isotope: ^{50}Cr, ^{52}Cr and ^{53}Cr are initially in identical proportions in all the mineral fractions investigated with the present procedure. At present, carbonaceous chondrites seem to contain only only two primordial Cr isotopic components: one with normal ^{50}Cr, ^{52}Cr, ^{53}Cr and a deficit in ^{54}Cr, and a second one which consists of pure ^{54}Cr. Data on new, recently found carbonaceous chondrites will also be presented [4].

Protracted cooling from Neoproterozoic metamorphic events in the NW Highlands, Scotland investigated using garnet Lu-Hf and Sm-Nd geochronology

A. BIRD[12], M. F. THIRLWALL[2] AND R. STRACHAN[3]

[1]Department of Geography, Royal Holloway, Egham, Surrey, TW20 0EX, anna.bird@rhul.ac.uk
[2]Department of Earth Sciences, Royal Holloway, Egham, Surrey, TW20 0EX, m.thirlwall@es.rhul.ac.uk
[3]School of Earth & Environmental Sciences, Burnaby Road, Portsmouth, PO1 3QL, rob.strachan@port.ac.uk

The Moine Supergroup of the Northern Highland Terrane in Scotland records several orogenic events. The earliest of these is the Knoydartian (830-740 Ma). All previously published evidence for this event comes from West Inverness-shire. Lu-Hf and Sm-Nd garnet geochronology records much more widespread Neoproterozoic metamorphism, with evidence from Shetland to Mull. This data also shows that the Morar Group has been affected by the Renlandian event of the Valhalla Orogen. It also demonstrates that the younger limit of Morar Group deposition is older than previously thought (>950 Ma).

All of the samples all record a systematic difference between the Lu-Hf and Sm-Nd ages, the Sm-Nd ages being 10-20% younger than the Lu-Hf ones. Garnet cores and rims have been dated using Lu-Hf and Sm-Nd and the difference between the cores and rims is the same for both isotopic systems. This suggests that the difference between Sm-Nd and Lu-Hf is due to the difference in closure temperatures. One exception gives Lu-Hf and Sm-Nd ages which are within error and could suggest that this sample records garnet growth in both isotopic systems or relates to very fast cooling.

Iron Oxidation and Reverse Electron Flow In a Photoferrotroph

BIRD, LINA [1], NITSCHKE, WOLFGANG[2] AND NEWMAN, DIANNE *[1]

[1] California Institute of Technology, Pasadena, Ca, USA (linabird@caltech.edu)
(* correspondence: dkn@caltech.edu)
[3]CNRS Marseilles, France (nitschke@imm.cnrs.fr)

Biological iron oxidation is of interest to geobiologists as an oxygen independent mechanism of ferric iron production. *Rhodopseudomonas palustris* TIE-1 is a versatile purple phototroph with the ability to grow using ferrous iron (Fe[II]) as the sole electron donor. Previous studies showed that the *pio* operon, encoding an outer membrane porin, a decaheme cytochrome, and a high potential iron protein (HiPIP), are vital to Fe(II) oxidation. This work further explores the iron oxidation pathway through *in vitro* characterization of the HiPIP and *in vivo* visualization of photosynthetic electron transport with flash induced absorbance spectrometry. *In vitro* studies showed that the HiPIP can donate electrons to the reaction center at a rate much slower that that found in energy generation. Our *in vivo* studies, however, show that antimycin (a bc_1 complex inhibitor) blocks reduction of the quinone pool by Fe(II), indicating that electrons may reduce the quinone pool of the cell through the bc_1 complex instead of through the reaction center as previously thought. We have also found that the quinone pool of *R. palustris* TIE-1 is reduced by Fe(II) over short time scales even in mutants lacking the *pio* genes, although the precise rates of this reaction were not determined. These results indicate that the mechanisms of iron oxidation are more complex than originally thought, and that the path electrons take from Fe(II) to carbon reduction is similar to the pathway found in acidophillic Fe(II) oxidation.

Crystallization kinetics of apatite nanocrystals from amorphous calcium phosphate in water by *in situ* synchrotron powder diffraction

H. BIRKEDAL[1]*, H. LEEMREIZE[1] AND C. J. S. IBSEN[1]

[1]iNANO & Department of Chemistry, Aarhus University, Aarhus 8000, Denmark (*correspondence: hbirkedal@chem.au.dk)

Crystallization of minerals from amorphous precursor phases is emerging as a major pathway for crystallization in several systems but remains poorly understood. Here we use *in situ* X-ray diffraction to study the crystallization kinetics of nanocrystalline apatite from amorphous calcium phosphate in water. We find a striking dependence of crystallization behavior on whether K^+ or Na^+ is used as counter ion.

In situ X-ray diffraction experiments were performed with ~10 s time resolution [1, 2, 3]. The data were analyzed by Rietveld refinement procedures determining the nanocrystal size, the amount of crystalline material present, the lattice constants, and the background [1, 2]. The amorphous precursor phase was clearly observed in the first time points [2] and was gradually replaced by the nanocrystal diffraction pattern of the forming apatite phase.

The crystals were found to be formed as almost spherical crystallites that soon after formation started growing preferentially in the *c*-axis direction of the hexagonal apatite crystals giving needle-shaped nanocrystals. This rapid anisotropic growth was followed by an Ostwald ripening stage, with slower crystallite size growth rates. During this stage, growth was preferentially perpendicular to the *c*-axis slightly lowering the shape anisotropy.

Using K^+ instead of Na^+ as counter ion resulted in drastic changes in growth kinetics. Sodium allows the incorporation of dissolved carbonate into the forming apatite while potassium does not. This difference led to more rapid crystallization for sodium as a counter ion and resulted in crystallites with different sizes and size anisotropies.

The present work provides detailed insights into how anisotropic crystal morphologies develop and shows that seemingly innocent changes in environment, such as choice of counter ions may have profound impacts on crystallization behavior.

Origin of porphyries related to Cu-Mo mineralization, California-Vetas district, Colombia

THOMAS BISSIG*[1], LUIS C. MANTILLA[2] AND CRAIG J.R. HART[1]

[1]Mineral Deposit Research Unit, University of BC, Vancouver, Canada. (*correspondence: tbissig@eos.ubc.ca)

[2]Universidad Industrial de Santander, Bucaramanga, Colombia.

Porphyry Mo- Cu mineralization in the California-Vetas district, Eastern Cordillera, Colombia is coeval with 10.9 - 8.4 Ma granodiorite porphyry stocks and overprinted by epithermal Au-Ag mineralization. Mineralization is hosted by Grenvillian-aged paragneisses (Bucaramanga Gneiss) and Late Triassic to Early Jurassic peraluminous granites with > 70% SiO_2 and metaluminous diorites with SiO_2 54.9 - 60.4 wt%. Late Miocene rocks are weakly peraluminous granodiorite porphyries with SiO_2 61- 67%, sharing some characteristics with adakite-like rocks widely associated with porphyry mineralization elsewhere in the Andes. Although Miocene rocks do not have low Y (<15 ppm) or depleted HREE, they have high Ba (930-1500 ppm), high Ba/La (28 to 50), high Sr (850 to 1100 ppm), high Sr/Y (50-78) only minor Eu anomalies and depleted MREE compared to the Mesozoic granites (400-700 ppm Ba; Ba/La 14-25; 80-150 ppm Sr; Sr/Y 2.5-14), and diorites (900 -1200 ppm Ba; Ba/La 20-32; 610-750 ppm Sr; Sr/Y 22-25). Their initial $^{87}Sr/^{86}Sr$ ratios of 0.7052-0.7066 are significantly less radiogenic than those of the Mesozoic diorites (0.70712-0.7072), granites (0.7094-0.710) and the paragneiss (0.7144-0.7332, @ 199 Ma). Miocene granodiorite porphyries represent water-rich subduction related melts. Their initial $^{87}Sr/^{86}Sr$ is less radiogenic than Neogene Caribbean sediments, precluding a sedimentary source for the high Sr and Ba. Instead, a fluid source from serpentinized lithospheric mantle, fluxing the overlying subducted oceanic crust and mantle wedge is suggested. The geochemical signal may have been enhanced by the overlapping subducting Nazca and proto-Caribbean slabs at depth.

Estimating the role of competing ions on the arsenic mobilization processes in the aquifers of Bengal basin by surface complexation modeling

A. BISWAS[12]*, J.P. GUSTAFSSON[13], H. NEIDHARDT[4], D. HALDER[12], A.K. KUNDU[2], D. CHATTERJEE[2], Z. BERNER[4] AND P. BHATTACHARYA[2]

[1]KTH Royal Institute of Technology, SE-100 44 Stockholm, Sweden (*correspondence: ashis@kth.se)
[2]University of Kalyani, 741235 Kalyani, West Bengal, India
[3]Swedish University of Agricultural Sciences, SE-750 07 Uppsala, Sweden
[4]Karlsruhe Institute of Technology, D-76131 Karlsruhe, Germany

This study investigates the relative roles of the different competing ions on the arsenic (As) mobilization in the sedimentary aquifers of Bengal basin by surface complexation modeling of the temporal varaibility of As in shallow (<50 m) groundwater. Two sets of piezometers (2 × 5 = 10), installed at the two sites with relatively contrasting dissolved As concentration in groundwater, were monitored bi-weekly for As and other hydrogeochemical parameters over a period of 20 months. The estimation of the standard deviation (SD) for As(III) reflects strong temporal variation (SD ≥10 μg/L) in all the piezometers of two sites over the monitoring period. Particularly, the variation is more prominent in the shallowest part of the aquifer, where the site specific cyclic trends are evident. While, As(V) shows significant temporal variation in the piezometers of high As site only and no specific trend is reflected in the variation.

Two different surface complexation models (SCMs), developed for ferrihydrite and goethite have been explored to account for the observed temporal variation in As(III) and As(V) concentrations. The SCM for ferrihydrite has provided the better estimation for both As(III) and As(V) variations. Among the different competing ions, PO_4^{3-} appears as the major competitor of As(III) and As(V) adsorption onto ferrihydrite and the competition ability decreases in the order PO_4^{3-} >> Fe(II) > H_4SiO_4 = HCO_3^-. It is further revealed that a small decrease in pH significantly increases the concentration of As(III) and decreases the As(V) concentration and vice versa. The present study suggests that the reductive dissolution of Fe oxyhydroxides alone cannot explain the observed high As concentration in groundwater of the sedimentary aquifers. Perhaps, the reductive dissolution of Fe oxyhydroxides followed by competitive sorption reactions with the aquifer sediment is the processes conducive for As enrichment in the groundwater of Bengal basin.

Neoproterozoic late to post-collisional, quartz-bearing ultrapotassic syenites from southernmost Brazil

MARIA DE FATIMA BITENCOURT[1]*, LAURO VALENTIM STOLL NARDI[1], GIUSEPPE BETINO DE TONI[1] AND LUANA MOREIRA FLORISBAL[2]

[1] Instituto de Geociências, Universidade Federal do Rio Grande do Sul, Av. Bento Gonçalves, 9500, Porto Alegre 91500-000 RS, Brazil. fatimab@ufrgs.br; lauro.nardi@ufrgs.br; gdetoni@ufrgs.br
[2] Instituto de Geociências, Universidade de São Paulo, Rua do Lago, 562, São Paulo, 05508-080, SP, Brazil. geoluana@yahoo.com.br

Continental collision is registered in southernmost Brazil at ca. 650 Ma by tectonic interleaving of paragneisses and orthogneisses of different ages under granulite facies metamorphic conditions. Megacrystic and fine-grained syenites are intrusive subparallel to the main gneissic banding and have locally undergone subsolidus deformation at around 700 °C. The syenites contain slighly perthitic K-feldspar and variable proportions of pyroxene, amphibole and red biotite, with small amounts of plagioclase and quartz. Their crystallization age is 642 ± 10 Ma (U-Pb zircon LA-MC-ICP-MS), determined in least deformed variety. Their main geochemical features (SiO_2 58-62 wt%) are high HFSE, REE, Rb, Sr, and Ba contents, as well as K_2O/Na_2O ratios (4-10), typical of ultrapotassic rocks. The trace-element patterns suggest that they are derived from OIB-type sources. Their initial $^{87}Sr/^{86}Sr$ ratios vary from 0.719 to 0.729, and $^{143}Nd/^{144}Nd$ ratios from 0.5116 to 0.5118. Similar values for both isotope ratios have been reported for post-collisional ultrapotassic magmatism in southwest Tibet. Melting of phlogopitic, Rb-enriched mantle sources may account for the extremely high $Sr_{(i)}$ values found in the studied syenites. The ultrapotassic character, trace-element and isotope patterns are consistent with sources previously affected by subduction, and are therefore compatible with structural data indicative of post-collisional setting.

The Lu-Hf BSE parameters and the early Earth zircon record

M. BIZZARRO[1] AND J.N. CONNELLY[1]

[1]Centre for Star and Planet Formation, University of Copenhagen, Copenhagen K, 1350 Denmark

The long-lived ^{176}Lu-to-^{176}Hf decay system is a powerful tool to understand ancient chemical fractionation events associated with planetary differentiation. Intrinsic to application of such isotopic tracers to study the early Earth is knowledge of chondritic reference values for the Lu-Hf system (bulk silicate Earth, BSE) and the precise value of the decay constant for the parent ^{176}Lu isotope. Using a BSE estimate based on chondrite meteorites [1], detrital Hadean zircons (>3.8 Gyr) from the Jack Hills metasedimentary belt record extremely enriched Hf-isotope signals suggesting early extraction of a continental crust (>4.5 Gyr) but fail to identify a prevalent complementary depleted mantle reservoir. However, this conclusion assumes that the present-day Hf-isotope composition of bulk chondrite meteorites can be used to estimate the composition of BSE. Recent internal ^{176}Lu-^{176}Hf systematics of the pristine 4564.58±0.14 Myr SAH99555 angrite [2] define a Lu-Hf age that is ~300 Myr older than the age of the solar system [3]. This confirms the existence of an energetic process yielding excess ^{176}Hf in affected early formed solar system objects through the production of the ^{176}Lu isomer ($t_{1/2}$=3.9 hours). This conclusion is now supported by new ^{176}Lu-^{176}Hf data of eucrite meteorites [4]. This implies that chondrite meteorites contain excess ^{176}Hf (~5ε-unit) and their present-day composition may not be used to infer the Lu-Hf parameters of BSE. Using a revised BSE estimate based on the SAH99555 isochron, we note that Earth's oldest zircons preserve a record of coexisting enriched and depleted hafnium reservoirs as early as 4.3 Gyr in Earth's history, with little evidence for the existence of continental crust prior to 4.4 Gyr. This contrasting interpretation of the early zircon record requires reassesing the validity of using chondrites to define the Lu-Hf BSE parameters. To better understand the extent of ^{176}Hf excesses in meteorites and the solar system's initial ^{176}Hf/^{177}Hf value, we initiated a ^{176}Lu-^{176}Hf study of additional quenched angrites via the internal isochron approach, including D'Orbigny, NWA 1670 and NWA 7203. Our new U-corrected Pb-Pb dates for these meteorites indicate coeval formation of NWA 7203, SAH99555 and D'Orbigny. NWA 1670 crystallized ~1 Myr earlier and, thus, is the oldest known angrite.

Sulfur isotopic evidence for sources of volatiles in Siberian Traps magmas

BENJAMIN A. BLACK[1]*, ERIK H. HAURI[2], STEPHANIE M. BROWN[1] AND LINDA T. ELKINS-TANTON[2]

[1]MIT EAPS, Cambridge, MA USA, bablack@mit.edu (* presenting author)

[2]Carnegie Institution of Washington, Washington, DC, USA

We present new measurements of δ^{34}S in melt inclusions from the Siberian Traps. The Siberian Traps flood basalts transferred a large mass of volatiles from the Earth's mantle and crust to the atmosphere [1]. The eruption of the large igneous province temporally overlapped with the end-Permian mass extinction, and also generated ore deposits of major economic importance. Constraints on the sources of Siberian Traps sulfur and other volatiles are critical for determining the overall volatile budget, the role of assimilation of crustal materials, and genesis of Noril'sk massive sulfide deposits. Sulfur isotopic ratios vary among mantle and crustal materials, with characteristic mantle δ^{34}S values around 0±2 ‰ with respect to Vienna Cañon Diablo Troilite (VCDT), and crustal δ^{34}S values between -50 ‰ and +40 ‰. In conjunction with previously published whole rock measurements from Noril'sk [2], our sulfur isotopic data suggest that crustal assimilation was widespread and heterogeneous—though not universal—during the emplacement of the Siberian Traps. Evidence for open-system degassing implies that episodes of explosive volcanism may have been phreatomagmatic. Carbon concentrations constrain minimum entrapment depths of melt inclusions to shallow crustal depths. Magmas likely interacted with sedimentary materials depleted in ^{34}S such as shale or coal, in addition to evaporites enriched in ^{34}S. These crustal materials may have increased the total volatile budget of the large igneous province, thereby contributing to Permian-Triassic environmental deterioration.

Chlorite dissolution experiments under CO_2 saturated conditions

JAY R. BLACK[12] AND RALF R. HAESE[1,3]

[1]Cooperative Research Centre for Greenhouse Gas Technologies, CO2CRC
[2]Geoscience Australia, GPO Box 378, Canberra, ACT 2601, Australia (jay.black@ga.gov)
[3]The University of Melbourne, VIC 3010, Australia (ralf.haese@unimelb.edu.au)

The injection and long-term storage of supercritical CO_2 ($scCO_2$) into geological reservoirs is seen as an important option to mitigate rising levels of atmospheric CO_2. Predicting what changes take place to geochemical and petrophysical properties of a reservoir once CO_2 has been injected requires an understanding of how mineral dissolution and precipitation proceed. The dissolution of CO_2 in groundwaters in contact with an $scCO_2$ plume leads to a decrease in the pH of pore fluids, driving the system far from equilibrium and accelerating the dissolution of minerals in the reservoir. Experiments exposing a siltstone to CO_2 saturated fluids have shown that the dissolution of carbonates and clays, including chlorite, lead to increased porosity and permeability in a sample of a siltstone caprock [1].

The dissolution kinetics of chlorite have been extensively studied [2], but not under CO_2 saturated conditions. Here we present the results of batch reactor experiments on a clinochlore chlorite (CCa-2, The Clay Minerals Society); testing the potential effects of pH, chloride and bicarbonate concentration, temperature and pressure (pCO_2) on the dissolution rate of the mineral. The dissolution rates observed are of a comparable magnitude (c. -12 log mol m^{-2} sec^{-1} at 50ºC) to previous studies, but the proton promoted dissolution normally observed is not as prominent. The results suggest that dissolved bicarbonate affects the dissolution mechanism and new rate laws are presented accounting for the effect of [HCO_3^-]. An apparent activation energy for the dissolution process of 19 kJ mol^{-1} is calculated assuming a simple empirical rate law with an Arhhenius form. This result is much lower than the activation energy of 88 kJ mol^{-1} previously reported under acidic conditions [3], and often used in geochemical models under all pH regimes. However, it is consistent with the results of a recent study using flow-through techniques [4].

U-Pb thermochronology and the thermal history of planetary crusts

TERRENCE BLACKBURN[1]

[1]Carnegie Instituion for Science

U-Pb accessory phase thermochronology (minerals: apatite, titanite and rutile) allows estimates of cooling rates of rocks as they pass through moderate temperatures (400-800 °C). Despite a growing number of datasets employing these techniques, these data--like all thermochronologic data-- are highly non-unique and can often be interpreted as the result of any number of geologic scenarios. This problem of non-uniqueness can largely be resolved by exploiting the U-Pb system's dual decay scheme, where two parent isotopes, ^{238}U and ^{235}U, decay to daughter isotopes ^{206}Pb and ^{207}Pb respectively. The difference in decay rates between parent isotopes imposes a time-variant parent and instantaneous daughter isotopic composition for any point in Earth's history. This new thermochronologic methodology works to capture this isotopic evolution using the variation in the time of Pb retention between both: 1) samples of different crustal depths, where variations in the timescale of cooling result from the thermal gradient within a conductively cooling crust, and; 2) crystals of different size, where volume diffusion behavior, in particular for slowly cooled systems, result in larger crystals retaining lead at higher temperatures and over a longer and older timescales in comparison to smaller crystals, which retain lead at lower temperatures and at younger times. The differences in U/Pb and $^{207}Pb/^{206}Pb$ among samples from different depths, and within each sample—between grains of different size — can be used to reconstruct the long-term thermal histories within planetary crusts. By moving beyond assigning nominal closure temperatures to dated minerals one can avoid the cooling rate uncertainties that propagate from experimental diffusion kinetics. The sensitivity to cooling rate lies in the topology of U-Pb data and has been demonstrated using forward modelling to be highly insensitive to diffusion kinetics. I'll work to demonstrate how this methodology can be employed to reconstruct the thermal histories of: 1) the continental lithosphere through reconstruction of thermal histories of lower crustal xenoliths, and; 2) the chondrite parent bodies, through reconstruction of chondrite meteorite thermal histories. In each example, I'll focus on interpreting thermochronologic data with the aid of thermal models in order to elucidate the relative roles of heat conduction, production and advection (erosion/burial) and in doing so provide constraints on the timing and processes controlling continent stabilization and the assembly of planetesimals.

The reactivity of microbially-reduced goethite: assessing the potential of a naturally-occurring waste material for mine drainage remediation

N. BLACKWELL[1]*, W. T. PERKINS[1], A. EDWARDS[2], D. B. JOHNSON[3], K. B. HALLBERG[3], G. W. GRIFFITH[2], J. M. BEARCOCK[4] AND B. PALUMBO-ROE[4]

[1]Institute of Geography and Earth Sciences, Aberystwyth University, UK (*correspondence: nlb09@aber.ac.uk)
[2]Institute of Biological, Environmental and Rural Sciences, Aberystwyth University, UK
[3]School of Biological Sciences, Bangor University, UK
[4]British Geological Survey, Keyworth, UK

Naturally occurring iron (Fe) oxides are ubiquitous in nature, particularly at abandoned mine sites where extraction processes have resulted in the oxidation of Fe-bearing sulphide minerals. Goethite, an Fe(III) oxide, is stable over a wide range of Eh and pH conditions and is present at several coal mine drainage treatment systems in the South Wales Coalfield, UK.

Microbial investigations at the Ynysarwed mine in the Coalfield revealed the presence of bacteria closely related to known Fe(III)-reducing species within the goethite deposit. Microcosm experiments designed to investigate the activity of these naturally-occurring bacteria were prepared using sodium acetate as the electron donor and the naturally occurring goethite as the electron acceptor.

After 100 days the solid phase Fe(II) content was determined and the results show an increase from ~1.5% Fe(II) in the starting material to ~9% in the microbially-reduced material. No increase in Fe(II) was observed in the kill or live controls. Dilute acid extractions (0.1M HCl) of the material, designed to solubilise Fe(II) weakly bound to the goethite crystal surface, recovered 97-99% of the total Fe(II).

The ability of Fe(II) bound to the surface of goethite to reduce potentially harmful elements has been shown in several studies. The reactivity of microbially-reduced natural goethite and its ability to remove problematic elements, such as zinc (Zn), from natural mine waters through addition of the slurried reduced material (5g L^{-1} dry weight) was investigated. The results show a 5-fold increase in Zn removal from a circum-neutral mine water when compared to natural goethite. These data show the potential of naturally-occurring mine waste for the remediation of contaminated mine waters.

The Fate of Small Active Margin River POC in the Marine Environment

NEAL BLAIR[1]*, CATHERINE GINNANE[2], LAUREL CHILDRESS[1] AND LONNIE LEITHOLD[3]

[1]Earth & Planetary Sciences, Northwestern University, Evanston, IL 60208, USA (*correspondence n-blair@northwestern.edu)
[2]GNS, PO Box 30-368, Lower Hutt 5040 New Zealand, (c.ginnane@gns.cri.nz)
[3]Marine, Earth & Atmospheric Sciences, North Carolina State University, Raleigh, NC 27695-8208, USA (leithold@ncsu.edu)

Small active margin rivers export a mixture of particulate organic carbon (POC) pools derived from contemporary primary production, aged soils and uplifted sedimentary rocks. These pools are expected to exhibit a wide range of reactivities in the marine environment because of their vastly different ages and diagenetic histories. The stable carbon and radiocarbon isotopic compositions of sedimentary POC and pore water dissolved inorganic carbon (DIC) from the Waiapu River shelf, New Zealand were measured to determine the fate of the exported riverine POC. The Waiapu River exports material that is dominated by fossil C derived from the rapidly eroding Cretacceous to Paleocene mudstones (riverine POC F_{mod} ~0.3). Shelf sediments incorporate both riverine and marine POC as indicated by an enrichment in ^{13}C and accumulation of ^{14}C-rich material (F_{mod} ~ 1).

Porewater DIC carbon isotope compositions are controlled primarily by the addition of remineralized organic carbon to a seawater background. In the case of the Waiapu shelf, DIC $\delta^{13}C$ values indicate preferential oxidation of terrestrial OC nearshore (~60 meters water depth) with a transition to more marine C-supported remineralization further offshore (80-130 m water depth). In all cases, the remineralized C is modern in age, thus no appreciable oxidation of fossil C or aged soil C is evident.

Oxidation of the modern terrestrial OC is far from complete based on POC isotopic data from both the Waiapu and the adjacent Waipaoa system. The terrestrial OC is well preserved in areas of fine-grained sediment accumulation as a result of rapid and episodic deposition. On balance, we argue that small active margin river continental margins have the potential to be efficient carbon sinks regardless of POC age.

Expanding potential source area studies of dust in East Antarctica by integrating trace element chemistry and radiogenic isotopes

M. BLAKOWSKI[1]*, S. ACIEGO[1], B. DELMONTE[2] AND C. BARONI[3]

[1]University of Michigan, Ann Arbor, MI, USA (*correspondance: mollybla@umich.edu)
[2]University of Milan-Bicocca, Milan, Italy
[3]University of Pisa, Pisa, Italy

By studying dust records preserved in Antarctic ice cores, we can evaluate variability in dust source areas over geologic timescales. For instance, it has been determined that during the Last Glacial Maximum (LGM), South America was the dominant dust source for the entire East Antarctic Plateau [1,2], whereas ice core analyses from the Talos Dome reveal that the fraction of large particles deposited during the Holocene was significantly greater than during the LGM, indicating contribution from proximal, Antarctic sources. These findings differ from cores drilled further inland on the East Antarctic Ice Sheet (EAIS), such as the Dome C core [1,3,4].

Here we provide new results of trace Rare Earth Element (REE) chemistry and Sr-Nd, Hf signatures of <5μm diameter and bulk samples from 19 potential source areas (PSAs) in northern and southern Victoria Land (NVL and SVL), including from the ice-free McMurdo Dry Valleys (MDV). Because records from the Talos Dome currently suggest that ice-free areas such as the MDV may be important sources for local, wind-driven dust transport on the EAIS after the LGM, we expect to observe similar trends when comparing our PSA samples from SVL to Holocene dust profiles from the Taylor Dome core, and likewise from NVL to Holocene profiles in the Talos core. $^{87}Sr/^{86}Sr$ and ε_{Nd} compositions from our PSAs are similar to existing PSA records from Antarctica.

At present, Sr and Nd isotopic systems are commonly used to identify dust provenance in Antarctic ice cores [1], however, such studies have yet to be complimented with Hf signatures and REE chemistry. Thus, forthcoming results from this study may be especially useful for distinguishing dust flux evolution during the last deglaciation.

Modelling the migration of mercury in a column experiment: biotic against abiotic mechanisms

P. BLANC[1]*, A. BURNOL[1], J. HARRIS-HELLAL[1] AND V. LAPERCHE[1]

[1] BRGM, BP36009, 45060, Orléans, France (*correspondance : p.blanc@brgm.fr)

Apart from the behavior of mercury in terrestrial surface aquatic environnement, few data are still available concerning its migration in subsurface and deep aquifers. A column experiment had been design in order to reproduce the Hg methylation by sulphate and iron reducing bacteria. Based on the experimental results, a modelling exercise had been carried out to enlighten the chain of reactions responsible for methylmercury formation in such an environnement.

The numerical modelling is realised by using the PhreeqC-2 code [1] and the Thermoddem database [2]. The hydraudynamics of the column is first parameterized by modeling a tracer test, allowing to realistically adjust a double porosity model. Then, the inorganic part of the model imputs include the solid substrates used (silicic sand + iron hydroxydes previously spiked with a mercury nitrate solution) and the inflowing solution. In the latter cases, this includes the chemical perturbations induced by three successive bacterial innoculation events. The organic part of the model strats from the innoculum preparation and takes into account the nature of the bacterial load (sulphate and iron reducing) and the addition of an organic substrate (Na-Lactate).

For the parameters pH, Eh, $[S]_T$, $[Fe]_T$ and $[Hg]_T$, a satisfactory agreement is found by considering only the inorganic part of the chemical system. The total dissolved mercury concentration is slighlty improved by adding a non electrostic Hg surface complexation model. Methyl mercury is also produced. However, its amount in the analysed samples is shown to depend strongly on the presence of potential methyl donnors in the inflowing solution.

Computational science in nuclear waste management: *ab initio* investigation of f-elements bearing Monazite.

A.BLANCA-ROMERO*[1], G. BERIDZE[1] AND P. M. KOWALSKI[1]

[1] Forschungszentrum Juelich GmbH, Institute of Energy and Climate Research - IEK-6: Nuclear Waste Management, D-52425 Juelich, Germany (*correspondence: a.blanca.romero@fz-juelich.de, p.kowalski@fz-juelich.de)

A safe disposal of nuclear waste is of great importance not only for the nuclear engineering but also for the general safety of society. One of the challenges in nuclear waste storage is to find suitable materials that are able to immobilize minor actinides such as Np, Am and Cm. The monazite-type orthophosphates are known to be able to incorporate actinides into their structure and preserve their crystalline character. Because of its resistance to radiation damage and chemical durability monazite is a promising host matrix [1]. In our institute we perform systematic experimental and computational studies of monazite ceramics that aim into in-depth understanding of the properties of these materials and their behavior upon incorporation of actinides. In our research we extensively use first-principles calculations to complement the experimental effort. Combination of both approaches allows us to learn how to reliably compute "tricky" 4f and 5f materials using modern methods of computational quantum chemistry.

In this contribution we present a systematic first-principles studies of the structural, thermodynamic, electronic and vibrational properties of Monazite-type $LnPO_4$ ceramics (where Ln=La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy). The calculations were performed using Density Functional Theory (DFT) with different variations of the generalized gradient approximation as well as with the DFT+U approach to correct for the strong on-site Coulomb repulsion. We calculated the structural parameters, vibrational frequencies, and the enthalpies of formation as well as the excess enthalpies of solid solutions of these compounds. Our results are confronted with a variety of experimental data (structural data [2,3], solid formation and solution enthalpies [3,4], IR and Raman spectroscopies [3,5]) and previous DFT calculations [3]. We will show that such a comparison allows for a proper assessment of the computational methods, and a better constraint of Hubbard U parameter for DFT+U method.

First-principles investigation of equilibrium iron isotope fractionation in oxide and sulfide minerals

MARC BLANCHARD[1]*, CARLOS PINILLA[1], FRANCK POITRASSON[2], MERLIN MÉHEUT[2], MICHELE LAZZERI[1], FRANCESCO MAURI[1] AND ETIENNE BALAN[1]

[1]IMPMC, Université Pierre et Marie Curie, CNRS, IRD, 4 place Jussieu, 75252 Paris Cedex 05, France (*correspondence: marc.blanchard@impmc.upmc.fr)

[2]GET, CNRS-Université de Toulouse, IRD, 14-16 avenue Edouard Belin, 31400 Toulouse, France

The equilibrium isotope fractionation factor between two phases, which is a key parameter for the interpretation of isotopic variations among natural samples, can be determined from their reduced partition function ratios, also called β-factors. In most cases, β-factors cannot be measured directly but they can be calculated from vibrational properties following various approaches. For solids with Mössbauer-sensitive elements like Fe, the β-factor can be determined either from Mössbauer spectroscopy by measuring the temperature dependence of the isomer shift [1], or from nuclear resonant inelastic X-ray scattering spectra (NRIXS) by measuring the partial density of states of the resonant atom or by using the moments of the raw NRIXS spectrum [2,3]. An alternative approach consists in determining the theoretical vibrational density of states of the solid using first-principles calculations [4].

In this presentation, the Fe β-factors of oxide and sulfide minerals (mainly hematite, goethite and pyrite) computed using first-principles methods based on density functional theory with or without the addition of a Hubbard U correction (DFT and DFT+U) will be compared with the available Mössbauer- and NRIXS-derived data. While all three methods must give consistent results, discrepancies are observed in some cases. The possible sources of discrepancy will be discussed.

Cosmogenic ^{3}He and ^{10}Be production rates at high elevation (> 3800 m)

P.-H. BLARD[1], R. BRAUCHER[2], D. BOURLES[2] AND J. LAVE[1]

[1] CRPG, UMR 7358 CNRS-Université de Lorraine, Vandoeuvre-lès-Nancy, France, blard@crpg.cnrs-nancy.fr
[2] Aix-Marseille Université, CNRS-IRD UM 34 CEREGE, Aix-en-Provence, France

Recent cross-calibrations of cosmogenic ^{3}He in pyroxene and ^{10}Be in quartz [1] showed that, at low elevation (< 2000 m), the ^{3}He/^{10}Be production ratio was probably ~40% higher than the value of ~23 initially defined in the 90's. This recent update is consistent with the last independent determinations of the sea level high latitude production rates of ^{10}Be and ^{3}He, that are about 4 and 125 at.g^{-1}.yr^{-1}, respectively [e.g. 2, 3]. However, major questions remain about these production rates at high elevation, notably because the elevation dependence of the ^{3}He/^{10}Be production ratio is controversial [4]. It is thus crucial to produce new high precision cross-calibration data at high elevation.

Here we report new precise measurements of ^{3}He in pyroxenes and ^{10}Be in quartz, from dacitic moraines located at 4820 m in the Southern Altiplano (22°S, Tropical Andes). The obtained ^{3}He/^{10}Be production ratio is 33.3±0.9 (1σ). This value is statistically undistinguishable from the production ratio measured at 1333 m [1], which reveals that the ^{3}He/^{10}Be production ratio in pyroxene and quartz is almost invariant with elevation. When combined with the absolute ^{3}He production rate locally calibrated in the Central Altiplano, at 3800 m, from a 15.3±0.5 ka old surface, these new data permit to define the absolute production rate of cosmogenic ^{10}Be at high elevation. After scaling to sea level and high latitude, this calibration yields a sea level high latitude P_{10} ranging from 3.7±0.2 to 4.1±0.2 at.g^{-1}.yr^{-1}, depending on the used scaling scheme.

This new refinement of the cosmogenic dating tool will significantly improve both the accuracy and the precision of paleoglaciers chronologies in the Tropical Andes.

Calcium isotopes in evaporites constrain sulfate- vs calcite-rich seawater chemistry

C.L. BLÄTTLER* AND J.M. HIGGINS

Department of Geosciences, Princeton University, Guyot Hall, Princeton, NJ 08544, U.S.A.
(*correspondence: blattler@princeton.edu)

The calcium-isotope behavior of evaporite formations is proposed as a new method for constraining the composition of ancient seawater. Evaporite cycles that reach the halite facies are expected to record a different range of calcium-isotope values depending on the initial major-element chemistry of seawater. In the modern ocean, where sulfate is far in excess of calcium (28 mmol/kg SO_4^{2-} compared to 10 mmol/kg Ca^{2+}), approximately 90% of the initial calcium is removed as carbonate or sulfate minerals by the time halite saturation is attained. In contrast, an excess of calcium relative to sulfate, as suggested for intervals such as the Cretaceous and the Silurian [1], leads to significant depletion of sulfate, but a much smaller proportion of calcium removed at the point of halite saturation. Isotopic fractionations associated with the precipitation of carbonates, gypsum, and anhydrite lead to Rayleigh distillation of calcium within an evaporite basin, where precipitates from more concentrated brines become enriched in the heavy isotopes of calcium, dependent on the total amount of calcium removed. The range in calcium-isotope ratios obtained by sampling different stages of the carbonate–sulfate evaporite facies is therefore diagnostic of initial sulfate- or calcium-rich seawater.

In beaker evaporation experiments, the $\delta^{44/42}$Ca value of modern sulfate-rich seawater becomes enriched by 1.2‰ from its initial composition to the beginning of halite precipitation, whereas the $\delta^{44/42}$Ca of a calcium-rich and sulfate-poor solution evolves by <0.2‰. The $\delta^{44/42}$Ca values of accompanying precipitates demonstrate the same characteristics, but are offset from the fluid by 0.5–0.7‰. Analyses of geological evaporites from various Phanerozoic periods show how this behavior translates to natural samples as well. This new method provides an independent test for variations in the major-element chemistry of paleoseawater.

The study of the ferruterous mineral water in Kareliya by isotopic and chemical tracers.

BLAZHENNIKOVA I.V.[1], AVRAMENKO I.A.[2] AND TOKAREV I.V.[3]

[1] blazhennikova@mail.ru
[2] i.a.avramenko@gmail.com
[3] tokarevigor@gmail.com

From 1979 to 2012 the ferruterous mineral water in Karelia (northwest of Russia) was studied by monitoring the isotope and chemical tracers.

In 1979-1980 stable isotopes (^{2}H, ^{18}O) had fractionated composition (on the plot $\delta^{2}H$ vs. $\delta^{18}O$ the points shifted right from the meteoric line), which was caused by cryogenic metamorphism at partial freezing of water in the last glacial period. The composition of stable isotopes has strongly changed for the last 25 years (the points fit on the global meteoric line now). Other isotope tracers ($\delta^{13}C$, ^{3}He, ^{4}He, ^{20}Ne, $^{234}U/^{238}U$, ^{3}H) also have changed and become closer to the recharge water. So the isotope data show that the water of the studied area in 1979-1980 was formed by mixing “old” and “young” components. But now we observe the rapid penetration of the atmospheric precipitation and gradually disappearance of the "old" component.

Though the seasonal variations are detected, the average chemical composition of the mineral water (major components and microelements) has not changed for the last decades in contrast to the isotope tracers. Probably the relative constancy of the chemical composition indicates that iron accumulation in the water is due to melanterite ($Fe[SO_4]\cdot 7H_2O$) dissolution. Melanterite has formed from pyrite during the last glaciations and filled cracks and pores. The reserves of this mineral are not known and because of the rapid changes in the isotopic characteristics we can talk about the over-exploitation of the mineral water deposit. Data suggests the need for strict sanitary control of water quality.

Selenium distribution linked to monsoon climate in the Chinese Loess Plateau

TIM BLAZINA[1]*YOUBIN SUN[2] MICHAEL BERG[1] LENNY H.E. WINKEL[1,3]

[1] Eawag: Swiss Federal Institute of Aquatic Science and Technology, 8600 Duebendorf, Switzerland (*correspondence: tim.blazina@eawag.ch) michael.berg@eawag.ch, lenny.winkel@eawag.ch
[2] Institute of Earth Environment, Chinese Academy of Sciences, 710075 Xi’an, China, sunyb@ieecas.cn
[3] Swiss Federal Institute of Technology (ETH) Zurich, 8092 Zurich, Switzerland, lwinkel@ethz.ch

Selenium (Se) is a vital trace element for human health with a narrow range between deficiency and toxicity. Diets deficient in Se have been linked with various diseases, while those with an excess can lead to toxicity. Predicting where Se deficiency/toxicity occurs is challenging due to the heterogeneous terrestrial distribution of Se and limited knowledge on what controls this heterogeneity. It has been proposed that the largest natural flux of Se to the terrestrial environment is via wet deposition from the atmosphere.

Our research uses the loess-paleosol and red clay deposits on the Chinese Loess Plateau (CLP), the largest area of windblown sediments on Earth and one of the best available records of climate change, to elucidate how atmospheric deposition of Se relates to its terrestrial distribution. We present a 6.8Ma record of variation in the Se concentration in the Lingtai section from Central CLP. In interglacial climatic periods from 2.31-1.56Ma and 1.6-1.3Ma, we find very strong positive correlations (R^2=0.97 and 0.85 respectively) between Se concentration and summer monsoon index, a proxy for effective precipitation. In later interglacial periods from 1.26-0.83Ma and 0.78-0.16Ma, the strong positive correlation with precipitation is absent or there is a negative correlation (R^2=0.21 and 0.50, respectively) and we find dust input plays a greater role. As both precipitation and dust inputs are determined by the strength of the East Asian Monsoon, we are able to show that Se deposition in the CLP (at the Lingtai section), is directly related to past changes in the monsoon climate system.

Methanotrophic bacteria drive seasonal anoxia and the formation of a benthic nepheloid layer in a deep alpine lake

J. BLEES[1], H. NIEMANN[1], C. B. WENK[1], J. ZOPFI[1], M. VERONESI[2], C. J. SCHUBERT[3] AND M.F. LEHMANN [1]

[1]Department of Environmental Sciences, University of Basel, Basel Switzerland; moritz.lehmann@unibas.ch
[2] Institute of Earth Sciences, University of Applied Sciences of Southern Switzerland, Canobbio-Lugano, Switzerland
[3] Swiss Federal Institute of Aquatic Science and Technology (EAWAG), Kastanienbaum, Switzerland

We investigated the composition and formation mechanisms of a seasonal benthic nepheloid layer (BNL), a layer of high suspended particle concentration, in the monomictic southern basin of Lake Lugano. During stratified water column conditions, lasting from early summer until winter mixing in January/February, the BNL developed from the sediment-water interface and expanded 20–30 m into the water column, in tandem with the rising redox transition zone. Methanotroph-derived fatty acids ($C_{16:1\omega5\text{-}8}$), with $\delta^{13}C$ values as low as -90‰, dominated the fatty acid pool within the BNL. Based on C-isotope data, we calculated that up to 98% of the lipid carbon is methane-derived, suggesting that the BNL is primarily composed of aerobic methane oxidising bacteria. The lipid composition indicates that the methanotrophic community in the BNL in Lake Lugano is dominated by Type I methanotrophic bacteria. Total cell numbers ranged between 0.9 and 3.6 × 10^6 cells mL^{-1} during full development of the BNL. In incubation experiments we determined CH_4 turnover rate coefficients that translate into potential CH_4 oxidation rates as high as 20 μM d^{-1}. The corresponding cell-specific rates were up to 49 × 10^{-5} pmol $cell^{-1}$ h^{-1}, which is reasonable for Type I methanotrophic bacteria. CH_4 oxidation in the BNL was limited by the diffusive supply of O_2 from the upper hypolimnion, implying that CH_4 oxidation is the primary driver of the seasonal expansion of the anoxic bottom water volume, and explaining the vertical migration of the BNL in response to its own O_2 consumption. Our study demonstrates that methanotrophic activity at the interface between oxic and anoxic water masses can drive the formation of a BNL. Such a layer of high bacterial density and high CH_4 oxidation potential may thus function as an efficient CH_4 barrier, preventing CH_4 transport into surface waters, and eventually evasion to the atmosphere.

Niobium Mineralization in a Magnetite-Rich Carbonatite, Elk Creek, Nebraska (USA)

[1]M. BLESSINGTON, [1]R. KETTLER, [2]P.VERPLANCK AND [3]G.L. FARMER

[1]Department of Earth and Atmospheric Sciences, University of Nebraska, Lincoln, NE, 68588-0340, USA
[2]U.S. Geological Survey, Central Mineral Resources Science Center, Box 25046, Denver Federal Center, MS-973, Denver, CO 80225-0046, USA
[3]Department of Geological Sciences, University of Colorado, Boulder CO 80309-0399, USA

The Elk Creek carbonatite is a roughly circular 7km*7km intrusive carbonatite-alkaline syenite complex located in Southeast Nebraska. The complex is overlain by younger marine sediments and quaternary glacial till – No surface exposure exists, but drill cores collected by Molycorp in the 1970s-80s have been made available to the public for research. The carbonatite comprises several geochemically distinct intrusive phases with notable anomalous enrichment in rare earth elements and niobium. These phases include a dolomite-magnetite carbonatite ("magnetite beforsite") phase which consists of two lobes, each approximately 0.1 square kilometer in size and extending downward to the maximum extent of drilling (900 meters). This dolomite-magnetite carbonatite is typically an aphanitic microbreccia including accessory apatite, biotite, and pyrite. Hematite dusting on mineral surfaces is pervasive, and veining is widespread. Fragments of dolomite-magnetite carbonatite are also present in a spatially-associated breccia along with fragments of apatite-dolomite carbonatite.

XRF analysis of a powdered bulk sample of the dolomite-magnetite carbonatite yields data that indicate that the dolomite-magnetite carbonatite differs from other carbonatite phases in that it has much higher Ti, Th, and W compared to the other intrusive phases. It also differs from the other instrusive phases in that Fe > Mg and it is depleted in light REE relative to the other rocks. The magnetite carbonate also contains micron-scale (0.01-0.10mm diameter) accessory niobium pyrochlore, disseminated in dolomite and biotite, in economically-significant concentrations (10,000ppm or higher Nb in bulk sample). The prevalence of pyrochlore across the entire complex is directly related to the presence of this dolomite-magnetite carbonatite.

Tuning the Torch for Lead Isotopes: The Battle in Lugdunum

JANNE BLICHERT-TOFT[1]

[1]ENS Lyon, 69007 Lyon, France (jblicher@ens-lyon.fr)

To celebrate Francis Albarède's pioneering work in developing high-precision, high-throughput Pb isotope analysis by Tl doping and sample-standard bracketing MC-ICP-MS [1], I here review some selected contributions by the Lyon group to cosmochemistry, geochronology, Mars, mantle geochemistry, and archeometry using this technique. The superior precision of MC-ICP-MS compared to unspiked Pb TIMS work led us to revisit several classic but crucial questions involving Pb isotopes. We determined the age of the Solar System from Pb-Pb measurements of refractory inclusions in meteorites [2], a result only now confirmed by independent means despite tumultuous revisions of U isotope compositions and major improvements in analytical precision and blanks since our early work. We further re-determined the initial Pb isotope composition of the Solar System and the solar nebula Th/U [3] and found Pb isotope evidence that some asteroids accreted and differentiated within only one million year of the formation of the Solar System [4], thereby placing constraints on nebular evolution. Our Pb-Pb ages of SNCs [5], the shergottites in particular, are important because they finally bring the ages of Martian meteorites (4.1 Ga) into agreement with cratering chronology and satellite observations for Mars, as well as with extinct radioactivities, but are controversial because ages inferred from other chronometers are far younger (160 Ma). The high throughput of MC-ICP-MS further changed the geochemical approach to understanding mantle heterogeneities in volcanic time series, such as in Hawaii [6], and the exploring of length and time scales of isotopic heterogeneities along the world's mid-ocean ridges and, hence, the deep Earth, allowing for full-fledged spectra amenable to physical and statistical modeling to be obtained [7, 8]. A spectacular new result is the evidence of Pb-Hf isotopic 'toggles' along the SEIR, and their random distribution, indicating that the local mantle has lost all memory of its mixing history [9]. Another key result was the Pb-Hf correlation in Hawaiian lavas showing that entrainment of the upper mantle by plumes is minimal [10]. We currently apply Pb isotopes to tracking Pb ore provenance in ancient Rome in order to shed new light on the heavy metal record of local economic activity, urban development, and warfare.

Impact of long-term nitrogen deposition on the fate of nitrogen in peatlands

CHRISTIAN BLODAU[1,2] KATARZYNA ZAJAC[2] AND YUANQIAO WU[1]

[1]University of Münster, christian.blodau@uni-muenster.de
[2]University of Bayreuth, katatzyna..zajac@uni-bayreuth.de

Large areas of northern peatlands in Europe and North America have been affected by elevated long-term nitrogen deposition at levels of 0.5 – 2 g N m^{-2} yr^{-1}, and in extreme cases upt to 5 g N m^{-2} yr^{-1}. The consequences of this deposition for the fate of nitrogen, especially the allocation of the element between vegetation and peat and the mobility in dissolved form, and for the carbon cycle are only poorly known to date. We investigated this issue using ecosystem modelling based on a long-term fertilized site and experimentally with mesocosms from five different European peatlands that have been exposed to range of 0.2 to 5 g N m^{-2} yr^{-1}. The mesocosms were placed in a greenhouse under controlled light and water table conditions for a period of 160 days after an initial equilibration period. We added a ^{15}N-NO_3 tracer with irrigation water to determine how the allocation of nitrogen in these peatlands differed and also investigated the carbon exchange and productivity of the sites under these conditions. The results show that the Sphagnum moss layer was not severly impaired at any site and that even under severely N polluted conditions nitrogen was still taken up by the moss layer. The effectivity of the moss filter for the element declined, however, and some breakthrough occurred, whereas nitrogen in the pristine sites seemed to be indirectly transferred into peat by the root system of vascular plants. Overall more nitrogen was taken up by vascular plants in the more polluted sites. Elevated nitrogen deposition lead to raised ammonium and DON concentrations even at lower deposition levels but strongly elevated nitrate concentrations only occurred at the most polluted site. Substantial differences in carbon cycling between sites did not occur in the mesocosm experiments. The ecosystem modelling exercise using the new model PEATBOG showed that the most important impacts of nitrogen deposition are to be expected are through indirect changes in the ecosystem structure, which was altered from moss to shub and then grass dominated in the simulated system. The replacement of plant functional types lead to a higher rate of nitrogen processing in the system and higher productivity and carbon uptake. Also in the simulations the peatland remained a sink of nitrogen with only moderately raised nitrogen export.

Characterization of metabolically active microorganisms in an hydrothermal active field in the Okinawa Trough (IODP Exp. 331)

MACRO BLÖTHE*, ANJA BREUKER AND AXEL SCHIPPERS

Federal Institute for Geosciences and Natural Resources (BGR), Stilleweg 2, D-30655 Hannover, Germany (marco.bloethe@bgr.de; anja.breuker@online.de; axel.schippers@bgr.de)

The BGR project, as part of the post-cruise research of IODP Expedition 331, Deep Hot Biosphere, shall test the hypothesis that the quantitative microbial community composition and the cultivable microorganisms in hydrothermally influenced deeply-buried marine sediments are significantly different from those in cold and temperate deeply-buried marine sediments. The previously successfully applied molecular techniques real-time PCR (qPCR) and catalyzed reporter deposition - fluorescence *in situ* hybridisation (CARD - FISH) shall be used as well as cultivation and stable isotope-probing to proof the existence of a deep hot biosphere, to describe it and to isolate novel microorganisms. The domains *Archaea, Bacteria* and *Eukarya* as well as the JS1 candidate group, *Chloroflexi*, *Geobacteraceae, Crenarchaeota* and the functional genes *dsrA, mcrA, aprA*, and Rubisco (*cbbL*) have been quantified via qPCR. All genes have been detected in different copy numbers. The overall order of abundance is *Archaea* > *Bacteria* > *Eukarya*. Directly after IODP Expedition 331 in October 2010, culture media were inoculated with IODP samples at different temperatures and the enrichment cultures are maintained since then. Growth is continuously checked about every three months and in case of growth, colonies are picked and transferred to fresh media. Several aerobic and anaerobic enrichments have been obtained so far. To explore microbial activity in the original samples microcalorimetric measurements showed a considerable activity at 90°C which was partly attributed to microbial activity. The microcalorimetric measurements revealed activity of thermophilic microorganisms in the IODP Exp. 331 samples.

Sulfur and iron speciation in warm deep sediments affected by dry deposition of iron

B. BLONDER[1]* AND A. KAMYSHNY, JR.[1]

[1]Department of Geological and Environmental Sciences, The Faculty of Natural Sciences, Ben-Gurion University of the Negev, P.O. Box 653, Beer Sheva 84105, Israel, (*correspondence: blonderbarak@gmail.com, alexey93@gmail.com

The Gulf of Aqaba is a unique natural laboratory for a research of the impact of atmospheric dry deposition on biogeochemistry of marine sediments. Atmospheric iron deposition is 3.65 mmol m^{-2} $year^{-1}$ [1], and total iron content of sediment at 700 m depth is 2.0 – 5.7 mmol kg^{-1} wet sediment. We sampled sediment at four locations with various overlaying water depths.

At water depths 300 – 700 m the depth of oxygen penetration into warm upper sediment (c.a. 21°C) is 8-14 mm. In anoxic sediments, combination of moderate TOC content (0.1-0.6%) with high sulfate concentration (32 mM) fuels organoclastic bacterial sulfate reduction. Concentrations of Fe(II) in the pore-waters are as high as 78 μM, and concentrations of dissolved Mn are as high as 76 μM. Combination of low hydrogen sulfide concentration in pore-waters (≤0.37 μM), low concentrations of soluble sulfide oxidation intermediates ($[S_2O_3^{2-}] \leq 0.55$ μM, $[SO_3^{2-}] \leq 0.14$ μM) and low sedimentary S^0 content (≤0.37 mmol kg^{-1} wet sediment) indicate that transformation of hydrogen sulfide to pyrite is fast enough to prevent sulfide oxidation by Fe(III) phases. Pyrite is the main sulfur pool in the sediment solid phase, and its content is up to 10.6 mmol kg^{-1}, with a maximum at 15 – 25 cm bsf.

At the shallow sediments (21 m water depths) penetration depth of oxygen is only 1 mm, and hydrogen sulfide concentration in pore-waters is as high as 12 μM. Dissolved iron and manganese concentrations below 5 cm bsf are lower than in the deeper sediments <1 μM and <0.5 μM, respectively. Concentrations of sulfide oxidation intermediates in pore waters ($[S_2O_3^{2-}] < 4.05$ μM, $[SO_3^{2-}] < 3.64$ μM) as well as in the solid phase [S^0] = 0.07-1.37 μmol kg^{-1} wet sediment are higher than at deeper locations.

The sediment of the Gulf of Aqaba presents an interesting example of transition of pore-water composition with depth from sulfidic (H_2S-rich) to ferruginous (Fe(II)-rich).

Mass independent isotope fractionation of mercury: Why it is such a useful tool in biogeochemistry and ecology

J. D. BLUM[1]

[1]Dept of Earth and Environmental Sciences, University of Michigan, Ann Artbor, MI 48109 (jdblum@umich.edu)

Mercury is a globally distributed and highly toxic heavy metal with both natural and anthropogenic sources. Its mobility, toxicity and bio-accumulative properties change dramatically as it is transformed through microbial, photochemical and dark abiotic reactions in the environment. Multiple biogeochemical transformations of mercury determine its movement and bioavailability, and knowledge of these processes can aid in developing strategies for minimizing human and wildlife exposure to its most toxic forms. The seven stable isotopes of mercury fractionate in the environment due to an unusually wide range of physical processes. Mass-dependent fractionation (MDF) occurs during most biotic and abiotic reactions that have been investigated. Mass-independent fractionation (MIF) of mercury can be caused by the magnetic isotope effect, the nuclear volume effect and by UV self-shielding. Each fractionation mechanism imparts a diagnostic pattern of isotopic variation and thus mercury isotope ratios can be used to unravel complex biogeochemical pathways for mercury. Large-magnitude MIF of odd isotopes is uniquely produced by photochemical reactions, which are important because they can degrade mercury from the toxic methylated form to a volatile gas. In addition to isotopic fingerprinting of sources, MIF and MDF in natural samples have been calibrated against experimental determinations of fractionation factors to identify reactions in natural systems and estimate their reaction progress. Because MIF is unaffected by biotic processes it preserves a memory of biogeochemistry before entry into the base of foodwebs.

Seawater Trace Metals in acidified condition: an accumulation study in the blue mussel Mytilus galloprovincialis off Vulcano Island submarine vents (Italy)

BOATTA F.[1]*; D'ALESSANDRO W.[2]; GAGLIANO A.L.[1]; FEDERICO C.[2]; CALABRESE S.[1]; LIOTTA M.[2,3]; MILAZZO M.[1] AND PARELLO F.[1]

[2] INGV, Palermo, via U. La Malfa 153, 90146 Palermo, Italy
[3] DiSTABiF; Seconda Università degli Studi di Napoli, 43, 81100 Caserta, Italy

Ocean acidification is linked to the increasing concentration of atmospheric anthropogenic carbon dioxide, and this process might have negative ecological and economic effect worldwide.

Areas with naturally high levels of CO_2 can help us to achieve a better understanding of this issue. Submarine vents in the Levante Bay of Vulcano Island (Italy) are CO_2-dominated resulting in seawater acidification, and producing a stable pH gradient (from 8.2 down to 5.5) across the bay [1]. We now know that ocean acidification is tightly linked to the mobility and bio-availability of heavy metals.

In that area a transect covering the pH conditions which will be found up to the end of this century has been individuated and a Blue Mussels transplant experiment was done along this gradient in order to estimate the trace metal accumulation capability related to the seawater acidification.

Major and Trace elements were analyzed both in seawater and in the mussels' tissue.

At the end of the experiment, the animals showed an increase of concentration for some elements such as Fe and V with respect to blanks.

The present study provides preliminary data on a particular aspect related to the ocean acidification problem.

MgSO4 phases: hydration, spectroscopy and S isotope partitioning

EMA BOBOCIOIU AND RAZVAN CARACAS

Laboratoire de Geologie de Lyon (LGLTPE) CNRS UMR 5276, Ecole Normale Supérieure de Lyon Universite Claude-Bernard Lyon 1, 46, allée d'Italie, 69364 Lyon cedex 07, France

We study the relative stability of several magnesium sulfate minerals using first-principles calculations based on the density functional theory in the ABINIT implementation. These phases might be present on the surface of Mars or on a variety of smaller icy bodies form the outer solar system. Our calculations show that, if involved in the water cycle of Mars, the magnesium sulfates must be already present as hydrated phases: the anhydrous phases are easily absorbing water and, in turn, the complete dehydration of these phases requires large temperature, unattainable on Mars. We equally compute the Raman and infrared spectra of several phases to offer reference spectra for *in situ* spectroscopic identification. Apart from the appearance of the water bands, the hydration also changes the position of several lower-frequency bands. Using the spectroscopic calculations we determine the influence of hydration on the S isotope partitioning. We show that it is highly dependent on the temperature. For temperatures specific to the surface of Mars, hydration of the anhydrous phase leads to an enrichment in the S34. The effect on the already hydrated phase is opposite: further hydration enriches lighter isotopes.

Partitioning of trace elements between Na-bearing majoritic garnet and melt at 8.5 GPa and 1500–1900°C

A.V. BOBROV[1]*, YU.A. LITVIN[2], A.V. KUZYURA[2], A.M. DYMSHITS[3] AND T. JEFFRIES[4]

[1]Geological Faculty, Moscow State University, Moscow, Russia (*correspondence: archi@geol.msu.ru)
[2]Institute of Experimental Mineralogy, Chernogolovka, Russia
[3]Sobolev Institute of Geology and Mineralogy, Novosibirsk, Russia
[4]National History Museum, London, UK

The new experimental data on trace element partitioning between Na-bearing majoritic garnet and melt at 8.5 GPa and 1500–1900°C applicable to partial melting of Na-rich eclogite is presented. The Na-bearing garnet is a liquidus phase of the system at 1850–1650°C being accompanied by enstatite-rich pyroxene at lower temperatures. With the temperature decrease, Na concentration in garnet increases up to >1 wt % Na_2O due to progressive incorporation of Na majorite ($Na_2MgSi_5O_{12}$). Most of the studied trace elements are incompatible, except for Er, Tm, Yb (in some runs), Lu, and Sc (in all runs), which partition into garnet. The main feature of the trace-element partitioning in our experiments is the different behaviour of the LREE (La, Ce, Pr) in comparison with MREE and HREE (Nd, Sm, Eu, Gd, Tb, Dy, Y, Ho, Er, Tm, Yb, and Lu). Significant increase of D values for LREE with increase of Na_2O concentration in garnet is observed. As predicted from lattice strain, partitioning coefficients for REEs entering the X site of garnet exhibit a near-parabolic dependence on ionic radius. Other elements including the LILE (Rb, Sr, Ba), Sc, as well as Zn, Ta, and Pb have a clear affinity for aluminosilicate melt. The results of the study are applied to the formation of inclusions of Na-bearing majoritic garnets in diamonds and equilibrium melts, which are significantly enriched in LREEs being very similar to kimberlitic and OIB melts.

This study was supported by the Russian Foundation for Basic Research (project no. 12-05-00426).

[3] Bioemco, Equipe Géochimie organique et minérale de l'environnement, UMR 7618 UPMC, Université Pierre et Marie Curie, 75252 Paris Cedex 05

Marine mangroves are intertidal marine ecosystems found in tropical and sub-tropical areas. A development of white bacterial mat can be found in Guadeloupian marine mangroves. This mat consists of a layer of micro-organisms deposited above the anoxic sediment consisting of eukaryotes (e.g. diatoms, nematodes) and prokaryotes (e.g. filamentous cyanobacteria, filamentous sulfur-oxidizing bacteria, archae). Most of the filamentous bacteria found in the mat belong to the genus *Beggiatoa*. These bacteria contain genes encoding both for sulfur oxidation (production of sulfate) and ammonium oxidation (production of nitrate).

The aim of this study was to determine the potential for nitrification is these *Beggiatoa* mats. Potential nitrification rates were carried out with the *Beggiatoa* mat collected in a marine mangrove. The *Beggiatoa* mat or filaments were amended with sea water containing different NH_4^+ concentrations and incubated under oxic conditions. The increase in nitrate concentration was measured after 15 hours of incubations. Potential nitrification rates showed a large variation ranging from 0.2 to 2200 μg nitrate N L^{-1} h^{-1}. Our study showed the potential for nitrification in *Beggiatoa* filaments, implying an important link between the N and S cycles, by sulfur oxidizing bacteria, in these mangrove systems.

Examination of Magma Degassing Paths Based on Melt Inclusions

R. J. BODNAR[1], R. ESPOSITO[2], E. GAZEL[1], L. MOORE[1], M. STEELE-MACINNIS[1] AND P. WALLACE[3]

[1]Dept. of Geosciences, Virginia Tech, Blacksburg, VA 24061 USA. rjb@vt.edu; egazel@vt.edu; moorelr@vt.edu; mjmaci@vt.edu

[2]DISTAR, Università degli Studi di Napoli Federico II, Napoli, 80134, Italy. rosario.esposito3@unina.it

[3]Dept. of Geological Sciences, University of Oregon, Eugene, OR 97403 USA. pwallace@uoregon.edu

In a landmark paper, Newman *et al*. [1] suggested that the CO_2 and H_2O contents of volcanic glasses could be used to understand magma degassing processes. This approach was immediately adopted by Anderson *et al*. [2] and applied to melt inclusions (MI) in quartz phenocrysts from the Bishop Tuff to investigate the pre-eruptive volatile contents and pressures in the magma chamber during phenocryst growth and MI entrapment. In the nearly three decades since these pioneering studies, numerous MI studies have been conducted to determine magma degassing paths using this method.

The scientific basis for using CO_2/H_2O systematics in MI is robust and supported by experimental data, but several unstated assumptions are required for the results to accurately define a magma degassing path. First, the trapped melt must have been at volatile saturation. Additionally, the melt (glass) that is analyzed must represent the melt that was originally trapped and must be free of any post-entrapment modifications (or it must be possible to reverse these processes before analysis or account for these changes by other means). Thus, post-entrapment crystallization on the walls of the MI, diffusional loss of H_2O from the MI and exsolution of a vapor bubble after MI entrapment are all processes that will affect the CO_2/H_2O systematics of the MI.

Examination of data from a variety of sources suggests that in many cases there is clear evidence for post-entrapment modifications (primarily shrinkage bubble formation) that have not been corrected for during analysis or data interpretation. Moreover, recent studies have shown that these modifications can produce "false degassing paths" that cannot be distinguished from true degassing paths. It is also critical that MI be studied within a paragenetic context in order to constrain relative times of MI formation, and that other indicators of crystallization progress and/or depth of formation be monitored along with the CO_2/H_2O systematics to confirm that the volatile data record a degassing history.

Cordierite nucleation and growth rates in the Torres del Paine contact aureole

[1] ROBERT BODNER, [2] LUKAS BAUMGARTNER AND C. THOMAS FOSTER

1 University of Lausanne, Switzerland, Institute of Earth Sciences [robert.bodner@unil.ch]
2 University of Lausanne, Switzerland, Institute of Earth Sciences [lukas.baumgartner@unil.ch]
3 University of Iowa, USA, Department of Geoscience [tom-foster@uiowa.edu]

The Torres del Paine (~ 12.59 Ma) intrusion consists of three granite and four mafic batches, which formed within 160 ± 11 ka (Michel *et al*. 2008, Leuthold *et al*. 2012). It intruded into fine grained pelites, sandstones, and conglomerates of the Cerro Toro and Punta Barrosa formations at a depth of 2-3 km. Its contact aureole is characterized by the occurrence of porphyroblastic cordierites (crd). The crd forming reactions are the chlorite break-down reaction (ca. 480°C) and the phengite break-down reaction (530-550°C), which is accompanied by a modal decrease in biotite and the appearance of k-feldspar

We present differences of crystal size distributions (CSDs) in a 400m long sample profile from the igneous contact to the outer part of the aureole. Samples close to the contact have the smallest crystals (radius < 0.06mm), while samples at 400m from the intrusion contain the largest crystals (radius < 0.09 mm). The maximum population density decreases from 11.5mm^{-4} close to the intrusion to 9.5mm^{-4} at distances between 200 and 400m from the intrusion. T-t paths close to the intrusion are characterized by rapid heating (e.g. to 610 °C at 40 m), while the temperature increases much slower to the cordierite-in reaction temperature in the outer aureole. The observation on crd textures were fit with with a numerical nucleation-crystallization model. We assumed diffusion controlled mineral growth and we tested different nucleation laws (e.g. Ridley and Thompson 1986, Carlson *et al*. 1995). The large differences in the temperature-time paths for samples of similar chemistry allowed us to fit nucleation and growth parameters by matching calculated and observed textures.

The resulting parameters indicate rapid completion of reaction before the thermal peak in the inner parts of the contact aureole, and continued reaction after the thermal peak in the outermost contact aureole. In the innermost part of the aureole the overstepping is several tens of degrees (50-150 °C), depending on the nucleation model and the choice of parameters. Calculations with these parameters further show a narrow transition zone (~ 5m width) of full reaction to no reaction between the prograde contact aureole and the unreacted host rock, indicating a relatively sharp isograd for sampling purposes.

Interpretation of Calcium Isotope Variations in Marine Fossil Records

BÖHM, F. AND EISENHAUER, A.

Geomar, Helmholtz Centre for Ocean Research Kiel, Kiel, Germany; fboehm@geomar.de; aeisenhauer@geomar.de

Many studies indicate the existence of calcium isotope excursions and trends in sequences of fossil marine carbonates (e.g.[1, 2]). However, interpretation of these calcium isotope variations is still controversial [3]. Several studies explain calcium isotope excursions as indicators of an imbalance between the major calcium fluxes in the oceans, riverine input and output by carbonate sediments (e.g. [2, 4]). These studies tend to neglect the direct coupling between calcium and carbonate ion fluxes in both weathering and carbonate precipitation. As a consequence the neglection may lead to very unlikely scenarios for the corresponding ocean carbon cycle. Here we present a simple numerical model to calculate mass balances for both marine calcium and carbonate ion concentrations in response to changes in the weathering and carbonate sediment fluxes. The model results clearly show that neither weathering nor carbonate sedimentation may explain observed calcium isotope variations unless extreme scenarios for the inorganic carbon cycle are assumed. Hence alternative explanations other than weathering and carbonate sedimentation are necessary to explain the calcium isotope excursions observed in the Phanerozoic record.

Yet for interpretation of the marine Ca isotope record it has not been taken into account that precipitation rate has a significant influence on calcium isotopes in calcium carbonate minerals [5, 6, 7]. Nielsen *et al*. [8] recently suggested that the influence of the Ca^{2+}:CO_3^{2-} ratio on precipitation rate has a significant impact on calcium isotope fractionation. Variations of the marine Ca^{2+}:CO_3^{2-} ratio by up to one order of magnitude may have occurred in the Phanerozoic oceans and may explain at least some of the observed calcium isotope trends.

Weathering processes and supergene formation of uranium bearing minerals at U-mines in the Saint-Sylvestre Area (French Massif Central)

FLORA BOEKHOUT[1]*, MARTINE GÉRARD[1], VANNAPHA PHROMMAVANH[2], MICHAEL DESCOSTES[2] AND GEORGES CALAS[1]

[1]Institut de Minéralogie et de Physique des Milieux Condensés, Université P&M Curie, IRD, France, martine.gerard@impmc.upmc.fr, calas@impmc.upmc.fr
[2] AREVA, BG Mines, R&D, Paris la Défense, France vannapha.phrommavanh@areva.com, michael.descostes@areva.com
(*presenting author)

In France, uranium mines were exploited between 1945 and 2001 leading to the production of 76,000t of U but also 200 Mt of waste rocks. We present the supergene evolution of waste rock piles generated during mining operations at the Vieilles Sagnes site (Fanay) located in the Saint-Sylvestre leucogranite complex (northwestern Limousin, French Massif Central). This two-mica granite was emplaced at 324 ± 4 Ma and hosts an important U-ore mineralization deposited at 270-280 Ma, due to sustained hydrothermal circulation.

At the Vieilles Sagnes site mining operations between 1957 and 1965 generated waste rock piles of dominantly granitic rocks that have been exposed to supergene processes since the mining time. The U content of the blocks in the waste rock pile is 10-120 ppm, while in the ore body it is around 1000-3000 ppm.

To assess their supergene evolution and the neo-formation of uranium bearing phases two trenches were escavated through the waste rock pile, enabling the sampling of both superficial blocks and samples from the interior of the pile. Granitic blocks, proto-soils and alteration products that form the matrix of the waste rock pile, as well as paleo-soils underlying the rock pile were sampled.

The micromorphology, mineralogy and geochemistry of the samples representative of the different horizons of the profile investigated were examined by optical microscopy, and SEM observations, XRD and ICPMS whole rock analyses, respectively.

The degree of weathering of the granitic blocks is evidenced by the occurrence of chlorite and kaolinite alteromorphs after biotite and smectite and kaolinite after feldspar. The liberation of Fe gives rise to the local formation of Fe-phosphates and sulphates. Magmatic and hydrothermal U-bearing minerals release U as alteration and arenisation of the granites take place. So far no coffinite or uraninite from the initial mineralization have been observed.

Preliminary results suggest that the migration of uranium and formation of uranyl phosphates is at least partly associated with the supergene formation of Fe-phosphates. U-sorption onto clay minerals also seems to play an important role in decreasing U-mobility during meteoritic weathering.

Non-mass-dependent oxygen isotope enrichments in O_3 and CO_2: New insights from experiments, observations, and modeling

K.A. BOERING[1]*

[1] Departments of Chemistry and of Earth and Planetary Science, University of California, Berkeley, Berkeley, California, 94720-1460 USA (boering@berkeley.edu)

Results from recent laboratory experiments, atmospheric observations, and photochemical kinetics modeling provide new insights inot the anomalous ^{17}O and ^{18}O enrichments in ozone and their transfer to carbon dioxide. In particular, new observations of the triple oxygen isotope composition of stratospheric CO_2 reveal surprisingly large anomalous enrichments that vary with latitude, altitude, and season. The triple isotope slopes were 1.95±0.05(1σ) in the middle stratosphere and 2.22±0.07 in the Arctic vortex versus 1.71±0.03 from previous observations and a factor of 4 times larger than the mass-dependent value of 0.52. Kinetics modeling of laboratory measurements of CO_2-ozone isotope exchange demonstrates that non-mass-dependent isotope effects in ozone formation alone quantitatively account for the ^{17}O anomaly of CO_2 in the laboratory, resolving long-standing discrepancies between models and laboratory measurements. Model sensitivities then provide a framework for understanding ^{17}O in stratospheric CO_2 and the larger three isotope slopes observed there than in laboratory experiments and, thus, a firmer foundation for the many biogeochemical and paleoclimate applications of ^{17}O anomalies in tropospheric CO_2, O_2, minerals sulfates, and fossil bones and teeth, all of which derive from isotope exchange between ozone and stratospheric CO_2. Finally, measurements of the pressure and bath gas dependence of the ^{17}O and ^{18}O enrichments in ozone in bulk photochemistry experiments in the laboratory [1] provide new insight into and constraints on the physical chemical origin of the dynamically-driven symmetry isotope effects in ozone formation.

Algal mats of the North Pole: How sea ice melt can cause anoxic spots on the Arctic deep-sea floor

ANTJE BOETIUS,
FRANK WENZHÖFER[123] AND THE SCIENTIFIC TEAM OF RV POLARSTERN ARK 27-3

[1]Alfred Wegener Institute Helmholtz Center for Polar and Marine Research, D-27515 Bremerhaven
[2]Max Planck Institute for Marine Microbiology, D-28359 Bremen
[3]MARUM Center for Marine Environmental Sciences, University of Bremen, D-28359 Bremen

The centric diatom *Melosira arctica* forms kelp-like accumulations under the Arctic sea ice, in the form of meter-long filaments, anchoring in troughs and depressions under ice floes. These mat-forming algae are extremely sensitive to warming and melting of the ice, leading to their rapid sedimentation. The research icebreaker POLARSTERN visited the ice-covered eastern-central basins between 82° to 89°N and 30° to 130°E in summer 2012 in the framework of the expedition ICEARC. By September, the Arctic sea ice had declined to a record minimum of 3.6 million square kilometers. Consequently, we observed the massive sedimentation of sub-ice algal biomass of up to 150 g C per m^2 (median: 9 g C per m^2) to the deep-sea floor of the Arctic basins. Patches of algal mats of 1-50 cm in diameter covered up to 10% of the seafloor at 3300-4500m water depth. *in situ* and ex situ microprofiling of diffusive oxygen fluxes into sediments covered by algal aggregates showed elevated rates of 5-6 O_2 mmol m^{-2} d^{-1}, compared to <0.4 mmol m^{-2} d^{-1} in the surrounding sediments. Apparently only sediment bacteria, and large mobile megafauna were able to profit of the ice-algae deposition event. In cores covered by Melosira strands, oxygen penetration in the sediment was reduced to a few mm as compared to the surrounding sediment, where oxygen penetrated >50 cm deep. From the *in situ* oxygen profiles we conclude that the sinking *Melosira* strands had contributed >85% of total carbon flux to the deep-sea floor in 2012, but that such massive algal falls were previously rare. Our observations support the hypothesis that the thinning ice cover enhances under-ice productivity and export. If this phenomenon repeats seasonally, substantial changes in the biogeochemistry and biodiversity of the ice-covered Arctic basins are expected.

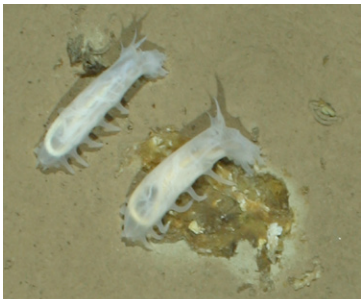

Figure1:Sea cucumbers feeding on freshly deposited algal mats at 4500 m water depth

Aqueous Li^+ speciation and ancient climate monitoring

STUART BOGATKO[1], PHILIPPE CLAEYS[2], FRANK DE PROFT[1] AND PAUL GEERLINGS[1]

[1]Free University of Brussels, General Chemistry, Pleinlaan 2, 1050, Brussels, Belgium. Email: sbogatko@vub.ac.be
[2]Free University of Brussels, Earth System Science, Pleinlaan 2, 1050 Brussels, Belgium

Lithium is recognized as a valuable trace metal in the area of ancient climate monitoring. This arises from the isotopic composition of Li in seawater being strongly influenced by continental weathering, one of the major sources of Li in seawater, and the incorporation of aqueous Li^+ into calcium carbonate shells. By systematically analyzing the isotopic composition of Lithium in ancient calcium carbonate it is possible to reconstruct a record of Li isotope fractionation (IF) in seawater over the past 68 Ma. Due to the close association of Li IF with ancient weathering, this record is able to provide critical information concerning the ancient earth climate.

Previous studies base their paleo-reconstructions on the close correspondence between modern values of Li isotope ratios in calcium carbonates and seawater. Implicit is the assumption that Li IF is not sensitive to environmental conditions such as Temperature and pH. This assumption is not supported from a molecular structure point of view; there is little information concerning the identity and molecular structure of aqueous Li^+ species and it is not clear to what extent ligand coordination effects may play in the incorporation of Li^+ into calcium carbonate.

We have carried out a theoretical (Density Functional theory) study of aqueous Li^+ speciation including effects of ligand coordination, temperature and solutin pH. We have calculated the isotope exchange equilibrium constant associated with the Li Acid/Base equilibium and can constrain it to positive values. The consequences of this species dependent IF are then studied using a model for Li-Carbonate coordination. We define an effective IF to model temperature and pH induced changes in Li IF in Li-Carbonates. We predict that under normal oceanic conditions Li IF is not sensetive to pH but may be significantly influenced by temperature.

Based on our results we revisit the basic assumption that Li IF is not sensitive to environmental conditions such as Temperature and pH. Namely, our observation of significant species dependent Li IF strongly suggests that the mechanism through which Li is incorporated into calcium carbonate is not sensetive to the Li speciation.

Geochemical spectra as an integral characteristic of the concentration and dispersion of elements in soils, peats and natural waters

L.G. BOGATYREV[1], E.Y. POGOZHEV[2], E.A. POGOZHEVA[1] AND I.I. ANTONOVA[1]

1 Department of Soil Sience, Moscow State University, Russia (*correspondence: pogozhevaea@mail.ru)
2"Geoforum", Vernadsky avenue, 51, Moscow, Russia

Geochemical spectra are the useful tool for comparison of elements concentration or dispersion in the different components of the biosphere. In this work elements distribution patterns were studied in soil samples from Yakutia, West Siberia and European Russia. Geochemical spectra were also obtained for particle-size fractions and ortsteins isolated from some soils of taiga zone, as well as for natural waters.

Geochemical spectra depend largely on soil mineralogical composition. Investigation of the elemental composition of sand, silt and clay fractions showed clear divergence of their geochemical spectra. Geochemical spectra of iron-manganese nodules from different horizons of sod-podzolic soils were quite similar. This suggests that they were formed in single geochemical space from similar soil formation products and in presence of similar soil solutions. This supposition also seems to be true for mineral horizons of alluvial soils and underlying peats. Probably, geochemical spectra of elements for soils are inherited from the parent rock and represent some sort of the "genetic code" [1]. Preservation of this code is determined by the lifetime of the soil. soil geochemical spectra provides stable functioning of terrestrial ecosystems.

Zircon from Mesoarchean enderbites of Volgo-Uralia: U-Pb age, REE, Hf- and O-isotope compositions

S.V. BOGDANOVA[1]*, E.A. BELOUSOVA[2], B. DE WAELE[3] AND A.V POSTNIKOV[4]

[1]Department of Geology, Lund Univ., SE-22362, Sweden (*correspondence: Svetlana.Bogdanova@geol.lu.se)
[2]GEMOC ARC National Key Centre, Macquarie Univ. Sydney, NSW 2109 Australia (elena.belousova@mq.edu.au)

[4]Gubkin State University of Oil and Gas, Moscow, Russia (apostnikov@mtu-net.ru)

As shown by numerous drillings, Archean charnockitic rocks are common in most of the lower crust in southern Volgo-Uralia, which is one of the major crustal megablocks of the East European Craton [1]. They are mainly enderbites that form large bodies (e.g. the Kolyvan intrusion, this study). Zircon from the enderbites contains relics of inherited cores with magmatic oscillatory zoning. These are surrounded by CL black-and-bright alternating bands of curved metamorphic rims. The crystallization age of the cores is between 3140±7 Ma (SHRIMP) and 3127±46 Ma (LA-ICPMS), while the outmost CL-bright rims are ca. 1945 Ma. The ages in-between are interpreted as a result of different degrees of Pb-loss caused by the high grade metamorphism. The ingressive recrystallization of primary magmatic zircon correlates with depletion in REE, which is observed consistently in each studied core-rim pair. No differences in O-isotope composition are detected between the cores and rims; the δO^{18} values vary from ca. 5 to 6.5. The Hf-isotope compositions of magmatic cores (-3 to -9 εHf) and metamorphic rims (-14 to -28 εHf), and their similar crustal model ages from 3.42 to 3.86 Ga, imply Eo- to Paleoarchean crustal sources for the charnockitic magmas and very little, if any, juvenile additions during the metamorphic event at ca. 1945 Ma. The dated Kolyvan enderbites belong to calc-alkaline, meta- to peraluminous, mainly ferroan series, also indicating substantial participation of crust in charnockitic melt sources relevant to a continental arc setting at 3.1 Ga. We reported similar results on rocks from the Bakaly block to the northeast of the Kolyvan region [1] confirming widespread Early Archean crust in Volgo-Uralia.

Almost 90 years ago, V.I. Vernadsky [1] created the holistic doctrine of the Biosphere where he demonstrated the primacy of life as a geological force. Concentrative function of living matter plays a significant role in biomineralization, which is the process when living organisms assemble structures from naturally occurring inorganic compounds [2].

The purpose of this work was to investigate biomineral formation in peat and show an important role of living matter in element accumulation. The objects were peat of the Vidrino highmoor (south-east of the Baikal region, Russia).

The high concentrations of Zn and Cu (500-600 g/t) were determined in peat of the Vidrino highmoor in the layers of early Holocene (360-440 cm) which were formed in period 11-8.5BP. It was shown that authigenic sulfides of Zn and Cu with micron dimension (0.5-3 μm) were formed in the plant cells of sphagnum. Also particles of native silver (5-7 μm) were found out in the peat of the Vidrino highmoor and which were accumulated in cell membrane of sphagnum. The mechanism of silver micro-particles formation in the cell membrane of sphagnum was proposed in this work.

The obtained results show a considerable role of biogenic mineral formation in the investigated peat that is a very important result in discussion about genesis of ore formation in which the preference is given to physical and chemical processes and often the role of living matter is not considered. This research was supported by the RFBR grant 11-05-12038-ofi-m-2011 and grand OPTEC.

A tool for exploring the impact of crustal contamination: The Magma Chamber Simulator

WA BOHRSON[1], FJ SPERA[2], MS GHIORSO[3] AND J. CREAMER[2]

[1] Geological Sciences, Central Washington University, Ellensburg, WA 98926, USA (*correspondence:bohrson@geology.cwu.edu)

[2] Earth Science, University of California, Santa Barbara, CA 93106, USA

[3] OFM Research - West, 7336 24th Ave NE, Seattle, WA 98115, USA

The Magma Chamber Simulator is a new computational tool that quantifies the impact of simultaneous recharge, assimilation and crystallization on melt±solids±fluid in a magma-recharge magma-wallrock composite system. Enthalpy from magma cooling/crystallization and recharge heats wallrock (WR). When the fraction of anatectic melt attains or exceeds a critical percolation limit of ~0.05-0.15, assimilation begins. Magma cooling/crystallization, addition of recharge magma and anatectic melt, and WR heating continue until magma and WR reach thermal equilibrium. For each simulation step, thermodynamic and material balance assessment provides major/trace element and isotopic compositions, masses and temperatures of all phases in each part of the composite system. Initialization includes bulk composition, temperature and pressure of all subsystems, as well as relevant solid/melt and solid/fluid partition coefficients. Simulation of high alumina basalt intruding dioritic to granitic WR at 500-550°C and 0.1 GPa yields a large volume of dacitic melt at equilibrium temperatures of 950-975°C. Assimilation enhances pyroxene crystallization but suppresses plagioclase; this and addition of anatectic melt yield a melt body up to 5x larger than that generated by FC alone. Selected trace element and isotopic results for magma show that, at the equilibrium temperature, Sr isotopes are >0.708, with only 2% of Sr contributed by crust. Nd isotopes are <0.5126, with ≤11% of Nd from crust. In contrast, the total mass of anatectic melt assimilated is ~40%, highlighting the critical difference between mass of element and total mass of assimilated melt. Trace element results also illustrate that variations in mass of element and mass of magma melt can yield dilutions of incompatible element concentrations in contaminated magma, providing an explanation for systems that have "decoupled" trace element and isotopic signatures. Because the MCS predicts detailed phase abundance, mass and compositional information, exploration of a wide range of open-system problems in igneous petrology is possible.

Mineral Surface Hydroxyl Group Identity and Reactivity

JEAN-FRANÇOIS BOILY

[1]Department of Chemistry, Umeå University, Sweden (jean-francois.boily@chem.umu.se)

Mineral surfaces are reactive transformation centres and sinks for gases, solutes and solvents. These surfaces are populated by (hydr)oxo functional groups that can undergo protonation, ligand exchange, and form extensive networks of hydrogen bonds (Figure 1). Knowledge of the types, distributions and orientations of these groups is consequently essential understanding molecular-scale processes taking place at mineral surfaces.

This work is focused on the properties of hydroxo groups on important crystallographic planes of synthetic nano-sized (α, β, γ)-FeOOH particles exposed to vacuum, water vapor and carbon dioxide. Vibration spectroscopic signatures of isolate and hydrogen bonded hydroxo groups on these minerals will be presented alongside predictions from molecular dynamics simulations. This body of work forms the basis for a molecular-scale understanding of reactions taking place at surfaces of geochemically relevant mineral particles.

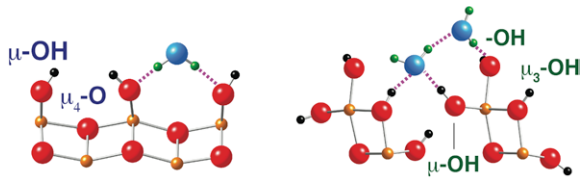

Figure 1. Schematic representation of dominant configurations of gaseous water molecules (blue) adsorbed on the (010) (left) and the (001) (right) planes of γ-FeOOH.

[3]Now at : Massachusetts Institute of Technology, Cambridge, MA, USA (pdeanna@mit.edu)

Field quantitative estimation of reaction kinetics is required to predict biogeochemical reactions in aquifers. We extended the analytical solution developed by Haggerty *et al.* [1] to model an entire 1st order reaction chain and estimate the kinetic parameters for each reaction step. We then evaluated the ability of this solution to model experimental results from a push pull test in a fractured crystalline aquifer (Ploemeur, Brittany). Nitrates were used as the reactive tracer, since denitrification is a sequential reduction of nitrates to nitrogen gas occuring in a chain reaction ($NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$) under anaerobic conditions. The kinetics of nitrate consumption and by-products formation (NO_2^- and N_2O) during autotrophic denitrification were quantified by using a reactive tracer (NO_3^-) and a non-reactive tracer (Br-). Comparison of the Br^- and NO_3^- breakthrough curves showed that 10 % of the injected NO_3^- molar mass was transformed during the 12 hour experiment. Similar results, but with slower kinetics, were obtained from laboratory experiments in reactors. The good agreement between the model and the field data shows that the complete denitrification process can be efficiently modeled as a sequence of first order reactions. The variability of biogeochemical reactivity in the field will be also discussed.

Copper contamination of lake sediments in the vicinity of Konin (Poland)

IZABELA BOJAKOWSKA*, STANISŁAW WOŁKOWICZ AND JOANNA KRASUSKA

PGI-NRI, 4 Rakowiecka, 00-975 Warsaw, Poland (izabela.bojakowska@pgi.gov.pl)

Copper is an element essential to the life of many organisms. However, excessive concentrations of copper can be toxic. Due to the harmful effects of copper to aquatic organisms, its *PEC* level in sediments has been fixed at 149 mg kg-1.

Sediment samples were collected from the 5-cm thick surface layer of the profundal zone of 14 lakes located in the near Konin (central Poland). Determinations of the concentrations of Al, Ag, As, Ba, Ca, Cd, Co, Cr, Cu, Fe, Mg, Mn, Ni, P, Pb, S, Sr, Ti, V and Zn were determined by ICP-AES methods from solutions obtained after digestion in aqua regia. The Hg concentration determinations were made using TMA method and the organic carbon content (TOC) was determined by coulometric titration method.

The concentrations of the some trace elements varied over a wide ranges of content: for Cu - 9-674 mg/kg, Ba 57-409 mg/kg, Hg – 0.058-0.366 mg/kg, Ni - 5-25 mg/kg, Pb - 16-53 mg/kg, Sr - 53–758 mg/kg and Zn - 30-184 mg/kg. It has been found that the sediments of five lakes (Gosławskie, Licheńskie, Pątnowskie, Ślesińskie, and Wąsosko-Mikorzyńskie), whose waters are included in the power plant cooling system, are characterized by much higher contents of Cu, Ba, Hg, Mn, Sr and Zn, as compared to the other lakes. The average concentrations of Cu, Ni, Pb, Hg and Zn in the sediments of the latter lakes are comparable with the concentrations of these elements in sediments of lakes from other regions. The sediments of lakes included in the Konin-Pątnów power plant cooling system are conspicuous by a very high concentration of Cu (avg. - 415 mg/kg), which is 35-times higher than its average concentration in lake sediments (7 mg/kg). The average content of Ba in the sediments of these lakes is three times higher; of Ni, Hg and Zn – twice higher.

The studies of the Konin region lakes sediments have shown that they contain high Cu concentrations that may cause harmful effects on aquatic organisms. However, it is necessary to perform further tests to determine the copper content in fish tissues due to the fact that these lakes are used for recreational and angling purposes on a large scale.

A comparison of Pitzer databases for nuclear waste disposal modelling

FRANK BOK[1]*, ANKE RICHTER[1] AND VINZENZ BRENDLER[1]

[1]Helmholtz-Zentrum Dresden-Rossendorf e.V., Dresden, Germany, (*correspondence: F.Bok@hzdr.de)

For the modelling of different chemical aspects of a nuclear waste repository in salt rock, the Pitzer formalism is necessary. Therefore, a comprehensive database with the relevant species reaction constants and associated ion-ion interaction parameters including temperature-dependencies is required. A number of different tailored Pitzer databases are available [1]. To judge their capabilities and limitations we performed comparative calculations for well-defined chemical systems (binary or ternary solubility diagrams). To avoid possible deviations due to different speciation codes all databases where transformed into the format specific for Geochemist's Workbench [2]. Additionally, model results are compared to experimental values from the literature.

Most results for the Oceanic Salt Systems (Na^+, K^+, Ca^{2+}, Mg^{2+} / Cl^-, SO_4^{2-} – H_2O) at 25 °C show a good agreement between experiment and model. At higher temperatures, sparse temperature-dependent data causes strong differences in the results.

For the radionuclides (e.g. Nd, Np), the solubility of their amorphous hydroxides in high salinar solutions was calculated as a function of pH. Missing anionic hydroxo-complex species or less reliable data produce inadequate predictions of the increasing solubility of mineral phases (e.g. fresh amorphous $Nd(OH)_3$ or NpO_2OH) in the strongly alkaline medium. This demonstrates the importance of complete chemical speciation data.

Caesium was chosen as example for a fission product. Only minor differences can be found in the calculated solubility diagrams and the occasional absence of solubility data for Cs phases is not significant for real-world scenarios due to the high solubility of these phases in comparison to other salts.

The revealed dsicrepancies illustrate the need for further database work. Joint benchmark activities could help to identify missing or weak data, enhance the quality of all databases and consequently increase the confidence in modelling results.

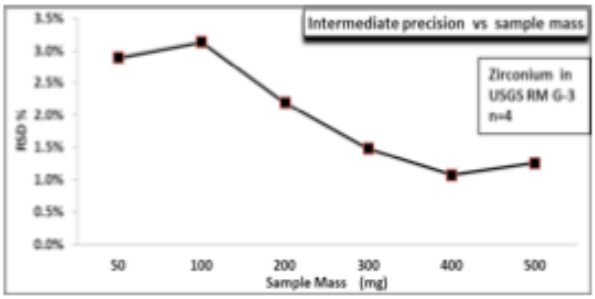
The determination of homogeniety of geological reference material

SYED N. H. BOKHARI AND THOMAS MEISEL

[1] General and Analytical Chemistry, Montanuniversität, 8700 Leoben, Austria (*correspondence: syed-nadeem-hussain.bokhari@unileoben.ac.at)

Reference materials (RM) support measurements in geological research due to the degree of homogeneity, traceability and confidence interval of their property values. Homogeneity testing is essential in certification of reference materials, as it should demonstrate the validity of the certified values and their uncertainties. Ingamells sampling theory [1] has been applied to test homogeneity of IAG Candidate RM trachyandesite (MTA), rhyolite (MRH), RM CGL MGL-AND andesite and uncertified USGS Granite (G-3). The sample digestion for test portions 50 mg to 500 mg was performed following the protocol [2] by sodium peroxide sintering and measurements with ICP-MS.

It is proposed that at least 300 mg is the minimum test portion size for trachyandesite (MTA) and Granite G-3 and 100 mg test portion for Rhyolite (MRH) and MGL-AND andesite to assure acceptable precision less than 2%. Complete digestion of all the analytes including mineral zircon is possible with sample/Na_2O_2 ratio 1:6.



In establishing reference values for reference materials, the contribution of detectable heterogeneity to the overall uncertainty of individual reference values has been quantified. The method has been developed to recover all analytes in particular zircon for 50 mg test portion size but it is suggested that 50 mg test portion is not representative for the particular rock types. It is also recommended to use ICP-MS as a tool of analysis as WD-XRF cannot determine homogeneity in specified test portion due to lower detection limits.

Isotopic Studies of Rapid Carbonate Precipitates

J. R. BOLES[1]*, S. OMELON[2] AND G. GARVEN[3]

[1]University of California Santa Barbara, CA , 93106, USA (*correspondence: boles@geol.ucsb.edu)
[2]University of Ottawa, Ottawa, ON, K1N 6N5, Canada
[3]Tufts University, Medford, MA, 02155, USA

In geologic systems, where crystallization is ***rapid***, the carbonate isotopic systems may be out of equilibrium. Our studies of well scales in hydrocarbon production tubing and tunnel speleothems indicate carbonate to be out of equilibrium when growth rates exceed mm/year. Calcite scales resulting from CO_2 degassing results in covariance in $^{13/12}C$ and $^{18/16}O$ of the precipitate where the limited CO_2 degasses from a thin fluid film. Vaterite occurrences have extremely light isotopic values (>10 per mil) relative to calcite scales in the same reservoir.

Recent experiments to sequester CO_2 from coal combustion involve ***extremely rapid*** $CaCO_3$ precipitation, and oxygen values 10 to 20 per mil lighter than expected for equilibrium. These observations suggest that during extremely rapid crystallization rates the low mass light isotopes are preferentially incorporated into the carbonate, as observed by McCrae [1]. Light isotopes may reach the reaction site, and may form $CaCO_3$ species in solution more rapidly, once crystallization rates exceed some threshold rate. We are currently conducting experiments to determine the relation between crystallization rate, carbonate poly morph type, and stable isotopic composition, by $CaCO_3$ precipitation by $CO_{2(g)}$ addition at different CO_2 partial pressures in calcium chloride solutions at neutral pH.

Water storage in the Earth's mantle

N. BOLFAN-CASANOVA[1] AND ANAIS FÉROT

[1]Laboratoire Magmas et Volcans, CNRS, Université Blaise-Pascal, OPGC, Clermont-Ferrand France,
* correspondance : N.Bolfan@opgc.univ-bcpclermont.fr

Experiments were performed under water-saturated conditions in the MFSH and MFASH systems as a function of pressure and temperature from 2.5 to 13.5 GPa covering the whole depth range of the upper mantle. Water contents were analysed by Fourier transform infrared spectroscopy [1] and water values reported here use the new extinction coefficient for olivine [2]. The incorporation of Al enhances water incorporation in olivine and pyroxene, but only at pressures of 2.5 and 5 GPa. The partitioning of water between pyroxene and olivine is very high (4.4) at 2.5 GPa and below 1250°C, but decreases to an average value of 1.2+/-0.4 for higher pressures and temperatures. At 13.5 GPa and 1400°C, the water content of olivine is 1100±200 ppm wt H_2O. We conclude that the water storage capacity of the upper mantle just above the 410 km discontinuity can be anchored to ~900 ppm wt H_2O. If we interpret that the Low Velocity Layer observed near 350 km is due to mantle melting, we can constrain the water content of the mantle at that depth to be ~650±150 ppm wt H_2O. This new value is twice higher than previous estimates for the mantle source of Mid Oceanic Ridge Basalts but within the range of OIB sources.

Gujba age formation revisited : a possible use as time anchor

J. BOLLARD[1], J.N. CONNELLY[1] AND M. BIZZARRO[1]

[1]Centre for Star and Planet Formation, University of Copenhagen, Øster Voldgade 5-7, Copenhagen K, 1350 Denmark

The meteorite Gujba is a primitive CBa carbonaceous chondrite (Bencubbin-type) that differs markedly from common chondrites. It displays a high metal abundance (metal/silicate ~1.7-3), a depletion in volatile elements, a quasi absence of CAIs and matrix, and large silicate chondrules (up to one cm) [1]. Metal and silicates are proposed to have both formed by condensation in a high temperature environnement, as completely molten droplets and both exhibit quench textures. These features suggest a formation from a vapour-melt plume produced by a giant impact between planetary embryos after dust in the protoplanteray disk had largely dissipated [2]. This supposed formation in a single event followed by a rapid cooling predicts that all chronometric systems closed at the same time such that Gujba is an ideal candidate to anchor the short-lived chronometers onto an absolute timescale.

We have undertaken a project to date individual Gujba chondrules, using the precise assumption-free U-corrected Pb-Pb dating method [4,5] to first confirm the single-event formation model and refine its absolute age.

Five cm-sized chondrules from a single slab of Gujba have been extracted and characterized by SEM. Three of them have been processed by a stepwise dissolution method [4]. Using a ^{202}Pb-^{205}Pb double spike, we analyzed the Pb isotopic composition by thermal ionization mass spectrometry to obtain well-constrained internal isochrons on single chondrules. For now, ages were calculated using the $^{238}U/^{235}U$ ratio of 137.786±0.013 that was determined by [5] for inner solar system materials except CAIs.

Three chondrules have been dated with ages that range from 4562.61±0.28 to 4562.32±0.48 Myr, with a weighted average of 4562.52±0.44Myr. This is ca 1 Myr older than previously published absolute Pb-Pb age [2], when it is adjusted for a U isotopic composition of 137.786. If the adjusted-age from [2] is correct, this discrepency could suggest different populations of chondrules within Gujba, which, in turn, requires a new formation model.

Isotopic composition of water vapour in strong convective updrafts

M. BOLOT[1]*, E.J. MOYER[2] AND B. LEGRAS[1]

[1]Laboratoire de Météorologie Dynamique, CNRS/ENS, UMR 8539, Paris, France (*correspondance: bolot@lmd.ens.fr)
[2]Department of the Geophysical Sciences, University of Chicago, Chicago, USA

The isotopic composition of water is a tracer of interest for understanding convective processes, and the last decade has seen a surge of modelling and observational studies in that field. Yet, the physics of convective clouds governing the transformation of water across its different phases is potentially very complex and the exact dependence of isotopic compositions upon it is not well known nor has been extensively documented since the pioneering work of Jouzel *et al*. [1]. Important processes to consider include kinetic effects that arise from super-/subsaturated conditions due to liquid-ice disequilibrium in mixed phase zones and to lengthy phase adjustment over ice; isotopic re-equilibration between vapour and a variable reservoir of cloud liquid water; and different routes to cloud glaciation (freezing vs. the Wegener-Bergeron-Findeisen process). Using a simplified adiabatic model, we clarify the role of those processes in altering the isotopic composition of water vapour in strong convective updrafts.

We find that the deuterium-excess, which is the conventionally used metric of the joint distribution of deuterium and oxygen 18, is highly sensitive to cloud physics at low temperatures (< -30°C), with a complicated structure of variability resulting from multiple factors. We propose new metrics that relate deuterium and oxygen 18 isotopic ratios at cloud base and cloud top and that are better related to the structure of evolution of those isotopic ratios [2]. We show that, in a statistical sense, those metrics are respectively informative on the level of supersaturation reached by the cloud upon the completion of glaciation (which removes the control of saturation by liquid water); and on the temperature at which cloud glaciation is effective. The retrieved information can serve as a probe of the physics of deep convective clouds.

The Early Eocene Climate Optimum (EECO, 53-50 Ma) was the warmest interval of Cenozoic time. This warm climatic interval was induced by a high atmospheric pCO_2. Several mechanisms have been proposed to explain this climatic anomaly (e.g. LIP of North Atlantic). However one of them seems to be the most convincing in term of carbon fluxes degassing: the Neotethys closure, resulting in large amounts of pelagic carbonates recycled as CO_2 in arc volcanoes during the subduction process. Hoareau *et al*. (submitted) [1] have modelled the volume of subducted sediments and the related amount of CO_2 and CH_4 emitted at active arc volcanoes along the northern Tethys margin. The volume of hemipelagic carbonates and the Indian continental margin carbonate sediments subducted, can produced a maximum of $3.7x10^{18}$ molCO_2/Ma during the EECO, corresponding to a maximum of 85% of the modern CO_2 outgassing rate. A numerical modelling has been performed to test the impact of these carbon fluxes on the climate using a model of biogeochemical cycles of carbon (COMBINE) coupled with a general circulation model (FOAM). Different parameters, as the size of Greater India continental margin and the timing of the continental subduction, have been tested in order to reconstruct the potential scenarii which could occurred during this interval.

Highly variable ^{15}N-enrichments in Solar System reflect different routes of interstellar N isotopic fractionation

BONAL L.*, HILY-BLANT P., FAURE A. AND QUIRICO E.[1]

[1]IPAG , Institut de Planétologie et d'Astrophysique de Grenoble, UJF-Grenoble 1 / CNRS-INSU, France, [lydie.bonal@obs.ujf-grenoble.fr]

Large nitrogen (N) isotopic variations are observed in our Solar System (^{14}N/^{15}N ~ 50 to 450), with most of the objects being ^{15}N-enriched compared to the presolar nebula (PSN, ^{14}N/^{15}N = 442) [1]. We suggest that these variations originate from distinct sampled N interstellar reservoirs. Indeed, N-bearing molecules detected towards dark clouds may be divided into two groups, whether they carry the amine (-NH) or nitrile (-CN) chemical function. Our recent observations towards interstellar dense clouds, together with a review of data from the literature, suggest these two reservoirs are characterized by distinct isotopic ratios [2]. Compared to the PSN, *(i)* nitrile carriers (e.g., HCN) might be systematically enriched in ^{15}N ^{14}N/^{15}N=100-320 and *(ii)* amine carriers (e.g., NH_3) are characterized by comparable isotopic ratios (^{14}N/^{15}N ~ 400). Gas-phase chemical networks suggest that nitriles derive from N while amines are formed via N^+, product of the dissociative ionization of N_2. The ^{14}N/^{15}N exchange reactions are therefore different for nitriles and amines, most likely with different timescales and efficiency [2], explaining the differential fractionation of these two reservoirs.

The proposed scenario [2] appears to explain several observations on Solar System objects. In particular, the absence of significant ^{15}N-enrichments in interstellar clouds, as previously assumed, is no longer a valid argument to reject an interstellar origin of organic precursors in primitive cosmomaterials.

A bimodal crystallite size distribution for mackinawite (FeS)

BONE, S.E.[1] SPOSITO, G.[1] AND BARGAR, J.R.[2]

[1]University of California, Berkeley, CA
[2]Stanford Synchrotron Radiation Lightsource, Menlo Park, CA

The nanomineral mackinawite (tetragonal FeS, space group P4/nmm), ubiquitous in sulfidic sediments, impacts the cycling of metals and metalloids through sorption and reduction reactions. The crystallite size, hence the specific surface area, of FeS precipitated from supersaturated solutions is poorly described; variations in crystallite size may arise from differences in mineral synthesis conditions and from differences in measurement techniques used to estimate crystallite size. Transmission electron microscopy (TEM) images and X-ray diffraction (XRD) patterns have been used to study FeS crystallite size. However, XRD is sensitive to the largest crystallites and identification of small crystallites in TEM images can be difficult when the crystallites are embedded in a matrix of aggregated particles.

In this research, we employ a combination TEM, XRD, and Fe K-edge extended X-ray absorption fine structure (EXAFS) spectroscopy to estimate the size of FeS crystallites formed under varying conditions of pH, ionic strength and reaction time. X-ray absorption spectroscopy is sensitive to the smallest crystallites, providing an estimate of size that is complementary to TEM and XRD. Furthermore, we calculate crystallite size distributions that are able to reconcile the XRD-, TEM-, and EXAFS spectroscopy-derived estimates of size. We suggest that the crystallite size may be bimodal, with a larger number of crystallites less than 2 nm in size than has previously been estimated using TEM and XRD. The presence of numerous small (< 2 nm) crystallites will have large ramifications for the properties of FeS, including its solubility and the rate and mechanism of particle growth. Lastly, the crystallite size distribution can be used to inform studies of particle reactivity by constraining the reactive surface area and the number of surface sites.

Demixing instability in dense molten $MgSiO_3$

STANIMIR A. BONEV[12] AND BRIAN BOATES[1]

[1]Department of Physics, Dalhousie University, Halifax, Nova Scotia, Canada B3H 3J5
[2]Lawrence Livermore National Laboratory, Livermore, California, 94550, USA

The phase diagrams of $MgSiO_3$ and MgO are studied from first-principles theory for pressures and temperatures up to 600 GPa and 20,000 K. We present evidence for a vast pressure-temperature regime where molten $MgSiO_3$ decomposes into liquid SiO_2 and solid MgO. The demixing transition is driven by the crystallization of MgO - the reaction only occurs below the high-pressure MgO melting curve. The predicted transition pressure at 10,000 K is in close proximity to an anomaly reported in recent laser-driven shock experiments of $MgSiO_3$. We also present new results for the high-pressure melting curve of MgO and its B1-B2 solid phase transition, with a triple point at 327 GPa and 11,800 K. Comparison with experimental measurements and explanation of the observed phase boundaries in terms of the computed free energies will be discussed.

Clumped isotope thermometry of marbles as an idicator of the closure temperatures of calcite and dolomite with respect to solid-state reordering of C–O bonds

MAGALI BONIFACIE[1], DAMIEN CALMELS[1] AND JOHN EILER[2]

[1] Institut de Physique du Globe de Paris, France (bonifaci@ipgp.fr, calmels@ipgp.fr)
[2] California Institute of Technology, Pasadena, CA, USA

Carbonate clumped isotope thermometry is based on the temperature-dependent preference of rare isotopes ^{13}C and ^{18}O to bond with each other within lattices of carbonate minerals (as measured by Δ_{47} of CO_2 extracted by phosphoric acid digestion). In rocks that have experienced burial and/or high temperature histories, this phenomenon may be controlled by solid-state diffusion of C and O within the mineral lattice. Here we examine this issue through clumped isotope measurements of a variety of natural marbles that differ in metamorphic environment, age, cooling rates, grain sizes, and mineralogical and chemical compositions; and compare them to heating experiments conduced at laboratory timescales.

Calcitic marbles increase in Δ_{47} (by a range of ~ 0.05‰) with decreasing cooling rates (from ~ 100 to few °C/My), suggesting that ^{13}C–^{18}O reordering during cooling is controlled by solid state diffusion. Also, dolomite marbles are systematically lower in Δ_{47} (by at leat 0.06‰) than calcitic marbles, all other factors being the same. This does not appear to reflect differences between calcite and dolomite in the temperature dependence of clumping or the fractionation on acid digestion; rather, it appears that the blocking temperature with respect to solid-state ^{13}C–^{18}O reordering is significantly higher in dolomite (~300˚C) than in calcite (~150-200˚C), due to currently unknown chemical and/or structural controls.

These data are relevant for the use of clumped isotope thermometry to study deeply buried sedimentary carbonates and carbonate bearing diagenetic, metamorphic and igneous rocks. Perhaps most importantly, this work suggests that authigenic or early diagenetic dolomite may provide a means of recovering clumped isotope surface temperature records from even deeply buried sedimentary sections and sub-greenschist facies metamorphic rocks.

Underestimation of the authigenic fraction of Cu and Ni in organic-rich sediments and particles

P. BÖNING[12]*, H. FRÖLLJE[12] AND H.-J. BRUMSACK[1]

[1]ICBM, University of Oldenburg, 26129 Oldenburg, Germany (*correspondence: p.boening@icbm.de)
[2]Max-Planck Research Group for Marine Isotope Geochemistry, 26129 Oldenburg, Germany

Organic-rich sediments from marine environments typically show authigenic enrichments in Ni and Cu. However, the exact determination of the authigenic metal level is difficult given the considerable level of the lithogenic metal background. The authigenic metal level can be estimated according to $M_{auth} = M_{total} - (M/Al_{background} \cdot Al_{total})$ while M = metal of interest and Al = aluminum. Alternatively, a metal enrichment factor (EF) is calculated according to $EF = M/Al_{total} / M/Al_{background}$. Both techniques rely on the appropriate use of the M/Al ratio of the lithogenic background. For the latter, the M/Al ratio of average shale or crust is widely applied as lithogenic background in marine geochemistry. Here, we show that the authigenic level of Cu and Ni in sediments and particles (upwelling areas of Peru, North and South Chile, Gulf of California, Norwegian Kyllaren fjord and German Wadden Sea) is significantly underestimated when using the M/Al ratio of average shale or crust as lithogenic background. The correlation between Cu/Al and Ni/Al with organic carbon in the samples indicates the apparent M/Al ratio of the background, which is 2-4 times lower than the M/Al ratio of shale or crust. A prerequisite for our technique is high linearity and high quality of correlation ($r^2 \geq 0.8$) otherwise the lithogenic background cannot be exactly determined. The resulting higher authigenic level of Cu and Ni underlines their use as productivity indicators in modern and paleo records while the enrichment of Cu and Ni shifts from moderate to high if it is assessed via EFs.

The stable chromium isotopic composition of Lunar basalts

P. BONNAND[12]*, I.J. PARKINSON[13] AND M. ANAND[45]

[1]Department of Environment, Earth and Ecosystem, The Open University, Milton Keynes, UK.
[2]Department of Earth Sciences, University of Oxford, Oxford, UK (*correspondence: pierre.bonnand@earth.ox.ac.uk).
[3]Bristol Isotope Group, School of Earth Sciences, Unversity of Bristol, UK.
[4]Department of Physical Sciences, The Open University, UK.
[5]Department of Earth Sciences, The Natural History Museum, UK.

Planetary formation has been widely studied using major-element constituents of planetary mantles [e.g. 1]. The Moon's formation is a highly debated topic and it has been proposed that the Moon is the result of a Mars-sized impactor which collided with the proto-Earth [2]. Non-traditional stable isotopes have been used to try to understand the formation of the Moon and its differentiation [e.g. 3].

Chromium isotopes are fractionated during core formation and differences in Cr isotopic composition between meteorites and the Earth's mantle suggest that light Cr isotopes have been preferentially partitioned into the metal fraction [4]. Lunar samples are characterised by a lack of nucleosynthetic anomalies for Cr isotopes [5].

In the absence of samples from the Moon's interior and in order to better constrain the lunar mantle composition and understand its formation we report stable chromium isotopic composition for a suite of low-Ti and high-Ti mare basalts. We find resolvable Cr isotopic variations within the lunar sample suite but no clear differences between low-Ti and high-Ti basalts. There is no correlation between $\delta^{53}Cr$ and $\delta^{18}O$. However, Cr isotopes seem to be correlated with Mg# and TiO_2 content which suggest that Cr isotopes are fractionated during magmatic differentiation on the Moon. The more primitive samples have Cr isotopic composition similar to the Earth's mantle.

These results suggest that the terrestrial and lunar mantles have similar stable Cr isotopic composition. This implies that processes responsible for the difference in isotopic composition between the Earth's mantle and chondritic material occurred before the formation of the Moon.

Fungi-mineral interface : hotspot of weathering in soils

S. BONNEVILLE[1]*, A. BRAY[2], A. SCHMALENBERGER[3], D.J. MORGAN[2], A. BROWN[4], S. BANWART[5] AND L. G. BENNING[2]

[1]U.R. Biogéochimie et Modélisation du Système Terre – Université Libre de Bruxelles, BE (*steeve.bonneville@ulb.ac.be)

[3]Department opf Life Sciences – University of Limerick, IE
[4] Institute for Materials Research – University of Leeds, UK
[5] Kroto Research Institute – University of Sheffield, UK

Throughout geological times, tectonic forces have continuously exposed rocks to the slow but inexorable actions of weathering at the Earth's surface. This geological process forms soils upon which the entire terrestrial biosphere depends. Weathering of primary rocks also has a key-role in the carbon cycle as the alteration of Mg- and Ca- silicates coupled to the deposition in sediments of Mg- and Ca-carbonates results in a net flux of CO_2 from the atmosphere to the lithosphere. Over geological timescales, this transfer controls atmospheric CO_2 levels and hence the climate. Initially conceptualized in terms of abiotic dissolution reactions alone, there is now growing evidence that plants and their root-symbiotic partners, mycorrhiza, are key to the weathering because of their impressive capacity to interact physically and chemically with minerals.

In soils, mycorrhiza grow preferentially around, and on the surface of nutrient-rich minerals, making such contact zones potential hot-spot of mineral alteration. Here, we present a compilation of results and observations from alteration experiments in which ectomycorrhiza (*Paxillus involutus*) were grown symbiotically with a pine tree (*Pinus sylvestris*) in presence of freshly-cleaved biotite under humid, yet undersaturated, conditions typical of soils. Using FIB (Focussed Ion Beam), cross-sections of fungi-biotite interfaces were sampled along single, surface-bound hypha and analysed for (i) their contents in Si, O, Fe, Al, Mg and K at a nanometer-resolution (by STEM-EDS) and for (ii) the speciation of redox-sensitive elements (by STXM) [1]. In parallel to the biotite characterization, the chemical conditions in the near-environments of hypha and their biochemical composition were analyzed by molecular probes coupled to confocal microscopy and synchrotron-based μ-FTIR. This dataset shed light into mechanisms and also allowed for a first estimation of chemical alteration rates at the interface between fungi and rock-forming minerals [2].

XAS and isotopic approaches to identify Zn and Cu sources in the Seine River watershed

C.A. BONNOT[1]*, A. GELABERT[1], G. MORIN[2], P. LOUVAT[1] AND M.F. BENEDETTI[1]

[1] Université Paris Diderot, Sorbonne Paris Cité, Institut de Physique du Globe de Paris, UMR 7154 CNRS, F-75013 Paris, France, (* correspondence: bonnot@ipgp.fr)
[2] UPMC, UMR CNRS 7590, IMPMC, Paris, France

In order to preserve the global freshwater resource, new directives on water policy have been established imposing a good ecosystem status for 2015. For the Seine-Normandie basin, it includes the metals sources determination in order to identify the metal amount resulting from the geochemical background, and the metal amount arising from industrialisation. The combination of isotopic and XAS approaches should allow to identify the different sources, and to understand the different processes controlling the Zn and Cu cycling. Variations on the δ^{66}Zn and δ^{65}Cu can provide information relative to the main sources of metals. XAS spectra study (through the knowledge of Zn and Cu speciation) is needed to understand the processes acting on the rivers (isotopic fractionation induced by biogeochemical processes [1,2,3] versus water mixing) and determine the bioavailability of Zn and Cu. As a potential Zn source, the sediment dynamics in the river have been investigated. To do so, sediment traps representative of river bottom sediments have been analysed using XAS at the Zn K-edge. In these samples, poorly crystallized Zn sulfides constitute the Zn major species, and could explain the presence of ZnS in suspended particulate material in the river water column. In addition, two “geographic” sampling campaigns have been performed to estimate the impacts of the different environmental conditions on the Zn/Cu signal, and to help locating the potential metal sources in the system. These two campaigns highlight a general seasonal effect linked to the discharge, in addition to punctual concentration anomalies.

Paroxysmal degassing at Mt. Etna in 2011-12

E. BONNY[1,2], C. MANDON[1,2], S.A. CARN[2], A.J. PRATA[3], M. COLTELLI[4] AND F. DONNADIEU[1]

[1]Observatoire de Physique du Globe (OPGC), Laboratoire Magmas et Volcans, Université Blaise Pascal, 63038 Clermont-Ferrand, France (ebonny@mtu.edu)

[2]Dept. of Geological and Mining Engineering and Sciences, Michigan Technological University, Houghton, MI 49931, USA (scarn@mtu.edu)

[3]Norwegian Institute for Air Research, Kjeller, Norway

[4]INGV-CT, 95123 Catania, Sicily, Italy

Between January 2011 and April 2012, Mt. Etna produced a series of 25 paroxysmal lava fountaining events, representing a significant change in its eruptive style. Understanding the causes and impacts of this activity is crucial for improved hazard assessment at Etna, and for refinement of models of the volcano's magma plumbing system. Sulfur dioxide (SO_2) emissions associated with most of these paroxysms were measured by the ultraviolet (UV) Ozone Monitoring Instrument (OMI) on NASA's Aura satellite and the Atmospheric Infrared Sounder (AIRS) sensor on the Aqua satellite. The ground-based OPGC VOLDORAD 2B L-band Doppler radar system, operated in cooperation with INGV-CT, also detected the associated ash plumes, providing accurate constraints on the timing and duration of the lava fountains. We present a comprehensive analysis of the OMI and AIRS SO_2 data for the Etna paroxysms in 2011-12. Back trajectory analysis of the observed SO_2 clouds using the HYSPLIT trajectory model indicates that SO_2 emissions generally coincided with the peak lava fountain intensity detected by VOLDORAD. By combining the UV OMI and IR AIRS SO_2 measurements we constrain the SO_2 loss rate in the Etna SO_2 clouds, many of which were tracked for several days after emission. Using SO_2 loadings corrected for the time of emission, we observe a correlation between SO_2 production and inter-paroxysm repose time. Comparison of the erupted magma mass estimated from the radar data and the SO_2 loadings also indicates a vast excess of gas in the emissions. Of the two models typically invoked for explosive basaltic eruptions (the rise speed dependent (RSD) and collapsing foam (CF) models [1]) we propose that our dataset supports the CF mechanism as the predominant driver for paroxysms at Etna in 2011-12. Satellite data indicate low or undetectable ash content in the drifting eruption clouds, suggesting efficient separation of ash and gas in the eruption column, with implications for aviation hazards.

Dissolved gases and radioactivity in spring waters of southeast Brazil

D. M. BONOTTO

Instituto de Geociências e Ciências Exatas, UNESP, Rio Claro, Brasil (dbonotto@rc.unesp.br)

Twenty two spring water samples from spas located at São Paulo and Minas Gerais states, southeast Brazil, have been sampled and analyzed for temperature (T), conductivity (C), pH, redox potential Eh, dissolved gases O_2, CO_2, H_2S and radionuclides ^{228}Ra, ^{220}Rn and ^{222}Rn. The samples provided from different geological contexts, i.e. Paraná sedimentary basin, Poços de Caldas alkaline massif and high grade metamorfic suites. The RAD7 portable detector (Durridge Co.) has been used for ^{220}Rn and ^{222}Rn analyses, as well traditional potentiometric/colorimetric methods and radiochemical steps followed by gamma ray spectrometry through NaI(Tl) scintillation detector.

The following data range has been found: T=21.7-28.4 °C; C=0.04–4.73 $mS.cm^{-1}$; pH=5.56–9.38; Eh=-115–122 mV; O_2 =1.3–9.0 $mg.L^{-1}$; CO_2=<1.0–800 $mg.L^{-1}$; H_2S=<1.0 – 3064 $\mu g.L^{-1}$; ^{228}Ra=<5.4–123.2 $mBq.L^{-1}$; ^{220}Rn=<0.1–23.4 $pCi.L^{-1}$; ^{222}Rn=0.6–2020 $pCi.L^{-1}$. Such great variability of values reflects the different lithologies, mineralogy of the rock matrices, discharge and climatic conditions, among others factors.

According to the Brazilian Code for Mineral Waters (BCMW) established by Register 7841 published on 8/8/1945, in terms of T values, the springs analyzed are cold (<25°C) and hypothermal (25-33°C). Several significant correlations were found involving the parameters analyzed, for instance: Eh and pH (r=-0.58), H_2S and C (r=0.64), T and ^{222}Rn (r=-0.61), T and ^{220}Rn (r=-0.42), ^{222}Rn and ^{220}Rn (r= 0.59). Neither O_2 nor CO_2 and H_2S exhibited significant correlation with T, as expected, however, this scenario may modify if an expanded database including values for mesothermal, isothermal and hyperthermal waters is taken into account. According to the BCMW, in terms of radiological aspects, the springs analyzed can not be considered thoriferous as the ^{220}Rn activity concentration is lower than 26.9 $Bq.L^{-1}$. One spring may be classified as weakly radioactive, as exhibited ^{222}Rn activity concentration between 67.2 and 134.5 $Bq.L^{-1}$. Most of the ^{228}Ra activity concentration data were below the detection limit, whereas one spring exhibited a value exceeding the guideline value of 0.1 $Bq.L^{-1}$ established by the Brazilian Health Ministry Register 2914 published on 12/12/2011. Therefore, the acquired data are relevant for the appropriate management and use of the studied spring waters.

Complexation of Sr in aqueous solutions equilibrated with silicate melts: Implications for fluid-melt partitioning

M. BORCHERT[1]*, M. WILKE[2], C. SCHMIDT[2], K. KVASHNINA[3] AND S. JAHN[2]

[1] Deutsches Elektronen-Synchrotron, Hamburg, Germany (* correspondence: manuela.borchert@desy.de)
[2] Helmholtz Zentrum Potsdam GFZ GeoForschungsZentrum, Potsdam, Germany
[3] European Synchrotron Radiation Facility, Grenoble, France

Fluid-melt partitioning of Sr, Ba, La, and Y strongly depends on fluid and melt composition [1-2]. That is, partition coefficients of these elements increase with i) salinity of the fluid and ii) increasing alumina saturation index (ASI: Al/(Na+K) in moles) of the silicate melt (Fig.1).

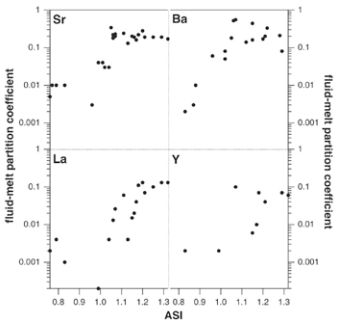

Fig. 1. Fluid-melt partition coefficients of Sr, Ba, La and Y as function of melt composition at 750°C, 200 MPa, and using a chloridic fluid.

On one hand, the distinct affinity for chloridic fluids points to a preferential complexation of these elements with chlorine. On the other hand, the strong dependence on melt composition suggests that a different release of melt components into the aqueous fluid in peralkaline systems changes the speciation in the aqueous fluid. Up to now, the exact nature of the complexation in the fluid is not clear.

Here, we present experimental and theoretical data on the complexation of Sr in three fluid-melt systems. X-ray absorption spectroscopy was applied to probe the local environment around Sr in silicate-bearing fluids, i.e., peralkaline or peraluminous melts completely dissolved in the aqueous fluid, and in various model systems, e.g., crystalline compounds, silicate glasses, and aqueous solutions. In order to decode the complexation of Sr in model systems and silicate-bearing fluids, theoretical spectra are calculated either using model structures, by testing several small cluster geometries or based on snapshots of trajectories produced with MD simulation to account for atom movements in aqueous solutions. Experimental data clearly show differences in the local environment around Sr in studied silicate-bearing fluids. Theoretical spectra point to a predominant formation of i) SrO_6 cluster in chlorine-free peralkaline fluids, ii) distorted SrO_6 clusters in chloridic-peralkaline fluids, and iii) complexes that very likely incorporate Cl^- in chloridic-peraluminous fluids.

Formation of arsenic bearing apatite from calcite. Chemistry and microstructures

STACEY BORG[12]*, WEIHUA LIU[1], MARK PEARCE[1], JAMES CLEVERLEY[1] AND COLIN MACRAE[3]

[1] CSIRO Earth Science and Resource Engineering, Australia (*correspondence: stacey.borg@csiro.au)
[2] CODES ARC Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Australia
[3] CSIRO Process Science and Engineering, Australia

Apatite, a calcium phosphate mineral, can form naturally as solid solutions with between 0-100% of the phosphate anions substituted with compatible molecules in the crystal lattice [1]. Arsenate, $As^{V}O_4^{3-}$ is one such molecule, and there are many examples in nature of high As bearing apatite [2].

In order to track the chemistry of ancient fluids that formed the observed composition variation in apatite and related mineral deposits, a series of hydrothermal synthesis experiments were performed, aiming to establish a relationship between apatite composition and fluid chemistry. Utilising a general method from a previous study [3], we have generated a range of synthesised apatite samples starting from calcite, primarily by reaction with phosphate (PO_4^{3-}), substituting with similar molecules (e.g. AsO_4^{3-}, SO_4^{2-}). Chemical analysis of thus formed apatite-like compounds show differing level of incorporation depending on the molecule being substituted, while SEM and CL mapping of grains show very interesting and complex textures and element distribution patterns. Two stage experiments, where one solution composition is reacted with pure calcite, then a different solution is reacted with the product, show that phosphate is an important driver for As-bearing apatite growth, and that arsenic incorporated into the apatite structure is not readily remobilised. This level of understanding is important when considering natural apatite samples as indicators to track ore fluids.

Meter-scale chemical interaction between pyroxenite-derived melts and mantle peridotites in the Northern Apennine ophiolites (Italy)

G. BORGHINI[123], E. RAMPONE[1], A. ZANETTI[4], C. CLASS[2], A. CIPRIANI[25], A.W. HOFMANN[25], S.L. GOLDSTEIN[2] AND M. GODARD[6]

Mantle peridotites from the Northern Apennine ophiolites are characterized by the occurrence of cm-thick pyroxenite layers originated by rather deep segregation of MORB-type melts. Our recent work documents that during the pyroxenite emplacement portions of the country peridotite have been significantly modified in their modal, chemical and isotopic compositions by reaction with melts percolating from pyroxenite veins [1]. Here we report the results of detailed bulk and mineral major and trace element profiles carried out through pyroxenite-peridotite boundaries to investigate the physico-chemical parameters governing the melt-rock reaction process. Relative to the peridotites far (> 2 m) from the pyroxenite veins, wall-rock peridotites show i) modal orthopyroxene enrichment at the expense of olivine, ii) higher Al, Ca, Si contents and slightly lower Mg# iii) Al-richer spinel and lower-Mg# pyroxenes. Moreover, clinopyroxenes in the wall-rock peridotites have LREE-depleted patterns and initial εNd(430 Ma) = +4.7-+7.6, pointing to a reaction with an enriched tholeiitic silica-saturated melt. Along the pyroxenite-peridotite traverses, clinopyroxenes record a trace element gradient: at the pyroxenite-peridotite contact they have the lowest MREE-HREE abundances, with lower Sm/Nd ratios than the distal pyroxenite-free peridotites. The overall REE abundances progressively increase away from the pyroxenite-peridotite boundary up to about 20 cm as a result of percolative reactive flow at decreasing melt mass. Beyond 20 cm from the contact, the HREE content decreases with distance from the pyroxenite, while the LREEs remain at nearly constant level, pointing to a more efficient chemical buffering of the host peridotite on the HREE composition of the percolating melt through ion exchange chromatographic-type processes.

How do organic molecules affect interactions of water with environmental sorbents?

M. BORISOVER

Institute of Soil, Water and Environmental Sciences, ARO, The Volcani Center, Bet Dagan, Israel; correspondence: vwmichel@volcani.agri.gov.il

Water is the integral component of environmental phases and interfaces (e.g., in soils and sediments) and affects their structure and reactivity. Sorption interactions of water with environmental phases can be probed by their response to sorption of organic molecules. Such a test examines a sorbent hydration in a local microenvironment specific for a given probe. However, the direct measurement of the response of water-sorbent interactions to the presence of organic molecules at environmentally relevant conditions is difficult, due to typically low organic sorbate concentrations. Therefore, the use of the model-free thermodynamic approach [1] is proposed which allows determining the effect of organic compounds on sorbent-water interactions from the equilibrium sorption isotherms of organic molecules measured at varying water activities. The analysis included the data on (*1*) organic vapor sorption on such important soil components as minerals (i.e., quartz, clays, metal oxides) and organic matter (OM), and (*2*) the liquid phase sorption on the model soil OM. The amount of water *expelled* from a sorbent or *co-sorbed*, per an organic molecule sorbed, was obtained for different extents of sorbent hydrations. The water-expelling effect of organic molecules on minerals was analyzed by using Linear Free Energy Relationship (LFER). The LFER analysis suggested (*i*) the significance of organic sorbate polarizability associated with *n*- and π- electrons in driving water into the sorbent phase and (*ii*) the control of water driving-out effect by molecular size, H-bond acidity and basicity of sorbates. As distinct from minerals, water interactions with strongly hydrated OM phases (i.e., at water activities approaching one) become enhanced upon sorption of multiple organic sorbates containing oxygen, nitrogen or sulfur atoms. This OM hydration enhancement may involve several water molecules per a sorbed organic molecule and seems to be cooperative, which may need to be incorporated into models of organic compound sorption by soils and sediments. Importantly, this effect of the OM hydration enhancement suggests that a pre-hydration of OM does not necessarily create the OM configuration appropriate for further accommodation of other molecules.

^{57}Fe Mössbauer spectroscopy of pantelleritic melts

N. BOROVKOV[1]*, K.-U. HESS[1], K. T. FEHR[1], C. CIMARELLI[1], D. B. DINGWELL[1] AND A. GÜNTHER[1].

[1]Department of Earth and Environmental Science, Ludwig Maximilians Universität, Theresienstr. 41/III, 80333 Munich, Germany (*correspondence: nikita.borovkov@min.uni-muenchen.de)

Fe species in the melt can include 4-Fe2+, 5-Fe2+, 4-Fe3+, and 5-Fe3+. The relative proportions between these species can vary according to bulk glass composition and oxygen fugacity conditions. RedOx state and coordination of Fe can considerably affect important physical properties (density and viscosity) of magma, even where bulk composition and Fe content are constant. A set of silicate glasses with pantelleritic composition have been synthesized at different oxygen fugacity conditions (from air down to IW buffer) and then were analyzed by 57Fe Moessbauer spectroscopy (MB). The spectra were taken at 298K in transmission mode and fitted by applying an extended Voigt-based lineshape according to [1]. The MB spectra of all samples display three lines which can be described to two different doublets. One doublet with an isomer shift (IS) of ca. 0.9 mm/s relative alpha-iron and a quadrupole splitting (QS) of ca. 2 mm/s can be attributed to ferrous iron. The second doublet with IS of ca. 0.3 mm/s relative alpha-iron and QS of ca. 0.9 mm/s can be attributed to ferric iron. The later values are close to that of ferric iron on tetrahedral site in ferrobasaltic glasses [2]. With increasing oxidation the QS of ferric iron increases slightly from 0.85 mm/s (0.3 Fe3+/Fetotal) to 0.95 mm/s (0.8 Fe3+/Fetotal) where a decrease of QS for ferric iron as a function of oxidation was observed. The IS of 0.9 mm/s for ferrous iron remains constant up to an oxidation state of about 0.6 Fe3+/Fetotal and with increasing oxidation a rapid decrease to IS of 0.6 mm/s at 0.8 Fe3+/Fetotal occurs. At the oxidation state of 0.6 Fe3+/Fetotal the constant QS of 2.0 mm/s for ferrous iron increases up to 2.45 mm/s at 0.8 Fe3+/Fetotal in contrast to ferrobasaltic glasses, where a QS of 2.0 mm/s remains constant over the whole oxidation state [2]. Meanwhile, for tektites and alumino-silicate glasses [3, 4] the doublet with IS of 0.9 mm/s and 0.6 mm/s was attributed to ferrous iron on a five-fold and four-fold coordinated sites, respectively.

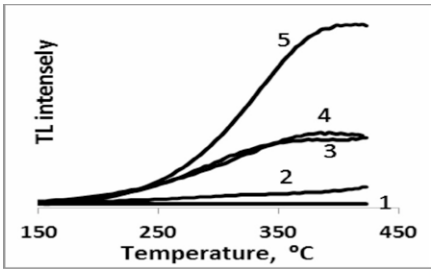
Luminescence of products of hypergenesis ore deposits

N.N. BOROZNOVSKAYA, L.A. ZYRYANOVA, T.S. NEBERA AND A.V. PAVLOVSKAYA

Tomsk State University, Tomsk, Russia (boroznovskaya@mail.ru)

Luminescence analysis (L) can be successfully used in mineralogical studies of hypergene products. We studied the spectra of roentgenoluminescence (RL), and the thermoluminescence (TL) of minerals the oxidized zone Rubtsovsk deposit (Russia, Ore Altai). Found that the species composition of the loose mono and polymineral formations consisting of basic sulphate Cu, Pb, Al, and clay minerals can be determined from the characteristic spectra of RL and TL schedules. L studied minerals associated with defects in silicon-aluminum-oxygen tetrahedra, the excited states of oxygen and the presence of other native defects. Monoclinic dickite is diagnosed by the intense RL at λ = 350-360 nm, and very different from the triclinic kaolinite, which is characterized by weak luminescence in a wide wavelength range (285-300 and 340-350 nm). RL of kaolinite varies depending on the degree of crystallization and structural regularity. Halloysite is allocated by short-wave radiation with a peak in the spectral range 290-310 nm. In contrast to clay minerals alunite and osarizavaite spectra RL very low in intensity. Quantitative ratios of clay minerals and sulfates in their common units can be determined from the graphs of TL ignition minerals up to 450 ºC.



Studied the L of hypogene and hypergene barite. RL spectra of barite formed in the oxidation zone differ from those of RL hypogene barite primary sulfide ore intense radiation in the wavelength range of 350-400 nm due to the excitation of oxygen. Thus, the study of products of hypergene luminescence methods allow: 1) to determine the degree of crystallinity of the mineral aggregates and order of the crystal lattice of minerals; 2) to use the luminescence for diagnostic purposes; 3) to solve individual genetic issues.

This study was funded by the Russian Ministry of Education and Science (projects 5.3143.2011, 14.B37.21.0686, 14.B37.21.1257).

Anthropogenic fractionation of zinc isotopes

DAVID M. BORROK[1]* AND ANITA THAPALIA[2]

[1]School of Geosciences, University of Louisiana at Lafayette, Lafayette, LA 70504 (*correspondence: dborrok@louisiana.edu)
[2]Department of Geological Sciences, University of Texas at El Paso (athapalia@miners.utep.edu)

Zinc (Zn) is used in many industrial processes, including the galvinization of steel and the vulcanization of rubber. Due to its relatively low volatilization temperature, Zn is emitted to the atmosphere in greater quantities than any other trace metal worldwide. The fractionation of stable Zn isotopes during anthropogenic processing provides a potential opportunity to understand and evaluate the sources, transport, and accumulation of pollutant Zn in the environment.

Here we present the results from a series of investigations of Zn isotopes in anthropogenic systems, including a new investigation of lake sediment cores from seven urban lakes and one reference lake in the USA. The time-resolved records of sediment (and Zn) accumulation suggest that, on average, the δ^{66}Zn (measured relative to JMC 3-0749L) of Zn from sediments deposited during intense urbanization is 0.09 ± 0.07‰ (n = 12), while the average isotopic signal for sediments deposited prior to urbanization (and in the non-urban reference lake) is 0.33 ± 0.07‰ (n = 23). The anthropogenic isotope signal for Zn fits well with previous investigations of Zn processing related to combustion, which may suggest that automobile emissions and waste burning are important contributors to urban Zn pollution. The natural background isotopic signal of Zn for lake sediments is similar to that reported for many igneous rocks. This may suggest that processes like weathering, transport, and biological uptake do not appreciably change the isotopic signature of the natural lake sediments.

This lake sediment study, as well as previous investigations of Zn-contaminated sediments, water, and atmospheric particles confirm that Zn isotopes can be useful to help distinguish between natural and anthropogenic Zn sources. However, because of the small amounts of fractionation and overlapping isotopic signatures, Zn isotope investigations are most successful when they are combined with other chemical and/or isotopic measurements.

Antigorite dissolution rates as a function of pH at 25 and 80 °C

O. BOSC, J. DECLERCQ, V. MAVROMATIS AND E. H. OELKERS

[1]GET, Université Paul Sabatier-CNRS/UMR 5563, Toulouse, France (*corresponding author bosc@get.obs-mip.fr)

Antigorite ($Mg_3Si_2O_5(OH)_4$) is a common serpentine mineral that could provide the divalent metal cations required for mineral carbonation as part of carbon storage efforts. Such carbonation could occur via the dissolution of acidic CO_2 saturated H_2O. Antigorite dissolution into this fluid would both release aqueous Mg and neutralize the fluid promoting carbonate precipitation [c.f. 1].

In an attempt to better quantify this carbonation process antigorite dissolution rates have been measured as a function of pH from 2 to 10 temperatures of 25 and 80°C in closed system reactors. Rates were calculated from measured aqueous Mg and Si concentrations

$$r = (dC/dt)v/S$$

where r is the dissolution rate, dC/dt is the time derivative of Mg or Si concentration, v is the fluid volume in the reactor and S is the surface area.

Magnesium is released preferentially at the beginning of most of the experiments compared to silica suggesting the importance of Mg for proton exchange reactions in the antigorite dissolution mechanism. Also similar to the behavior of other Mg-silicate minerals including talc and tremolite [2], antigorite dissolution rates decrease systematically with increasing pH over the whole pH range considered in this study; antigorite dissolution rates at pH 2 are ~1.5 orders of magnitude faster than corresponding rates at pH 10. The addition of ~0.1 mol/kg citrate to the aqueous fluid appears to increase constant pH rates by less than an order of magnitude suggesting that the addition of organic ligands would be an inefficient method to accelerate the carbonation of Mg silicate minerals.

Insights on the protracted evolution of the deep crust of the Arabo-Nubian Shield.

BOSCH DELPHINE*

[1]* Géosciences Montpellier, Montpellier France. (delphine.bosch@gm.univ-montp2.fr)

The Arabian-Nubian Shield (ANS) represents a mosaic of more than 15 Neoproterozoic juvenile island-arc terranes (850-600 Ma) formed in the Mozambique ocean realm. In spite of amalgamation events that subsequently led to accretion of the ANS, most exposed terranes are characterized by low- to moderate metamorphic overprint, greenschist-facies rocks being prevalent in the shield. It is thus difficult to examine how and when the lower crust of the ANS formed since it is mostly inaccessible. In this study, we analysed 3 gneisses from Zabargad Island (Egypt) corresponding to lower crustal units exposed at surface level during the Oligo-Miocene thinning of the ANS lithosphere related to the Red Sea rifting. Zircons from a felsic granulite have both low and high Th/U ratios (0.3 and 0.07), but yield undistinguishable ages of 652 ± 10 Ma, which we interpret as dating the age of the protolith and its conversion to granulite. Some zircons however yield low Th/U ratios and a significantly younger age of 597 ± 4 Ma, reflecting a second metamorphic event, possibly related to collision between island arc terranes of the ANS and the Saharan craton on the West. Monazites from a granulitic gneiss yield a much younger age of 497 ± 2 Ma which may reflect far-field stress associated to the latest stages of amalgamation of eastern Gondwana. Lastly, zircons extracted from a granulitic gneiss sampled at the contact with the Northern peridotite massif yield an age of 25.1 ± 0.4 Ma related to contact metamorphism during juxtaposition of the hot peridotite and lower crustal units. Gneisses from Zabargad island constitute a unique window to look at the polymetamorphic evolution of high-grade lower crustal units of the ANS.

Micro-fracturing induced by radioactivity of minerals: consequences on the permeability of rocks.

V. BOSCHERO[12], A.M. SEYDOUX-GUILLAUME[1], M. MARCOUX[2], C. NOIRIEL[1] AND L. ORGOGOZO[1]

[1] GET, UMR5563 CNRS-UPS-IRD, Université de Toulouse, 14 av E. Belin, 31400 Toulouse, France

[2] IMFT, UMR5502 CNRS-INPT-UPS, 2 Allée du Professeur Camille Soula, 31400 Toulouse, France

Some rocks may contain radioactive (U-Th) minerals ranging from micrometric to millimetric sizes. These minerals are submitted to intense self-irradiation (α-decay of U and Th chains) that can lead to amorphization and also modify their environment by irradiating the host minerals. Amorphization induces volume increase, leading to the formation of cracks which eventually connected into a network through the rock. This fracturing allows fluid circulation, and promotes alteration of source minerals and dispersion of elements (e.g. Pb and U). These observations highlight the importance of understanding the impact of radiation damage on radioactive transport by fluids passing through such fractured rocks. The aim of this study is, through the caracterization of natural samples, to explore the consequences of such fracturing on the ability of rocks to transfer radioactive elements within fluid phases. The study was made up of imaging, laboratory measurements and numerical modelling.

First, the permeability of natural rocks with high-level of radioactivity, was measured. Such low permeability needs the use of specific gaz-permeameter. In agreement with the Klinkenberg effect, permeability of the samples can be obtained.

In a second step, these results were compared with those from numerical modelling. For that, the geometry of a micro-fracture network was used after SEM image processing. The model simulates both the flow in the fractures and the reactive transport associated with the dissolution of the radioactive minerals and helped us to evaluate the flow and the transport heterogeneity in a natural sample, induced by this local fracturation surrounding radioactive minerals.

For a better understanting of this process, the use of X-ray CT-scan is necessary to develop a 3D model.

Carbonation of serpentine mine tailing: the example of Montecastelli mine (Tuscany, Italy)

BOSCHI C.[1], DINI A.[1], BEDINI F.[1], BANESCHI I.[1,] NATALI C.[1] AND DALLAI L.

[1]Istituto di Geoscienze e Georisorse, CNR (Pisa, Italy); c.boschi@igg.cnr.it

Carbonation of serpentinite or asbestos mine tailing is a passive, weathering-related process that take advantage of the thermodinamically driven natural transformation of ultramafic rocks into carbonate and thus it is cost and energy effective. The enhancement of this natural weathering is a challenge including multiple advantages: CO_2 capture, and remediation of asbestos tailing. Here, we present an example of natural carbonation of a small mine dump at Montecatelli (Tuscany, Italy).

At Montecastelli (Tuscany, Italy), a pluri-kilometric body of serpentinite, embedded in shales, has been deeply eroded by the Pavone River providing good exposures and sections. The central portion of the serpentinite body host a small copper ore deposit that was intermittently exploited during the XIX century, and was definitively closed in 1869. Bornite, chalcopyrite, chalcocite and pyrite veinlets and nodules, in a chlorite-serpentine-brucite-amphibole soapy gangue, characterize narrow deformation zones crosscutting the serpentinites. Most of the low-grade Cu-ore extracted in the past was not reliable for industrial processing and directly dumped in front of the entrances of the mine, forming by the time a small mining dump. Mining activity stopped 60 years ago.

Intense natural carbonation produced crust of hydrated Mg-carbonates (hydromagnesite, nesquehonite, manasseite, pyroaurite, brugnatellite) coating the serpentinite clasts of the mining dump and the serpentinite walls of the mine tunnels.

The Montecastelli carbonated serpentinite mine tailings represent an example of rapid atmospheric CO_2 uptake. Their study improved our knowledge of the carbonation processes. Future quantification of the amount of carbon sequestered in geologic samples from Montecastelli would give an estimate for the sequestration capacity of ultramafic mine tailings in general and will provide a framework for the development of standard protocol for enhanced mineral sequestration at mine sites.

The Behavior of Beryllium in Soils and Aquatic Environments

VANESSA BOSCHI[1]* AND JANE K. WILLENBRING[1]

[11]University of Pennsylvania, 240 South 33rd Street Philadelphia, PA 19104; *vaboschi@sas.upenn.edu

Beryllium is an important metal utilized in a diverse range of applications. Aside from its numerous industrial uses, it is as a central tool used in the field of geochronology and geomorphology. Recent work indicates ^{9}Be leached from mineral lattices during weathering processes moves through a landscape adsorbed to soil particles and in solution. As such, the flux of ^{9}Be from rivers is indicative of the weathering extent of soils within the catchment. Another isotope, cosmogenic ^{10}Be, is formed in the atmosphere and is precipitated onto the Earth's surface, adsorbing onto surface sediments. The concentration of ^{10}Be in soils and sediments scales with the residence time of sediments in a landscape. Although these applications are dissimilar, they require an understanding of the behavior of beryllium in soils and aquatic environments. A better understanding of the mobility of beryllium will help constrain its use for such geologic techniques.

In order to evaluate the interactions of beryllium with soil and aquatic related materials, we selected model organic compounds and minerals to perform distribution coefficient experiments. Model organic compounds such as graphite, cellulose, an amine compound and phenolic acid in addition to dissolved organic matter samples were selected on the basis of their chemical composition and potential ability to adsorb beryllium. Clay-sized fractions of montmorillonite, illite, kaolinite and hectorite were also selected. The retention of beryllium onto each of these compounds was evaluated over a pH range and various equilibration times to determine which conditions allowed for the greatest retention of beryllium. Preliminary results conclude that mineral compounds more efficiently adsorb beryllium relative to the selected model organic compounds. Retention of beryllium increases with increasing pH from 2 to 6. We also examined the effect of pH on the speciation and colloidal nature of beryllium. For beryllium concentrations typical of natural soil solutions, we find that the colloidal behavior of beryllium may play a significant role in its mobility within soils.

Determination and quantification of fatty acids in speleothems and cave drip water using HPLC-ESI-IT/MS

J. M. BOSLE[1]*, D. SCHOLZ[2] AND T. HOFFMANN[3]

[1]Institute of Inorganic and Analytical Chemistry, Johannes Gutenberg-University Mainz, Germany; (*correspondece: bosle@uni-mainz.de)
[2]Institute for Geoscience, Johannes Gutenberg-University Mainz, Germany; (scholzd@uni-mainz.de)
[3]Institute of Inorganic and Analytical Chemistry, Johannes Gutenberg-University Mainz, Germany (hoffmannt@uni-mainz.de)

Cave drip water, speleothems and the proxies preserved within them have significant potential to record palaeoenvironmental changes in the regional vegetation [1]. The most common proxies measured in stalagmites are inorganic proxies, in particular oxygen isotopes [2]. More recently the importance of organic matter analyses in this field is examined. This study focuses on the research of lipid biomarkers. The lipids contained in stalagmites originate from the overlying soil and different plants, bacteria and fungi. Therefore different compositions of lipids may provide records of environmental changes [3].

In the following the development of a new method for the extraction of fatty acids (FA) from stalagmites and cave drip water and their measurement by HPLC-ESI-IT/MS (high performance liquid chromatography coupled to electrospray ion trap mass spectrometry) is presented. Five different FAs with chain lengths from C12 to C20 were applied as analytical standards. A mixture of these was used to optimize the separation by HPLC. The FAs were measured in negative polarity, so a time consuming derivatization of the analytes was not necessary. To simulate the extraction of the FAs several spiking experiments were performed. Solid phase extraction and liquid liquid extraction were used for the extraction procedure. Both methods were optimized and good reproducibilities with deviations below 10% were achieved. Quantitative analyses were accomplished and the limits of detection determined. As a proof of principle, first applications to the actual samples were successfully fulfilled. To testify the role of the FAs as palaeoclimate proxies further experiments will be performed.

Sub-micrometer scale chemical mapping of complex monazites: the contribution of the NanoSIMS.

V. BOSSE[1]*, A. DIDIER[1], J.L. PAQUETTE[1], S. MOSTEFAOUI[2] AND J.L. DEVIDAL[1]

[1] Clermont Université, Université Blaise Pascal, Laboratoire Magmas et Volcans, BP 10448, 63000 Clermont-Ferrand, France.(*V.Bosse@opgc.univ-bpclermont.fr)
[2] Laboratoire de Minéralogie et Cosmochimie du Muséum, UMR 7202, CNRS INSU, Muséum National d'Histoire Naturelle, 57 Rue Cuvier, 75231 Paris Cedex 05, France

Monazite [(Ce,La,Nd,Th)PO_4] is a very robust geochronometer which can record and preserve U-Th-Pb ages in various geological environments. For around ten years, monazite has also been increasingly studied because it is a key tracer for geological processes, especially fluid/rock interactions. Monazite grains often display variable chemical compositions at the grain scale and complex chemical zoning, sometimes correlated to age domains, reflecting the changes in physical and chemical parameters of the host rock. The development of *in situ* techniques (EMPA, LA-ICPMS, SHRIMP) enables the combined study of chemical and isotopic characteristics in the monazite at the scale of few μm. However, many recent studies show that: (1) it is not always possible to correlate age and chemical domains at these scales, (2) monazite often display very complex chemical zoning at infra μm scale and (3) TEM analyses show strong perturbations of the crystal lattice between 10 and 200 nm. In order to better understand the ages recorded by monazite it is necessary to obtain chemical informations at nm scale. In this context, the NanoSIMS appears to be the best suited tool.
We present here chemical elements (^{89}Y, ^{139}La, ^{208}Pb, ^{232}Th and ^{238}U) NanoSIMS images and analyses obtained in monazites studied in thin section or separates. ^{89}Y, ^{139}La, ^{208}Pb, ^{232}Th and ^{238}U ion images were obtained in monazite areas previously studied with EMPA and dated with LA-ICPMS. The NanoSIMS maps allow to characterise isotopically and chemically distinct domains that were not distinguishable on WDS X-ray maps. ^{208}Pb/^{232}Th maps derived from NanoSIMS images offer the possibility to correlate different age domains with the measured ^{208}Pb/^{232}Th ages obtained at larger scale (few μm) by LA-ICPMS.

These results are very promising for compositional and isotopic mapping with a highest spatial resolution in the monazite geochronometer.

The chemical and dynamic processes as well as the atmospheric composition, in the Planetary Boundary Layer (PBL) over the Aegean Sea, are investigated during an 'Etesian' event (29/8-9/9/2011) based on modeling results and a combination of airborne and ground observations. During this period atmospheric parameters, concentrations of gaseous species and size-resolved aerosol chemical composition have been measured using instrumentation flown on the UK's BAe-146-301 Atmospheric Research Aircraft operated through FAAM [1,2]. The simulations were performed by the on-line meteorological and chemical transport WRF-Chem model. Anthropogenic and on-line calculated natural (biogenic, sea-salt) emissions have been considered. Fire emissions generated by the FMI Fire Assimilation System [3] have been also included. The horizontal and vertical distribution of gaseous and aerosol species is interpreted in relation to the evolution of the PBL, and is shown that the model captures the geographical and temporal variations observed.

Polyoxometalates and Their Effect on Tungsten Speciation and Transport

BENJAMIN BOSTICK[1]* AND JING SUN[12]

[1]Lamont-Doherty Earth Observatory, Palisades, U.S.A, bostick@ldeo.columbia.edu

[2]Columbia University, New York, U.S.A, AND Lamont-Doherty Earth Observatory, Palisades, U.S.A, jingsun@ldeo.columbia.edu

Tungsten (W) is a toxic element with complex aqueous speciation. Tungstate, W(VI), is the dominant oxidation state of tungsten in soils, forms a variety of insoluble tungstate minerals, and often adsorbs strongly to iron oxides. This W(VI) often is significantly more readily transported than expected based on the available thermodynamic data. We have examined the role of metastable and heteropolyatomic polytungstates in enhancing the solubility of tungsten in natural systems. We have measured W concentrations following reaction with model soil minerals, and natural soils, over a variety of solution compositions and reaction periods in which a variety of polytungstate species may form in solution. In particular, we examined the effect of initial W(VI) concentration and speciation, pH, and the presence of silicate and phosphate on W(VI) sorption. The speciation and structure of adsorbed W(VI) on ferrihydrite also were examined using synchrotron-based X-ray absorption spectroscopy (XAS). Adsorption isotherms and envelopes show a complex relationship between pH and W(VI) adsorption, with more W(VI) retained at circumneutral pH. Adsorption was less extensive in solutions containing more polymeric species, suggesting that these species do not adsorb to ferrihydrite surface as strongly as does the tungstate anion. Polyoxometalate (POM) clusters form in the presence of phosphate, or persist as metastable complexes for sufficient duration to considerably enhance the solubility and transport of tungsten in natural environments. XAS confirmed that tungstate usually represents the bulk of adsorbed W(VI), but polytungstates also appear to be adsorbed to the mineral surface, particularly in systems in which W(VI) was most soluble. Equilibrium adsorption onto ferrihydrite was not achieved and takes more than one month; this unusually slow adsorption is due to the slow decomposition of weakly-adsorbing polyatomic anions to monomeric tungstate anions. The kinetic stability of metastable polytungstates thus may further enhance W solubility in natural waters and its migration in natural environments.

Relating U-Th-Pb ages of accessory minerals to metamorphism: A case study from the Barrovian sequence of the Central Alps, Switzerland

KATE BOSTON[1]*, DANIELA RUBATTO[1], JÖRG HERMANN[1], YURI AMELIN[1] AND MARTIN ENGI[2]

[1]Research School of Earth Sciences, the Australian National University, Building 142 Mills Rd Acton ACT Australia. (Correspondence: Katherine.Boston@anu.edu.au)
[2]Institute of Geological Sciences, University of Bern, Baltzerstrasse 1 + 3 CH3012 Bern Switzerland.

Accessory minerals allanite, monazite and rutile from amphibolite facies rocks across the Barrovian sequence of the Central Alps (Switzerland) were investigated for composition and U-Th-Pb ages. The growth ages of these minerals record stages of prograde and peak metamorphism.

Allanite formed during the prograde path at 26-33 Ma. It occurs aligned along an early foliation that is overprinted by later generations of mica. In some cases, the foliation along which allanite is aligned is only preserved in garnet. Rutile from one metapelite in the central region also records a ~33 Ma age. Zr-in-rutile thermometry yields a temperature of 550±20°C, which is lower than the 620°C peak temperature deduced from the main mineral assemblage [1], indicating that rutile crystallised under prograde conditions. We interpret this early age as the time when the rocks reached peak pressure conditions.

The timing of peak temperature conditions is recorded in monazite, rutile and, in one sample, allanite rims. Monazite yields an age of 22 Ma and grew at the expense of allanite and after the first stage of garnet growth. In monazite-bearing samples, allanite is preserved as inclusions in garnet, whereas monazite is part of the matrix. Zr-in-rutile thermometry suggests that 23 Ma rutile in a calcschist records the timing of peak temperature conditions. 20 Ma allanite rims in one metapelite crystallised on older (27 Ma) cores, and are also interpreted to reflect the timing of peak to retrograde conditions.

Through multi-mineral geochronology a prograde metamorphic history, spanning some 10 Ma, can be reconstructed: from prograde greenschist facies to peak amphibolite facies conditions. The observation that 33 Ma prograde rutile is preserved despite the later temperature peak at 22 Ma suggests a closure temperature of Pb in rutile in excess of 620°C.

Like The Black Sea, The Baltic Sea Has Switched Between Fresh Water And Brackish Water Modes. The Changes In Paleo-Environmental Conditions Caused Downcore Gradients In The Concentrations Of Dissolved Species In The Pore-Waters With Consequences For Microbial Activity And Physicochemical Water-Solid Interactions Associated With Multiple Stable Isotope Fractionation Processes. Here, We Introduce A New Combined Multi-Isotope And Trace Element Approach To Investigate Diagenesis In These Non-Steady State Systems.

In a Gotland Basin core, it is found that concentrations of conservative elements and the pore water H-2 and 18-O contents decrease with depth due to diffusion from brackish waters into underlying fresh waters. A downward increase and decrease of Ca and Mg concentrations, respectively, is associated with decreasing Ca-44 and Mg-26 isotope values. B-11 isotope values decrease in the limnic part. An increase in Ba concentrations with depth is associated with a slight increase in Ba-137/134 isotope values. Microbial activities lead to an increase in DIC, but a decrease in SO4 concentrations and in C-13 contents of DIC with depth. Desorption of Ba from glacial sediments due to downward diffusing ions is responsible for the formation of sedimentary barites. S-34 and O-18 isotope values of barites suggest that these were formed in glacial sediments from pore waters strongly depleted in O-18. Impacts of diagenetic processes on multi-isotope signals in pore waters and authigenic phases are discussed. Mixing between brackish and fresh waters, solid-liquid interactions, and transport reactions explain most of the observed isotope variations along the vertical pore water profile.

High Velocity Collisions Recorded in Asteroidal Meteorites: New Ways to Constrain Planet Formation

W.F. BOTTKE[12] AND S. MARCHI[1,2]

[1] Southwest Research Institute, Boulder, CO, USA
[2] Center for Lunar Origin and Evolution, NLSI

It was recently shown that 40Ar–39Ar ages in meteorites reflect unusually high impact velocities exceeding 10 km/s [1]. Compared with typical impact velocities for main-belt asteroids of about 5 km/s, these collisions produce 100–1,000 times more highly-heated material by volume. It was proposed that the 40Ar–39Ar ages between 3.4 and 4.1 Gyr ago from Vesta, the H-chondrite parent body and the Moon record impacts from numerous main-belt asteroids that were driven onto high velocity and highly eccentric orbits by the effects of the late migration of the giant planets. The timing of these asteroidal and lunar impact signatures help define the so-called Late Heavy Bombardment.

An intriguing implication of this work concerns the 40Ar–39Ar events seen between ~4.4–4.53 Gyr ago among many stony meteorite groups. Although some of those ages may reflect cooling through the blocking temperature after igneous crystallization, others are unambiguously related to early impact events on primordial asterioids during the planet formation era [e.g., 2]. More recent impacts in the main asteroid belt ejected this material off the parent body, allowing it to reach Earth through dynamical processes. We postulate that these early high-velocity impacts likely came from leftover planetesimals residing in the terrestrial planet region, many of which had highly eccentric and inclined orbits. If true, these ~4.5 Gyr ago events constrain the nature and decay rate of this putative population, as well as early planet formation processes. Using numerical simulations, we will explore the implications of these results in our talk. We will also probe how these same methods and data allow us to glean insights into the timing of the giant impact that formed the Moon.

Hypersaline volatiles in a palladium-enriched mafic pegmatoid from the 2.48 Ga East Bull Lake intrusion, Sudbury District, Ontario, Canada

BRANDON BOUCHER[1], JACOB HANLEY[1] AND RICHARD JAMES[2]

[1]Saint Mary's University, Halifax, NS, Canada. B3H 3C3 (boucher.brandon.m@gmail.com; jake.hanley@gmail.com)
[2]MERC, Laurentian University, Sudbury, ON, Canada (rjames@laurentian.ca)

The East Bull Lake intrusion (EBLI) is a Paleoproterozoic mafic-ultramafic (low-Ti, high-Al tholeiitic) intrusion located roughly 90 km west of Sudbury, ON. The intrusion itself consists primarily of massive- and layered leucogabbro and leucogabbronorite and is interpreted to be the product of crystallization of partial melts from sublithospheric depleted mantle, a remnant of a ~2.48 Ga large igneous/metallogenic province. The heavily contaminated lower zones of the intrusion host disseminated-blebby PGE-Cu-Ni sulfide mineralization (up to ~10s ppm PGE locally in massive sulfide pods).

Microthermometry was conducted on fluid inclusion assemblages containing late-stage magmatic-hydrothermal fluids in interstitial quartz from a mineralized pegmatitic leucogabbro from the central portion of the intrusion. The FIAs contain three-phase liquid-rich inclusions with halite daughter phases. Final homogenization occurred by halite dissolution at temperatures significantly higher than vapour bubble disappearance. Using a method for calculating minimum trapping pressures at the T of homogenization [1,2], FIAs not influenced by post-entrapment modification show minimum trapping pressures from 1.6-3.0 kbars, with final homogenization temperatures ranging from 291° to 367°C (bulk salinities of 38-44 wt% NaCl equiv.) For comparison, Ti-in-quartz thermometry for fluid inclusion-rich domains in the quartz indicate crystallization from 650-750°C. The data suggest that if the inclusions are primary then actual trapping pressures are significantly higher than the minimum values estimated above, constraining the depth of emplacement of the mineralized intrusion to at least 18km.

The study provides first constraints on the nature of late-stage magmatic-derived fluids associated with the EBLI and provides a means for comparison to other mineralized intrusions that show involvement of magmatic fluids in the redistribution of chalcophile/highly siderophile ore metals.

Deep crustal melting revealed by Pb isotopes and seismology in the western US

R.A. BOUCHET[1], J. BLICHERT-TOFT[1,2], A. LEVANDER[2], M.R. REID[3] AND F. ALBAREDE[1,2]

[1]Ecole Normale Superieure de Lyon, 69007 Lyon, France (romain.bouchet@ens-lyon.fr)
[2]Rice University, Houston, Texas 77005, USA
[3]Northern Arizona University, Flagstaff, Arizona 86011, USA

In comparison to the uniform coverage of the western US (WUS) provided by the USArray, the NAVDAT database shows many poorly sampled regions. We therefore measured the Pb isotope compositions of crustal xenoliths from numerous volcanic and plutonic rocks across the Colorado Plateau (CP), and also sampled felsic plutonic rocks outcropping east of it, where data for the crust have been particularly scarce. When possible, we separated low-U/Pb K-feldspars to obtain the Pb isotope composition of the host magmas. We combined our new data with literature Pb isotope data from ores and felsic plutonic rocks, all of which we cast into the geologically informative variables of Pb model ages, U/Pb, and Th/U using a two-stage model. These parameters were then imaged on isotopic maps of the WUS using grid-cell averaging. Comparing the isotopic maps to seismic maps of tomographic anomalies [1] and Moho and LAB depths determined from receiver functions [2] leads to the following observations: (1) Pb model ages match geological ages only where the continental mantle is cold and the Moho is deep. Elsewhere, Pb model ages have been reset. (2) While U/Pb does not vary systematically with other geochemical or seismic data, Th/U, as inferred from measured $^{208}Pb/^{206}Pb$ systematics, is high in the Snake River plain, in Northern Utah, along the Uinta Mountains, along the western rim of the CP, along the Rio Grande Rift, and in the Laramide uplifts in Colorado, all places where Vp/Vs is high, and represent regions of either crustal thinning or basement exposure. We suggest two scenarios: (1) The Th/U systematics, which are not visibly controlled by heat flow, attest to thinning of the local continental crust above hot mantle. Lateral removal of the upper and middle crust, by extensional faulting or channel flow, allowed the uplift of deep high-Th/U crustal rocks and their melting. (2) Exhumation of basement rocks by either deep-seated Laramide style thrust faults or as metamorphic core complexes provides access to deeper levels of the crust, providing the observed high Th/U values.

Large river floodplains: weathering without erosion?

J. BOUCHEZ[1], M. LUPKER[2], J. GAILLARDET[3], C. FRANCE-LANORD[4], P. LOUVAT[3] AND L. MAURICE[5]

[1]GFZ - Helmholtz Centre Potsdam, Potsdam, Germany
[2]ETH, Zürich, Switzerland
[3]IPGP – CNRS, Paris, France
[4]CRPG – CNRS, Vandoeuvre-les-Nancy, France
[5]GET – IRD, Toulouse, France

On their journey to the ocean, large river sediments undergo a series of sedimentation, temporary storage and reworking episodes in active floodplains, in which time is available for sediments to mature chemically. Weathering affecting material eroded from tectonically active mountain belts in these flat, non-erosive areas is a potential mode of coupling between erosion and weathering fluxes at the continental scale.

We quantified the chemical fluxes associated with weathering of sediments in the floodplains of the Amazon and Ganga river systems [1,2]. To this end, river sediments were sampled upstream and downstream four river reaches across these basins. Sampling along depth-profiles grants access to the whole grain size and chemical composition range of river sediment. Weathering intensities of major elements (i.e. losses of Na, K, Mg and Ca) associated with chemical weathering in floodplains were examined as a function of grain size and integrated over the entire grain size range. Finally, we computed weathering fluxes, using a steady-state mass balance model at the scale of the river reach.

Across the four river reaches (Marañon, Beni, Madeira, and Ganga rivers), two consistent features emerge: (1) significant carbonate dissolution and subsequent Ca and Mg release to the dissolved load; (2) retention of K and Mg in the silicate phase of the sediment. These observations are in agreement with what is predicted from mineral kinetics. In this respect, sediment transport time across the river reach is a controlling factor on the floodplain weathering flux. However, across the studied river reaches, the variable extent of Na and Ca release by plagioclase dissolution points at an additional control on the intensity, namely the potential exhaustion of weatherable minerals before the sedimentary material enters the floodplain (be it in modern soils of the erosive area, or during ancient weathering episodes).

Altogether, our results show that floodplains constitute the predominant locus of weathering in the Gangetic system but not in the Amazon Basin. However, CO_2 consumption fluxes associated with silicate weathering in floodplains in these two river basin floodplains is on the order of magnitude as those resulting from weathering in their erosive areas.

Biogeochemical responses to gamma irradiation treatment of Alberta oil sands fluid fine tailings

RYAN BOUDENS[1]*, THOMAS REID[1], JAN CIBOROWSKI[1] AND CHRIS WEISENER[1]

[1]Great Lakes Institute for Environmental Research,University of Windsor, Windsor, Canada (*boudens@uwindsor.ca, weisener@uwindsor.ca)

Exploitation of the oil sands in Alberta has created large volumes of waste materials termed fluid fine tailings (FFT). These materials are stored in large settling basins to allow adequate separation of the oil sands process water and the FFT. The separated water in these holding areas are used either for future processing or it is allowed to settle before reclamation into functional wetlands and end pit lakes. A major concern is the presence of Naphthenic Acids (NA); these are a toxic, recalcitrant group of carboxylic acids naturally released from bitumen during the extraction process. An unexplored treatment option to promote or speed the degradation process and reduce *in situ* effects of NA's is gamma irradiation. In this study we examined the development of chemical REDOX gradients; and kinetic responses of indigeneous microbes inoculated into irradiated FFT material using laboratory microcosms.

The systems will be set up using representative young and aged FFT material in both oxic and anoxic environments. Temporal changes to porewater and headspace water geochemistry was tracked along with *in situ* microsensor profiles and microbial community succession patterns. These results will have implications in development of a model framework to optimize treatment based on biogeochemical responses to waste type.

Closed system vs. open system degassing: a combined textural and geochemical approach

G. BOUDON[1]* AND H. BALCONE-BOISSARD[2]

[1] Institut de Physique du Globe de Paris, Sorbone Paris Cité Paris, France (*correspondence : boudon@ipgp.fr)
[2] ISTeP, Université Pierre et Marie Curie, Paris, France

Eruptive styles of volcanoes span a wide range of dynamic, from effusive to explosive. They depend on the magma composition, the volume of ejected magma and the magma ascent conditions in the conduit, from the reservoir to the surface. Magmas with the same composition and pre-eruptive conditions can generate different eruptive styles (eg. multistyles eruptions) evidencing the dominant effect of the ascent conditions of magmas. Understanding the behavior of the volatile phase in relation with the rheology of the magma (viscosity) during magma ascent is one of the main stake.

A detailed study of the textural characteristics (vesicularity, microcrystallinity) of the products of explosive eruptions associated to their composition and volatile content (pre-eruptive and residual) allow to better define the relations between the magma behavior in the upper part of the conduit and the eruptive style. In low-viscous basic magmas, pre-eruptive volatile content is low (2-3 wt%) and bubbles move independantly in the melt, with a higher ascent velocity. Their coalescence forms large bubbles that blow up at the surface: the explosivity is low (strombolian eruptions). On the contrary, in high-viscous differentiated magmas, the pre-eruptive volatile content is high (up to 5-7 wt%) and bubbles display generally the same ascent velocity. The magma reaches the surface with a large proportion of bubbles (up to 75vol%) as an unstable foam, the fragmentation of which generates a high explosivity (plinian to vulcanian eruptions). In some cases, with similar magma composition and volatile content, part of the volatiles may escape through permeable conduit walls generating a bubble flattening and melt microcrystallisation, which in turn increase the magma viscosity, decreasing its ascent rate. At the vent, this magma is partly degassed with a very low explosivity potential (dome-forming eruptions), excepting some particular cases. All intermediate eruptive style exist between high and low explosivity, depending of the behavior of the magma during its ascent in the conduit.

We'll discuss all these cases including the extremes and inusual cases as basaltic plinian eruptions or explosive dome-forming through several examples taken in recent eruptions.

Thermodynamics of Lower Mantle Minerals

M.A. BOUHIFD[1], D. ANDRAULT[1] AND N. BOLFAN-CASANOVA[1]

[1]Laboratoire Magmas et Volcans, CNRS UMR 6524, Université Blaise Pascal, Clermont-Ferrand, France

There is a general consensus that the Earth's lower mantle is mostly composed of (Mg,Fe)SiO_3 perovskite (Mg-Pv) and (Mg,Fe)O ferropericlase (Fp). Knowledge of the chemical and physical properties of these minerals is, therefore, essential for understanding the structure and dynamics of the lower mantle.

In this work, we performed a new compression study of Mg-perovskite ($MgSiO_3$) and periclase (MgO) phases synthesized at variable conditions of the Earth's lower mantle by using pure Mg_2SiO_4 as a starting material. In our experiments a Double-sided Laser-Heated Diamond Anvil Cell at the ESRF – ID27 (Grenoble) was used up to 100 GPa and 3000 K. The equation of state (EOS) at various conditions of *P* and *T* for Mg-Pv and Fp were obtained by integrating the available experimental data into a single P-V-T EOS to constrain the elastic parameters (bulk modulus, densities, etc …) under conditions of the Earth's lower mantle, which provides a basis for evaluating the compositional models of the Earth's lower mantle.

In this study, we will also combine our new results and the existing data in the literature to discuss and compare the combined effects of Fe and/or Al on the EOS of both phases and the chemical constraints that we can obtain from such comparisons. Finally, we will discuss our results on the light of the most recent studies on the melting curves of the lowermost Earth's mantle and the stabilization of the ultra-low velocity zones associated with partial melting at the core-mantle boundary [*e.g.* 1-3].

C and O isotope compositions of the Matongo carbonatite (Burundi) : new insights into alteration and REE mineralization processes

P. BOULVAIS*[1], S. DECREE[2], C. COBERT[1], G. MIDENDE[3], L. TACK[2], V. GARDIEN[4] AND D. DEMAIFFE[5]

[1] Géosciences Rennes – UMR 6118 - Université de Rennes 1 (France)
(*correspondence : philippe.boulvais@univ-rennes1.fr)
[2] Royal Museum for Central Africa, Tervuren (Belgium)
[3] Université de Bujumbura (Burundi)
[4] LGL-TPE, UMR CNRS 5276 Université Lyon 1/ENS-Lyon (France)
[5] Université Libre de Bruxelles (Belgium)

The Matongo carbonatite intrusion is part of the Neoproterozoic Upper Ruvubu alkaline plutonic complex (URAPC), located in Burundi along the western branch of the East African Rift. This alkaline complex, which also comprises feldspathoidal syenites, diorites, quartz-bearing syenites and granites, emplaced around 750 Ma [1].

Most of the oxygen and carbon isotope compositions obtained on the several carbonatitic facies are typical of carbonatites: the $\delta^{18}O$ values are between 7.2 and 8.5‰ (vs. SMOW), the $\delta^{13}C$ value are between -4.7 and -5.4‰ (vs. PDB). These values correspond to the magmatic signature of the intrusion. Some samples show a significant increase in the $\delta^{18}O$ value, between 11 and 20‰, with an extreme value of 21.6‰. Rare Earth Element fractionation is visible in the most isotopically altered samples, which points to mobilization of these elements. The site of re-deposition of the leached elements may well be found in distal hydrothermal veins, which contain albite, calcite, apatite and REE-fluorocarbonates. The Matongo carbonatite thus appears as a complete metallogenic hydrothermal system where both the source and sinks of REE are identified.

The Nuvvuagittuq supracustal belt (Québec) and the Acasta gneiss complex (NWT), Canada represent some of the oldest crustal remnants on Earth and are thus outstanding archives for inferring the early history of the continental crust. There are, however, controversies about how existing data should be interpreted in terms of geochronology and time scales. In this study, Sm-Nd isotope data, combined with U-Pb dating and Lu-Hf isotope data, were examined.

We analyzed thirteen samples, previously dated by U-Pb, zircon and Lu_Hf geochronology from the Acasta gneiss complex for high-precision ^{146,147}Sm-^{142,143}Nd-systematics. The ^{147}Sm-^{143}Nd data yield an alignment corresponding to an age of 3371 Ma age. Ten out of the thirteen samples show negative ^{142}Nd anomalies with an average deficit of -9.6±5 ppm.

We show that, unlike previous claims, the ^{146}Sm-^{142}Nd systematics are susceptible to resetting. Furthermore, when combined with the corresponding ^{147}Sm-^{143}Nd and ^{176}Lu-^{176}Hf data for the same samples, these data provide a fairly accurate picture of the evolution of Nuvvuagittuq and Acasta rocks. To examine quantitatively the effect of thermal resetting, we designed a new model whereby isotopes undergo exchange in a closed system at whole rock lengthscale. The Nuvvuagittuq mafic rocks were only partially reset, implying that direct dating of these rocks is not possible. In contrast, the degree of resetting was more extreme in Acasta, which yields rather constant ^{142}Nd anomalies, while the ^{147}Sm-^{143}Nd system records a younger age of ~3400 Ma. In both cases, the existence of negative ^{142}Nd anomalies can be attributed to Hadean crustal extraction between 4500 and 4300 Ma. The lifetime of this crust was investigated using time-dependent box models, including recycling into the mantle, and is shown to persist over 0.5-1 Gyr. In addition, the existence of positive ^{142}Nd anomalies in younger rocks was found to depend strongly on this parameter, and on the mantle stirring time.

Diffusive heavy metal fluxes in bottom river sediments

ALAIN C.M. BOURG[1]* AND CHRISTOPHE MOUVET[2]

[1]EA4592 Georessources and Environment, Dept Geosciences, Univ. of Pau, BP 1155, 64013 Pau Cedex, France (*correspondence: alain.bourg@univ-pau.fr)
[2]BRGM, BP 6009, 45060 Orléans Cedex 2, France

Suspended particles are scavengers of contaminants in streams. When they become deposited on the river bed they can act as efficient traps. Early diagenetic processes in bottom sediments are known to induce diffusive fluxes towards the overlying water in lakes and seas for some elements and downwards for others [*e.g.*, 1, 2].

We applied to a river one of the methodologies commonly used for non turbulent water bodies, i.e., porewater *peepers*. The Lot River (in SW France) was selected because of its history of long-term metallic contamination and the consequent concern about the possible re-entering in the river dissolved flux of previously trapped heavy metals. The benthic pore water samplers (with a 10 mm vertical resolution) were installed manually by a SCUBA diver at a depth of ca. 2 m in a slow channel of the river.

The interstitial water redox potential, pH, dissolved sulfate and phospahe all decrease with depth, contrary to Fe and Mn which increase with depth. All of this is coherent with diagenesis.

For Cd and Zn we observe a peak in dissolved concentration 1 to 3 cm below the sediment-water interface, this implies a double flux, one towards the river and the other towards the sediments. This last component is in favor of removal of Cd and Zn from the river flux to the ocean, but in turns it might cause some concern for groundwater supply in local well fields in alluvial aquifers. These observations are explained in terms of geochemical processes.

Particulate matter in São Paulo City: comparison between industrial and urban area

BOUROTTE C.[1]*, FORNARO A.[2], FORTI M.C.[3], CAVICCHIOLI A.[1] AND MIRANDA R.[1]

[1] EACH-University of São Paulo, Rua Arlindo Béttio, 1000, CEP 03828000 São Paulo-SP, Brazil (*correspondence: chrisbourotte@usp.br,)

[2] IAG-University of São Paulo, Rua do Matão, 1226, CEP 05508-090, São Paulo-SP, Brazil

[3] INPE, Centro de Ciência do Sistema Terrestre CCST, C.P.515 - CEP 12245-970, São José dos Campos-SP, Brazil

Airborne particulate matter in urban atmosphere is derived from natural and anthropic sources. The chemical composition of coarse and fine particles is critical when considering their hazardous effect. This particulate matter study is part of a greatest research project that investigates the relationship between aerosols, road dusts and surface soils.

The sampling sites are located in two region (eastern and western zones) of the São Paulo City, in the two Campi of the University of São Paulo that present distinct characteristics i.e. industrial and commercial/residential backgrounds. The eastern area (EACH) is located in the floodplain of the Tietê River, near several industries, a highway and the international airport. The western area (Butantã) is located in a commercial and residential area and submitted to intense vehicular traffic.

The particulate matter ($PM_{2.5}$ and $PM_{2.5-10}$) was continuously collected during day and night periods, simultaneously in the two areas. Sampling was initiated on August 22th, 2012 and finalized on December 7th, 2012 in the eastern area and from July, 7th to September 9th, 2012 in the western area. This period includes winter and the beginning of summer (raining season). Black Carbon and multi-elemental composition where quantified in the fine fraction by reflectometry and FRX, respectively.

The results show that particulate matter concentrations during winter, in the eastern area were 23.70 ±13.05 μg m^{-3} in the fine fraction and 42.73 ±37.71 in the coarse one. Concentrations in the western area were 21.09 ±14.00 μg m^{-3} in the fine fraction and 16.19 ±8.17 μg m^{-3} in the coarse one. During summer, concentrations were lower and similar between the two fractions. Concentrations were 20.05 ±7.72 μg m^{-3} and 21.75 ±13.93 μg m^{-3} in the fine and coarse fraction, respectively, in the eastern area. In the western area, concentrations were 17.25 ±8.36 μg m^{-3} and 17.09 ±8.12 μg m^{-3}, in fine and coarse fraction, respectively. During winter, higher concentrations in the coarse mode in the industrial area may be due to higher soil resuspension since the vegetation area is reduced comparing with the western one. Chemical analysis are still being done but preliminary results showed that for the industrial area, black carbon contributed to 18.2% of the fine particulate matter mass. The elements with higher concentrations were S, Si, Fe, K, Al, Na, Zn, Pb and Cd.

New method for precise Cl isotopes measurement by SIMS

A.-S. BOUVIER[1] AND L. BAUMGARTNER[1]

[1] ISTE, University of Lausanne, Lausanne, Switzerland

Chlorine is an important volatile element. Its two stable isotopes are used to track the global halogen cycle and to determine fluid sources. Chlorine isotopes are fractionated by fluid/rock interaction, degassing, diffusion and mineralogical transformation. However, the range of Cl isotopes on Earth may be relatively limited [e.g., 1], requiring precise measurements of $\delta^{37}Cl$. Usually Cl isotopes are measured by TIMS or IRMS, and only a few measurements have been performed so far by ion probe. Previous SIMS studies reported a reproducibility of 0.8 to 1.5‰ (2 Standard Deviation (SD)) for glasses with > 200 ppm Cl [e.g., 1, 2]. We develop a new SIMS method to improve the precision of $\delta^{37}Cl$ measurements. Analyses were done on a CAMECA IMS 1280-HR, using a cesium source. One analysis consists of two minutes presputtering using a 25μm raster to clean the surface, followed by 7 minutes of analysis using a ~10μm rastered beam. $^{37}Cl^-$ and $^{35}Cl^-$ were simultaneously measured on electron multipliers in multicollection mode.

Results show internal precisions as good as <0.2‰ (2SE) and reproducibility (spot to spot) of 0.6 to 0.8‰ (2SD) for standard glass with Cl content down to 100 ppm. For standard glasses with Cl content < 100 ppm (down to 5 ppm), the reproducibility reaches 1.5‰ (2SD).

With this precision reached it is now possible to investigate *in situ* $\delta^{37}Cl$ variations at small scale, even in minerals with low Cl content, using the appropriate standard material.

Lu-Hf and Sm-Nd systematics of the first solids in the Solar System

A. BOUVIER[1] AND M. BOYET[2]

[1]University of Minnesota, Minneapolis, MN, USA. (abouvier@umn.edu)
[2]Laboratoire Magmas et Volcans, Clermont-Ferrand, France. (m.boyet@opgc.univ-bpclermont.fr)

Hafnium-176 excesses are found in bulk chondrite and eucrite isochrons, and in some (not all) eucrite [1] and angrite mineral isochrons [2,3]. It was proposed that cosmic rays accelerated by supernova(e) shocks in the early Solar System could produce a higher decay rate of a ^{176}Lu isomer within the irradiated planetary materials [2]. This hypothesis complicates the direct determination of the initial Lu-Hf isotopic composition of the Solar System and by extent that of the terrestrial planets [4]. The interpretation of the earliest terrestrial Lu-Hf isotopic records relies on knowing these initial conditions [5].

Such external irradiation sources should affect any objects already formed and exposed in the protoplanetary disk. We thus investigated the stable and radiogenic Lu-Hf and Sm-Nd compositions of CAIs, the first solids formed in the Solar System. The selected five CAIs were formed after injection of ^{26}Al into the protoplanetary disk [6]. The ^{144}Sm/^{152}Sm ratios have the largest variations with p-process deficits typically at ~-250ppm. Deficits in ^{149}Sm (<100ppm) are correlated to excesses in ^{150}Sm within the same CAI suggesting small neutron capture effects. All stable Nd isotope ratios have deficits smaller than 50ppm. The bulk CAIs have no resolvable Hf isotopic variations for ^{174}Hf, small positive anomalies (<20 ppm) for ^{178}Hf and ^{180}Hf which demonstrate minimal corrections (<40ppm) for ^{176}Hf/^{177}Hf ratios. The bulk and mineral ^{147}Sm-^{143}Nd and ^{176}Lu-^{176}Hf isochron ages for three melted CAIs together are 4519 ±140 Ma (MSWD =0.77, ^{143}Nd/^{144}Nd$_i$= 0.50675 ±20) and 4560 ±190 Ma (MSWD =59, ^{176}Hf/^{177}Hf$_i$ = 0.27985 ±15) respectively. We thus interpret the anomalous Lu-Hf isochron slopes [1,2] as the consequence of secondary parent body processes. Our direct determination of the initial ^{176}Hf/^{177}Hf of the Solar System is consistent with, but less precise than, those obtained from present CHUR values and from updated bulk chondrite isochrons [7].

Ion concentration at the kaolinite – water interface

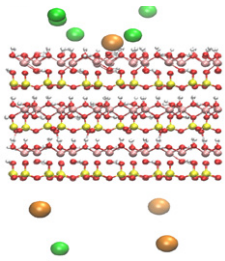
N. BOVET*, T. BAUR, T. CLAUSEN, M. OLSSON, B. LORENZ AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark (*bovet@nano.ku.dk)

Kaolinite is a clay present in soils, sediments and rocks, including sandstones and carbonates, as well as shales and mudstones. Its high surface area and large cation exchange capacity make it reactive in natural environments. For example, it plays an important role in uptake of contaminants in the environment and in tertiary oil recovery.

To observe the surface chemical composition of kaolinite, as it is during contact with solution, we used X-ray photo-electron spectroscopy (XPS) with the fast freezing technique. This allows the mineral - fluid interface to be preserved and investigated, even under ultrahigh vacuum which is necessary for XPS, because the ion distribution is “frozen in” as it was in the original liquid phase.

Solutions investigated were NaCl, $CaCl_2$ and $Ca(C_2H_5COOH)_2$ at pH 5.5, in their reaction with pure kaolinite (KGa1-b). The results show that the relative ion concentration is different at the surface than in the bulk, consistent with electrical double layer (EDL) theory. We also observed that the ratio of Ca and Cl ions is not constant with distance out from the interface. For low $CaCl_2$ concentrations (< 6 mM), the Ca:Cl ratio is higher at the interface, whereas at higher Ca concentration, more negative counter ions, i.e. Cl, are present to balance charge. Results from molecular dynamics (MD) simulations (figure) and atomic force microscopy (AFM) experiments complement the XPS results with structural information to build a full picture of interface interaction.



MD simulation snapshot of Ca (orange) and Cl (green) adsorbed on kaolinite during exposure to solution. Water is present but we have made it invisible.

The co-evolution of Fe-,Ti-oxides and other microbially induced mineral precipitates during the diagenesis of sandy sediments

D.M. BOWER[1], D.R. HUMMER [2], A. KYONO [3], A. STEELE [1] AND J. ARMSTRONG[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington,Washington, D.C., 20015, (dbower@ciw.edu.asteele@ciw.edu,jarmstrong@ciw.edu)

[3]Division of Earth Evolution Sciences, University of Tsukuba, Tsukuba, Ibaraki 305-8572, Japan, (kyono@geol.tsukuba.ac.jp)

Ilmenite ($FeTiO_3$) and related Fe-,Ti-oxides are ubiquitous components of modern beach sands and are often associated with "fossil" microstructures in ancient sedimentary rocks [1,2]. The mineral composition of the ancient sedimentary rocks we see today, however, differs from what was originally formed in the sediments billions of years ago. This change in composition is usually attributed to long, complicated histories and atmospheric influences, while the contribution of microbes is not typically considered. Here the goal is to understand the co-evolutionary path of microbes and minerals in sandy, shallow sub-aquatic environments under early diagenetic conditions. Laboratory experiments were done to document the precipitation of minerals on cyanobacterial cellular material as well as the phase changes in natural ilmenites to determine if microbes passively influence mineral phase pathways. The precipitates, ilmenite grains, and fossilized cells were analyzed using scanning electron microscopy (SEM), x-ray diffraction (XRD), and micro Raman spectroscopy. The results show that microbial fossilization occurs and a variety of mineral phases precipitate under early diagenetic conditions ($T<70^oC$) in wet, sandy environments. The minerals that form in the presence of microbes differ in crystal habit and chemical composition from those without microbes. This study aids in understanding the microbial role in diagenesis and helps redefine geochemical biosignatures that can be used for the detection of ancient microbial life in sedimentary rocks on Earth as well as for future planetary life exploration missions.

Using Genomics to Reveal the Secrets Underlying the Ecological Success of Marine Diatoms

CHRIS BOWLER [1]

[1] Head of Environmental and Evolutionary Genomics Section, Institut de Biologie de l'Ecole Normale Supérieure, Paris, France. cbowler@biologie.ens.fr

Diatoms are thought to be the most successful group of eukaryotic phytoplankton in the modern ocean. Recently completed whole genome sequences from two species, *Thalassiosira pseudonana* and *Phaeodactylum tricornutum*, have revealed a wealth of information about the evolutionary origins and metabolic adaptations that may have led to their ecological success. A major finding is that they have acquired genes both from their endosymbiotic ancestors and by horizontal gene transfer from marine bacteria. This unique melting pot of genes encodes novel capacities for metabolic management, for example allowing the integration of a urea cycle into a photosynthetic cell. Our studies focus on *P. tricornutum* and exploit the availability of techniques for reverse genetics, digital gene expression profiling, genome and epigenome maps, ecotypes with differential capacities to adapt to different conditions, and distinct morphotypes that can be induced to change shape in response to ecologically relevant stimuli. Using these resources we explore both the physiological functions of diatom gene products and the evolutionary mechanisms that have led to diatom success in contemporary oceans.

A next objective is to explore the functional roles of diatom biodiversity in the world's oceans. With biology becoming quantitative, systems level studies can now be performed at spatial scales ranging from molecules to ecosystems. Biological data generated consistently across scales can be integrated with physico-chemical contextual data for a truly holistic approach. While the marine planktonic ecosystems that diatoms inhabit comprise the base of the ocean food web, and are crucial in the regulation of Earth's biogeochemical cycles and climate, their organization, evolution and dynamics remain poorly understood. The *Tara* Oceans expedition was launched in September 2009 for a 3-year study of the global ocean ecosystem aboard the schooner *Tara*. A unique sampling programme encompassing optical and genomic methods to describe viruses, bacteria, archaea, protists and metazoans in their physico-chemical environment has been implemented. The project aims to generate systematic, open access datasets usable for probing the morphological and molecular makeup, diversity, evolution, ecology and global impacts of plankton on the Earth system, as well as to explore and exploit their biotechnological potential.

Global distribution of sulfate reduction rates in marine sediments

M. W. BOWLES[1]*, J. M. MOGOLLÓN[2], S. KASTEN[2], M. ZABEL[1] AND K.-U. HINRICHS[1]

[1] MARUM Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany (*correspondence: bowlesmw@uni-bremen.de)

[2]Alfred-Wegener-Institut für Polar- und Meeresforschung, Bremerhaven, Germany

Sulfate is the dominant terminal electron acceptor in marine sediments. Sulfate reduction proceeds under anoxic conditions and is supported by a variety of electron donors (e.g. hydrogen, acetate, methane, propane, and butane), most of which are supplied by the decomposition of sedimentary organic matter. Consequently, a combination of primary productivity and water column depth is often thought to control sulfate reduction throughout most of the ocean's seafloor [1, 2]. However, global models of sulfate reduction do not resolve the many different physical and ecological parameters that are encountered on a global scale, and that ultimately play a major role in driving local and regional sulfate reduction rates. We sought to better determine sulfate reduction rates on a global scale, irrespective of region or location by 1) including sulfate profiles from diverse settings and 2) compiling multiple geochemical parameters that are relevant to sulfate reduction and can help discern the magnitude of sulfate reduction rates. All available sulfate concentration profiles from DSDP/ODP/IODP (to Exp. 312) and additionally those in the database Pangaea (www.pangaea.de) were compiled reaching a total >600 non-repetitive concentration profiles. Basic metadata describing the cores was included, such as water depth and distance to shore. Water column data such as minimum percent O_2 saturation, bottom water O_2, NO_3^-, PO_4^{3-}, and concentrations of surface water chlorophyll a and POC [3, 4] were included as additional variables that describe the biogeochemical setting of the cores. All compiled data and concentration profiles were applied to a training algorithm to estimate global sulfate reduction rates. The result was the most precise depiction of global sulfate reduction rates at the highest resolution to date. Our model serves as a platform for the examination of biogeochemical processes on the global scale and lets us predict energetic constraints for microbial metabolism in the subseafloor.

Geometry of carbon and oxygen isotope exchange fronts in the Alta aureole, Utah: Records of hydrodynamic dispersion and scale-dependent permeability during infiltration-driven metamorphism

J. R. BOWMAN*

Dept. of Geology and Geophysics, Univ. of Utah, Salt Lake City, UT 84112 USA (*corr: john.bowman@utah.edu)

A carbon (C) isotope exchange front, periclase reaction front and an oxygen (O) isotope exchange front are developed with increasing distance from the igneous contact in dolomitic marbles of the south Alta aureole, Utah in response to infiltration-driven metamorphism of the marbles. Their relative distances from the igneous contact, approx. 100, 200 and 380 m, respectively, are consistent with down-temperature infiltration of water-rich fluid [$X(CO_2)$ <0.1 to 0.15] that was equilibrated isotopically with the adjacent Alta stock. At the aureole scale both the C and O isotope exchange fronts exhibit significant dispersion: there is significant variation in both $\delta^{18}O$ and $\delta^{13}C$ values at any given position for ≥50 to 100m to either side of the geometric centers of both fronts. Applications of one-dimensional models of advection-dispersion to these aureole-scale dispersed fronts yield a minimum dispersion coefficient of 2E-8 m^2/sec. However at outcrop and bedding scale, steep, coherent gradients in both $\delta^{18}O$ and $\delta^{13}C$ exist at or near bedding boundaries between marble layers of contrasting lithology and isotopic compositions; modeling of these profiles requires much lower diffusion/dispersion coefficients in the range of 7E-12 to 1E-14 m^2/sec.

The variable characteristics of the exchange fronts can be explained by scale-dependent heterogeneity and anisotropy in permeability of the marbles. Both C and O exchange fronts are characterized by significant dispersion at the aureole scale because of significant bed-to-bed variations in permeability, which are reflected by significant bed-to-bed variations in $\delta^{18}O$ and $\delta^{13}C$ values. These bedding-controlled variations in permeability lead to significant permeability anisotropy, with permeability parallel to bedding>>permeabillity normal to bedding. In contrast, permeability within individual beds appears to be relatively homogeneous, as suggested by relatively consistent mineral modes and homogeneous $\delta^{18}O$ and $\delta^{13}C$ values within individual beds, and by steep, highly coherent $\delta^{18}O$ and $\delta^{13}C$ gradients preserved at or near bedding boundaries.

Petrologic and Metasomatic Controls on H and Cl Abundances and Isotopes in Lunar Rocks

JEREMY W. BOYCE[12], ALLAN H. TREIMAN[3], JOHN M. EILER[2], CHI MA[2], YUNBIN GUAN[2], JAMES P. GREENWOOD[4], JULIANE GROSS[5] AND EDWARD M. STOLPER[2]

[1]Dept. of Earth & Space Sciences, UCLA (jwboyce@alum.mit.edu)
[2]Division of Geological and Planetary Sciences, Caltech
[3]Lunar and Planetary Institute, Houston TX
[4]Dept. of Earth & Environmental Sci, Wesleyan University
[5]Dept. of E & P S, American Museum of Natural History

Abundances and isotopic compositions of H and Cl have been measured in apatites from twelve lunar samples, permitting systematic comparison of relationships between these properties and other petrologic and geochemical characteristics. High $d^{37}Cl$ values are found in relatively H-rich apatites, apparently falsifying the hypothesis that elevated $\delta^{37}Cl$ arises only from single-stage degassing of anhydrous magmas. Nevertheless, high $\delta^{37}Cl$ is preferentially associated with relatively low H apatites and so seems to be a property of relatively degassed reservoir(s). The most H-rich apatites tend to have 'low' $\delta^{37}Cl$, < +25‰. Higher $d^{37}Cl$ values (> +25‰) are seen only in highlands rocks and breccias, and the highest value is in a rock that may be from an impact melt/breccia sheet. Among the eight mare basalts analyzed by us and others, δD of apatite shows no correlation with H abundance or $\delta^{37}Cl$. δD is, however negatively correlated with pyroxene homogeneity [(minimum Mg#)/(maximum Mg#)]; basalts that experienced protracted thermal histories (igneous, impact, or metamorphic) have low δD. Finally, it is common to observe both significant heterogeneity in abundance and isotopic composition of H and Cl within apatites from a single sample, or even individual crystals, indicating a lack of equilibrium.

These results can be interpreted in terms of planet-scale evolution; for example, the high $d^{37}Cl$ of highlands rocks could be inherited from a partially degassed (H-poor) magma ocean. However,it is also possible that elevated $d^{37}Cl$ in some samples arose through devolatilization during impact metamorphism and/or metasomatism of the crust. Variations in dD could represent mixing of a high δD (>+500‰) component in pristine igneous rocks (either because this is a signature of their mantle sources or because of magmatic degassing) with a low-δD component like solar wind implanted into regolith. If so, much of the volatile element geochemistry of lunar rocks may reflect crustal and near-surface processes.

Hot spring environments as accessible portals into the metabolic underpinnings of the deep hot biosphere

ERIC S. BOYD[1], ERIC A. ALSOP[2], EVERETT L. SHOCK[3] AND JASON A. RAYMOND[4]

[1]Department of Chemistry and Biochemistry, Montana State University, Bozeman, MT, USA, eboyd@montana.edu

[4]School of Earth and Space Exploration, Arizona State University, Tempe, AZ, USA, jraymond@asu.edu

The Earth's crust contains an extensive and diverse deep biosphere that is sustained by chemical energy under dark and oligotrophic conditions. Much remains unknown and in need of discovery in these ecosystems due to their deep and hard-to-reach nature. Herein, it is proposed that much information directly relevant to the deep, hot, biosphere of continental subsurface systems is directly accessible in the form of sediments and near-subsurface investigation in the globally relevant hot springs of Yellowstone National Park (YNP), Wyoming, USA. We investigated the composition of ~30 community metagenomes in YNP using a suite of bioinformatic and ecological modeling tools. The results suggest that the metabolic composition of microbial mat communities can be accurately predicted based on the physical and chemical attributes of the environment. Of particular significance is the strict temperature-dependent demarcation noted between the metabolic composition of chemotrophic communities and phototrophic communities as well as the pH-dependent demarcation in the metabolic composition of chemotrophic communities. . Additional results from modeling and *in situ* activity-based studies will be presented that reveal the environmental constraints that shape the distribution of metabolic processes in these accessible portals to the deep hot biosphere.

Reports of seasonal plumes of methane emanating from the near sub-surface of Mars have fueled speculation that they may be the result of biological activity. The biological production of methane is catalyzed by a unique group of anaerobic archaea, the methanogens. Common to all methanogens is a unique metabolic pathway that enables methane production from a limited number of substrates such as H_2 + CO_2, formate, CO, methanol, methylamines, and acetate. Methanogens live close to the thermodynamic limit of life, a problem exacerbated at extremes of cold temperature. Here, we present genetic, physiological, geochemical, and thermodynamic data in support of the presence of a unique and active assemblage of methanogens in the near freezing (~0-1°C) and oligotrophic subglacial environment of Robertson Glacier, Alberta, Canada. Dominant methanogens present in the RG sediments may constitute a new order that bridges the physiologically distinct *Methanomicrobiales* and *Methanosarcinales* lineages. Methane flux measurements (2011) indicate seasonal variation in the release of methane from this permanently cold extraterrestrial analog environment.

What are the ^{146}Sm-^{142}Nd reference parameters for the Earth?

M. BOYET[1], A. BOUVIER[2], A. GANNOUN[1] AND R.W. CARLSON[3]

[1] Laboratoire Magmas et Volcans, Université Blaise Pascal, CNRS UMR 6524, 5 rue Kessler, 63038 Clermont-Ferrand, France. boyet@opgc.univ-bpclermont.fr
[2] Department of Earth Sciences, University of Minnesota, 310 Pillsbury Drive SE Minneapolis, MN 55455-0231, USA.
[3] Carnegie Insitution of Washington, Dept. of Terrestrial Magnetism, Washington DC 20015, USA.

Since the first publication of high precision ^{142}Nd/^{144}Nd ratios in chondrites [1], different early Earth differentiation models have been proposed. The excess in ^{142}Nd measured in terrestrial samples relative to the average chondrite value requires that all terrestrial rocks sampled by volcanism over the Earth's history come from a geochemical reservoir characterized by a super-chondritic Sm/Nd ratio. Some authors proposed that the complementary enriched reservoir has been lost during the Earth's accretion [2,3] whereas others suggested that a hidden reservoir may have been preserved in the deep Earth [1,4]. The measurement of stable Sm and Nd isotope ratios in chondrites has created additional confusion in the interpretation of ^{142}Nd deviation. Different groups of chondrites clearly have different ^{142}Nd signatures and variations in stable Sm and Nd isotopes were found [5-7], all of which likely reflect different mixtures of r-, s-, and p-process nucleosynthetic products.

We will present a summary of the data available on Sm-Nd systematics of chondrites as well as new data obtained on enstatite chondrites (whole rocks and leaching experiments), achondrites and CAIs from CV3 chondrites. On the basis of these results, carbonaceous chondrites must be considered as a minor constituent of the Earth. Enstatite chondrites overlaps with the terrestrial ^{142}Nd/^{144}Nd ratio. CAIs Sm/Nd-^{142}Nd/^{144}Nd isochrons pass through the terrestrial value.

Considering the level of precision now achieved on Sm-Nd isotope measurements and looking at the results obtained on stables Sm and Nd isotopes our opinion is that the Earth-chondrite difference in ^{142}Nd suggests that silicate part of Earth experienced a very early differentiation event. However these models will be discussed considering these new results.

A bioturbation-induced decrease in atmospheric oxygen across the Precambrian-Cambrian boundary

R.A. BOYLE[1], T.W. DAHL[1,2], A.W. DALE[3], G. SHIELDS-ZHOU[4], M. ZHU[5], M.D. BRASIER[6], D.E. CANFIELD[7] AND T.M. LENTON[1]

Bioturbation is the reworking of sediments by animal motility, and its emergence across the Precambrian-Cambrian boundary occurred against the backdrop of major changes in the biogeochemical cycles of oxygen, phosphorus and organic carbon. Bioturbation substantially increases sedimentary phosphate content, limiting the phosphate available for primary production and thus reducing the marine organic carbon burial flux, which is the source of atmospheric oxygen over geological timescales. We use simple modelling to show how an increase in marine organic phosphate burial associated with the onset of bioturbation caused a net decrease in atmospheric oxygen across the Precambrian-Cambrian boundary. The resulting de-oxygenation of the ocean restricted the spread of oxygen-demanding bioturbating animals, and established negative feedback loops that stabilised atmospheric oxygen at a lower level. Although more data are needed to quantitatively constrain model parameters, our results are supported by evidence for a resurgence of anoxic and sometimes euxinic conditions in the early Paleozoic.

The rate of iron compounds precipitation from AMD waters in the Łęknica region (the Muskau Arch, western Poland)

P. BOŻĘCKI AND G .RZEPA

AGH - University of Science and Technology, Faculty of Geology, Geophysics and Environmental Protection, Departament of Mineralogy, Petrography and Geochemistry, Krakow, Poland (pbozecki@agh.edu.pl)

The Muskau Arch is a large horseshoe-shaped glaciotectonic belt formed mainly during the Mid Polish Glaciation. Lignite deposits containing pyrite were excavated there till the end of the 70-ties of the 20th century. Abandoned excavations are recently filled with water forming large so called "*anthropogenic lake district*" (with about 110 reservoirs). Oxidation of sulphide leads to the generation of abundant quantities of sulphuric acid. Therefore many of these lakes, especially at the Łęknica area, are of acidotrophic type characterized by low and very low pH values (usually < 4.0). This is associated with the formation of numerous ochreous precipitates as a consequence of iron oxidation and hydrolysis.

The aim of this study is to assess the precipitation rate of iron compounds from acid mine drainage waters. Experiment was conducted in over one year period, from July 2009 to September 2010, in eleven locations. For this purpose, unglazed ceramic plates (dimensions: 10x10 cm) were, after removing possible traces of iron, placed on the bottom of selected lakes. The plates were collected monthly and the amount of precipitated iron compounds was evaluated by the determination of Fe leachable in hydrochloric acid. Mineralogical analyses of the precipitates using X-ray diffractometry and SEM-EDS were carried out as well.

The amount of precipitated iron compounds turned out to be very variable, ranging from ca. 50 *[mg Fe*cm^{-2}]* per month to nearly 13 000 *[mg Fe*cm^{-2}]* per month. The average value for all monitored locations was approximately 1100 *[mg Fe*cm^{-2}]* per month.

.X-ray diffractometry indicate that the only mineral phase formed was schwertmannite – poorly crystalline iron oxyhydroxysulfate.. Images obtained with use of scanning electron microscope reveal the presence of numerous bacteria structures, confirming that the precipitation of schwertmannite was microbially-mediated.

This work was supported by AGH-UST (Faculty of Geology, Geophysics and Environmental Protection statutory grant).

Coupled LA U-Pb chronology of detrital zircon and rutile: A powerful provenance tracer

L. BRACCIALI[12]*, R.R. PARRISH[13], M.S.A. HORSTWOOD[1] AND Y. NAJMAN[2]

[1]NERC Isotope Geosciences Laboratory, British Geological Survey, Keyworth, UK (*correspondence: laur@bgs.ac.uk)
[2]Lancaster Environment Centre, Lancaster University, UK
[3]Department of Geology, University of Leicester, UK

The development of improved precision dating methods, increased diversity of methods and proliferation of high spatial resolution approaches in recent years has made a dramatic impact to Earth Science research. However, focusing on the right method/procedure to address different geological problems is essential to solve problems and maximise the impact of research. Dating techniques are widely applied to provenance studies in order to discriminate between potential source areas, to track the evolution of river drainage basins, to assess sediment budgets and erosion patterns across orogens and to infer feedback relationships between erosion, tectonics and climate. These methods involve high throughput analysis, and it is not uncommon to lose sight of the complexity of zircon and other grains in relation to the problem being addressed.

We have developed a new approach to LA-ICP-MS U-Pb dating of rutile and characterised two new reference materials [1]. We have also refined an approach to LA ICP-MS U-Pb dating of detrital zircons that uses CL imaging to identify and date all zircon components with a focus on very thin (<5 μm) rims that record the latest growth events that otherwise would be missed due to their <5 μm width on a polished surface.

U-Pb dates on zircon and rutile records medium- to high-temperature igneous and metamorphic crystallisation events and cooling through ~500 ºC, respectively. The U-Pb analysis of detrital zircon and rutile from the same sample allows tracking of multiple crystallisation and tectono-thermal events of the source areas over a broad range of temperatures in a much more definitive and revealing manner than zircon alone. This is key to provenance studies where the detritus is sourced from areas with complex polyphase metamorphic histories such as collisional orogens. We have applied our method to Himalayan-derived sediments in the Eastern Himalaya to unravel Neogene tectonic-erosion relationships, and have found rutile and zircon rim ages as young as 1 and 5 Ma, respectively, inferring derivation from the Namche Barwa eastern syntaxis area.

Insight on formation and evolution of cratonic mantle: Re-Os dating of single sulfides from Somerset mantle xenoliths (Rae Craton, Canada)

A. BRAGAGNI[1]*, A. LUGUET[1], D. G. PEARSON[2], R.O.C. FONSECA[1] AND B. A. KJARSGAARD[3]

[1] Steinmann Institute, Universitaet Bonn, Germany (*correspondence: bragagni@uni-bonn.de)
[2] Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Canada
[3] Geological Survey of Canada, Ottawa, Canada

Cratonic mantle xenoliths provide an unique opportunity to study the formation and evolution of the Archean lithosphere. However, widespread metasomatic processes that cause profound textural and geochemical changes, make it difficult to determine the original melting age. Mantle xenoliths from Somerset Island (North Rae Craton) are characterized by a large range of whole-rock Re-depletion ages (T_{RD}) ranging between 1.3 and 2.8 Ga [1]. Moreover, the oldest samples have low Pd/Ir ratio inherited from the original melting process, whereas younger samples are characterized by variable enrichments in Pd, Pt and Re suggesting extensive metasomatic overprint [1].

To better constrain the age distribution in the mantle root of the Rae Craton and to evaluate whether cratonic lithosphere formation may be older than recorded by the whole-rocks, we performed a Re-Os isotopic study on sulfides from four mantle peridotite xenoliths showing variable HSE (highly siderophile elements) signature (Pd/Ir=0.03-0.6). Sulfides (down to ⌀<10 μm) were micro-sampled from thick sections, with Os extracted via μ-distillation and analyzed by N-TIMS.

Sulfides from the peridotite with the most HSE residual signature yield T_{RD} ages of 2.7-2.8 Ga, in agreement with its whole rock T_{RD} age. Sulfide T_{RD} ages from metasomatised xenoliths vary from 2.8 Ga to future ages, with the 2.8 Ga age significantly older than the whole rock T_{RD} ages (even T_{MA}). The 2.7-2.8 Ga age, recorded in sulfides from three xenoliths out of four, overlaps with widespread magmatism in the Rae Craton [2] suggesting possibly a synchronous event of crustal and lithospheric mantle formation. Our results show that xenoliths with residual HSE signatures are likely to preserve the original melting age while the more metasomatic xenoliths have been rejuvenated by extensive addition of 'younger' sulfides.

Ocean drilling: MORB geochemistry in the third (and fourth) dimension

BRANDL, P.A.[1], REGELOUS, M.[1], BEIER, C.[1] AND HAASE, K.M.[1]

[1]GeoZentrum Nordbayern, FAU Erlangen-Nürnberg, Schlossgarten 5, 91054 Erlangen, Germany

Most of our knowledge on the composition and formation of the oceanic igneous crust derives from lava samples collected from active ridge axes by dredging or submersible. However, lavas erupted at the ridge axis eventually make up the lowermost part of the extrusive section. If these differ in composition from those emplaced off-axis, then compilations of axial mid-ocean ridge basalt (MORB) may not yield an accurate estimate of the composition of the bulk crust.

Lavas drilled from the oceanic crust provide another way to estimate the composition of the bulk crust. In addition, they record changes in MORB chemistry over both long and short timescales. We have shown previously [1] that mantle temperatures recorded in the major element composition of ancient drilled MORB vary systematically over long timescales (10^6-10^8 a) in rifted ocean basins due to continental insulation effects. The chemical stratigraphy of lavas from individual drillsites could be used to investigate chemical changes over 10^3-10^5 a timescales, which may result from variations in fractionation, magma replenishment rates or source and melting effects.

We carried out major element analysis of 340 fresh glasses (>110 also for trace elements) from 30 different DSDP and ODP sites in the Atlantic and Pacific. First results indicate that lavas from single drill sites are remarkably uniform in their chemical composition when compared to the chemical variation present at the corresponding segment of the active ridge axis. We find systematic chemical variations with depth, sigmoidally shaped in the slow-spread crust of site 417D (Atlantic) and unregularly-shaped in the drillcore of site 1256D, drilled into superfast-spreading crust. This may indicate major differences in the residence time of magma in crustal magma chambers as well as in the magma replenishment rate, e.g. size and time intervals of rising magma batches. The oscillation between magmatic differentiation and magma recharge may be responsible for some of the globally observed trace element patterns in MORB as recently suggested by [2] but based on predominantly dredged samples.

Testing models for continental growth and melt-rock interaction from ^{186}Os-^{187}Os isotopes in southwest usa mantle xenoliths

A. D. BRANDON*

Department of Earth and Atmospheric Sciences, University of Houston, Houston, TX 77204, USA (*correspondance: abrandon@uh.edu)

Melting in the convecting mantle results in lower density residual peridotite that may stabilize as subcontinental lithospheric mantle (SCLM), results in juvenile crust production, and is likely a primary mechanism to grow continents over Earth history. Perdidotite and pyroxenite xenoliths provide a compositional record of formation and subsequent modification of the SCLM.

Xenolith samples 3 classic locales in the Southwestern United States - Dish Hill (California), Kilbourne Hole (New Mexico), and Vulcan's Throne (Arizona), span an 860 kilometer-wide region within two crustal provinces, the 2.0-2.3 Ga Mojavia, and the 1.7-2.0 Ga Yavapai-Mazatzal provinces. Preliminary ^{187}Os/^{188}Os data for spinel-bearing peridiotites show positive correlations with melt depletion indicators such as Al_2O_3. Applying the aluminachron age concept gives ^{187}Re-^{187}Os model ages ranging from 2.0 to 2.3 Ga, broadly consistent with the ages of the overlying continental crustal provinces. If so, these data support models where continental growth is directly linked to stabilization of its underlying SCLM via partial melting in the convecting mantle. It also indicates that large off-craton continental regions may grow in rapid pulses through large-scale mantle melting events. A potentially viable alternative is that the aluminachrons record melt-rock interaction subsequent to earlier partial melting. If so, then these data instead only provide minimum model ages of partial melting via the lowest ^{187}Os/^{188}Os ratio measured in each suite and thus may be unrelated to the initial stages of juvenile crust production leading to continental growth, and alternatively represent later continental magmatic processes.

To futher evaluate the timing and mechanisms of SCLM stabilization and evolution and their potential link to continental growth, Os isotope data for pyroxenites from these locales will be presented to constrain compositional signatures imparted to the peridotites via melt addition or melt-rock interaction. Further, the first high-precision ^{186}Os-^{187}Os measurements of continental peridotite xenoliths will be obtained to monitor Pt-Re-Os fractionation events. Coupled ^{186}Os-^{187}Os fingerprints partial melting versus melt-rock interaction to the Os budgets of each of these xenolith suites.

Solid solution formation and uptake of Radium in the presence of barite

F. BRANDT[1]*, M. KLINKENBERG[1], V.L. VINOGRAD[1,2], K. ROZOV[1] AND D. BOSBACH[1]

[1]Institute of Energy and Climate Research (IEK-6), Forschungszentrum Jülich, Germany; f.brandt@fz-juelich.de (*presenting author), m.klinkenberg@fz-juelich.de, k.rozov@fz-juelich.de, d.bosbach@fz-juelich.de

[2] Institute of Geosciences, Goethe University, Frankfurt (Germany); v.vinograd@kristall.uni-frankfurt.de

The phase relations in the $BaSO_4$-$RaSO_4$-H_2O system may determine the solubility of radium in natural waters due to the formation of a solid solution. In the near-field of nuclear waste repositories for spent fuel, radium may enter a system in which barite is in equilibrium with the aqueous solution. Thermodynamically, a $Ra_xBa_{1-x}SO_4$ solid solution is expected to form as solubility controlling phase rather than $RaSO_4$. However, due to a lack of reliable data, the solid solution system $RaSO_4$-$BaSO_4$-H_2O is currently not considered in long term safety assessments for nuclear waste repositories. The solubility product of the pure $RaSO_4$ endmember is poorly constrained between pK_{RaSO4} = 10.26 to 10.41 by only very few experimental data [1,2]. Published interaction parameters W_{BaRa} of the $RaSO_4$-$BaSO_4$-H_2O system varies varies in different studies [3, 4] between 0.9 and 3.9 - 6.5 kJ/mol.

In this study we have combined experimental data, atomistic calculations and thermodynamic modeling to study in detail how a radium containing solution will equilibrate with solid $BaSO_4$ under repository relevant conditions. Batch sorption experiments at close to equilibrium conditions indicate the formation of a $Ra_xBa_{1-x}SO_4$ solid. Our first principles calculations based on the single defect method [5] indicate a value of W_{BaRa} = 2.5 ± 1.0 kJ/mol, implying a non-ideal solid solution. Thermodynamic assessment calculations indicate that the final experimental Ra(aq) concentration at room temperature and 90 °C can be matched with W_{BaRa} ≈ 1.5 kJ/mol and pK_{RaSO4} ≈ 10.41.

The co-ordination of Boron in foraminiferal calcite

OSCAR BRANSON*[1], SIMON REDFERN[1], KARINA KACZMAREK[2], TOLEK TYLISZCZAK[3] AND HENRY ELDERFIELD[1]

[1]Department of Earth Sciences, University of Cambridge, Downing St, Cambridge CB2 3EQ, UK. (*correspondence: ob266@esc.cam.ac.uk)

[2]Alfred Wegener Institute, Am Handelshafen 12, D-27570 Bremerhaven, Germany. (Karina.Kaczmarek@awi.de)

[3]ALS Beamline 11.0.2, One Cyclotron Road, MS 6R2100 Berkeley, CA 94720, USA. (TTyliszczak@lbl.gov)

The analysis of boron in foraminiferal calcite is a burgeoning palaeo-proxy for past ocean-acidification events [1]. This is particularly relevant to today's 'carbonated ocean' [2]. However, considerable uncertainty surrounds the mechanisms of boron incorporation into the shell. Foraminiferal calcite is known to be highly chemically heterogeneous [3], and understanding how boron fits into this complex structure is central to our understanding of, and confidence in, this important proxy.

We have applied synchrotron NEXAFS spectroscopy to examine the distribution and coordination of boron in foraminifera at the nm length scale.

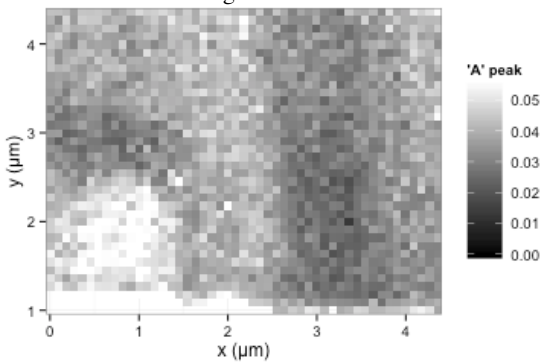

Figure 1: A Scanning Transmission X-ray Microscope (STXM) image of a section of foraminifera test at the trigonal B edge, showing variations in the concentration of B [4].

STXM results reveal clear homogeneity in boron concentration, which appears to be uniformly hosted in a trigonal coordination in the calcite crystal lattice (BO_3 groups). Analysis of boron coordination is ongoing.

The establishment of the steady-state activity at Stromboli volcano (Italy): evidence from diffusion and mixing processes revealed at mineral scale

ELEONORA BRASCHI[1], CHIARA M. PETRONE[2], LORELLA FRANCALANCI[13] AND SIMONE TOMMASINI[3]

[1] CNR-IGG, Sezione Firenze, Via G. LaPira, 4, Firenze, Italy

[3] Università degli Studi di Firenze, Dipartimento di Scienze della Terra, Via G. La Pira, 4, Firenze, Italy

The present-day activiy of Stromboli is characterized by strombolian explosions ejecting black scoriaceous lapilli and ash. This persistent activity is interrupted by effusive eruptions and more energetic explosions (paroxysms) also emitting a small volume of light pumices. The entire system is in a persistent steady-state activity whose driving forces are still not completely understood. Investigating the evolution of the plumbying system toward the present-day condition is thus crucial to better constrain and understand the onset and development of the present-day activity.

We studied in detail two selected samples representative of the transitional eruptive period from the more explosive phase forming the Pizzo Sopra la Fossa tuff cone (ca. 2 ka) to the present-day activity: (i) an older spatter-lava sample (shoshonite) from the Post-Pizzo fountain-fed fallout activity; (ii) a large and flattened, black scoriaceous spatter (shoshonitic basalt) probably ejected during one of the early paroxysms of the present-day activity. Both samples have similar paragenesis with phenocrysts of olivine, clinopyroxene, plagioclase. We recognize several types of clinopyroxene textures with different recurrence among the two samples. In detail, multiple banded clinopyroxene with evident resorption features, characterizes the older sample, recording several pulsatory intrusions of new mafic magmas into the system and pointing to the establishment of the steady-state condition. Contrarily, single diffused band and/or patchy cores are found in the present-day sample. We applied the diffusion chronometry to suitable clinopyroxene crystal zones to estimate the timing of these refilling events in the shallow magma reservoir from the Post-Pizzo period onward pointing to a progressive,transition toward the present-day steady-state conditions.

A $\delta^{13}C$ record from marine carbonates deposited below diamictites between ca. 2430 and 2440 Ma

A.T.BRASIER[1]*, A.P. MARTIN[2], V.A. MELEZHIK[3,4], A.R. PRAVE[5], D.J. CONDON[2] AND A.E. FALLICK[6]

Palaeoproterozoic Polisarka Sedimentary Formation diamictites underlain by marine carbonates and overlain by volcanic ash sediments were recovered from International Continental Scientific Drilling Program Fennoscandian Arctic Russia - Drilling Early Earth Project (ICDP FAR-DEEP) Hole 3A (Kola Peninsula, NW Russia). The tuff yielded 2434 Ma dated zircons, constraining deposition of the diamictites and underlying carbonates to within an interval ca. 2430 to 2440 Ma. The carbonate rocks originally included aragonitic limestones deposited mostly in a deep-water setting. They record two inorganic carbon $\delta^{13}C$ excursions, from values of ca. 0‰ to minima of ca. -5.4‰ as the diamictite is approached. Mg/Ca ratios correlate strongly with $\delta^{13}C$ in the sections containing the excursions. Combined with petrographic observations, this correlation reflects secondary alteration of the first excursion, and resedimented dolostone clasts in the second excursion. It is tempting to speculate that these dolostone clasts were deposited in penecontemporaneous shallow-marine waters as the global glaciation began. Their low $\delta^{13}C$ values might reflect input of oxidised atmospheric methane to the ocean surface (and therefore the cause of the glaciation), while the majority of the ICDP FAR-DEEP Hole 3A carbonates record deeper-marine inorganic carbon $\delta^{13}C$.

Dolomite formation within microbial mats from the Dohat Faishakh sabkha, Qatar

MARISA BRAUCHLI[1], TOMASO R. R. BONTOGNALI[2]*, JUDITH A. MCKENZIE[2], CHRISTIAN J. STROHMENGER[3], JEREMY JAMESON[3], FADHIL SADOONI[4] AND CRISOGONO VASCONCELOS[2]

[1]Institute of Evolutionary Biology and Environmental Studies, University of Zürich, Switzerland

[3]ExxonMobil Research Qatar, Doha, Qatar
[4]Environmental Studies Center, Qatar University, Doha, Qatar

The hypersaline coastal sabkha of Dohat Faishakh (Qatar) was one of the first settings recognized as a rare modern geological environment where dolomite formation occurs (Illing *et al*., 1965). Although the origin of dolomite remains one of the most debated subjects in sedimentary geology, microbial mediation has been recently proposed as a possible solution for this controversy. Until now, the relationship between microbial activity and dolomite precipitation in the Dohat Faishakh sabkha has not been evaluated. The limited previous studies of the Dohat Faishakh sabkha considered dolomite formation to be the result of a penecontemporaneous replacement of authigenic aragonite. However, no conclusive evidence confirms this hypothesis. To evaluate whether a "microbial factor" is important in this classic evaporitic environment, we collected core samples along a transect from the lower intertidal to the surpatidal zone of the sabkha. A preliminary investigation of the sampled sediments revealed a close association between buried microbial mats and dolomite. The exopolymeric substances constituting the microbial mats are recognized as an important component for dolomite nucleation. We, therefore, hypothesize that the main factor controlling the occurrence of dolomite within the sediments of the Dohat Faishakh sakha is the presence of an organic matrix (i.e., the buried microbial mats) and not a replacement process transforming primary aragonite into dolomite. Aragonite and dolomite likely precipitate nearly simultaneously from highly evaporated marine waters. The presence/absence of an organic matrix determines whether the carbonate minerals will have a dolomitic vs. an aragonitic composition. Applying a geomicrobiological approach to study mineral formation beneath the Dohat Faishakh sabkha will provide new insights into evaporite mineral associations in the rock record, as well as into extraterrestrial environments, as evidenced by recent observations of evaporitic sediments on Mars.

A new aqueous phase protocol for the mechanism generator GECKO-A used for the CAPRAM mechanism extension

P. BRÄUER[1], C. MOUCHEL-VALLON[2], A. TILGNER[1], R. WOLKE[1], B. AUMONT[2] AND H. HERRMANN[1]*

[1]Leibniz Institute for Tropospheric Research (TROPOS), Permoserstr. 15, D-04318 Leipzig, Germany. (*correspondence: herrmann@tropos.de)
[2]LISA, UMR CNRS 7583, Universités Paris Est Créteil et Paris Diderot, 61 Av. du G[al] de Gaulle, 94010 Créteil cedex, France.

The ubiquitous abundance of organic compounds in natural and anthorpogenically influenced eco-systems has put these compounds into the focus of environmental research. To investigate the chemistry of organic compounds in the tropospheric multiphase system, explicit modelling can provide a useful tool.

However, the oxidation of large organic molecules (typically $C_{>5}$) involves a huge number of intermediate compounds produced during the oxidation process. Furthermore, most of the needed experimental thermodynamic and kinetic data are unavailable in the literature. Therefore, the creation of explicit mechanisms relies on automated self-generating mechanism construction as achieved with GECKO-A (Generator for Explicit Chemistry and Kinetics of Organics in the Atmosphere) for the gas phase.

As the chemistry in deliquescent particles and cloud droplets can be important for the oxidation process, a protocol has been developed to describe the degradation of aliphatic organic compounds in the aqueous phase. This aqueous phase protocol has been implemented into GECKO-A and was used to advance the aqueous phase mechanism CAPRAM 3.0n (Chemical Aqueous Phase RAdical Mechanism). The latest CAPRAM version was extended by about 3500 reactions, where, besides the addition of new subsystems, branching ratios were introduced in the mechanism.

Box model studies were performed with a non-permanent cloud scenario to reveal more insights into the degradation and formation of organic compounds in deliquescent particles and cloud droplets as well as the feedback on gas phase concentrations. Detailed time-resolved investigations of the chemical fluxes assisted the investigations of concentration-time profiles. Comparisons with previous model studies and experimental data from field and laboratory investigations were used to validate the mechanism generator and show significant improvements in the generated model results.

New ^{187}Re-^{187}Os isotope data on organic rich mudrocks from the Neoproterozoic Fifteenmile Group, Coal Creek Inlier, Yukon, Canada provide direct age control for biomineralizing scale microfossils [1] and the termination of the Bitter Springs isotopic stage in northwest Canada. The uppermost Reefal Assemblage of the Fifteenmile Group has a preliminary ^{187}Re-^{187}Os isochron age of 752 ±44 Ma (2σ; Model-3; MSWD 4.2; $^{187}Os/^{188}Os_i$ 0.42 ±0.22).The obtained age is identical within error to ^{187}Re-^{187}Os ages from the correlated Wynniatt Formation, Victoria Island, Canada [2]. This result is also in good agreement with known U-Pb TIMS zircon analysis which brackets the sampled portion of the Upper Fifteenmile Group between 811.0 and 717.4 Ma [3]. If the ~750 Ma age model is correct, the Bitter Springs isotopic stage could be younger or extend longer than previously thought (~800 Ma). A younger age for the Bitter Springs Stage may also impact global paleogeographical reconstructions based on anomalous global paleomagnetic records from the Bitter Springs stage [4]. These measurements also represent an important benchmark for the $^{187}Os/^{188}Os_i$ composition of Neoproterozoic seawater. The $^{187}Os/^{188}Os_i$ record is an emerging seawater proxy which has the ability to trace rapid climatic perturbations [5]. This proxy record can provide independent confirmation of climatic fluctuations observed in important Neoproterozoic $^{87}Sr/^{86}Sr$, $\delta^{13}C$ reference sections [6]. Further ^{187}Re-^{187}Os work on samples from the Fifteenmile Group is ongoing.

How bugs get their food: Linking mineral surface chemistry to nutrient availability

A.W. BRAY[1,2]*, E.H. OELKERS[2], S. BONNEVILLE[1,3] AND L.G. BENNING[1]

[1]Cohen Geochemistry, School of Earth and Environment, University of Leeds, LS2 9JT, United Kingdom (*correspondence: a.bray@see.leeds.ac.uk)
[2]Géochimie et Biogéochimie Experimentale, GET CNRS, UMR 5563, 14 av. Edouard Belin, 31400 Toulouse, France

The bio-acquisition of mineral-bound key nutrients by microorganisms is currently of great interest because of our desire to understand soil nutrient cycling. It has been shown that fungi seek out nutrient sources through expansive mycorrhizal networks, acting as biosensors for 'tasty snacks'. The mechanism by which fungi extract nutrients from minerals is by combining bio-mechanical forcing of the structure [1] with subsequent chemical alteration [2]. Usually, release of nutrients from minerals is discussed in terms of bulk chemical content. Here, we present data showing the importance of the surface composition of biotite, a key terrestrial source of primary nutrients (in particular potassium), to influence nutrient availability. This gives us new insights into the mechanisms by which microorganisms weather minerals, aiding in soil formation.

A suite of batch potentiometric and electrokinetic titrations (pH 1-12 and 25 ºC), were carried out to determine the surface chemistry and reactivity of biotite by quantifying protons consumed and metals released. Potassium was found to be preferentially removed from the biotite surface down to an average depth of ~ 20 nm at all pH values. A slight pH dependency of this removal and the proton consumption profile suggest a significant portion of K was removed from the structure immediately upon contact between the biotite surface and the fluid. The existence of such a K depleted surface suggests that microorganisms are required to physically break the mineral structure to access nutrients from newly created surfaces. Our data set underpins the need for an initial bio-mechanical forcing of the mineral surface prior to its chemical alteration, leading to increased weathering.

Biogeography of serpentinite-hosted ecosystems

WILLIAM J. BRAZELTON[14]*, DAWN A. CARDACE[2], GRETCHEN L. FRUH-GREEN[3], SUSAN Q. LANG[3], MARVIN D. LILLEY[4], PENNY L. MORRILL[5], KATRINA I. TWING[1] AND MATTHEW O. SCHRENK[1]

[1]East Carolina University, Greenville, NC, USA. (*correspondence: wbrazelton@gmail.com)

[3]ETH-Zurich, Switzerland
[4]University of Washington, Seattle, WA, USA
[5]Memorial Univ. of Newfoundland, St. John's, NL, Canada

Ultramafic rocks in the Earth's mantle represent a tremendous reservoir of carbon and reducing power. Upon tectonic uplift and exposure to fluid flow, serpentinization of these materials generates copious energy, sustains abiogenic synthesis of organic molecules, and releases hydrogen gas (H_2). To date, however, the "serpentinite microbiome" is poorly constrained: almost nothing is known about the microbial diversity endemic to rocks actively undergoing serpentinization.

We have obtained metagenomic and 16S rRNA tag sequence datasets from fluids and rocks collected in serpentinizing ophiolites in California, Canada, and Italy. The samples include wells which directly access subsurface aquifers, rocks obtained from drill cores into serpentinites, and natural, high-pH serpentinite springs that are presumably representative of deeper environments within the ophiolite complex. Our results point to potentially H_2-utilizing Betaproteobacteria thriving in shallow, oxic-anoxic transition zones and anaerobic Clostridia thriving in anoxic, deep subsurface habitats. Similar bacterial taxa and genes encoding hydrogenase enzymes were also observed in seafloor Lost City hydrothermal chimneys, indicating that we are beginning to identify a core serpentinite microbial community that spans marine and continental settings.

These data represent a unique opportunity to examine biogeographic patterns among a specialized set of organisms and genes and to explore their evolution during the uplift and obduction of mantle rocks onto continents over geological time scales. We are currently testing for correlations between these metagenomic data and the geochemical conditions and the geological histories of the host rocks with an ultimate goal of inferring an integrated metagenomic-biogeochemical natural history of the serpentinite habitats.

Characterization of natural gem diamonds and UV light sources using fluorescence spectroscopy

C.M. BREEDING* AND Y. LUO

Gemological Institute of America (GIA), Carlsbad, CA, USA (*correspondence: christopher.breeding@gia.edu)

Gemologists have used fluorescence reactions to long wave ultraviolet light for identification of gemstones for decades. Simple visible observations of fluorescence color, intensity, pattern, and duration have proven invaluable for separating natural diamonds and other gemstones from synthetic or treated equivalents. Fluorescence viewing and imaging, however, can only provide a limited amount of information about the lattice defects that produce the luminescence. Spectroscopy provides details about the nature of the fluorescence, the combinations of defects that produce the observed colors, and the effects of different excitation sources. Spectra collected from natural gem diamonds show blue fluorescence from N3 defects (415 nm), green from H3 (503.2 nm) and H4 (496 nm), orange/red from N-V centers (575, 637 nm), and yellow from a combination of several defects associated with a visible absorption band at 480 nm. Using variable excitation, three dimensional maps (excitation, emission, fluorescence) of the luminescence spectra from each defect reveal complexities that cannot be discerned visually. In addition to this fundamental fluorescence information, spectroscopy also allows characterization of the excitation light source output and evaluation of how it affects the fluorescence produced from a diamond. A wide range of UV light sources are currently used in the gem and mineral industry with large differences in output intensity and wavelength. Small variations in bulb/LED and filter materials can significantly impact the visual fluorescence, leading to inconsistent results. The use of fluorescence spectroscopy provides additional detail that is not available from visual observation to help to identify subtle differences produced by variable light sources as well as many of today's modern gemstone treatments.

Hydrochemical patterns in a structurally controlled geothermal system

M. BREHME[1], C. HAASE[2], S. REGENSPURG[1], I. MOECK[1], F. DEON[1], B. WIEGAND[3], Y. KAMAH[4], G. ZIMMERMANN[1] AND M. SAUTER[3]

[1]Helmholtz Centre Potsdam - GFZ German Research Centre for Geosciences, International Centre for Geothermal Research, Telegrafenberg, 14473 Potsdam, Germany
[2] Institute for Geosciences, Kiel University, Ludewig-Meyn-Strasse 10, 24118 Kiel, Germany
[3]University of Göttingen, Applied Geology, Goldschmidtstr. 3, 37077 Göttingen, Germany
[4]Pertamina Geothermal Energy, Jl.M.H. Thamrin No.9, Jakarta 10340, Indonesia

In this study, we investigate a magmatic structurally controlled geothermal reservoir in North Sulawesi-Indonesia focusing on structural geology and hydrochemistry. A combination of a thermal-hydraulic model with hydrochemical modelling is the goal of this study. The running geothermal system is located above a subduction zone surrounded by a complex network of faults and repetitive volcanic eruptions.

Analyses of the samples collected from wells, hot springs, rivers and lakes show typically two types of water. Acid high saline waters were found in the northern reservoir area (pH: 2.7-3.2, electrical conductivity: 4620-9700 μS/cm). A similar water type rises above this reservoir through several hot springs (pH: 1.8-2.7) and a lake (pH: 2.5) located above the reservoir. A second type of reservoir water was observed in the South where wells show a pH range of 4.2 to 6.5 and conductivities from 400 to 1729 μS/cm. Neutral hot springs occur in the sourrounding area with pH values ranging of 5.8 to 7.0. While the northern and southern reservoirs are only 2km away from each other we observe strong difference between the water types. This is assumed to be due to laterally low permeability in the fault network. All the data analysed in this study converges to a consistent hydrotectonic model, which shows different reservoir compartments controlled by complex fault systems.

In addition to the conceptional model a hydrochemical model was set up in PHREEQC and suggests scaling from both water types such as Fe- and Si-bearing minerals. In this context, a cycle including hot water production, surface mixing and several reinjection scenarios was simulated. Modelled precipitations will eventually be compared with XRD-analyses of cores, precipitation-, alteration- and rock-samples in order to calibrate the hydrochemical model.

$\delta^{97/95}$Mo in molybdenites from the Azegour skarn (Morocco)

BREILLAT NOEMIE [1,2], GUERROT CATHERINE [1], NEGREL PHILIPPE[1] AND MARCOUX ERIC [2]

[1]BRGM, ISTO, UMR 7327, BP 36009, 45060 Orléans, France (n.breillat@brgm.fr)
[2]Univ d'Orléans, ISTO, UMR 7327, 45071 Orléans, France

Molybdenum (Mo) isotopes are frequently used to investigate ocean and lake (paleo-)redox conditions. In the frame of mineral ressources, only few studies have been performed regarding Mo-Re-Os isotopes. The aim of this study is to understand the source, processes and mobility of metals concentrations using Mo isotopes on molybdenites in different ore deposits. The present study focuses on the Azegour skarn (Morocco). Located in the High-Atlas, the Azegour site is one of the rare Mo-W-Cu exploited skarns (three historic mines). It is formed by a granitic intrusion (271±3Ma) in cambrian volcano-sedimentary serie composed by schists, volcanic complex (andesites, pyroclastites) and carbonate formations (calcareous and dolomites). The skarn takes place in the carbonate formations where pyroxenites and grenatites occured. The grenatites being the Mo-bearing minerals in the form of molybdenites.

Molybdenites sampling has been performed in the main mine (Azegour) and in the Tizgui mine (1km north of the Azegour mine). The Mo isotopic composition has been determined on molybdenites using a MC-ICP-MS Neptune after aquaregia dissolution and adjustment to [Mo] = 1μg.g^{-1}. The $\delta^{97/95}$Mo ratios have been normalized to NBS3134 and a reproducibility of 0.07‰ (2σ) is reached.

Presently, we have analysed 12 molybdenites from Azegour and 2 from Tizgui and 14 others are in progress. Regarding the first 14 samples, the $\delta^{97/95}Mo_{NBS}$ ratios vary between -0.40 and 0.32‰ for Azegour and between 0.08 and 0.30‰ for Tizgui. It is worth noting that variations can occur either at the whole site (difference of about 0.72‰) but also at the cm scale in the same sample (here the largest observed difference is up to 0.40‰).

Regarding the Azegour skarn, there is no direct relationship for explaining the Mo fractionation in molydbenites between the facies or the two sites of sampling. Different processes will be discussed to explain the observed variability (redox conditions prevaling during the molydbenites deposits, late metamophism phase…). Further investigations using Pb and S isotopic compositions will help deciphering the oxidation state and the origin of molybdenites regarding the possible different fluids.

Experimental constraints on HSE fractionation during basalt genesis

JAMES M BRENAN

Earth Sciences, University of Toronto, (brenan@es.utoronto.ca)

Terrestrial basalts are characterised by CI-normalised depletions in the highly siderophile elements (HSE), as well as moderate to large interelement fractionation within the group; the IPGE (Os, Ir, Ru) are relatively depleted compared to the PPGE (Rh, Pt, Pd), Au and Re. The overall low abundance of the HSE in basalts is attributed to core formation, whereas the origin of the fractionation within the HSE group has been less certain. Experiments and empirical observations indicate that Ir, Ru and Rh are compatible in olivine, as is Ru in ferric-iron-poor chromian spinel, and both phases strongly reject Pt, Pd, Re and Au. It is expected, but unproven, that cpx and opx will exhibit broadly similar partitioning behaviour as olivine. This sense of fractionation is correct for terrestrial basalts, but the magnitude of partition coefficients is too low to account for the overall depletion levels.

Residual sulfide, either as liquid or crystalline MSS, has a significant impact on basalt HSE levels, owing to large sulfide-silicate partition coefficients. Crystalline MSS can be stable with silicate melt if the silicate liquidus is supressed by water. Based on known MSS-sulfide melt partitioning, MSS-silicate melt partitioning can impose a strong inter-HSE fractionation, whose sense and magnitude is similar to terrestrial basalts. With the exception of Au, however, direct measurements of MSS-silicate melt partitioning of the HSE have not been done. If melting occurs at higher temperatures, MSS is replaced by sulfide liquid. Experiments show that Re and Au are significantly less compatible than PGE in sulfide liquid at moderately oxidised conditions, accounting for the relative enrichment of Re and Au in terrestrial basalts. It is not clear, however, if sulfide liquid can impose IPGE/PPGE fractionation on silicate melt, as partition coefficients for these elements are currently too imprecise.

Recent measurements indicate sulfide-silicate partition coefficients for the PGE are on the order of 10^6 or larger. Since the mass fraction of sulfide liquid decreases during melting, this implies that the PGE content of residual sulfide could reach 1000s of ppm, leading to saturation in the less soluble PGE, such as Os, likely alloyed with Ir and Ru. The HSE content of terrestrial basalts might therefore be controlled by a combination of metal solubility and sulfide-silicate partitioning. Detailed modelling of this behaviour is considered by Mungall [this session].

Evidence for supernova injection into the solar nebula and the decoupling of *r*-process nucleosynthesis

G.A. BRENNECKA[1], L.E. BORG[1] AND M. WADHWA[2]

[1]Lawrence Livermore National Laboratory, Livermore, CA, USA 94550 (brennecka2@llnl.gov)

[2]School of Earth and Space Exploration, Arizona State University, AZ, USA 85287

Variations in the non-radiogenic isotope abundances of meteoritic materials have long been interpreted as nucleosynthetic signatures resulting from the input of distinct materials produced from *p*-, *s*-, and *r*-processes [e.g., 1-8]. Previous studies of the Solar System's first solids, calcium-aluminum-rich inclusions (CAIs), have demonstated that isotopic compositoins of various elements differ from terrestrial compositions and may be modeled using addition or subtraction of different nucleosynthetic components [6-8]. However, these studies did not determine the isotopic compositions of multiple elements spanning a large mass range in the same CAIs. We present for the first time an integrated study of Sr, Mo, Ba, Nd, and Sm isotope compositions determined on multiple coarse- and fine-grained CAIs from the Allende CV3 chondrite.

The data demonstrate that the isotopic compositions of these elements in CAIs are uniform and yet distinct from the average Solar System, necessitating that CAIs were formed in a homogenous and isotopically distinct reservoir. Taken in whole, the observed mass-independent anomalies cannot be explained by: (1) presence of presolar components, (2) simple addition/subtraction of *r*-process nuclides, (3) incomplete digestion of the sample, (4) nuclear field shift fractionation, or (5) neutron capture. Relative to terrestrial standards, CAIs contain positive *r*-process anomalies in isotopes A<140 and negative *r*-process anomalies in isotopes A>140. Previous work has suggested that multiple supernova sources are required to account for the proportions of short-lived isotopes in the early Solar System [9]. The fundamental difference in the isotopic character of CAIs around mass 140 is consistent with [9] and necessitates (1) the existence of multiple sources for *r*-process nucleosynthesis, and (2) the injection of supernova material into a reservoir untapped by CAIs.

Noble gases as physiological tracers for gas dynamics in human blood

M.S. BRENNWALD[1], C. LUNDBY[2], Y. TOMONAGA[1] AND R. KIPFER[1,3]

[1]Eawag, Dep. Water Resources and Drinking Water, Swiss Federal Institute of Aquatic Science and Technology, Switzerland
[2]Center for Integrative Human Physiology (ZIHP), Institute of Physiology, University of Zurich
[3]Institute for Geochemistry and Petrology, Swiss Federal Institute of Technology Zurich, Switzerland

The exchange of the inert noble gases (He, Ne, Ar, Kr, Xe) between gas and liquids is controlled solely by the gas-exchange kinetics in the gas/liquid interface, and by the solubility equilibrium (Henry's Law). Noble gases are therefore excellent tracers for the physical processes involved in gas/fluid exchange, and they have widely been applied as environmental tracers in aquatic systems. Here, we present our first attempts in using noble gases to trace physiological processes in the human body, such as the gas exchange in the lung or the gas distribution within the human organism.

Blood samples were taken from an atecubital vein. Samples were transferred into copper tubes (sample containers) without exposure to air or any other gas phase, and copper tubes were sealed. After coagulation of the blood, the samples were centrifuged to separate the liquid blood plasma from the blood cells. Blood samples were then analysed by vacuum extraction and mass spectrometric quantification of the dissolved gases using the standard methods used for water and sediment samples.

While breathing ambient air, noble gas concentrations in blood plasma were very similar to those in air saturated water, However, the $^{3}He/^{4}He$ ratio was 10% higher in blood than in air-saturated water, which is possibly due to the difference in diffusivities of ^{3}He and ^{4}He isotopes in the air/blood interface of the lung. Also, the heavier noble gases were found to be enriched in the blood-cell fraction relative to the blood plasma.

Breathing air enriched with noble gases resulted in an increase of the noble gas concentrations in the blood, and a new steady state was attained within a few minutes. All noble gas concentrations increased with the same kinetics. This suggests that gas exchage is not limited by diffusion through the air/blood interface in the lung, and that solubility equilibrium is attained in the lung. In contrast to O_2, which is bound to hemoglobin, the steady-state noble gas concentrations were considerably lower than expected, which points to a secondary partitioning or loss of noble gases within the body.

Recent advances of noble gas geochemistry in aquatic systems

M.S. BRENNWALD[12], C. MADEN[3], N. VOGEL[1], Y. TOMONAGA[1] AND R. KIPFER[13]

[1]Eawag, Dep. of Water Resources and Drinking Water, Swiss Federal Institute of Aquatic Science and Technology, Switzerland
[2]Dep. of Environmental Systems Science, Swiss Federal Institute Technology, Switzerland
[3]Institute for Geochemistry and Petrology, Swiss Federal Institute of Technology Zurich, Switzerland

Noble gases and bio-geochemically conservative transient trace gases (SF_6, CFCs) in aquatic systems have commonly been used to determine water residence times and to reconstruct past environmental and climatic conditions.

Recent conceptual and experimental developments have considerably extended the applicability of noble gas and transient gas analysis in aquatic systems. The mechanistic understanding of the formation of excess air (EA), a surplus of dissolved atmospheric gases commonly observed in groundwater, now allows robust interpretation of EA as a proxy for the hydraulic conditions during groundwater recharge, e.g., in areas that were covered by ice sheets during the LGM. Recent experimental breakthroughs now allow noble gas analysis in sediment pore fluids and in fluid inclusions of speleothems to reconstruct environmental condition from minutes amounts of water. Furthermore, the coupling of vacuum systems commonly used for noble gas analysis with and gas chromatographic methods allow combined analysis of noble gases and other gases (e.g., SF_6, CFCs, O_2, N_2) from a single water sample. This facilitates reliable EA correction for SF_6 and CFCs improving ground water dating. Finally, portable membrane-inlet mass spectrometers enable continuous and real-time analysis of noble gases and other dissolved gases directly in the field, allowing, for instance, quantification of O_2 turnover rates on small time scales.

In presenting these recent achievements, we intend to stimulate a broader discussion to define future applications of noble gases in conventional and unconventional aquatic systems.

How isotopic hydrogeochemical tools can help policy makers to target priority area for drinking water preservation?

A. BRENOT[1]*, L. GOURCY[2], E. PETELET-GIRAUD[2] AND PH. NEGREL[2],

[1]BRGM Rhône-Alpes, 151, boulevard Stalingrad 69626 – Villeurbanne Cedex – France (*correspondence : a.brenot@brgm.fr)

[2]BRGM, 3, avenue Claude-Guillemin BP 36009 45060 – Orléans Cedex 2 – France (l.gourcy@brgm.fr ; e.petelet@brgm.fr ; p.negrel@brgm.fr)

The main objective of the Water Framework Directive (2000/60/EC) is to prevent further deterioration, protect and enhance the status of aquatic ecosystems in Europe. In details, WFD enforces member states to identify the hydrosystems that should be protected for present or future use as drinking water. In this context, water policy makers of the Rhône-Méditerranée-Corse district (south-eastern part of France, covering 1/5 of the French territory) plan to list and delimit all the areas related to groundwater that present outstanding interests regarding quality and quantity for drinking use.

Our study is focused on two groundwater bodies located on the Rhône-Méditerranée-Corse district that have been identified as being of primary importance and/or at risk by the policy makers. These groundwater bodies (Isere alluvial aquifer and molasse aquifer) are used for drinking water supply for the large cities of Lyon, Grenoble and Albertville, to a lesser extent. Objectives were to characterize and better understand the origin of water and dissolved elements of these aquifers in order to identify the areas of major interest and protect them in priority. For that purpose, combined geochemical analysis of major and trace elements, and isotopes ($\delta^{18}O$ and $\delta^{2}H$ of water, ^{3}H, $\delta^{34}S_{SO4}$ and $\delta^{18}O_{SO4}$ of sulfates, $^{87}Sr/^{86}Sr$) have been successfully applied. This approach, in addition to geological and hydrogeological information, allow to identify groundwater units in each aquifer that i) present an uniqueness functioning and recharge and ii) permit low cost production for drinking purpose (water treatments reduced). For instance, the Isere alluvial aquifer presents high concentrations up to 3μg/L in As and Sb due to weathering of local rocks in the Alpes mountains. Hydrogeochemical knowledge, and especially isotopic tools, allow to target the groundwater units whose recharge area are less controlled by high As and Sb contents.

Lithium isotopic composition of the Tonga-Kermadec arc and its constraints on subduction recycling

RAUL BRENS JR.*[1], XIAO-MING LIU[2,3], ROBERTA RUDNICK[3], SIMON TURNER[1] AND TRACY RUSHMER[1]

[1]Department of Earth & Planetary Sciences, Macquarie University, Sydney, NSW 2109, Australia (*correspondence: Raul.Brens@mq.edu.au)

[2]Geophysical Laboratory, Carnegie Institute for Science, Washington, DC 20015, USA

[3]Department of Geology, University of Maryland, College Park, Maryland 20782, USA

Understanding elemental transfer within subduction zones is integral to quantifying crust-mantle exchange and recycling. Lithium is water-soluble and potentially a useful tracer of subduction zone processes. We have analyzed the lithium concentrations and isotopic compositions of a suite of lavas from the Tonga-Kermadec island arc, as well as a depth profile through forearc marine sediments from ODP hole 204, and lavas from the Fonualei back-arc spreading center in order to trace how lithium isotopes manoeuvre through an intra-oceanic subduction zone.

The $\delta^{7}Li$ of the entire suite of sediments and lavas vary from 0.3 to 14.4. The depth profile, along with published data from another nearby core sample (DSDP 595/596), shows a systematic increase in $\delta^{7}Li$ (1.2 to 14.4) with depth. This is in relation with the sediment type; lithium isotopic signatures for pelagic sediments are often lighter because of fractionation from weathering, while volcanogenic sediments can be lighter or heavier as a direct result of their alteration effects.[1] The $\delta^{7}Li$ of hole 204 pelagic sediments overlap that of the mantle, but range to lower values (1.2 to 5.2), while the $\delta^{7}Li$ of volcanogenic sediments are higher than the mantle (7.2 to 14.4). Thus, the Li isotope variation in the subducting sediments greatly exceeds that observed in the lavas. The fact that $\delta^{7}Li$ in some arc lavas (0.3 – 7.6) falls outside the range of MORB requires enrichments by fluid transfer of lithium from the sediments (which is reinforced with published B/Be data). Lavas from the back-arc spreading center ($\delta^{7}Li$ = 3.0 – 5.0) show no variation from the widely accepted lithium isotopic signature range of the MORB (1.5 – 5.5), suggesting that there is little Li transfer from the slab in the back-arc.

Electron flow in bacterial multi-heme cytochromes

M. BREUER[1], D.M.A. SMITH[2], J. BLUMBERGER[1] AND K.M. ROSSO[2]*

[1]University College London, London, UK
[2]Pacific Northwest National Laboratory, Richland, WA, USA (*correspondence: kevin.rosso@pnnl.gov)

Understanding mechanisms and kinetics of electron transfer processes in environmental systems is an important frontier for molecular theory and computation. This presentation addresses elementary aspects of predicting electron transfer rates, demonstrates the essentiality of computational molecular simulation relative to lacking experimental probes, and establishes a new methodological state-of-the-art for this purpose, using bacterial multi-heme electron transfer proteins as the case study.

Electron transport to extracellular solid metal oxides by metal-reducing bacteria is a fundamental biogeochemical process optimized by evolution to catalytic perfection. To shed light into why and how individual electron transfer steps in associated multi-heme cytochromes are combined into overall molecular function, we carried out extensive computer simulations of the recently crystallized decaheme cytochrome MtrF. We report redox potentials of individual hemes, reorganization energies and electronic coupling matrix elements for heme-to-heme electron transfer in MtrF explicitly solvated in water. The free energy profile for electron flow along various evident heme 'wire' pathways was computed using thermodynamic integration and classical molecular dynamics, and could be related to differences in the charged amino acids local to specific hemes. Reorganization free energies yield a range consistent with theoretical expectations for partially solvent exposed cofactors, and reveal an activation energy range surmountable for electron flow. Quantum mechanical calculations of electronic coupling matrix elements show a clear correlation between couplings and endergonic steps of through-protein electron transfer, suggesting that the protein evolved to harbor low-potential hemes for thermodynamic range without slowing down electron flow.

Because the individual hemes are not easily distinguished spectroscopically in such proteins, none of these insights are experimentally accessible. The theory and simulation campaign on this system is thus not only enabling a fundamental advance in understanding bacterial electron transfer protein function and key design elements, but it also provides a window into the broader biogeochemical context by the evident selection pressure underlying its purpose.

Storage of Hadean oceanic crust in the Kaapvaal subcratonic mantle

G.P. BREY[1]*, Q. SHU[12], A. GERDES[1] AND H.E. HOEFER[1]

[1]Institut für Geowissenschaften, Goethe-Universität, Altenhöferallee 1, D-60438 Frankfurt, Germany (*brey@em.uni-frankfurt.de)
[2]China University of Geosciences (Beijing). Xueyuan Road 29. Haidian, Beijing, China. 100083;

Eclogites from the subcratonic lithosphere appear to be ancient and Re-Os isotope data from eclogite xenoliths from Newlands on the Kaapvaal craton suggest that some may date back to the Hadean [1]. If mantle eclogites are products of subduction of oceanic crust [2], their ages place strong constraints on the beginning of plate tectonics. The calculated bulk rock compositions of a subset of bimineralic and of kyanite and corundum bearing eclogite xenoliths from the Bellsbank diamond mine (about 30 km north of Newlands) have similar flat middle to heavy REE patterns. Their range and that of their calculated major element compositions lies within the range of modern day mid ocean ridge basalts and gabbroic rocks. The kyanite- or corundum-bearing eclogites (3 samples) display positive Eu anomalies and show depletion in the more incompatible trace elements except for an enrichment in U and Th. In accord with earlier work we interpret them as former plagioclase rich cumulates which were possibly slightly modified by dehydration during subduction and during metamorphism. We interpret the bimineralic eclogites with overall higher abundances of the more incompatible trace elements (2 samples; no Eu anomaly) as clinopyroxene-rich cumulates. Based on the chemical similarities we regard these eclogites as a cogenetic suite.
The Lu-Hf two-point isochrones from these samples with temperatures of last equilibration above 920 °C give kimberlite eruption age (= 120 Ma for Bellsbank), i.e. garnet and clinopyroxene were in continuous isotopic exchange in the mantle until the time of eruption. The reconstructed bulk rock Lu-Hf isotopic compositions of four of the five samples plot along a line in an isochron diagram which yields 4.12 ± 0.27 Ga (MSWD = 0.04) with εHf_i ~0. The reality of an Hadean age is supported by the extremely high $\varepsilon Hf_{(120Ma)}$ values up to 1004 and 1006 respectively for coexisting cpx and garnet. Further support comes from garnet model ages between 3.13-3.5 Ga. These are minimum possible ages. Values of $\delta^{18}O$ lower than the mantle (2.5‰ to 4.8‰ in garnets) are consistent with low temperature sea floor alteration as their cause. This supports the existence of oceans 4.1 Ga ago. The eclogites and their MORB-like compositions imply modern day potential mantle temperatures, at least locally, and subduction underneath microcontinents in the Hadean.

Zeolites as ion exchanger in harsh ultra-alkaline conditions

E. BREYNAERT*, L. VAN TENDELOO, E. GOBECHIYA, W. WANGERMEZ, B. DE BLOCHOUSE, J.A. MARTENS, C.E.A. KIRSCHHOCK AND A. MAES

KULeuven - Center for Surface Chemistry and Catalysis. Kasteelpark Arenberg 23. B-3001 Heverlee. Belgium. (*correspondence: eric.breynaert@biw.kuleuven.be)

Cement based waste disposal is among the more important options to provide safe storage of non-recyclable often highly toxic waste.[1] Despite all engineering efforts, potentially contaminated ultra-alkaline concrete derived pore waters (pH 12 – 14) will always remain associated with cement based waste disposal. To avoid contamination of the environment due to slow leaching of the metals from these waste forms, engineered barriers are built around the waste disposal sites in order to provide containment. Such engineered barriers, needed to increase the safety level of the waste disposal sites, always incorporate a sorption sink capable of reducing the concentration levels of the toxic metals below specified safety limits.

Zeolites typically crystallize in alkaline, Na/Si/Al rich aqueous conditions and exhibit cation exchange properties.[2, 3] Therefore this family of crystalline porous materials has a significant potential as sorption sink in engineered barriers optimized to function in ultra-alkaline concrete derived pore waters

Cs^+ sorption was evaluated as function of Cs^+ concentration (10^{-11} up to 10^{-5} mole L^{-1}) and time (up to 180 days). The sorption results obtained in ultra-alkaline concrete pore water were compared with data obtained in electrolyte solutions at pH 8 containing identical Na^+, K^+ and Ca^{2+} concentrations.

The isotherms demonstrated an unexpected increased Cs^+ sorption in pH 13 solutions as compared to pH 8 solutions with similar cation content. Sorption results in ultra-alkaline concrete pore water as function of time indicate chabasite and clinoptilolite as two zeolite frameworks stable in these conditions. This confirms results obtained in zeolite formation/transformation studies that indicated a strong stabilizing effect of the alkali cations on specific zeolite frameworks. Binary sorption isotherms confirmed that the selectivity series and calculated selectivity coefficients expected for chabasite and clinoptilolite at trace concentrations (<10^{-4} M Cs^+) are also valid in ultra-alkaline aqueous conditions.

The Marseillon spring is a strategic resource for the drinking water supply of the Aquitaine region (SW of France). Fed by deep Cretaceous limestone aquifer and local infiltration (favored by karstic limestone outcrop), it is threatened by increasing nitrate concentrations (from 10 to 25 mg/L in 20 years).

Measurement of $\delta^{15}N\text{-}NO_3^-$ and $\delta^{18}O\text{-}NO_3^-$ coupled with $\delta^{11}B$ allows a good discrimination between the multiple potential sources of nitrate in the area [1]. Additional microbiological markers (bacteriophages, bacteroïdales) can offer better precision over the origin of fecal contamination [2].

This work presents a dynamic approach based on these natural isotopic and microbiological tracers measured over samples of Marseillon's groundwater and local surface waters collected from October 2010 to January 2013. Their evolutions within each compartment allow a better understanding of nitrate origin and flow paths in the studied watershed.

Modifications of Cu isotopic ratios in coastal sediments in relation to the increased use of copper based antifouling paints

N. BRIANT[1]*, R. FREYDIER[1], F. ELBAZ-POULICHET[1], C. BANCON-MONTIGNY [1] AND S. DELPOUX[1]

[1]Laboratoire HydroSciences UMR 5569, CNRS, Universités Montpellier I & II, IRD, Place Eugène Bataillon, CC MSE, 34095 Montpellier cedex 5, France (*correspondence : nicolas.briant@univ-montp2.fr)

Cu is released in water by weathering processes and human activities. It is widely applied on vines and used as a biocide in antifouling paints. This study aimed to assess the potential of Cu stable isotopes to identify Cu sources in coastal sediments.

For this study, sediment cores were collected from three sites in the marina of Port Camargue on the French Mediterranean coast. This marina, the largest in Europe, was built around forty years ago and has never been dredged. Sediment samples (<63μm fraction), antifouling paints were analyzed for copper concentration and Cu isotope ratios. Isotopic measurements were performed using a Neptune Multi Collector ICP-MS after a double separation on anionic resin.

Copper concentrations in antifouling paints (7 different brands) ranged from 6 % w/w to 36 % w/w. Their δ^{65}Cu values varies from 0.55 to 0.97‰. Close to the boat maintenance area, Cu concentrations in sediment cores exhibited an increase from the bottom to surface with a maximum value of 1961 μg.g^{-1} at 7 centimeters depth. In parallel δ^{65}Cu values increased from 0.08‰ at the bottom of the core up to 0.52‰ around 5 cm depth (Figure 1). This evolution toward δ^{65}Cu values similar to those observed in antifouling paints in surface sediments, indicates that copper isotopes are good tracers of copper contamination by antifouling paints in a coastal marina.

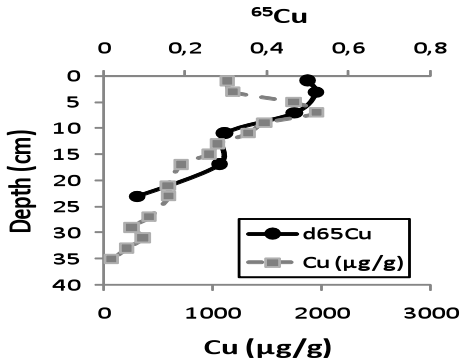

Figure 1: Depth profile of δ^{65}Cu and copper concentration in sediments from Port Camargue Marina.

Understanding the marine biogeochemical cycle of Pb in the equatorial Atlantic

L.J. BRIDGESTOCK[1]*, M. PAUL[1], T. VAN DE FLIERDT[1], M. REHKÄMPER[1,2], E. ACHTERBERG[3] AND M. LOHAN[4]

[1]Imperial College London, London, SW7 2AZ, UK (*correspondence:luke.bridgestock07@imperial.ac.uk)
[2]Natural History Museum, London, SW7 5BD, UK
[3]University of Southampton, Southampton, SO14 3ZH, UK
[4]University of Plymouth, Plymouth, PL4 8AA, UK

The biogeochemical cycle of Pb has been significantly perturbed by anthropogenic activity over the past 100 years, with transient changes in the relative importance of different anthropogenic Pb sources [1]. Lead isotopes are an effective tracer of anthropogenic Pb emissons, and the short residence time of Pb in ocean surface waters (~2 years, [2]) make them a useful recorder of recent Pb sources in a particular region. Furthermore, the comparatively conservative behaviour of Pb isotopes in intermediate and deep waters enables tracing advection of pollutant Pb [3].

A newly developed method, using TIMS in conjunction with a Pb double spike, has been applied to the measurement of the Pb isotopic compositions (^{206}Pb/^{204}Pb, ^{207}Pb/^{206}Pb and ^{208}Pb/^{207}Pb) and concentration of seawater depth profiles and surface seawater samples collected in the eastern equatorial Atlantic Ocean during the GA06 UK GEOTRACES cruise in 2011. The data are used to assess the current importance of anthropogenic versus natural Pb inputs to this region, and the advection of anthropogenic Pb into deep waters.

The Pb concentrations of surface waters (17-26 pmol/kg) are comparable to those determined in the early 1990's in the region [4], suggesting a stable Pb flux over the past 20 years. The Pb isotope composition of surface waters between 8° N and 3° S (1.163-1.169, ^{207}Pb/^{206}Pb) are similar to those determined for Saharan dust [5]. In contrast, surface waters in the North Equatorial Current have higher ^{207}Pb/^{206}Pb ratios (1.173-1.174), a signature which can be attributed to advection of Pb from the west, fingerprinting eastern US emissons. A deep water maximum in Pb concentration (3000 m; 46 pmol/kg) located close to the mid Atlantic ridge is interpreted to represent hydrothermal input of Pb.

Heavy metals characteristics in the gold and iron mine soils in the upstream area of Miyun Reservoir

MERYEM BRIKI[1], XINGXING HUANG[1], PANPAN JU[1], CAI LI[1] AND HONGBING JI*[12]

[1]Department of Environmental Engineering, Civil and environmental Engineering School, University of Science and Technology Beijing, Beijing 100083, China (brimer@hotmail.fr)

[2]The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550002, China (*correspondence: hongbing.ji@yahoo.com)

Metal contamination of soil from anthropogenic sources is an important global issue. Some recent studies have worked on the importance of metal contamination of soils in ecologically sensitive areas that are the source sites of drinking water. In this study, a preliminary survey of soil contamination had been carried out around the Miyun Reservoir, Beijing, China. Some results as follows: (1) the metal concentrations in the gold and iron mines soil samples exceed the background soil levels in Beijing, and the content of heavy metal in gold mine soils are higher than those of iron mine soils with Ti and Mn as an exception; the pollution of heavy metals in mine soils have reached a serious degree, and Hg is the most serious pollution element of all selected elements in gold mine soils. (2) Selected elements have been found the residual fractions is the most predominant in all gold and iron mine soil samples; the distribution of Ni in gold mine was similar to that of iron mine; Mn had the greatest acid-soluble per portion (27.95% and 23.24%, respectively) reflecting that Mn was more mobile and potentially more bioavailable in the study areas; the acid-soluble and reducible portion of Cd (20.06%, 16.45%) in gold mine was significantly higher than that of iron mine (3.70%, 1.36%), and as well as Pb. (3) the selected heavy metals in both soil samples have different degrees of enrichment; the pollution degrees of gold mine soil samples was aligned to Pb>Hg>Cd>Cr>Cu>Zn>Co>As, while Pb>Cd>Cr>Co>Cu >Zn> Hg>As for iron mine soil samples.

Zn immobilization by *Lumbricus terrestris* calcium carbonate biomineralized granules

LOREDANA BRINZA[1]*, J. FRED W. MOSSELMANS[1], PAUL F. SCHOFIELD[2], ERICA DONNER[4], ENZO LOMBI[4] AND MARK E. HODSON[3]

[1] Diamond Light Source, UK , (*correspondence: Loredana.Brinza@diamond.ac.uk; Fred.Mosselmans@diamond.ac.uk)

[4]University of South Australia, Australia (Erica.Donner@unisa.edu.au; Enzo.Lombi@unisa.edu.au)

Many species of earthworm secrete granules of calcium carbonate. In this study we investigated the incorporation of Zn into granules produced by the earthworm *L. terrestris,* cultured in an agricultural soil (Hamble) amended with Zn and a soil from a former Zn mine (Cwmystwyth, UK).

Bulk and μ-X-ray diffraction were used to determine granule mineralogy. Both vaterite and calcite were detected.

Synchrotron μ-X-ray fluorescence (XRF) was used to determine the distribution of Zn within granules. Zn occurred in concentric zoning (Fig. 1) and as discrete hotspots. X-ray absorption spectroscopy was used to determine the Zn bonding environment within the calcium carbonate granules. The Zn exhibited several different speciations; replacing Ca in the calcite structure and as the minerals hydrozincite, $Zn_5(CO_3)_2(OH)_6$ and aurichalcite, $(Zn,Cu)_5(CO_3)_2(OH)_6$.

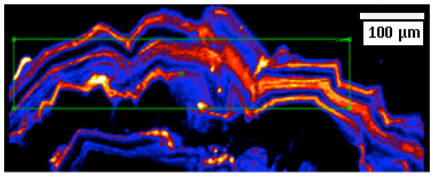

Figure 1: XRF map showing Zn distribution as concentric rims on the edge of a slice of a granule originating from Hamble soil amended with 750 ppm Zn. XRF average Zn concentration for this granule is 64 ppm and the bulk concentration from digested granules from this treatment is 164 ppm.

Zn is immobilized within biomineralized granules. Although, the degree of Zn uptake and granule production rates indicate that these biogeochemical processes have a less significant impact on Zn mobility compared to that for Sr [1] and Pb [2] at contaminated sites.

High sensitivity of ammonia and nitrite oxidation rates to nanomolar oxygen concentrations

L.A. BRISTOW[1,*], T. DALSGAARD[2], L. TIANO[3], D.B. MILLS[1], O. ULLOA[4], D.E. CANFIELD[1], N.P. REVSBECH[3] AND B. THAMDRUP[1]

[4] Departamento de Oceanografia, Universidad de Concepcion, Casilla 160-C, Concepcion, Chile
(*correspondence: lbristow@biology.sdu.dk)

To date it remains unclear as to whether ammonia and nitrite oxidation can co-occur alongside and hence supply substrates for fixed N loss via either denitrification or anammox under nanomolar oxygen (O_2) concentrations. Both culture and field based studies have been restricted to O_2 concentrations greater than 0.25 μM. With O_2 concentrations regularly observed to be less then 10 nM in the core of oxygen minimum zones (OMZ) it is essential to assess the oxygen sensitivity of these processes at these levels.

Sampling was undertaken across the oxycline in the seasonal OMZ off Concepcion, Chile to determine rates of ammonia / nitrite oxidation from short-term incubations at manipulated O_2 levels between 5 nM and 20 μM. Rates of both ammonia and nitrite oxidation were detectable to the limit of our O_2 measurements and demonstrated a strong dependence on nanomolar concentrations of O_2. Michaelis-Menten kinetics fitted to this data produced half saturation constants (K_m) of 330 and 780 nM O_2 for ammonia and nitrite oxidation respectively. These values were consistent across multiple depths sampled in this study and are shown to be applicable across OMZ systems. These K_m values must be included in future modelling studies, in order to more realistically assess the impacts of ocean deoxygenation on nitrogen cycling.

Titration curves, column experiments, and reactive transport models

S. M. BRITZ[1]*, U. NOSECK[1], V. BRENDLER[2], AND M. STOCKMANN[2]

[1]GRS Braunschweig, D-38122 Braunschweig, Germany Germany (*correspondence: susan.britz@grs.de)
[1]Helmholtz-Zentrum Dresden-Rossendorf, D-01314 Dresden

Surface reactions related to e.g. transport and retardation processes in groundwater systems are correlated with geochemical conditions that vary in time and space. For long-term safety analysis of radioactive waste repositories it is of great interest to better understand and to realistically assess these geochemically driven surface and transport reactions, since they might strongly impact radiation exposure.

To get an advanced insight into these processes column experiments are conducted and subsequently modeled with the geochemical speciation code PhreeqC, Version 2.18 (coupled with UCODE_2005). In order to set-up realistic reactive transport models so-called surface complexation parameters (SCP) such as surface site density, specific surface area, and protolysis constants need to be derived from titration experiments of relevant mineral phases.

Two different titration techniques are conducted for muscovite and orthoclase: continuous and batch titration. Derived results are compared offering an insight into pH-influencing reactions that contribute to surface reactions but also to cation exchange and mineral dissolution.

In column experiments diffent solids are applied: natural sediments from the Gorleben site, Germany and pure mineral phases (orthoclase, muscovite, quartz). Parameters such as pH, ligands, ionic strength, and cation concentrations are varied in each experiment to reflect realistic enviromental conditions. Moreover, transient pH conditions are applied in selected columns.

Both types of experiments (titration, column experiments) including each geochemical variation provide data to model reactive transport processes of hazardous pollutants more realistically in groundwater-flow driven environments with PhreeqC. Calculations will be conducted and first results offered for discussion.

This project is funded by the German Federal Ministry of Economics and Technology (BMWi) under contract no. 02 E 11072A and 02 E 11072B.

Recycled volatiles beneath the Western Antarctic Rift

M.W. BROADLEY[1]*, C.J BALLENTINE[1], L. DALLAI[2] AND R.BURGESS[1]

[1]SEAES, University of Manchester, M13 9PL, UK (michael.broadley@postgrad.manchester.ac.uk)
[2]CNR, Institute of Earth Sciences and Resources, Pisa, Italy (dallai@igg.cnr.it)

The Western Antarctic Rift System (WARS) represents an area of long lived extension between East and West Antarctica. The origin of this rift is poorly understood, with both an actively up-welling plume and passive rising of the asthenosphere being championed as the cause [1]. To explore the origin and evolution of the rift, a suite of 11 mantle xenoliths from Northern Victoria Land have been analysed for their halogen and noble gas isotopic signatures.

Noble gas and halogens are excellent tracers of volatiles within the mantle; providing a key source of information on the underlying mantle which is driving the rift. The fluid inclusions present within mantle xenoliths provide the best medium through which magmatic volatiles can be transported to the surface and still be able to retain a pristine magmatic signature. Noble gas and halogens contained within these fluid inclusions are released by in vacuo crushing and analysed through mass spectrometry.

Noble gas signatures extracted from the fluid inclusions show MORB like $^{3}He/^{4}He$ ratio of $7.4R_A$ whilst the $^{20}Ne/^{22}Ne$ ratios are indicative of a deeper primordial mantle source. Halogen analysis has shown the samples to be extremely enriched in iodine with I/Cl ratios ranging from a MORB like 0.09148×10^{-3} to highly enriched value of 54.6×10^{-3}. These values are indicative of mixing between mantle and subduction fluid endmembers.

Halogen ratios indicate that seawater derived volatiles have been incorporated into the mantle during subduction. Volatiles were released from the slab at depth possibly by the breakdown of antigorite. This fractionated the halogens further causing an increase in the I/Cl ratio seen within the xenoliths [2]. Noble gas ratios indicate that the driving force of the rift is the convecting upper mantle, with an addition of a deeper mantle volatile source. Geochemical data, along with seismic evidence [3], suggests that slab detachment during the Cretaceous created localised convection currents which brought some primordial mantle up from depth. The rising mantle would have exerted a force on the bottom of the Antarctic Plate causing it to break apart.

Phototrophs and ore formation

J. J. BROCKS*,[1] B. J. BRUISTEN[1], A. PAGÈS[2] AND K. GRICE[2]

[1] Research School of Earth Sciences, The Australian National University, Canberra, ACT 0200, Australia. (*correspondence: Jochen.Brocks@anu.edu.au)
[2] WA Organic & Isotope Geochemistry Centre, Curtin University, WA 6845, Australia.

Sediments of the 1.64 Ga Barney Creek Formation (BCF) in northern Australia host one of the largest stratiform Pb-Zn deposits in the world. An early fraction of the zinc sulfide may have formed by discharge of zinc-rich fluids from a proximal fault into sulfidic bottom waters, causing synsedimentary precipitation of ZnS onto the sea floor (SEDEX model).

As the BCF contains the oldest known, thermally well-preserved molecular fossils (biomarkers) in the world, it is the ideal location to study the role of microorganisms and biogenic organic matter in this process. Solvent extracts of the sedimentary rocks yielded aromatic carotenoids produced by phototrophic sulfur bacteria, including extremely high concentrations of okenane from purple sulfur bacteria (Chromatiaceae) and chlorobactane produced by green-pigmented green sulfur bacteria (Chlorobiaceae) [1]. As okenone was exclusively known from planktonic Chromatiaceae, we envisaged a planktonic phototrophic community inhabiting a euxinic deep water system [2], consistent with a SEDEX component to ore formation. However, precursors of almost all fossil aromatic carotenoids have now also been discovered in microbial mats [3]. We present biomarkers from mat facies in the BCF and discuss whether the finely laminated sediments represent phototrophic microbial mats that thrived under a shallow, fully oxygenated water column or benthic mats that formed in a deep sulfidic basin.

Probing the water content of the Earth's mantle: Hydrogen mobility under extreme conditions

J. BROOKE*, G. BROMILEY, K. WHALER AND C. GRAHAM

Department of Geosciences, Grant Institute, University of Edinburgh, UK (jennifer.brooke@ed.ac.uk) (*presenting author)

Research over the past few decades has shown that nearly all of the nominally anhydrous minerals (NAMs) of Earth's mantle can incorporate substantial amounts of water as structurally bound hydrogen. This has important implications for understanding the geochemical and geophysical properties of Earth's interior as the presence of water influences numerous mantle properties and processes[1,2]. Water, as hydrogen, has been invoked to reconcile differences between conductivity models and geophysical observations of the mantle, but the amount present is yet to be satisfactorily quantified – with experimental estimates differing by several orders of magnitude[3,4]. Hydrogen-deuterium exchange experiments performed under mantle conditions are presented, that provide data on hydrogen mobility in olivine directly comparable with electrical conductivity data. These results will be used in conjunction with existing estimates of conductivity and magnetotelluric survey data in order to constrain the water content and conductivity of olivine, and thus the upper mantle.

Evaluating proxies for oxygen fugacity at the Mariana arc

MARYJO BROUNCE[12]*, KATHERINE KELLEY[1] AND ELIZABETH COTTRELL[2]

[1]University of Rhode Island, Graduate School of Oceanography, Narragansett RI 02882, USA
[2]National Museum of Natural History, Smithsonian Institution, Washington DC 20562, USA

Arc basalts are more oxidized than mid-ocean ridge basalts, but existing proxies for studying fO_2 present contrasting explanations for this offset. The $Fe^{3+}/\sum Fe$ ratio proxy indicates that the mantle wedge has higher fO_2 than mid-ocean ridge source mantle. In contrast, trace element proxies (V/Sc, Zn/Fe*, and [Cu]) suggest that the fO_2 of the upper mantle is uniform. Additionally, the $D_V^{ol/melt}$ proxy suggests that arc magmas are oxidized at the time of high-Mg olivine fractionation. We present major and trace element concentrations and $Fe^{3+}/\sum Fe$ ratios (μ-XANES) for melt inclusions and their olivine hosts from five Mariana arc volcanoes and Mariana Trough submarine glasses to compare the [Cu], Zn/Fe*, $D_V^{ol/melt}$, V/Sc, and $Fe^{3+}/\sum Fe$ ratio proxies for calculating fO_2.

The Zn/Fe* proxy returns $Fe^{3+}/\sum Fe$ ratios of primary mantle melts and is sensitive to variations in Zn/Fe^*_{source}. After accounting for source composition, the Zn/Fe* proxy yields agreement with calculated primary $Fe^{3+}/\sum Fe$ ratios for arc and back-arc glasses. Similarly, the [Cu] of arc melt inclusions are consistent with non-modal equilibrium melting of a source between QFM+1 and QFM+2, and fractional melting between QFM and QFM +0.5 for back-arc magmas. The V/Sc proxy returns more reduced primary fO_2s than the Fe-based proxy for all samples, however fO_2s for arc melt inclusions calculated using $D_V^{ol/melt}$ (QFM+2.7 ±0.3) are systematically more oxidized than their measured $Fe^{3+}/\sum Fe$ ratios indicate (QFM+1.3 ±0.3), suggesting that there may be a significant water, pressure, or source composition effect on the partitioning behaviour of V and Sc. These results show that the Fe-, Zn/Fe*-, and [Cu]-based proxies for fO_2 are in broad agreement and are consistent with an arc mantle source that is more oxidized than mid-ocean ridge source mantle.

Petrogenesis of peraluminous granites from deep crustal sources

CAITLIN BROWN[1]*, MICHAEL BROWN[1] AND PHILIP PICCOLI[1]

[1]University of Maryland, College Park, USA (*correspondence: cbrown88@umd.edu)

The study of exhumed high-grade continental crust formed at convergent plate margins reveals important details about the petrogenesis of granites and contributes to a better understanding of processes responsible for the differentiation of the continents. The Fosdick migmatite–granite complex, West Antarctica, records evidence of two melting events, during the Devonian–Carboniferous and in the Cretaceous. A Devonian–Carboniferous calc-alkaline granodiorite suite emplaced into a Lower Paleozoic metasedimentary sequence (outside the complex) and their granulite facies equivalents (inside the complex) represent the sources and make this region ideal for the study of processes and mineral behavior during polycyclic anatexis at granulite facies conditions using a combined petrologic and geochemical approach. We report 20 new LA–ICP–MS U–Pb zircon ages extending the age ranges as follows: protolith granodiorite suite 377–339 Ma; Devonian–Carboniferous anatectic granites 369–350 Ma; and, Cretaceous anatecic granites 119–96 Ma. The discovery of Devonian anatectic granites suggests that melting occurred earlier than previously thought. New geochemical data for 48 samples extends a limited dataset from earlier work. The major and trace element geochemistry of paragneisses and orthogneisses is consistent with the hypothesis that they are the high-grade equivalents of the metasedimentary sequence and granodiorite suite respectively. The metasedimentary sequence has K_2O of 2.15–4.32 wt%, Sr of 95–207 ppm and Rb of 96–216 ppm, whereas the calc-alkaline granodiorite suite has K_2O of 2.23–5.01 wt%, Sr of 90–418 ppm and Rb of 88–381 ppm. Devonian–Carboniferous granites are either high Sr (225–363 ppm) or low Sr (95–108 ppm) types with variable K_2O (2.73–6.85 wt%) and Rb (131–284 ppm). Cretaceous granites are either high Sr (207–298 ppm) or low Sr (90–167 ppm) types with variable K_2O (3.21–8.89 wt%) and Rb (80–284 ppm). Limited isotope data indicates that Devonian–Carboniferous granites were derived primarily from the granodiorite suite, whereas Cretaceous granites were derived from mixed sources (the metasedimentary rocks, the granodiorite suite, or their high-grade equivalents). Additional Sr and Nd isotope and REE data currently being collected will better constrain the sources of the granites and allow an evaluation of the role of accessory minerals such as apatite and monazite during crustal melting events.

Beneficial uses of engineered nanoparticles and the behavior of natural and engineered nanoparticles in the environment

Engineered nanoparticles (ENPs), including Ag(0), Au(0), C-nanotubes, ZnO, TiO_2, Fe_3O_4, have many beneficial uses ranging from catalysts used for efficient production of chemicals (e.g., Au(0)) and photocatalytic degradation of organic pollutants (e.g., TiO_2) to water treatment to remove As (e.g., Fe_3O_4)) and use as antibacterial agents (e.g., Ag(0) and ZnO). Here we will review some of these uses, as well as some of the transformations that ENPs undergo in different environments (e.g., sulfidation of Ag(0) and ZnO ENPs), which can significantly alter their properties (e.g., solubility) and result in lowered risk. We will also review some of the lessons learned about the behavior of ENPs from microscopic studies of engineered and natural nanoparticles, in particular the sorptive properties of Fe_3O_4 ENPs in removing As from drinking water. We will also discuss some insights about the use of nanoparticles as environmental indicators gained from ab initio thermodynamics studies of the morphologies developed by NPs under different environmental conditions.

Geochemistry and mineral exploration

GRAHAM BROWN

Anglo American, Carlton House Terrace, London, SW1Y 5AN, (graham.brown@angloamerican.com)

Mineral exploration is a multi-disciplinary team effort, in which conceptual geological thinking and traditional geological field work play leading roles. Geochemistry, when properly integrated into the process, is a key component for exploration, from initial targeting through to resource definition.

Anglo American's base metal discovery track record over the past decade (including ten significant discoveries) illustrates this point, where so-called conventional geochemical techniques played an important role in many of those discoveries.

Stream sediment geochemistry in areas of well developed topography, and soil geochemistry in areas of residual soil profiles are very effective techniques and played a role in the discoveries of the Morro Sem Boné Ni-laterite deposit, Brazil, and the Boyongan Porphyry Cu deposit, Philippines. In areas of thicker and/or transported overburden, surface geochemistry is unreliable, and Anglo American has preferred the more direct approach of drilling through the cover and sampling the base of regolith or top of bedrock (as used in the discoveries of the Gergarub Zn-Pb VMS deposit, Namibia, and the Sakatti Ni-Cu-PGE deposit, Finland). In addition to surface media geochemistry, lithogeochemical methods have been used in regional reconnaissance, and more locally for detecting distal effects of mineralisation, particularly around blind targets.

Fast and relatively cheap multi-element analysis by ICP-MS and computer software to aid interpretation have been the most significant technological advances over the last twenty years. More recently, portable XRF technology has enabled real-time decision-making in the field.

Anglo American actively supports geochemistry-related R&D through engagement with several key research centres globally (e.g., CODES and MDRU), and funding of PhD students. Strategic alignment of research objectives with the long term needs of industry is a key challenge, as is the gap in undergraduate teaching in applied exploration geochemistry at universities.

The fate of Archean primary crust and the transition to subduction

MICHAEL BROWN[1]*, TIM E. JOHNSON[2] AND JILL A. VANTONGEREN[3]

[1]University of Maryland, College Park, USA (*correspondence: mbrown@umd.edu)
[2]University of Mainz, Germany (tjohnson@uni-mainz.de)
[3]Yale University, USA (jill.vantongeren@yale.edu)

Petrological data and thermal models indicate Archean mantle potential temperatures (T_p) were up to 240°C hotter than at present, but with a similar variation (~100°C). Higher T_p generated thick MgO-rich ultramafic primary crust (PC) and highly residual lithospheric mantle (LM). Subduction and plate tectonics were unlikely. The preserved volume of PC is low suggesting that most is missing, which we address by modelling the equilibrium mineral assemblages for a range of metamorphosed (hydrated) PC compositions and complementary residues for a Moho T of 1000°C. We use calculated compositions of primary melts and complementary residues of high-MgO non-arc basalts as proxies for the secular change in composition of PC and LM. The density of LM decreases slightly with increasing T_p, whereas that of PC increases dramatically. The base of PC with MgO >21–22 wt%, produced at T_p >1600°C, was unstable at crustal thicknesses >45 km (>1.5 GPa), even when fully hydrated. Archean low-MgO eclogites and TTGs were derived from basaltic compositions and require that the PC was fractionated. Although the thermal structure of the mantle in the Hadean and Eoarchean is poorly constrained, heating from radioactive decay exceeded surface heat loss in the interval before 3.0 Ga and Archean geodynamics was probably variable, controlled by the spatial range in T_p. This regime was likely dominated by delamination/convective downwelling of PC that may have partially melted to produce basalt or refertilized the underlying mantle causing additional melting and crustal thickening. The resulting magmatic additions form plateau-like crust. Archean continental crust is dominated by TTGs. Collision of plateaux and/or plateaux overriding PC lithosphere was responsible for inducing melting to generate this TTG crust. Post 3.0 Ga tectonics was dominated by the onset of subduction, plate tectonics and a transition to the supercontinent cycle, consistent with the dominance of secular cooling since 2.5 Ga, and the rare occurrence of paired metamorphism and scarcity of eclogite in orogenic belts from the Mesoarchean to Paleoproterozoic. The onset of subduction may have triggered an overturn of the LM, as evidenced by T_{RD} model ages for the LM.

Mutiple isotopic tracers to monitor remediation of uranium solution mining

SHAUN T. BROWN[1], JOHN N. CHRISTENSEN[1], DONALD J. DEPAOLO[1], ANIRBAN BASU[1], PAUL W. REIMUS[2], ARDYTH M. SIMMONS[2] AND JEFF HEIKOOP[2]

[1]UC Berkeley and Lawrence Berkeley National Lab (stbrown@berkeley.edu, jnchristensen@lbl.gov, anirbanbasu@berkeley.edu, depaolo@eps.berkeley.edu)
[2]Los Alamos National Lab, (preimus@lanl.gov, asimmons@lanl.gov, jheikoop@lanl.gov)

Roll front uranium deposits form by interaction of U-bearing groundwater with reduction-oxidation gradients in the host sediments. This redox gradient in many roll-front deposits can be visually identified by hematite staining on the oxic side and green-gray sediment color on the anoxic side. A dark boundary between these two zones is concentrated in U(IV) minerals and other reduced metals such as Se and Mo. Solution mining of roll-front deposits perturbs natural redox conditions by oxidizing U (and other metals) in the main ore body for economic recovery. This perturbation coupled with an extensive monitoring well network provides a unique opportunity to assess the natural recovery of reducing conditions after the cessation of mining as a remediation strategy.

We have conducted a characterization survey of groundwater, mining fluids and complimentary ore body sediment core from the Smith Ranch mine in eastern Wyoming, USA for $^{87}Sr/^{86}Sr$, $\delta^{34}S$ sulfate, $\delta^{238/235}U$ and the $^{234/238}U$ activity ratio. Sampling locations include both active and inactive mining sites. Monitoring wells surrounding the ore body have 4-22 ppb U, 68-413 ppm SO_4, $^{234}U/^{238}U$ activity ratio 2.9-5.5, $\delta^{34}S$ -16.6-10.8‰, $\delta^{238/235}U$ is between 0-2‰ for most samples.

Acid leachates of sediment core from a previously mined unit have low $^{234}U/^{238}U$ activity (0.6-1.6) compared to groundwater outside the ore zone. $\delta^{34}S$ spans nearly 52‰ (-48-+3.8‰) and most samples have $\delta^{238/235}U$ between -2 and 0‰. The depletion of ^{238}U in dissolved U(VI) as indicated by negative $\delta^{238/235}U$ suggests U(VI) reduction in the groundwater. There are no observed correlations between $^{234}U/^{238}U$ activity and $\delta^{238/235}U$. However the U activity ratio does correlate with depth. The low ($^{234}U/^{238}U$) in the ore zone will be a sensitive tracer for quantifying the migration of ore zone U to uncontaminated groundwater.

Iron availability controls phytoplankton ecophysiology in the South Atlantic Subtropical Convergence Zone

THOMAS J. BROWNING[1], HEATHER A. BOUMAN[1], GIDEON M. HENDERSON[1], C. MARK MOORE[2], CHRISTIAN SCHLOSSER[2], GLEN A. TARRAN[3] AND E. MALCOLM S. WOODWARD[3]

[1]Department of Earth Sciences, University of Oxford, South Parks Road, Oxford, UK. (thomasb@earth.ox.ac.uk)
[2]National Oceanography Centre Southampton, University of Southampton, European Way, Southampton, UK.
[3]Plymouth Marine Laboratory, Prospect Place, The Hoe, Plymouth, UK.

Measurements of phytoplankton photophysiology using Fast Repetition Rate fluorometry (FRRf) from the UK-GEOTRACES 40°S Atlantic cruise (GA10; JC068) have characterized two dominant ecophysiological regimes which are interpreted on the basis of nutrient limitation. South of the South Subtropical Convergence (SSTC) in the Antarctic Circumpolar Current (ACC) of the Eastern Atlantic Basin, waters are characterized by elevated chlorophyll concentrations, dominance by larger phytoplankton cells, and low F_v/F_m values. The reason for the low F_v/F_m values was iron (Fe) limitation, which was confirmed via 24 hour on-board Fe addition incubation experiments. Fe supply to these waters, either through artificial bottle additions or natural downstream enrichment from Gough Island in the Central Atlantic, resulted in significantly increased F_v/F_m. Satellite images suggest a broader region of enhanced chlorophyll concentrations around the SSTC of the Western Atlantic relative to the Eastern Atlantic, which is hypothesised to be a result of higher iron supply from the South American continent. To the north of the SSTC at the southern boundary of the South Atlantic Gyre, phytoplankton are characterized by high values of F_v/F_m, which coupled with the low macronutrient concentrations and increased presence of picocyanobacteria, are interpreted as conditions of Fe replete, balanced macronutrient-limited growth.

Seismic anisotropy as a constraint on composition in the lower crust

*SARAH J. BROWNLEE[1], BRADLEY R. HACKER[2], ALAN CHAPMAN[3], JASON SALEEBY[4] AND GARETH SEWARD[2]

[1]Wayne State University, Department of Geology (*correspondence: sarah.brownlee@wayne.edu)
[2]University of California, Santa Barbara, Department of Earth Sciences
[3]University of Arizona, Department of Geosciences
[4]California Institute of Technology, Geological and Planetary Sciences

Our current interpretation of the composition of the middle and lower crust comes mainly from seismic observations, yet it remains a challenge to link seismic observations directly to composition. This is because isotropic seismic properties are similar across a range of compositions. Taking anisotropy into account allows for further refinement of our interpretation of composition provided that anisotropy is characterized for candidate rock types. This study uses electron backscatter diffraction (EBSD) measurements of crystallographic preferred orientation of minerals to calculate seismic anisotropy in samples of the Pelona-Orocopia-Rand (POR) schist from the Mojave region of southern California. The goals of this work are to characterize the seismic anisotropy of the POR schist and its relationship to observed lower crustal anisotropy in the region, and to refine predictions of lower crustal composition based on seismic anisotropy.

Velocity anisotropy in individual samples of the POR schist ranges from ~2–11% in V_P and ~3–15% in V_S, which is consistent with results of [1] for lower crustal anisotropy in southern California. When all schist samples are averaged together, the velocity anisotropy is significantly reduced to ~6% in V_P and ~8% in V_S. The symmetry of V_S anisotropy is roughly uniaxial with a unique slow axis perpendicular to foliation for all samples. Samples with significant modal quartz or amphibole have near orthorhombic V_P symmetry with slow velocities perpendicular to foliation. Maximum V_P is ~parallel to lineation, except in samples with significant quartz displaying prism-<a> slip; for these sample V_P-max is parallel to foliation, perpendicular to lineation. Modal quartz content is inversely correlated to isotropic V_P/V_S ratios, and mica and amphibole are positively correlated with anisotropy. Relative mica/amphibole contents can be distinguished using a combination of isotropic V_P, and V_S anisotropy. Quartz content can be estimated from V_P/V_S ratios.

Precambrian biomarkers convey invaluable information about the early evolution of life, ancient ecosystems, redox conditions, climate and depositional environment and prospective petroleum systems. They are however thermally unstable, easily obliterated by contamination and thus extremely difficult to find. This is particularly true if conditions favourable for biomarker preservation had to prevail for more than 2.5 billion years – the prerequisite for finding Archaean biomarkers. Many organic geochemists abandoned this hope after original discoveries of Archaean biomarkers proved to be of younger origin [1,2] but our study of ca. 550-825 Ma old sediments from the Centralian Superbasin now shows that biomarkers can be preserved in distinctive pockets in seemingly barren areas, even if sections are metamorphosed in parts. Most Centralian sections seem empty. Yet, eventually we identified intervals with preserved biomarkers in three drill cores. A detailed investigation of 825 Ma sediments in drill core Mt Charlotte-1 revealed maturity variations that are most likely due to hydrothermal influence and in turn control the hydrocarbon preservation. Sediments might appear metamorphosed after localized, subtle alteration by hydrothermal fluids but protected intervals can still contain biomarkers. The same might be true for Archaean sediments and we might still find those protected intervals with indigenous biomarkers that allow us to glimpse the early life on earth.

Melt extraction from the mantle has been shown to be driven by channelization favoured by melting of source heterogeneities possibly leading to melt accumulation both on- and off-axis[1]. Here we present a REE study of clinopyroxene in residual abyssal peridotites showing that melt extraction rarely follows fractional melting trends at the typical dredge haul scale (<1 km). Instead local melting trends reveal REE pattern evolution usually driven by infiltration of relatively enriched melts frequently accompanied by melt accumulation. Estimated compositions of the infiltrating melts suggest they derive by mildly enriched heterogeneities and/or grt-field melting of a DMM-like source[2]. Observed data can be modelled by open system melting in which instantaneous melts represent the mix of influxing and locally generated melts and where the melt exceeding the critical mass porosity escapes. The out coming scenario shows a possible intermittent behaviour where melting switches from near-fractional to near-batch. In open system melting this behaviour is imaged by fluctuations of the critical porosity/degree of melting value, where the critical mass porosity is a proxy of the accumulated melt fraction.

Lower thermal settings and spreading rates could favour the retention of the compositional trends associated to fluctuations in the melting regime. Accordingly, we found that the statistical distribution of REE trends accounts for a more effective melt accumulation and enriched melt infiltration along the South West Indian Ridge with respect to the Mid Atlantic Ridge.

Lifestyles of the slow and lonely – A story told by sulfate isotopes

B. BRUNNER*

Center for Geomicrobiology, Department of Bioscience, Aarhus University, Aarhus, Denmark (*correspondance: benjamin.brunner@biology.au.dk)

Sulfur is a bio-essential component of any living organism and is at the same time heavily used by microbes for energy yielding (dissimilatory) processes. Dissimilatory sulfate reduction (DSR) coupled to the oxidation of organic matter plays a pivotal role in the re-mineralization of organic matter in marine sediments, which is owed mostly to the high concentration of sulfate in the overlying seawater relative to other energetically more favorable electron acceptors such as oxygen or nitrate. When sulfate is depleted methane becomes the end product of organic matter degradation. At the interface between downward diffusing sulfate and upward diffusing methane (sulfate-methane transition) sulfate is consumed by sulfate reduction coupled to the anaerobic oxidation of methane (SR-AOM). In the classic view, DSR is thus confined to the main sulfate zone, a redox zone where the more favorable electron acceptors are absent.

Thanks to new findings, such as i) the discovery of sulfate generation in methanic sediments well below the main sulfate zone, the so-called "cryptic sulfur cycle" (Holmkvist *et al*. 2011 [1]), ii) the discovery that SR-AOM utilizes biochemical pathways different from DSR (Milucka *et al*. 2012 [2]) and iii) the discovery of sulfur oxidation by cable bacteria (Pfeffer *et al*. 2012 [3]) our view on sedimentary sulfur cycling has recently been dramatically changed and broadened.

Stable sulfur and oxygen isotope tracing of these newly discovered processes in the environment and in the rock record could provide us with compelling insights into these so far unrecognized biochemical sulfur transformations. However, there is a complication/caveat: we do not yet know what isotope signature we should look for.

I hypothesize that the sulfur and oxygen isotope effects of oxidative and reductive sulfur cycling mediated by microbes in the deep biosphere – organisms that live a slow and lonely life – may provide clues to what isotope signatures to expect.

Chances and challenges in applying sulfur-oxygen isotope relationships of sulfate to studying sulfur cycling in engineered environments

B. BRUNNER*

Center for Geomicrobiology, Department of Bioscience, Aarhus University, Aarhus, Denmark (*correspondance: benjamin.brunner@biology.au.dk)

In recent years, our understanding of the mechanics of sulfur and oxygen isotope fractionation by sulfate reducing microorganisms has drastically improved. Based on multi-step sulfate reduction models, we are not only able to answer the question of why there is a large range of sulfur and oxygen isotope fractionations related to this process, but can also predict sulfur-oxygen isotope fractionation relationships (Brunner *et al*. 2012 [1]).

While this progress is exciting, it does not automatically provide new insight into sulfur cycling in perturbed ecosystems, such as polluted soils and aquifers, sites where sulfate reduction can be anthropogenically stimulated as a means to remove or sequester organic and inorganic contaminants.

Such systems are often highly complex because they are affected by different modes of microbial and abiotic sulfur cycling (i.e., reductive and oxidative processes), non-steady state conditions, and by mixing of waters from different sources. Additional challenges arise from the fact that monitoring of such systems is typically restricted to a few sampling points and cannot be carried out continuously.

Despite these complications, by comparing the combined sulfur and oxygen isotope signature of sulfate to the predicted sulfur-oxygen isotope relationship for sulfate reduction, it should be possible to tease out crucial information about sulfur cycling in engineered ecosystems, such as the extent to which sulfate is reduced, and the extent to which reduced sulfur is re-oxidized to sulfate.

Approaches where natural abundance sulfur and oxygen isotope signatures are combined with the outcome of stable isotope tracer experiments and evaluated by comparison to numerical models yield promising results. However, such modeling efforts can only yield meaningful conclusions when appropriate model assumptions are chosen. The evaluation and definition of these assumptions may prove to be the biggest challenge in deciphering sulfur cycling in engineered environments.

The stability of uraninite in anaerobic conditions: Revisiting Cigar Lake and Oklo Natural Analogues

JORDI BRUNO[1] AND KASTRIOT SPAHIU[2]

[1]Amphos 21, Barcelona, (jordi.bruno@amphos21.com)
[2]SKB, Stockholm, (kastriot.spahiu@skb.se)

Recent experimental work indicates that the UO_2 matrix of the spent nuclear fuel is stable under the reducing conditions imposed by hydrogen evolution as the result of the anaerobic corrosion of the steel components.

There are a number of hypothesis concerning the mechanisms and processes that activate the hydrogen molecule on the UO_2 surface. They basically imply the catalytic effect of some of the metallic particles in the fuel, as well as the potential activation by alpha and gamma radiation.

One of the key remaining issues is to which extent the proposed mechanisms operate in the long-term of a spent fuel repository.

In this context, it is interesting to discuss to which extent the extensive information generated in previous natural analogue projects can be used to verify or falsify some of the mechanistic hypotheses. In particular , what concerns to the long-term validity of the proposed mechanisms.

Among the various natural analogue studies of uranium deposits, the Cigar Lake ore deposit in Canada and the Oklo fossile reactors in Gabon, provide some interesting observations and data under anaerobic conditions that may illustrate some of the key stabilisation processes under hydrogen conditions.

The objective of this presentation will be to discuss the findings of the Cigar Lake and Oklo natural analogue projects which may contribute to enlighten some of the open questions regarding the long-term validity of the so-called hydrogen effect in the stability of the UO_2 spent nuclear fuel matrix.

Although it is well known that organisms contribute significantly to the weathering process and to the distribution of elements within continental environments, the degree to which biota actively drive weathering versus the degree to which organisms benefit from nutrients released during largely inorganic weathering processes remains unknown [1]. Furthermore, the relative influence of different organisms on key elemental cycles, such as the base cations, especially Ca and Mg, is poorly understood. To address these questions, we have carried out a series of geochemical studies on semi-hydroponically cultured trees (*Pinus sylvestris*, *Acer saccharum* and *Betula alleghaniensis*) grown with appropriate mycorrhizal symbionts (ectomycorrhizal or arbuscular) in different geologic substrates (carbonate versus granitic) and under different nutrient regimes (N-limited in high or low nutrient supply and P-limited). Plant tissues across these biogeochemical experiments were studied for elemental abundances and Pb, Ca and Mg isotopic signatures. We conclude from our approach that: (1) Pb isotopes effectively complemented elemental signatures to identify key mineral dissolution reactions (e.g., the dissolution of phosphate phases in P-limited cultures); (2) for the same geologic substrate, arbuscular fungus did not demonstrate substantive phosphate dissolution; (3) the presence of mycorrhizal fungus significantly affected the Ca and Mg elemental distributions within the plant tissues but had a more muted effect on the Ca isotopic distributions; (4) foliar and root tissues recorded distinctive isotopic compositions (e.g., differences up to 0.6 ‰ $\delta^{44/40}$Ca); and (5) ectomycorrhizal symbioses may drive Mg isotopic variations during weathering.

Nanomagnetism of iron meteorites identified by X-ray photo-emission electron microscopy

J.F.J. BRYSON[1], J. HERRERO ALBILLOS[2], F. KRONAST[3], G. VAN DER LAAN[4], S.A.T. REDFERN[1] AND R.J. HARRISON[1]

[1]Deparment of Earth Sciences, University of Cambridge, UK (correspondence: jfjb2@cam.ac.uk)
[2]ICMA, University of Zaragoza, Spain (Julia.Herrero@unizar.es)
[3]BESSY II, HZB, Berlin, Germany (florian.kronast@helmholtz-berlin.de)
[4]Diamond Light Source, UK, (Gerrit.vanderlaan@diamond.ac.uk)

Paleomagnetic signals stored within meteorites are a key source of information regarding many processes in the early solar system. An increasing body of traditional macroscopic paleomagnetic evidence suggests that, while molten, the liquid cores of the meteorite's parent asteroids generated magnetic fields with comparable strength to those of present-day Earth. We have applied nanoscale magnetic techniques to show that spinodal nanostructures within meteorites are capable of providing a time-resolved record of dynamo activity of their parent asteroids - analogous to that stored in the Earth by the spreading ocean crust - across the first 100-200 Ma of the asteroid's history, a prospect that could revolutionise our understanding of asteroid development.

To investigate this magnetic nanostructure, we performed the first meteoritic high-resolution X-ray photo-emission electron microscopy experiments (on the Tazewell IIICD iron metoerite). The results display a distinct and unique magnetic pattern that is dependent on the underlying nanostructure. The spinodal region, termed the 'cloudy zone' (CZ), extends 2-10μm and is composed of tetrataenite (chemically ordered FeNi) embedded in a hitherto unobserved ordered Fe_3Ni phase. Within this region, a complex magnetic state is observed with interlocking groups of all three tetrataenite twin orientations. A clear variation in the amount of each twin with increasing lateral distance across the CZ (decreasing age of tetrataenite formation) is also present. The observed magnetisation pattern bears resembalence to anti-phase boundaries (APBs) that appear to coarsen over time. These results provide both a fundamental understanding of the CZ magnetisation as well as the magnetic state formed in the absence of a dynamo field. Chondritic meteorites can carry an analogous magnetic remanence that was influenced by a dynamo field. By comparing the results in this study to those of chondritic meteorites, we will identify both the direction and magnitude of this dynamo field over a 100 Ma period.

Experimental and theoretical study of malachite solubility in ammonia aqueous solutions

T.M. BUBLIKOVA, T.V SETKOVA* AND V.S. BALITSKY

Institute of Experimental Mineralogy Russian Academy of Science, Acad. Osipian st, 4, Chernogolovka, Russian Federation, (*correspondence: tmb@iem.ac.ru)

Experimental and theoretical investigations of malachite solubility was carried out as a part of search of copper carbonates (malachite and azurite) crystallization conditions [1]. The solubility of $CuCO_3$•$CuOH_2$ was studied experimentally in 1.0, 2.0, 3.0*m* ammonia solutions at temperatures of 25, 50, 75°C. Moreover, thermodynamic calculations were performed for indicated ammonia concentrations and temperatures. An initial material was placed in ampoules made of thermal-resistant glass, then it was grouted of ammonia solution of necessary concentration. The ampoules were sealed and placed into thermostat. After equilibration the ampoules were unsealed, and an aliquot part of the solutiton was filtered and analysed for a total copper content. We used the volumetric iodometric method for estimation of the copper content and a total CO_2 content in solution was determined using AN-7529 express-analyzer.

The experimental study have shown that the equilibrium copper content increases with ammonia concentration increasing and decreases with temperature rise in ammonia solutions. Malachite is unstable in the ammonia solution at given condition it decomposes with tenorite forming, that was confirmed by the thermodinamic calculations. The results of the thernodimamic calculations and the experimental study of malachite solubility has a satisfactory fit in general (Fig.1).

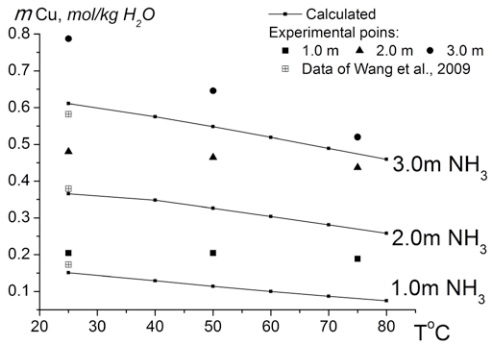

Figure 1: Calculated and experimental data of malachite solubility as functions of NH_3 concentration and temperature.

[3]Dep. Inf. Mat Aplicada i Estadistica, Univ. of Girona (E)

Compositional data consist of vectors whose components are parts of some whole. Their statistical analysis performed in the real Euclidean sample space is not able to capture their features. Data in fact lies in a constrained space, called simplex, where to characterise the difference, or changes from one composition to another, specific operators have to be considered. In this contribution, perturbation, the group operator working in the geometry of the simplex sample space [1], is applied to analyse the differences in the chemical composition of the solutes of stream waters at European scale [2]. The analysed data are from the FOREGS (Forum of European Geological Survey) [3] database. New numerical and graphical tools are proposed to investigate the behaviour of elements or chemical species in the constrained space. In the FOREGS project, running stream waters were collected from the small, second order, drainage basins (<100 km^2) at the same site as the active stream sediments. Starting from the analytical results matrix, chemical data of some selected variables, considering their geochemical affinity, were ranked by taking into account their conducibility values. Perturbation vectors from one composition to the subsequent one are calculated and results plotted in variation diagrams. The aim is to investigate the relative behaviour of the ions and chemical species, as well as the effect of weathering and dilution processes on a European scale, by considering the use of calculus ooperators working in the simplex geometry. The possibility to model processes at the base of the distribution of chemical elements/species (e.g., presence of trends depending on space, chemostatic behaviour, …) is also explored.

X-ray study of high pressure induced densification of lithium disilicate glass

S. BUCHNER[1]*, A. S. PEREIRA[1,2], J. C. DE LIMA[3] AND N. M. BALZARETTI[1]

[1] LAPMA, Physics Institute, UFRGS, ZIP 91501-970, Brazil (*correspondence: silviobuchner@gmail.com), (naira@if.ufrgs.br)
[2] Escola de Engenharia, UFRGS, ZIP 91501-970, Brazil (altair@if.ufrgs.br)
[3] Centro de Ciências Físicas e Matemáticas, UFSC, 88040-970, Brazil (jcardoso.delima@gmail.com),

Lithium disilicate glass ($Li_2O.2SiO_2$) is a very interesting vitreous material, because, besides several important technological applications (e.g. biomaterial to produce prostheses and implants), shows a large difference between the Tg and Tc values. This is important for the investigation of the crystallization mechanism on vitreous phases, as it allows the independent study of the nucleation and growth stages. In this work, we have investigated the effect of high-pressure processing in the induction of structural changes in the amorphous phase. This can give place to polyamorphism and/or to the generation of possible seeds for a crystalline phase nucleation. Using toroidal type high-pressure chambers, glass samples were processed at 2.5 GPa, 4 GPa, 6 GPa and 7.7 GPa at room temperature. X-ray diffraction using synchrotron radiation was used to obtain the radial distribution functions in order to follow the structural changes at different ranges. Compared to a pristine sample, the main change observed for the samples processed up to 6 GPa was associated to the distortion of the SiO4 tetrahedra, as already observed in the literature. However, for the sample processed at 7.7 GPa, we have identified a drastic change in the RDF, which points for the production of a different amorphous phase with a local structure closer to that observed for the Li_2SiO_3 crystalline phase.

The ^{15}N and ^{18}O isotopic signature of abiotic reduction of nitrite by iron

CAROLYN BUCHWALD[1]* COLLEEN HANSEL[2] DAVE JOHNSTON[3] AND SCOTT WANKEL[4]

[1]266 Woods Hole Road, Woods Hole, MA 02543 (*correspondence: cbuchwald@whoi.edu)

[4]266 Woods Hole Road, Woods Hole, MA 02543 (swankel@whoi.edu)

Evidence is mounting for the importance of interactions between reactive intermediates of multiple elemental cycles. For example, while previous studies have shown that oxidation of Fe(II) by nitrate (NO_3^-) and nitrite (NO_2^-) – a reactive intermediate of both reductive and oxidative N cycling processes - the controls on these reactions in the environment are poorly understood. Moreover, the N product of abiotic, anaerobic NO_2^- reduction by Fe(II) can include nitrous oxide, nitric oxide, ammonium or dinitrogen gas – yeilding a myriad of implications for the fate of N across all types of ecosystems. Furthermore, we posit that these types of reactions may represent an important control on the dual NO_3^- and NO_2^- isotopic composition in Fe-rich, reducing environments low in organic carbon (e.g., aquifers). To date, however, the kinetic isotope effects of these processes remain uncharacterized.

Here we present the first investigation of the dual isotope systematics of abiotic NO_2^- reduction by Fe(II) under a variety of environmentally relevant pH values and reactant concentrations. In our experiments, we observe a rapid decrease in NO_2^- postively correlated with Fe(II) concentrations, followed by a second phase of slower NO_2^- reduction, possibly implying the involvement of secondary Fe(II)/Fe(III) mineral phases. Samples were collected for NO_2^- N and O stable isotope analyses in order to determine the isotope effects associated with abiotic NO_2^- reduction by Fe(II). As many studies suggest a potential for anaerobic, abiotic nitrogen transformations coupled with iron cycling, the N and O isotope effects determined here will be helpful for using dual isotopes of nitrite (and nitrate) to decipher the biogeochemical fate of N in host of important environments including soils, sediments, wastewater treatment plants and aquifers.

Evaluation of atmospheric flows of mineral substances in the south-eastern coast of Baikal Lake during the last 200 years

V.V. BUDASHKINA* AND V.A. BOBROV

Institute of geology and mineralogy SB RAS, Koptyug Pr. 3, Novosibirsk 630090, Russia (*coresspondence: budash@igm.nsc.ru)

Oligotrophic bogs are capable to maintain in its peat deposits the mineral substance of atmospheric aerosol. The study of microelement composition of the stratified horizons allows us to determine the changes in chemical content of atmospheric aerosol under the influence of natural and anthropogenic factors in the historical time.

Dulihinskoe bog, located in the territory of the Baikal State Biosphere Reserve, took our attention as an object for retrospective geochemical monitoring. In the center of the bog (N 51°31', E 105°00') there were selected the top 47 cm of the 4-meter peat packs of 11000 years old [1] in the form of the monolith with square 22 * 13 cm^2. There was defined naturally radioactive (^{210}Pb, ^{226}Ra, ^{232}Th, ^{238}U, ^{40}K) and anthropogenic (^{137}Cs, ^{241}Am) elements in ash samples and held AAS determination of 19 chemical elements.

^{210}Pb permanently come from the atmosphere and disintegrated over the time in peat horizons, whereas ^{137}Cs, ^{241}Am supply was only in 1953- 1963 years [2]. Distribution of ^{210}Pb and ^{241}Am allowed us to allocate layers, formed in the 19-20th centuries, for which we calculated the rates of accumulation of mineral matter [3] (see table).

Table1: The average annual speed of substance inflows.

The obtained values of the elements proceedings on the earth surface for the second half of the XX century are commensurate the values for the Western Siberia, subjected to anthropogenic impact. Flows of mineral substances remain rather high and in the middle ages, that we explain by the proximity of mountain systems (Khamar-Daban) [3], in contrast to the Western Siberia with its arid environments.

Evaluation of the Lu-Hf-in-lawsonite geochronometer

G. BUDDE* AND E.E. SCHERER

Institut für Mineralogie, Westfälische Wilhelms-Universität Münster, Corrensstraße 24, 48149 Münster, Germany (*correspondence: gerrit.budde@uni-muenster.de, escherer@uni-muenster.de)

We present an evaluation of the recently established Lu-Hf-in-lawsonite geochronometer [1, 2] including a reliable separation procedure for lawsonite. For this purpose, four blueschist-facies rocks from the island of Syros (Greece) and the Tavşanlı Zone (Turkey) were investigated, covering a wide range of different lawsonite occurrences, as well as pseudomorphs after lawsonite.

The developed mineral separation procedure involves magnetic and density separation as well as hand-picking and yields almost pure lawsonite concentrates. Lutetium and hafnium concentrations as well as Hf isotope ratios were obtained by using a selective digestion technique for mineral separates [3], a single-column separation procedure for element purification by ion exchange [4], and high-precision isotope ratio measurements by MC-ICP-MS.

Lawsonite showed elevated Lu concentrations of 0.4-1.4 ppm and very low Hf contents of <0.1 ppm. The $^{176}Lu/^{177}Hf$ values of 0.6-4.4 are comparable to other minerals used for Lu-Hf geochronology and allow obtaining well-defined isochrons and precise ages. However, bulk pseudomorphs after lawsonite do not preserve the Lu and Hf concentrations or Hf isotope ratios of the former lawsonite after its prograde breakdown. The obtained Lws-WR age (50.3±1.2 Ma) of the HP-LT metamorphism on Syros is in excellent agreement with previously published geochronological and geothermobarometric studies [e.g., 3]. The Lws-WR ages (87.5±1.1 Ma, 89.3±1.8 Ma) of two metabasites from the Tavşanlı Zone provide the first tight constraints on the onset of HP-LT metamorphism in this region [e.g., 5].

Due to its relatively small P-T stability range and elevated Lu/Hf values, lawsonite is well suited for Lu-Hf geochronology and has proven to be a powerful tool to date high pressure-low temperature metamorphic events. This geochronometer allows dating lawsonite growth in rocks of the lawsonite-blueschist subfacies and offers numerous prospects for investigating different subduction zone processes.

Method for measurement of argon isotopes in helium flow for K/Ar geochronology

S.Y. BUDNITSKIY[1], A.V. IGNATIEV[2] AND T.A. VELIVETSKAYA[3]

[1]Far Eastern Geological Institute FEB RAS, Russia, Vladivostok. (Budnitskiy_Serg@mail.ru)
[2]FEGI FEB RAS, Russia. (Ignatiev@fegi.ru)
[3]FEGI FEB RAS, Russia. (Velivetskaya@mail.ru)

We present a method for the measurement of argon isotopes in the potassium-argon (K/Ar) geochronology of the controller based on the series (conventional) mass spectrometer operating in dynamic mode. Installation for the quantitative measurement of isotopes of argon laser system has a sample preparation, based on CO_2 laser, where the isolation and purification of argon is in a continuous flow of ultra-pure helium. The system is based on the mass spectrometer MAT-253 (Thermo Scientific), equipped with the detectors Faraday m/z 36, 37, 38, 39 and 40 and use chromatographic purification system.

Instead of the traditional method of isotope dilution of 38-argon method is comparing the signals from the sample gas and gas-standard of known isotopic composition (by air) before and after the measurement of each sample. This method, using of air argon as the reference gas has an advantage over conventional method of 38-Ar isotopic dilution : there is no contamination of the sample by $^{40}Ar/^{36}Ar$ incoming from a tracer 38-argon ; a quantity of argon in a dose is invariable for several years; availability of 40Ar/36Ar air ratio monitoring by reference gas.

A sample is placed in multi-charge chamber. The chamber contains 10 to 35 samples, depending on the size. To release the argon from a sample the CO_2 laser is used. The gas that was released during fusing, primary treatment is the U-shaped trap, placed in liquid nitrogen. Next argon helium flow passes through the capillary chromatography column for purification of argon from contaminants.

This method is an alternative method for measuring the argon isotopes in the static mode and can be used for analysis of radiogenic argon $N * 10^{-12}$ g with the same sensitivity and accuracy, the method is simpler and more reliable. Small amounts of radiogenic argon extracted from geological samples require high stability, low backgrounds, minimal content of argon in the blank experiment, and high sensitivity of the isotope ratio mass spectrometer.

The presented method has been successfully used to solve geological, geochronological and geoarsheological issues.

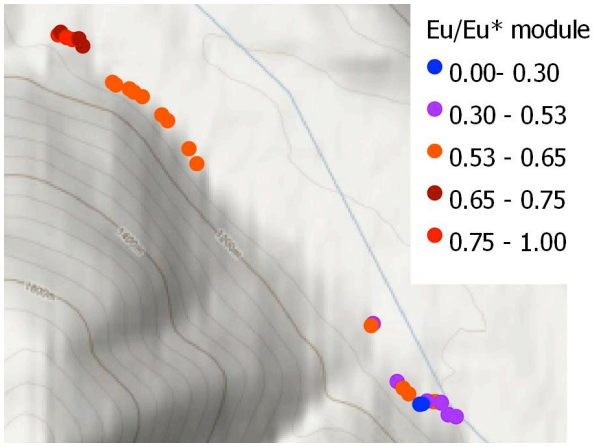
GIS mapping of geological features of the Baikal mountain region based on integrated geochemical indicators

A. BUDYAK AND A. PARSHIN

Vinogradov Institute of Geochemistry SB RAS, Russia. (correspondence: budyak@igc.irk.ru)

Baikal mountainous area and Kodar-Udokan structural-formational zone are perspective to search for deposits of noble and rare metals. The studies 2009-2012, the authors created a spatial database including geological and geochemical information for the various objects of the ore zone. For the analysis of this information is required to cartographically display more than 50 layers of geochemical data. Classical overlay-based GIS representation of such a large data set makes it difficult visual analysis. The authors found some mathematical and geographical distribution patterns of useful component that allowed the development of mathematical tools, providing spatial calculations of integrated geochemical indicators - "modules", which are comprehensive indicators of certain ore-forming processes. Form of their representation is suitable for GIS-mapping.



For example, the figure shows the calculation of Eu/Eu * module. Well traced the species change of rocks of different stratigraphic levels, to lying on each other. This approach provides the ability to make geological conclusions, based on visual analysis of only 5-7 data overlays. Created GIS software can serve as a navigator geochemical exploration.

Quantifying more than half the periodic table of elements in uranium ore concentrates: Results of the IAEA's interlaboratory comparison 2011-2012, and two new quality control materials

S. BÜRGER, S. BOULYGA AND M. PEŃKIN

International Atomic Energy Agency, A-1400 Vienna, Austria

The analysis of trace elements (impurities) in uranium ores and uranium ore concentrates (UOC), as well as uranium-bearing materials in general, is performed in a variety of fields, e.g., in geochemical research, for quality control in the production stream converting uranium ores to nuclear fuel, as material signatures in nuclear forensics, or in international nuclear safeguards to support the verification of States' declarations.

An interlaboratory comparison on the quantification of impurities in UOC was organized by the International Atomic Energy Agency (IAEA) during 2011-2012. The goal was to probe the analytical capabilities of the participating laboratories (i.e., the current state-of-the-practice), to determine any differences between laboratories and their potential causes, to identify chemical elements that are problematic and/or difficult to analyse with established analytical techniques, and to assess the measurement uncertainties. Six participating laboratories were tasked to quantify 69 impurity elements – more than half the periodic table – in two different UOC materials. The impurity concentrations, normalized to uranium content, covered more than six orders of magnitude. Inductively-coupled plasma mass spectrometry (ICPMS) was the main technique used by the participating laboratories.

A summary of the comparative results will be presented, highlighting the current state-of-the-practice in ICPMS analytical approaches as employed by the participants. Lessons learned, including the identification of polyatomic interferences and the challenge of estimating measurement uncertainties, will be discussed. This interlaboratory comparison yielded consensus values for the two UOC materials. They are suitable for future use as quality control materials addressing gaps in the availability of reference materials for impurity elements in uranium-bearing materials.

C, N_2, Ar, He in fluid inclusions in a garnet lherzolite from Oasis Jetty, East Antarctica

BUIKIN A. I.[1], VERCHOVSKY A. B.[2], SOLOVOVA I. P[3] AND KOGARKO L. N.[1]

[1]Vernadsky Institute of Russian Academy of Sciences, Moscow, Russia (bouikine@mail.ru)
[2]The Open University, Milton Keynes, UK
[3]IGEM RAS, Moscow, Russia

To reveal the sources and evolution of fluids during mantle metasomatism under East Antarctic we have carried out optical, thermobarogeochemical and Raman-spectroscopy investigations and studied C, N, Ar and He isotopic and elemental ratios in Px separate from Oasis Jetty garnet lherzolite by stepwise crushing method. The sample contains abundant fluid inclusions of different generations and compositions. The applied methods have revealed two majoir fluid activity stages. The early stage fluid inclusions are characterized by the most complex composition and high pressures (>13 kbar), some of them reach 10 μm in size. The late stage fluid inclusions (P ≥ 5-7 kbar) are all very small (2-5 μm and less); the predominance of CO_2 over all other gases is dramatically increasing in them, as well as the role of H_2O.

Our isotope-geochemical data confirm the existance of these two fluid sources. The high pressure and larger size fluid inclusions of the early stage mostly opened at the very first crushing steps are characterised by low C/N_2, C/Ar, N_2/Ar (31-34) ratios, typical for the MORB chilled glasses $\delta^{13}C$ values in CO_2 (-4.7‰), heavy nitrogen (up to +2.05±0.28‰), and slitely elevated $^{40}Ar/^{36}Ar$ ratios (up to 533±10). The late stage fluid inclusions being progressively opened with increasing number of strokes are better characterized by the gases extracted at the very last crushing steps. They have 2-3 orders of magnitude higher C/N_2 and C/Ar ratios, close to the atmospheric N_2/Ar (86) and $^{40}Ar/^{36}Ar$ ratios (down to 370±7), lighter $\delta^{13}C$ values in CO_2 (down to -6.8 ‰), and nitrogen (-2.28±0.26 ‰). The elemental and isotope ratios ($N_2/^{40}Ar$, $^{40}Ar/^{36}Ar$, $^4He/^{40}Ar$*, $\delta^{15}N$) correlate to each other, reflecting mixing between early and late stage fluids. The letter is the result of a mixture between MORB-type mantle and atmospheric components. The early stage fluids could be the result of more complex mantle-crustal components mixture with high proportion of atmosphere derived argon. Typical for intra-plate mantle xenoliths element fractionation due to fluid-melt partitioning is observed in low $^4He/^{40}Ar$* ratios (0.1-0.7, compared to the mantle production ratio of 1.5-2). Some isotope fractionation (for N_2 and C) also could not be excluded.

Radiometric ^{81}Kr dating reveals 120,000 year old ice at Taylor Glacier, Antarctica

C. BUIZERT[1]*, D. BAGGENSTOS[2], W. JIANG[3], R. PURTSCHERT[4], V.V. PETRENKO[5], E. J. BROOK[1], Z.-T. LU[3], P. MÜLLER[3] AND J. P. SEVERINGHAUS[2]

[1]CEOAS, Oregon State Univ., Corvallis OR 97331, USA (*correspondence: buizertc@science.oregonstate.edu)
[2]SIO, University of California, San Diego, CA 92093, USA
[3]Argonne National Laboratory, Argonne, IL 60439, USA
[4]University of Bern, CH-3012 Bern, Switzerland
[5]University of Rochester, Rochester NY 14627, USA

Ancient ice can not only be obtained from deep ice cores, but also at ice sheet margins and blue ice areas (BIAs) where it outcrops due to local ice dynamics and surface ablation [1]. Determining an accurate chronology for BIA records is more challenging than for regular ice cores. Here we report the first successful ^{81}Kr radiometric dating of ancient BIA ice. ^{81}Kr ($t_{1/2}$ = 229 ka) is produced cosmogenically in the upper atmosphere, and the modern ^{81}Kr-Kr ratio is used as the reference. Krypton is not reactive and is well mixed in the atmosphere. In principle ^{81}Kr dating can be used to date ice in the 50ka to 1Ma age range; it is widely applicable as all glacial ice contains trapped air; it does not require a continuous or undisturbed ice stratigraphy; and it does not suffer from *in situ* cosmogenic production in the ice (as is the case for ^{14}C). The large sample size requirement (> 40 kg) has precluded its use in ice core science to date.

Air was extracted on site from four 250 kg polar ice samples obtained from 5-15m below the surface of Taylor Glacier, McMurdo Dry Valleys, Antarctica. Krypton was separated from the air and dated using Atom Trap Trace Analysis [2]. The ^{81}Kr radiometric ages agree with independent stratigraphic dating techniques within 6ka. ^{85}Kr analysis shows that the samples are free of modern air contamination, validating our sampling strategy and experimental methods. We show that ice from the Eemian interglacial (130-120ka BP) can be found in abundance near the surface of Taylor Glacier. Our study paves the way for reliable radiometric dating of ancient ice in BIAs and margin sites, greatly enhancing their scientific value as archives of old ice and meteorites. As sample size requirements continue to decrease, ice core ^{81}Kr dating might be a future possibility.

Geochemical types of tantalum and niobium mineralization from the rare metal-bearing granites and pegmatites of the Western Mongolia

O.V. BUKHAROVA* AND A.A. BAEVA

Tomsk State University, Tomsk, Russia (getina@ggf.tsu.ru)

Tantalum-niobates are typical representatives of the rare metal mineralization in Middle Paleozoic and Early Mesozoic pegmatites and amazonite granites of the Western Mongolia (the Mongol Altay, the Charchirinsk upland region). They are seen in association with beryl in pegmatites, and characterized by heterogeneous composition of minerals, which is displayed in variability of Ta/Nb ratio from 0,3 to 3,0 from the grain core to boundaries. Tantalum-niobates in granites have microscopic sizes (2,5-150 μm) and are present as poikilitic inclusions in rock-forming minerals of protolitionite-microcline-albite paragenesis, more rarely in accessory fluorite and magnetite. At the same time, tantalum niobite grains are chemically homogeneous, but differ from each other by various Ta/Nb (0,03-0,4) and Ti/Nb (0,02-9,8) ratio, as well as significant content of LREE (20 wt.%), Sn (up to 4 wt.%). Ilmenorutile (Ta+Nb from 3-12 to 23-27 wt. %), columbite-(Mn), columbite-(Fe), tantalite-betafite, betafite, and polycrase were defined in the rocks studied. These elements show acid-base conditions for mineral-forming environment. Changing alkalinity during pegmatite crystallization is noted within some zonal minerals as transforming of columbite into ilmenorutile (Ta/Nb-1,3; Ti/Nb-3,1), and tantalite-betafite (Ta/Nb 2,5 до 3,0; Ti/Nb-0,5). Iron content coefficient (FeO/MnO) varies significantly (non-manganese up to 8,6), at the same time late non-manganese varieties are often enriched in REE, U, or Y. Despite the similar patterns of chemical evolution defined for granitoid melts, the differences in U, Pb, Y, F, W, Sn, LREE, Th contents observed in tantalum-niobates of pegmatite and amazonite granites indicate heterogeneous crust magma sources and their intrusion under different paleogeodynamic conditions.

A "non-CHONS" stable isotope view on weathering and hydrology

T.D. BULLEN

U.S. Geological Survey, Menlo Park, CA 94025, USA
(correspondence: tdbullen@usgs.gov)

The past 15 years have witnessed a remarkable expansion in our knowledge of "non-CHONS" stable isotope systems (that is, stable isotope systems other than Carbon, Hydrogen, Oxygen, Nitrogen or Sulfur). The metals and metalloids studied thus far having demonstrated isotopic variability span the periodic table, vary from major to trace element abundances in natural materials and have a broad range of geochemical affinities and behaviors. Highly precise stable isotope measurements for these elements are currently obtainable using multi-collector ICPMS, TIMS and SIMS instruments, potentially allowing efforts at cross-platform validation of data accuracy. In surveying the rapidly building literature on the topic, it is becoming increasingly clear that we have spent as much effort determining why the "non-CHONS" stable isotope systems behave as they do in our laboratory and field-based experiments (e.g. the focus on distinguishing equilibrium from kinetic isotope effects, biotic from inorganic controls, natural from anthropogenic signals) as we have in using the isotopes to tell us unique information about the systems we are studying. Now that we have gained a broad understanding of isotope fractionation mechanisms and their implications for natural isotope distribution patterns for at least some of the non-CHONS stable isotope systems, the time is ripe to concentrate on demonstrating and promoting the utility of these systems for understanding Earth processes such as physical and chemical weathering and their intricate linkage to hydrology. In the broad realm of weathering and hydrology research, the greatest attention has been directed to the Li, B, Mg, Ca, Fe and Si stable isotope systems and each seems to have found one or more particular testable niches (e.g., Li isotopes to distinguish silicate from carbonate weathering, Ca isotopes to discern biotic influences on global flux calculations, Fe isotopes as a (paleo)redox proxy and potential biosignature). More recently, additional redox proxies such as U, Tl and Cr stable isotopes and tracers of biological processing such as Sr and Ba stable isotopes have been explored. This presentation will highlight some new directions for linked weathering/hydrology research in which the non-CHONS stable isotope systems can play a key role, as well as some of the challenges remaining as we move these stable isotope systems from "non-traditional" to the mainstream.

The societal impact of urban and environmental geochemistry: Pathways to success

T.D. BULLEN

U.S. Geological Survey, Menlo Park, CA 94025, USA
(correspondence: tdbullen@usgs.gov)

Taken together, the fields of urban and environmental geochemistry represent a relatively new, broad and important branch of geochemical research. Given the obvious, that urban and environmental geochemistry focuses on where people live, it could be expected that ever-expanding scientific endeavors in this field would have considerable impact on policy, regulatory decision making and public perception of the importance of sound science. There are many examples of "success stories", where sound science and pursuasive communication has resulted in changes in the way we do business as a society (e.g. implementing limits on stack emissions in response to the effects of acid rain, regulating sulfate loading in the Everglades to limit methylation of mercury, encouraging green space in urban areas to lessen impacts of hydrologic rerouting). On the other hand, the ongoing debate over the validity of climate change science as a driver of policy implementation reveals that scientists are not always the best communicators when forced to defend their science to non-scientists. Because science is complicated and has a language all its own that can be difficult for non-scientists to grasp, it is important that research results having policy implications be carefully communicated to the people charged with making and implementing policy. In this regard, the scientific logic and approach must be beyond question and implemented without bias toward a particular position or outcome. However, possible outcomes should be anticipated and potential solutions considered. Results need to be communicated at an understandable level, keeping the message on target but as simple as possible. And scientists need to stand their ground, letting the science speak for itself. Perhaps most importantly, we need to make sure that policy experts are invited to participate in our scientific conferences and workshops and to make presentations outlining their needs and perspectives, thus allowing the conversation to begin early in the process of developing regulatory policy. This presentation will showcase a collection of success stories in which urban and environmental geochemical research has influenced policy at the local, national and international level, and will attempt to identify the underlying pathways to that success.

The structure and emplacement of the Rocche Rosse obsidian lava flow, Lipari, Aeolian Islands, Italy

L. BULLOCK*, R.GERTISSER AND B. O'DRISCOLL

School of Physical and Geographical Sciences, Keele University, Keele, Staffordshire, ST5 5BG, UK (*correspondence: l.a.bullock@keele.ac.uk)

Satellite image analysis and field-based, structural mapping of the Rocche Rosse obsidian lava flow, Lipari (Aeolian Islands, Italy) provide important constraints on silicic lava flow emplacement and deformation.

High resolution satellite imagery of the flow surface identifies large scale structures, such as two well-developed flow lobes, pronounced lineaments which are prevalent along the extent of the flow, and prominent crescent-shaped ridges (ogives), typically 20-80 m in length, spaced 10-15 m apart and parallel to flow-frontal margins. Structural features measured include a pervasive foliation (flow banding), small-scale folding and flow ramps. Small-scale folding is superimposed on larger scale folding (parasitic folds), and recumbent folding is also apparent. In general, data on the ground match with structures inferred from the satellite image. Foliation and lineation orientation patterns vary across the flow, generally showing a flow parallel and flow perpendicular arrangement. A prevailing stretching lineation follows the large-scale lineament features, and surface folding is traceable along the surface ridges identified by the satellite image.

It is proposed that the structural features outlined formed over a progressive series of flow emplacement and deformation, from initial extrusion, constrictional and compressional forces, polyphase folding, brittle deformation and devitrification in the solid state. Variations in structural trends relate to areas of complex and progressive deformation. The Rocche Rosse lava flow is emplaced endogenously as a continuous, composite lava flow, with two flow lobes (formed as the advancing flow divided).

We show that while structures associated with obsidian lava flows are remarkably complex, they are inherently related and form sequentially during continuous effusion, preserve evidence for progressive deformation, and can be used to decipher mechanisms of obsidian flow emplacement, in unprecedented detail.

Setschenow constants for prediction of salting-out of petroleum hydrocarbons in brines

A.S. BURANT[12], G.V. LOWRY[12] AND A.K. KARAMALIDIS[1,2]

[1]National Energy Technology Laboratory-Regional University Alliance (NETL-RUA), Pittsburgh, PA 15236 USA
[2]Department of Civil and Environmental Engineering, Carnegie Mellon University, Pittsburgh, PA 15213 USA (Correspondance to akaramal@andrew.cmu.edu)

Large scale implementation of carbon capture, utilization, and storage (CCUS), as well as the management of produced water associated with energy production activities (including extraction of natural gas from shale plays) requires a better understanding of the interaction of petroleum hydrocarbons with highly concentrated brines. It is not well known how very high levels of electrolytes influence the solubility of hydrocarbons. The objective of this study is to determine if existing salting-out paramters, called Setschenow constants, are applicable to predict the decrease in aqueous solubility of petroleum hydrocarbons, including polycyclic aromatics hydrocarbons (PAHs), phenols, and thiophenes, due to high levels of electrolyes in concentrated oilfield brines.

We measured the solubility of important organic compounds found in oilfield brines, such as naphthalene. Electrolytes studied include NaCl and $CaCl_2$, which are the most common salts found in oilfield brines (*1*). The organic compounds in the brines were extracted with a 100 μm polydimethylsiloxane (PDMS) fiber using solid phase microextraction (SPME) and analyzed by an Agilent 6890 gas chromatograph coupled with a flame ionization detector (GC-FID).

We hypothesize that existing Setschenow constants measured at lower ionic strengths (e.g. up to seawater) will also predict the salting-out effect at very high ionic strengths expected in brines (5M) for a range of compound classes of interest. These results are expected to have implications for enhanced oil recovery, CCUS, and any other industry that deals with produced waters. If valid, the solubility of these compounds can be readily modeled using existing Setchenow constants determined at lower ionic strengths.

New sedimentary $^{231}Pa/^{230}Th$ records from the northern Brazilian margin over MIS3

P. BURCKEL[1]*, C. WAELBROECK[1], J.-M. GHERARDI[1] AND S. PICHAT[2]

[1]Laboratoire des Sciences du Climat et de l'Environnement, Gif sur Yvette, France (*correspondence: pburckel@lsce.ipsl.fr, Claire.Waelbroeck@lsce.ipsl.fr, Jeanne.Gherardi@lsce.ipsl.fr)

[2]Laboratoire de Sciences de la Terre, Ecole Normale Supérieure de Lyon, Lyon, France (spichat@ens-lyon.fr)

The region of the North Eastern Brazilian margin is of major interest in the study of the variability of the oceanic circulation because of the large part of the Atlantic Meridonal Overturning Circulation passing through it. Moreover this region has been extensively studied leading to a good chronostratigraphical framework of its marine sediment cores [1, 2, 3]

In order to better understand the changes in the AMOC during Heinrich events, we chose to study two sediment cores at different water depths so that we may observe not only changes in the intensity of circulation of the water masses influencing the cores, but as well changes in the vertical extent of these water masses.

Due to the difference in particle reactivity of ^{231}Pa and ^{230}Th in the water column sedimentary $^{231}Pa/^{230}Th$ (Pa/Th) may be used to record changes in AMOC [4, 5], although particle scavenging may bias the signal in certain cases. In the case of the western equatorial Atlantic region, the sedimentary Pa/Th vertical profile measured on recent sediment is consistent with a dominant role of the AMOC, rather than particle scavenging, thereby demonstrating that Pa/Th can indeed be used to monitor changes in water mass overturning rates in that region [6].

We present new Pa/Th records from the last glacial and in particular from periods of rapid circulation changes associated with Heinrich events. Our results show that the Pa/Th ratio changed along with other proxies such as the benthic foraminifer carbon isotopic ratio.

Halogen abundances of the martian mantle

RAY BURGESS*[1] , JULIA ANN CARTWRIGHT[2] AND JUSTIN FILIBERTO[3]

[1]SEAES, University of Manchester, Oxford Rd, Manchester, M13 9PL, UK, (ray.burgess@manchester.ac.uk)

[2]Division of Geologicaland Planetary Sciences, California Institute of Technology, Pasadena, CA91125, USA.

[3]Geology Department, Southern Illinois University, Carbondale, IL 62901, USA

The surface of Mars is relatively halogen-rich, with a mean Cl concentration of 0.49wt% [1]. In contrast, little is known about the martian interior halogen composition, nor how it compares with the Earth's mantle, where subduction recycling of halogens occurs. Insights into the halogen composition of the martian interior can be gained from shergottite meteorites, whose parental magmas were formed by partial melting of the martian mantle. North West Africa (NWA) 6234 is an olivine phyric shergottite [2], it is unweathered [2] and relatively undegassed, having likely crystallised at depth within the martian upper crust [3]. We analysed bulk and mineral separates of NWA6234 to determine Cl, Br and I by extension of the ^{40}Ar-^{39}Ar technique. *In-vacuo* crushing experiments released only 2-10% of total halogens indicating that the major fraction is located within solid phases (melt inclusions or phosphate minerals). Stepped heating yielded constant molar Br/Cl = 0.0040 ± 0.0004 and I/Cl = 0.000358 ± 0.000046 throughout the release, indicative of a single halogen-bearing component. With the total Cl released (59 ppm), and assuming the basalt formed by 10-20% partial melting of the source, this implies a martian mantle Cl composition that is very similar to the terrestrial MORB source (4 ppm Cl [4]) and in agreement with a recent finding based on apatite chemistry [3]. However, NWA 6234 Br (560 ppb) and I (110 ppb) concentrations indicate a mantle enrichment of between 4-8 times and 30-70 times respectively relative to MORB. Thus, the martian interior is either less degassed of its heavy halogens compared to the Earth, or it formed with higher abundances.

Constraining the modern riverine sulfur isotopic budget

ANDREA BURKE[1], JESS F. ADKINS[1], JÉRÔME GAILLARDET[2], R. MAX HOLMES[3], JAMES W. MCCLELLAND[4], BERNHARD PEUCKER-EHRENBRINK[5], LAURA F. ROBINSON[6], ROBERT G.M. SPENCER[3] AND BRITTA M. VOSS[5]

[3]Woods Hole Research Center, USA
[4]University of Texas at Austin, USA
[5]Woods Hole Oceanographic Institute, USA
[6]University of Bristol, UK

The sulfur cycle has an important influence on global climate, for instance through weathering and aerosols, and is intricately linked to both the carbon and oxygen cycles. However, many aspects of the modern sulfur budget are not well understood. We present new $\delta^{34}S$ and $\delta^{33}S$ measurements on aqueous sulfate from more than 50 rivers from different geographical and climatic regions. These data were measured by a new MC-ICP-MS method that requires only 5 nmol of sulfate [1], with typical isotopic uncertainties of only 0.1‰. Combined with previously published sulfur isotope data, more than 44% of the world's freshwater flux to the ocean is involved in this estimate of the global riverine sulfur isotopic budget. We find a large range in the $\delta^{34}S$ of rivers, both temporally and spatially. Riverine $\delta^{34}S$ values range from -2‰ to 14‰, and some smaller tributaries lie outside of this range. Time series data from the Fraser River show a seasonal cycle in the $\delta^{34}S$ of more than 3‰.

Combined with major anion and cation data, the sulfur isotope data allows us to tease apart the relative contributions of different processes to the modern sulfur budget, including the oxidative weathering of pyrites, the weathering of sedimentary sulfates, and anthropogenic influences. These data yield important insights into the modern sulfur cycle and the weathering of sulfur bearing minerals, and are first order terms in balancing the modern sulfur isotopic budget. The large range of sulfur isotopic ratios in modern rivers also has implications for our intepretation of the past changes in the sulfur isotopic composition of seawater. Secular changes in the lithologies exposed to weathering through time could play a major role in driving the variations in $\delta^{34}S$ in seawater over the Phanerozoic.

Aerosols and plant leaf surfaces

J. BURKHARDT[1]*, M. HUNSCHE[2] AND S. PARIYAR[1]

[1]INRES-Plant nutrition group, University of Bonn, Bonn, Germany (*correspondence: j.burkhardt@uni-bonn.de)
[2]INRES- Horticultural science group, University of Bonn

Aerosols are ubiquitous and have always been part of the atmospheric environment of plants, while plant surfaces are probably the major terrestrial sink of fine aerosols. The deposition of fine aerosols is strongly influenced by leaf surface micro-roughness. Given constant aerosol concentrations over evolutionary timescales, plants have possibly developed leaf surface adaptations to control particle accumulation. Depending on the respective environment, plants may benefit from the nutrient content of aerosols or use them as a humidity sensor, but deposited particles may also promote leaf pathogen growth or act as desiccants [1].

The impact of aerosol exclusion on plant water relations was investigated in greenhouses, using pine seedlings, sunflower, and bean plants. Transpiration rates were lower for plants grown in filtered air (FA) than for plants grown in ambient air (AA) [2], and further effects were observed under increased CO_2 concentrations. Humidity fluctuations within an environmental scanning electron microscope (ESEM) caused a differentiated expansion of salt particles on leaf surfaces. This was related to the position of the ions within the Hofmeister series and reflected their impact on water surface tension [3]. A similar order applied when the drought tolerance of plants was measured after spraying leaves with different types of salt solutions.

Our results show that aerosol deposition strongly contributes to the ecophysiological reactions of plants, both in natural and in polluted conditions. Strong global increases of fine dust concentrations due to anthropogenic pollution or land use change may thus have world-wide impacts on plant communities.

The redox state of diamond-forming fluids: Constraints from Fe^{3+}/Fe^{2+} of garnets

A.D. BURNHAM*, S.C. KOHN, C. POTISZIL, M.J. WALTER, G.P. BULANOVA, A.R. THOMSON AND C.B. SMITH

School of Earth Sciences, Wills Memorial Building, Bristol, BS8 1RJ, UK. (*correspondence: ab12908@bristol.ac.uk)

Inclusions in diamonds afford unique glimpses of deep lithospheric and asthenospheric minerals, allowing the thermal and chemical state of the mantle to be characterised. In the host diamonds, the concentration of N, $^{15}N/^{14}N$ and $^{13}C/^{12}C$ all give information about the origin of fluids in the mantle. The speciation in these fluids is uncertain in many cases, with considerable debate as to whether CH_4 or CO_2 is the predominant component in the transport of C [1,2]. As methane and carbon dioxide (or carbonate) represent reduced and oxidised C respectively, this redox signature should also be reflected in other mantle minerals.

Redox conditions of diamond-forming regions in the mantle can be found from the Fe^{3+}/Fe^{2+} ratio of garnets as determined by X-ray absorption near edge structure (XANES) spectroscopy [3]. We present Fe^{3+}/Fe^{2+} data for several suites of diamonds: Argyle, Western Australia; Juina, Brazil; Diavik, Canada; Udachnaya, Russia; Murowa, Zimbabwe. For the first three sets of diamonds, both eclogitic and peridotitic garnets were analysed, allowing the two distinct diamond-forming events to be contrasted.

For suites in which olivine and orthopyroxene coexist with garnet, the fO_2 of the diamondiferous paragenesis was calculated following [2].

Our work aims to couple the fO_2 information obtained from garnets to trace element data and (for the eclogitic samples) their oxygen isotope ratios, allowing the geochemical evolution of the slab during subduction to be robustly constrained.

Patterning in stress: A new insight into the development of phase separation in metamorphic rocks

PAMELA C. BURNLEY

University of Nevada, Las Vegas, Department of Geoscience, (Burnley@physics.unlv.edu)

The development of slatey cleavage, foliation and compositional banding in metamorphic rocks is understood to result from mass transport by either dissolution or diffusion under the influence of a non-hydrostatic stress field. Explanations for how compositional differentiation initiates generally rely on high shear strains to orient pre-existing features or folding of a pre-existing foliation to form a pattern of fold noses and limbs that lead to preferential dissolution. Based on 2D plane-strain finite element models, I propose a new low-strain mechanism for the formation of compositional banding based on mass transport between local regions experiencing varying levels of differential stress caused by the variations in the single crystal elastic properties of the constituent minerals in the rock. Models were constructed of 2574 hexagonal grains each containing 48 elements. Grains were assigned elastic properties appropriate for crystals of quartz, feldspar and mica in a variety of crystallographic orientations. Compression results in local variations in the differential stress that are ~ 30% of the total load and a pattern minimum stresses that mimics foliation. This pattern could serve as a template for mass transport of the most mobile chemical components leading to phase separation.

Figure 1: Model is shortened by 0.2% vertically. The size of grains in each view is given by the yellow hexagons. Compresion is negative.

Coupling of arsenic mobility to microbial sulfate reduction in subsurface environments

EDWARD D. BURTON, SCOTT G JOHNSTON AND DAVID ADAMS

Southern Cross GeoScience, Southern Cross University, PO Box 157, Lismore, New South Wales, Australia; (ed.burton@scu.edu.au)

Arsenic mobilisation is an important concern in many subsurface soil, sediment and groundwater systems. In such systems, microbial sulfate reduction often dominants anaerobic electron flow, thereby leading to the production of aqueous sulfide and the formation of iron sulfide species. However, the effects of microbial sulfate reduction on arsenic mobility in subsurface environments is poorly constrained.

This presentation describes some of our recent discoveries illustrating how arsenic mobility is coupled to subsurface sulfur biogeochemistry, especially to the production of sulfide via microbial sulfate reduction.

Our approach has been to conduct a series of integrated studies on this topic, including (i) abiotic mono-mineralogical batch experiments[1], (ii) advective-flow column experiments[2] and (iii) anoxic incubation experiments with complex arsenic-contaminated floodplain soil.

The results show that microbial sulfate reduction can have contradictory consequences for arsenic; either substantially retarding or greatly enhancing arsenic mobility. These vastly divergent outcomes depend on multiple factors, including hydrological flow conditions, the presence or absence of elevated porewater sulfide concentrations, aqueous arsenic concentrations and reaction time.

The fact that sulfate reduction can both retard or enhance arsenic mobility, depending on environmental conditions, represents a serious challenge for managing arsenic-contaminated systems. In particular, it implies that great caution must be exercised when aiming to exploit natural sulfur biogeochemistry as a strategy for mitigating arsenic mobility in subsurface environments.

Unradiogenic lead in the mantle source of Mid-Ocean Ridge Basalts

KEVIN W. BURTON[1] AND IAN J. PARKINSON[2]

[1]Durham Isotope Centre, Department of Earth Sciences, Durham University, Durham. DH1 3LE, UK (kevin.burton@durham.ac.uk)

[2]Bristol Isotope Group, School of Earth Sciences, University of Bristol. BS8 1RJ, UK (Ian.Parkinson@bristol.ac.uk)

The isotope composition of lead (Pb) in the silicate Earth appears to be far too radiogenic for evolution from chondritic (primitive solar system) material over 4.57 billion years, the so-called 'Pb paradox'. Loss of Pb to the core, storage in the lower continental crust, or arrival in a late veneer, have all been proposed as mechanisms to account for this imbalance, but each remains problematic. Recently is has been suggested that the upper mantle itself, could serve as a complementary reservoir of unradiogenic Pb, sourced in either sulphide [1] or silicate minerals [2], but it remains unclear why such material is not sampled by oceanic basalts.

This study presents high-precision double-spike Pb isotope data for the consituent phases of Mid-Ocean Ridge Basalts (glass, plagioclase and sulphide) from a single ridge segment from the FAMOUS region (36°50'N) on the Mid-Atlantic ridge. Separated phases from individual samples show a remarkable variation in Pb isotope composition, greater than that seen for all basalts previously analysed from this ridge segment. These variations cannot be explained by assimilation of seawater altered oceanic crust or by contamination from the Azores hotspot, both of which carry a radiogenic Pb isotope signature. Rather they indicate mixing between an early extremely unradiogenic melt, from which plagioclase crystallised, sourced by mantle material showing long-term depletion of U, and a later more radiogenic melt sampled by the glass. Elemental data suggest that the mantle source of this early melt was small-degree, water-rich with a garnet-like signature. Therefore, at least, some of the Pb in the Earth's mantle that is sampled by MORB is unradiogenic and complements the radiogenic composition seen in many oceanic basalts and continental crust. It remains to be seen whether variations in ^{207}Pb-^{206}Pb seen in other ridge segments reflect a similar contribution from an unradiogenic source.

Reconciling ground deformation and degassing activity at Mt. Etna

M. BURTON[1], P. ALLARD[2] AND G. PUGLISI[3]

[1]IPG Paris (pallard@ipgp.fr)
[2]INGV PI, Via della Faggiola, 32, 56126 PISA (burton@pi.ingv.it)
[3]INGV-OE, piazza Roma 2, 95125 Catania, Italy, (*correspondence: puglisi-g@ct.ingv.it)

Etna exhibited both steady inflation and persistent degassing between 1993 and early 2001. The source volume increase associated with the inflation was deduced using a Mogi model to fit the observed deformation pattern. The mass of SO2 released in the same period was produced by degassing magma. With knowledge of the original S concentration dissolved in the parental magma it is possible to determine a minimum mass of magma consistent with the observed gas emissions. This mass of degassed magma is more than two orders of magnitude larger than the mass of erupted magma in the same period, implying that the degassed magma was endogenously stored within the volcano. We wish to test the hypothesis that this stored degassed magma was responsible for the observed inflation of the edifice.

An initial comparison of the volume of degassed magma compared with the change in volume associated with the ground deformation reveals that the former is 4 times greater than the latter, suggesting that our hypothesis is incorrect. However, when a combination of magma compression and viscoelastic deformation of hot crustal material heated is taken into account, the deformation source volume changes can, instead, be successfully reconciled with the volume of degassed magma.

Thus, it appears we cannot exclude the hypothesis that during the observation period ground deformation at Etna was controlled by permanent storage of degassed magma in the plutonic zone 5-8 km beneath the surface. In this manner, the constant magma supply indicated by the persistent degassing of the volcano produces a quiescent accumulation of degassed magma at the roots of the volcano, slowly pressurizing and inflating the edifice.

A global volcanic CO_2 flux inventory

MICHAEL BURTON[1], GEORGINA SAWYER[2] AND DOMENICO GRANIERI[3]

[1]INGV Pisa, Italy, (burton@pi.ingv.it)
[2]MetOffice, UK, (georgina.sawyer@metoffice.gov.uk)
[3]INGV Pisa, Italy, (granieri@pi.ingv.it)

CO_2 degassing from the Earth has played a fundamental role in controlling climate through a series of feedback mechanisms including CO_2 removal through weathering in proportion to the magnitude of greenhouse warming produced by CO_2 in the atmosphere. Constraining CO_2 emission rates from volcanic sources would allow an improved understanding of the relative magnitude of natural and anthropogenic outputs today, shed light on the role of volcanic emissions in the pre-industrial climate and improve our knowledge of carbon recycling though the mantle. Notwithstanding this, the flux of CO_2 from the Earth remains poorly quantified. The uncertainty in our knowledge of this critical input into the geological carbon cycle led Berner and Lagasa (1989) to state that it is the most vexing problem facing us in understanding that cycle.

To date, CO_2 fluxes have been directly measured on approximately 23% of the world's actively degassing subaerial volcanoes. Here we present an updated assessment of the global volcanic CO_2 flux, based on these empirical observations. We use this inventory to extrapolate to an estimate of global volcanic CO_2 emissions, and to investigate rates of carbon recycling though the mantle.

Disequilibrium melting recorded in isotopic and trace element compositions of a pulsed granitoid, Mt Kinabalu, Borneo

ALEX BURTON-JOHNSON[1], COLIN G MACPHERSON[1], ROBERT HALL[2] AND GEOFF M NOWELL[1]

[1]Department of Earth Sciences, Durham University, Durham, UK, DH3 1LE. (alexander.burton-johnson@durham.ac.uk)
[2]Southeast Asia Research Group, Department of Earth Sciences, Royal Holloway university of London, UK, TW20 0EX

Geochemical heterogeneity in silicic systems - and by implication heterogeneities in the continental crust - can be derived from the melting processes or variations in their deep source regions. Mixing and assimilation during the ascent and emplacement of silicic plutons are also invoked to explain observed heterogeneities. We present a range of geochemical data collected from the zoned granite and granodiorite pluton of Mt Kinabalu in NW Borneo to provide insight into the role of such processes in development of this body and the timescales over which they occur.

The Mt Kinabalu pluton is an isolated post-orogenic intrusion. It formed following the Miocene orogenic inversion event recorded in NW Borneo that emplaced attenuated S. China crust, similar to the attenuated Mesozoic tonalitic crust of the South China Sea, beneath the region's ophiolitic basement. Post-orogenic extension and rapid related uplift (aided by the fast erosion rates of the region) led to dehydration partial melting of the tonalitic crust.

Melting resulted in the emplacement of five petrographically distinct major units at ~ 0.2Ma intervals, the first four between 7.85 and 7.22Ma (U-Pb in zircon, [1]. The oldest unit possesses significantly more radiogenic Sr and Pb and less radiogenic Nd isotope ratios than later units. This could be interpreted as evidence for isolated derivation or mixing of multiple sources, or contamination of one source. However, there is no accompanying variation in $\delta^{18}O$ or trace element ratios. More substantial trace element variation is displayed between the later units that display little isotopic contrast with one another. Instead, we interpret the isotopic data and trace element variations as the result of progressive disequilibrium melting under increasingly warmer conditions of the same region of relatively homogeneous crustal source rocks.

Transport of carbon colloid supported nano zero-valent iron

JAN BUSCH[1]* AND SASCHA OSWALD[2]

[1]Institute for Earth and Environmental Science, University of Potsdam, Potsdam, Germany (*correspondence: jan.busch@uni-potsdam.de)
[2]Institute for Earth and Environmental Science, University of Potsdam, Potsdam, Germany (sascha.oswald@uni-potsdam.de)

Nano zero-valent iron (nZVI) is an emerging technology for *in situ* groundwater remediation. Due to its high reactivity, nZVI is able to dechlorinate organic contaminants and render them harmless. Carbo-Iron is a newly developed composite material consistiong of activated carbon colloids (d_{50} = 0.6-2.4 μm) that are doted with nZVI particles. These particles combine the sorption capacity and mobility of activated carbon colloids and the reactivity of nZVI. Results from column tests and a two dimensional laboratory aquifer test system are presented: Column tests using columns of 40 cm length were filled with porous media. A particle suspension was pumped through the system. Results show, addition of a polyanionic stabilizer such as Carboxymethylcellulouse (CMC) is required to enhance mobility. Ionic strength and pH concentrations in an environmental relevant range do not interfere significantly with transport, but particle size was found to be crucial. Another experiment was performed in a two dimensional aquifer test system. The test system contains a sand filled container with an inner size of 40 x 5 x 110 cm and seven ports on each side. A constant flow of water was applied from the left to the right side through all ports and the middle port was fed with a Carbo-Iron suspension. Results show transport through the laboratory aquifer within few exchanged pore volumes, and breakthrough of ~60% of the injected concentration of Carbo-Iron at the outlet. Deposits of immobile Carbo-Iron were found to be decreasing with distance from the injection port. No gravity effects were observed. Results suggest high mobility of carbon supported nZVI under environmental relevant conditions. Carbo-Iron might be helpful to deliver nZVI into contaminated aquifers. Here 1D and 2D results support the design of a field test and application of Carbo-Iron for nZVI delivery.

Delta ^{34}S of discrete authigenic framboidal pyrite: A powerful palaeo-indicator for barrier estuary closure

*RICHARD T BUSH[1], LEIGH A SULLIVAN[1], MICHELLE L BUSH[1] AND NICK WARD[1]

[1]Southern Cross GeoScience, Southern Cross University, 1 Military Rd, Lismore, NSW, 2480, Australia (*Correspondence: richard.bush@scu.edu.au)

This study relates microscale isotopic variability of discrete authigenic framboidal pyrite to the palaeo-depositional conditions of a barrier-estaury on the east coast of Australia. Light sulfur isotope (^{32}S) is preferentially utilised in microbially mediated pyrite formation, with the extent of fractionation dependent on how 'open', or 'closed', the depositional environment is to a replenishing supply of sulfate. An open system has an unlimited supply of the preferred, light sulfate during sedimentation. In a closed system, all of the sulfate, light and heavy (i.e.^{34}S), is eventually utilised.

Intact sediment cores were collected from the lower Richmond River floodplain. Sampling encompassed the last 6000 years of sedimentation, extending to a depth of 5m. The isotope composition of discrete pyrite framboids was determined on select layers using secondary ion mass spectrometry[1] The striking result was an anomalous enrichment of ^{34}S in pyrite at 1.7- 2.5m depth, with $\delta^{34}S$ peaking at +50‰. (-20 to +10‰ is the normal range for estuarine sediments). The microscale isotopic variability between pyrite framboids in this layer had a broad distribution, consistent with that theoretically predicted by Seal and Wandless[1] for a 'closed' system. This study provides the first demonstration of microscale sulfur iostope frequency distribution as a tool for identifiying in the sediment record, periods of closure of barrier estuaries or other coastal embayments to marine influences.

Nitrogen cycle in the late Archean ferruginous ocean

VINCENT BUSIGNY[1], OANEZ LEBEAU[1], MAGALI ADER[1], BRYAN KRAPEZ[2] AND ANDREY BEKKER[3]

[1] IPG-Paris and Univ. Paris Diderot, Sorbone Paris Cité, France
[2]Institute for Geoscience Research, Curtin Univ., Australia
[3]Dpt of Geological Sciences, Univ. of Manitoba, Canada

The Hamersley Group comprises a Late Archean sedimentary succession, which is thought to record the prelude to the atmospheric oxygenation in the early Paleoproterozoic, the so-called Great Oxidation Event (GOE) dated at around 2.4 Ga. In the present work, drill-core samples of sedimentary rocks from the upper Mount McRae Shale and Brockman Iron Formation deposited before the GOE at ~2.5 Ga were examined in order to characterize the environments and ecosystems prevailing during their deposition. We analyzed the concentration and isotopic composition of C in carbonate and organic matter, bulk N content and its isotopic composition, and major element concentrations.

The $\delta^{13}C_{carb}$ values, ranging from -10.7 to -3.2 ‰, reflect diagenetic carbonate precipitation, with markedly negative values representing Fe-rich carbonates formed via organic matter mineralization with ferric oxyhydroxides. In contrast, $\delta^{13}C_{org}$ and $\delta^{15}N$ values record primary isotope signatures derived from ancient living organisms. The near constant $\delta^{13}C_{org}$ values at -28.7 ± 0.8 ‰ are interpreted as reflecting photoautotrophs thriving on a large pool of dissolved inorganic carbon. Whole-rock N analyses show highly variable concentration, between 1.3 and 785 ppm, and $\delta^{15}N$ values range between 0.4 and 13.4 ‰. Inverse relationship between $\delta^{15}N$ and $\delta^{13}C_{carb}$ values characterize the Brockman Iron Formation. We propose that N and C biogeochemical cycles were connected via Fe redox processing in the water column and in sediments of the Late Archean ocean. Several models coupling N and Fe biogeochemical cycles are considered involving different redox states of the water column. Similar positive $\delta^{15}N$ values might record very different N biogeochemical cycles under fully anoxic, redox-stratified, and oxic conditions of the ocean. Interpretation of N isotopes in terms of N biogeochemical cycle thus requires independent constraints on the redox structure of the ocean.

Relating grain-scale weathering observations to catchment-scale critical zone morphology

H.L. BUSS[1]*, O.W. MOORE[1], M. CHAPELA LARA[1], M. SCHULZ[2] AND A.F. WHITE[2]

[1]School of Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK (*h.buss@bristol.ac.uk, o.moore@bristol.ac.uk)

[2]US Geological Survey, Menlo Park, CA 95025, USA (mschulz@usgs.gov, afwhite@usgs.gov)

It is well known that chemical weathering and porosity development in rocks are coupled. It is less understood how these coupled processes, which operate at the mineral grain-scale, impact larger-scale phenomena such as watershed fluxes and regolith and landscape development. The Bisley watershed in the Luquillo Critical Zone Observatory (Puerto Rico) is formed on meta-volcaniclastic bedrock that is blanketed by thick regolith comprised of thin soil overlying saprolite embedded with corestones. Saprolites here are highly leached; as a result, most chemical weathering fluxes are attributed to weathering at the bedrock-saprolite interface. However, corestone surfaces and fractures represent multiple "bedrock-saprolite interfaces" distributed throughout the regolith profile. Here we compare macro-scale weathering profiles (m's thick) in saprolite to micro-scale (mm's thick) profiles across corestone weathering rinds. Buried corestones were sampled by drilling two boreholes (27 and 37 m deep).

Weathering fronts are most dramatic in rinds on corestone fractures and surfaces. For example, ~40% of the protolith Mg is lost over ~3 mm of rind. In saprolite hand-augered to a corestone at 9.3 m, the final 20% of protolith Mg is lost over ~8 m. These fronts may reflect different weathering mechanisms as well as different weathering rates.

Pyrite crystals, which are of low abundance in these rocks and not detected by powder XRD, were identified by SEM in many of the thin sections and appear to be the first mineral to weather. In thin sections containing fracture surfaces, pyrite is associated with increased porosity and dissolving plagioclase and amphibole grains. These associations are observed even cm's inboard of the visible weathering rinds. Although present only in trace amounts, pyrite appears to play a controlling role in secondary porosity development and weathering of the major minerals by releasing sulfate during oxidative dissolution, creating micro-environments of highly reactive, low pH fluid within the corestones. Where the bedrock contains more pyrite, corestones may split and shrink more readily, affecting mineral weathering rates and larger-scale phenomena such as the size and distribution of corestones within the regolith profile.

Organic geothermometery: Defining metamorphic grades in coal

J.P. BUSSIO[1], R.J. ROBERTS[1] AND N.J. WAGNER[2]

[1]Department of Geology, University of Pretoria, South Africa; (John.Bussio@up.ac.za)

[2]School Chemical & Metallurgical Engineering, University of Witwatersrand, Johannesburg, South Africa, (Nicola.Wagner@wits.ac.za)

Mechanical and chemical variations created during metamorphism of organic compounds is an overlooked subject. The fundamentally structure of organic materials is analogous to that of inorganic materials such as minerals and rocks, but the organic equivalents are subject to generalities of both structure and chemistry which has left the interpretation of the metamorphic products of these materials vague and unspecific. The physiochemical nature of the coal and its macerals is currently quantified using thermogravimetric proximate analysis, which aims define the properties of coal through the quantification of moisture %, ash%, volatile% and calorific value.

A new approach was used to analyse the physicochemical character of the coal in close proximity to a dolerite intrusion on both macro and micro scales. Macro scale structural analysis has been done through the use of a Schmidt hammer to quantify *in situ* physical variation within the coal. In conjunction, conventional proximate analysis was employed to estimate the "chemical" variations within the coal. It was expected that the fundamental link between chemical properties and physical character would be displayed in the resultant analysis, but no direct link between the proximate analysis and Schmidt hammer results was observed, either as a result of inherent heterogeneity of coal or a display of the short comings of the proximate analysis method. In light of these results, a new approach was applied by using pressurized liquid exctraction (PLE) combine with two dimensional gas chromatography time of flight mass spectrometry (GC*GCTOFMS) to produce detailed chromatograms of the organic constituents of the coal. The technique will allow quantification of the organic components within the coal. Due to the variable sensitivity of organic compounds to fluids, salinity, pressure and temperature, it may be possible to define not only the temperature of metamorphism but also the type *i.e.* metasomatic or contact and also the salinity of the metamorphic fluid.

Characterization of a novel multicopper oxidase that oxidizes Mn(II)

C. N. BUTTERFIELD[1], A. V. SOLDATOVA[2], T. G. SPIRO[2] AND B. M. TEBO[1,*]

[1] Division of Environmental and Biomolecular Systems, Oregon Health and Science University, Beaverton, OR 97006, USA (*correspondence: tebo@ebs.ogi.edu)
[2]Department of Chemistry, University of Washington, Seattle, WA 98195

Manganese (Mn) oxides are some of the most reactive mineral phases in the environment and control the distribution and bioavailability of a variety of toxic and essential elements. Mn oxide minerals are believed to be formed either directly or indirectly through the activities of microorganisms. The ability to oxidize Mn in several phylogenetically distinct groups of bacteria has been attributed to enzymatic oxidation by a multicopper oxidase (MCO), a family of proteins that utilize multicopper atoms in catalytic sites to oxidize their substrates, typically Fe(II) or phenolic compounds, in one electron reactions. Here we report the expression, purification and partial characterization of a Mn-oxidizing MCO and preliminary efforts to reconcile the one-electron chemistry of MCOs with the two-electron oxidation of Mn(II) to Mn(IV) oxide.

Many attempts have been made to purify the suspected Mn-oxidizing MCO from a variety of different bacteria, including species of *Pseudomonas, Leptothrix, Pedomicrobium* and *Bacillus*. In many species of marine *Bacillus* it is the mature spores that oxidize Mn(II). Oxidation occurs on their exosporium, the outermost layer of the spore, encrusting them with Mn(IV) oxides. Previous studies identified the *mnx* genes, including *mnxG*, a putative multicopper oxidase, as responsible for the two-electron oxidation of Mn(II). Its characterization, however, has been hampered by the difficulty in obtaining purified protein. By purifying active protein from the *mnxDEFG* expression construct, we found that the resulting enzyme is a blue (Abs max 590nm) complex containing MnxE, MnxF, and MnxG proteins. The complex oxidizes both Mn(II) to Mn(III) and Mn(III) to Mn(IV) resulting in the formation of a Mn(IV) oxide mineral. X-ray absorption spectroscopy of the Mn mineral product confirmed its similarity to Mn(IV) oxides generated by whole spores or purified exosporium. With the purification of active Mn oxidase, we will be able to unravel the mechanism of Mn oxidation and broaden our understanding of Mn oxide mineral formation and the bioinorganic capabilities of MCOs.

Inventing the Phanerozoic biological pump - and inducing Snowball Earth

N. J. BUTTERFIELD

Department of Earth Sciences, University of Cambridge, Cambridge, UK CB2 3EQ (njb1005@cam.ac.uk)

Export production in the modern oceans is dominated by relatively large/biomineralizing eukaryotic phytoplankton, often accelerated by animal-mediated repackaging in the form of fecal pellets, appendicularian houses and carcasses. Prior to the evolution of animals, and the co-evolutionary radiation of photosynthetic eukaryotes, the biological pump would have worked in a fundamentally different fashion. The transition between these two alternate states appears to have begun in the mid-Neoproterozoic (Tonian/Cryogenian), and achieved a recognizably Phanerozoic condition in the early (but not earliest) Cambrian.

Modern aquatic ecosystems exhibit marked hysteresis between clear-water eukaryote-dominated conditions and an alternative turbid-water cyanobacterial state, typically mediated by suspension-feeding metazoans. In marine shelf environments, the particular ability of sponges to draw down turbidity-inducing DOC, and actively select for larger more export-prone phytoplankton, imparts a first-order control on the biological pump. This in turn presents the circumstances for a more general exploitation of the water column by eumetazoans, especially bilaterians, leading to multi-trophic food-webs, enhanced ventilation and complex feedback effects on nutrient cycling and export.

Biomarker evidence suggests that Proterozoic export was dominated by cyanobacteria. The first quantitatively significant occurrence of eukaryotic steranes appears shortly before the Cryogenian glaciations, along with a novel suite of eukaryotic microfossils. Although there is no direct fossil record of animals at this time, there is a case for recognizing these changes as a co-evolutionary consequence of newly introduced animal activty. Intriguingly, current molecular clock analyses place the first appearance of simple (sponge-grade) animals in this same mid-Neoproterozoic time-frame.

Changes to the mid-Neoproterozoic biological pump are likely to have induced major increases in oceanic alkalinity, leading to a draw-down of atmopheric CO_2 and potentially triggering Cryogenian glaciation [1]. As such, the pronounced evolutionary, biogeochemical and climatic perturbations of the terminal Proterozoic may all be causally linked to the evolutionary appearance of animals.

Experimental study on interaction of the H_2O-NaCl fluid and model peridotite at 6 GPa

V.G. BUTVINA AND O.G. SAFONOV

[1] IEM RAS, ul.Institutskay, 4, Chernogolovka, Moscow district, 142432, Russia, (butvina@iem.ac.ru)

In order to study the effect of NaCl on the Al_2O_3, CaO, Na_2O-rich H_2O-bearing peridotite transformation at pressures above 3 GPa, we have conducted the experiments on interaction of model peridotite $Fo_{57}En_{17}Prp_{14}Di_{12}$ with the H_2O-NaCl fluid at 6 GPa and 1050-1450^{O}C. Starting materials were mixtures of oxides, $Mg(OH)_2$ and jadeite (mg): SiO_2 (37.04); Al_2O_3 (3.66); CaO (3.62); $Mg(OH)_2$ (48.30); MgO (4.14), $NaAlSi_2O_6$ (3.24). NaCl added at 8 wt. %, that corresponds to mole fraction of X_{NaCl} = NaCl/(NaCl+H_2O) in the fluid 0.05. The present experiments were performed using Pt capsules of 0.02 mm of the wall thickness.

In absence of NaCl in the fluid, the assemblage Fo+Opx+Cpx+Grt was observed in the solidus of the model peridotite, while melting began at about 1200-1300^{0}C. Clinopyroxene shows the increase of jadeite content with increasing temperature. Addition of NaCl reduces melting temperature down to 1050-1100^{0}C. Amount of orthopyroxene and garnet in solidus decreases, the Al content in orthopyroxene decreases, and the jadeite content of clinopyroxene increases in presence of NaCl. These relationships can be described by the following reactions:

(1) 1/4 Mg-Ts + 7/4 En + 1/2 NaCl + 1/4 H_2O = Fo + 1/2 Jd + 1/2 HCl; **(2)** 1/4Prp + 5/4 En + 1/2 NaCl + 1/4 H_2O = Fo + 1/2 Jd + 1/2 HCl; **(3)** 1/4 Grs + 11/4 En + 1/2 NaCl + 1/4 H_2O = Fo + 3/4 Di +1/2 Jd + 1/2 HCl,

(where Mg-Ts – Mg- Tschemack molecule, $MgAl_2SiO_6$ in orthopyroxene, En – enstatite, Fo – forsterite, Prp – pyrope, Grs – grossular, Di – diopside, Jd – jadeite). These reactions show the destabilization of Grt-Opx association in the presence of the H_2O-NaCl fluid.

Thus, addition NaCl in the H_2O-peridotite system does not influence on phase assemblages. However, changing of mineral compositions, mostly increase of the jadeite content in clinopyroxene, results in the decrease of melting temperature. Present experiments further support our conclusion [1] that the effect of interaction of alkali chlorides with silicates in complex peridotite assemblages overpowers the effect of the reduced H_2O activity in the brine fluid [2].

Pyroxene megacrysts in anorthosites: Revealing continental crust-forming processes at Moho depths

G.M. BYBEE[1]*, L.D. ASHWAL[1] AND S.B. SHIREY[2]

[1]School of Geosciences, University of the Witwatersrand, Private Bag 3, WITS, 2050, South Africa (*correspondence: grant.bybee@wits.ac.za)

[2]Department of Terrestrial Magnetism, Carnegie Institute for Science, 5142 Broad Branch Road, Washington D.C. 20015, USA

The mismatch between bulk, intermediate compositions (SiO_2 > 60 %) of the continental crust and predicted basaltic compositions (SiO_2 < 50 %) of mantle-derived melts in crust-forming environments poses a major problem in models of crustal evolution and requires that a mafic component be physically separated from felsic end-members. Although information from the Moho, where some of these poorly understood crustal differentiation processes are thought to occur, is rare, giant (up to 1 m in length), high-pressure (30-40 km) pyroxene megacrysts and comagmatic Proterozoic anorthosite massifs provide insight into crust-mantle differentiation processes at these depths. Using Nd and Pb isotopes, we provide direct evidence for megacryst crystallization in isotopically homogenous magmas that ponded at the Moho (Figure 1). These megacyrsts are 110-130 m.y. older than the comagmatic anorthosites that host them, indicating that the magmatic system is long-lived. In combination with EC-AFC modeling, these data also indicate that Proterozoic anorthosites are derived from melting of the depleted mantle at long-lived Andean-type margins. This evidence for ultramafic cumulate formation illustrates that fractionation of ponded magmas at the Moho is a significant mechanism in crustal differentiation and that the loss of these dense phases to the deeper mantle may represent an important component of crustal recycling.

Geochemistry of trace elements in gas phase of thermal springs

A.YU.BYCHKOV[1,2] , I.YU.NIKOLAEVA[1] AND S.YU.NEKRASOV[1]

[1]Moscow StateUniversity, Moscow, Russia (bychkov@geol.msu.ru)
[2]Vernadsky Institute of Geochemistry RAS, Moscow, Russia

The composition of the thermal waters studied well, but there are only few articles on the geochemistry of trace elements in thermal springs gas phase. Samples of the coexisting liquid and gas phases were collected in thermal springs of Kamchatka peninsula (Russia): Mutnovsky volcano, Uzon Caldera, Geyser Vally, Karymsky volcano. For the sampling of thermal springs specially designed installation was used, wells of Mutnovsky geothermal plant was studied by standard two-phase separator of steam-water mixture. More than 200 samples of coexisting gas and liquid was collected. In samples the concentration of major and trace elements and hydrogen and oxygen isotope composition were determined.

The distribution of high volatile elements, such as boron and arsenic in geothermal wells steam-water mixture was found close to experimental data. However gas phase condensates from thermal springs compared with the liquid phase are enriched with boron and arsenic. This cannot be explained by the equilibrium distribution of components by experimental data. This effect is observed only for thermal springs with superheated steam and correlates with the isotopic composition of the condensates. Perhaps distribution of the superheated steam is determined by the equilibrium at high temperatures in the depth of hydrothermal system. Boron concentration of the condensate can be used to detect the temperature of the gas phase separation and deep boiling. The calculations show good agreement with other geothermometric methods.

For nonvolatile elements, such as REE, Ga and others, distribution coefficients were calculated. Some correlations between the partition coefficients were shown. So, for LREE they are higher than for HREE. These coefficients can't be calculated from thermodynamic data, since the speciation of elements in the gas sufficiently studied. New experiments of solubility in the gas phase can explain distribution coefficients, as shown by the example of gallium. For this element the gas form $Ga(OH)_3$ was determined by gallium oxide solubility in vapor. This experimental data can explain the dependence of the distribution coefficient of the pH of thermal water.

This study was supported by RFBR 12-05-00957.

Subduction modification of Western North America lithosphere - Priming for destruction?

B.L. BYERLY* AND J.C. LASSITER

Jackson School of Geosciences, University of Texas at Austin, Austin, TX, USA (* benbyerly@utexas.edu)

Destruction of continental lithospheric mantle has been recognized to be an important process that may affect the preservation of continental crust [1]. Geochemical data from mantle xenoliths indicate that the majority of the Proterozoic lithospheric mantle beneath the central Rio Grande Rift (RGR) has been convectively removed [2]. Weakening of the lithospheric mantle by addition of metasomatic fluids/melts during Laramide flat-slab subduction followed by increased mantle flow due to Farallon slab roll-back may have triggered this lithosphere destruction. If metasomatism is related to the recent deformation/destruction of the lithosphere beneath the RGR, then mantle metasomatism recorded in remnant lithospheric mantle xenoliths should also be recent.

We examined the trace element and Sr-Nd-Os-Hf isotopic compostion of two suites of lithosphere-derived spinel-peridotite xenoliths from Cerro Chato (Eastern Colorado Plateau margin) and Elephant Butte (central RGR) to constrain the timing and source of mantle metasomatism. $^{187}Os/^{188}Os$ ranges from 0.114-0.126 and T_{RD} ages for the most depleted samples range from 1.6-2.2 Ga; similar to the age of the crust in the region [3]. Both suites of xenoliths are LREE-enriched with variable negative HFSE anomalies relative to REE. $(La/Sm)_N$ in cpx ranges from 2-14 and is correlated with $^{87}Sr/^{86}Sr$ which range from 0.7031-0.7045. ε_{Nd} ranges from 4-10 and ε_{Hf} ranges from 17-304. There is no correlation between $^{143}Nd/^{144}Nd$ and Sm/Nd which suggests metasomatism is recent. This is consistent with young (< 250 Ma) Nd model ages for the xenoliths. A Hf pseudoisochron (using WR Lu/Hf due to equilibration above Lu-Hf closure temperature) yields an age of ~1.0 Ga, which is younger than the Os model ages. The young Hf age may be the result of mixing and partial resetting of Hf isotopes by metasomatism as evidenced by a correlation between 1/[Hf] and $^{176}Hf/^{177}Hf$. The most radiogenic sample has a DM-model age of 1.45 Ga which is close to the age of the overlying crust. Arc-like metasomatic signatures and young Nd model ages are consistent with metasomatism being recent and related to Farallon slab subduction. This may have primed the Colorado Plateau for defomation similar to that observed in the RGR.

Microbial redox cycling of surface Fe-ions in magnetite nanoparticles

JAMES M BYRNE*, NICOLE KLÜGLEIN AND ANDREAS KAPPLER

Geomicrobiology, University of Tuebingen, Germany (*correspondence: james.byrne@uni-tuebingen.de)

Iron is an essential element for all microbes, with different oxidation states by some even used as an electron source or as a terminal electron acceptor. The phototrophic iron-oxidizer *Rhodopseudomonas palustris* TIE-1 uses energy from light and electrons from ferrous Fe(II) for growth and respiration, whilst *Geobacter sulfurreducens* combines the oxidation of organic compounds or hydrogen with the reduction of ferric Fe(III). Iron is almost exclusively observed to be bioavailable to the bacteria as aqueous Fe(II) or in poorly crystalline Fe(III) (oxyhydr)oxides such as ferrihydrite. More crystalline iron minerals such as magnetite or siderite are not usually considered to be biologically active. Magnetite is a mixed valent iron oxide $Fe^{II}(Fe^{III})_2O_4$ which is often seen as the end member product of the microbial reduction of ferrihydrite, though very rarely as a result of microbial oxidation of Fe(II).

This study focuses on the oxidation of superparamagnetic magnetite nanoparticles (~20 nm) by strain TIE-1 and the potential mineralogical changes which result. Through *in situ* magnetic measurements and iron extraction methods, we found that the cells are capable of directly oxidizing the surface of magnetite nanoparticles and thereby decrease the overall magnetic susceptibility of the mineral. This effect occurs in the absence of any aqueous Fe(II) in the growth medium and only magnetite provided as the electron donor. Significantly, this process can be reversed through Fe(III) reduction by *G. sulfurreducens*, which in turn leads to an enhancement of the magnetic properties of the nanoparticles. Changes in magnetic properties were also detected in experiments using magnetite with varying stoichiometric ratios (i.e. Fe^{II}/Fe^{III}). Such effects were not observed in abiotic experiments which did not contain any bacteria.

These results demonstrate that iron ions bound at the surface of crystalline minerals such as magnetite are bioavailable for microbial respiration and can potentially be used as a source of iron in reducing or oxidizing conditions, with the potential to cycle the surface redox properties depending on the conditions present. Such modifications may provide a route towards enhancing remediation strategies that are based on the highly reactive surface of magnetite. These effects may also have implications on paleomagnetic measurements in microbially active environments.

Mass independently fractionated sulfur isotopes in HIMU lavas reveal Archean crust in their mantle source

R.A. CABRAL[1]*, M.G. JACKSON[1], E.F. ROSE-KOGA[2], K.T. KOGA[2], M.J. WHITEHOUSE[3], M.A. ANTONELLI[4], J. FARQUHAR[4], J.M.D. DAY[5] AND E.H. HAURI[6]

[6]Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington DC 20015

Ocean island basalt (OIB) lavas from Mangaia, Cook Islands (Polynesia) exhibit an extreme HIMU (high-μ, or high $^{238}U/^{204}Pb$) signature that has been attributed to melting of ancient recycled oceanic lithosphere within their mantle source. However, the residence time of subducted materials in the mantle is uncertain and model-dependent, and compelling evidence for their return to the surface in regions of mantle upwelling beneath hotspots is lacking. Here we report new SIMS data supporting our original finding of anomalous sulfur isotope signatures indicating mass-independent fractionation (MIF) in olivine-hosted sulfides from 20-million-year-old ocean island basalts from Mangaia (most extreme $\Delta^{33}S$ measurement = –0.34 ± 0.08‰) [1]. Terrestrial MIF sulfur isotope signatures were generated exclusively through atmospheric photochemical reactions until about 2.45 billion years ago. Therefore, the discovery of MIF sulfur in these relatively young OIB lavas suggests that sulfur once at the Earth's surface was subducted into the mantle before 2.45 billion years ago and recycled into the mantle source of Mangaia lavas. These data provide evidence for ancient materials, with negative $\Delta^{33}S$ values, in the mantle source of Mangaia lavas. Our data also complement evidence for recycling of the sulfur content of ancient sedimentary materials to the subcontinental lithospheric mantle that has been identified in diamond-hosted sulfide inclusions. This Archean age for recycled oceanic crust also provides key constraints on the length of time that subducted crustal material can survive in the mantle, and on the timescales of mantle convection from subduction to upwelling beneath hotspots.

Heavy metals of the Santiago Island (Cape Verde) topsoils

CABRAL PINTO, M.M.S.[123,*], E.A. FERREIRA SILVA[1], SILVA, M.M.V.G.[2] AND J. SOUSA BRITO[3]

[1]Geobiotec Center, University of Aveiro, Portugal
[2]Geociences Center, University of Coimbra, Portugal (*marinacp@ci.uc.pt)
[3]University Jean Piaget, Santiago Island, Cape Verde

In this work we present maps of Estimated Background Value (EBV) of some harmful metals (As, Cd, Co, Cr, Cu, Hg, Mn, Ni, Pb, V, Zn) in the soils of the Santiago Island and analyse their relationships with the geological cartography. We also carried out Risk assessment on the soils. The geochemical survey (sampling of 249 soil samples, sample preparation, analysis, data treatment and mapping) was conducted following the guidelines of the International Project IGCP 259. The concentration of selected elements were determined in the fraction <2mm. Each sample was digested with aqua regia and analyzed by ICP-MS. Heavy metals in Santiago Island topsoils were mostly originated from the weathering of underlying bedrocks. The EBV spatial distribution of the metals allowed us to establish relationships between the geological formations. These relationships were confirmed by the results of Principal Component Analyses (PCA). The metals with higher loadings in PC1 (Co, Cr, Ni, Cu and V) clearly show the influence of a rich lithology in siderofile elements, and metals typical of basic rocks. The high values of Geoaccumulation Indices for these elements demonstrated that the Santiago soils may have higher Co, Cr, Ni, Cu and V risks which are caused by its higher natural origin. The metals with higher loadings in PC2 (As, Hg, Cd, Zn and Pb) are also taken as a natural lithogenic factor, because the metals hot spots are mainly located at areas with soils derived from pyroclastic deposits of MV and AS Formations. However, contamination of As, Hg, Cd, Zn and Pb occurred in some areas that may have a human-influenced source.

Combustion carbonaceous particles: Evolution of their impacts

HELENE CACHIER[12] * AND CATHY LIOUSSE[2]

[1]Laboratoire des Sciences du Climat et de l'Environnement, Gif sur Yvette (France)
[2]Laboratoire d'Aérologie, Toulouse (France) (helcachier@gmail.com)

Combustion using either fossil or vegetation fuels both emit a complex array of particles. The resulting aerosol contains primarily polymeric substances which properties substantially vary with the nature of fuels and combustion conditions. Hence, inventories firstly distinguish fossil fuel and "biomass burning" emissions, but furthermore domestic versus industrial or traditional versus modern usages. Future evolutions expected in emerging countries are likely to influence the local and regional impact of particles on atmospheric balances and population health.

Combustion particles have been traditionally described by their BC/OC content a key parameter allowing a minima assessments of their different impacts. More or less recent works, however, let suggest that carbon aerosol chemical complexity must be traced by other proxies among which the prominence of humic-like substances (HULIS) is now recognized. Interplays between HULIS contents and carbon particle radiative properties ("brown carbon"…) and water solubility ("WSOC" content) have to be investigated. In this context, aerosol partitioning into BC and OC and the lack of analytical agreement might be also revisited.

Petrologic preconditioning: A predisposition to polymetamorphism?

MARK J. CADDICK[1]*

[1]Department of Geosciences, Virginia Tech, Blacksburg, VA, USA. email: (caddick@vt.edu)

Attainment of high or ultra-high temperatures (HT/UHT) in thickened continental crust requires significant heat input or generation, with a major thermal barrier being the latent heat requirement for melting. Melting or melt crystallization can thus buffer temperature on a local to regional scale [e.g. 1], with an additional (though far smaller) effect associated with sub-solidus dehydration reactions [2]. Incomplete retrogression of many amphibolite and granulite facies rocks implies that fluid influx during cooling is less pervasive than loss during heating [e.g. 2], so that these rocks effectively represent 'partially depleted residua'.

Subsequent heating (M_2) of previously metamorphosed (M_1) rocks requires less energy associated with melting if melt extraction during M_1 significantly reduced the rock's melt fertility. Thermodynamic calculations suggest that if a rock experienced significant melt loss at 850 ˚C in M_1, the energy required to re-heat that rock to 800 ˚C during M_2 (calculated as the difference in specific enthalpy from 400 to 800 ˚C) may be > 15 % less than required without the prior metamorphism. The extent of this energy difference is a function of (i) the pre-M_1 melt fertility, (ii) the efficiency of melt and H_2O loss during M_1 and (iii) the specific *P-T* histories involved. Furthermore, substantially different results are obtained by considering isochemical or progressviely fluid + melt-depleting thermodynamic systems.

A consequence of this 'preconditioning' is that large granulite facies terranes can require substantially less energy to reach upper-amphibolite grade conditions than previously unmetamorphosed equivalents. This effectively pre-disposes them to high-grade metamorphism in later orogenic events (if they are not pervasively rehydrated in an intermediate step). Recognition of this polymetamorphism is difficult if $T_{M1} > T_{M2}$ because little M_2 mineral growth is expected, but resetting of mineral compositions and compositional zoning might be expected. 'Cryptic' polymetamorphism is thus unsurprising in many cases. Furthermore, the presence of large preconditioned bodies can strongly influence the apparent thermal evolution of orogenic belts, substantially modifying both conduction and fluid flow pathways.

^{224}Ra:^{228}Th disequilibrium in coastal sediments: Implications for the transfer across the sediment-water interface

PINGHE CAI[1]* SHIYUN PENG[1], WILLIARD S. MOORE[2] XIANGMING SHI[1] GUIZHI WANG[1] AND MINHAN DAI[1]

[1]State Key Laboratory of Marine Environmental Science, Xiamen University, Xiamen 361005, P. R. China *(Correspondence: (caiph@xmu.edu.cn), (shiyunpeng@stu.xmu.edu.cn), (kidsxm_0110@foxmail.com), (gzh(wang@xmu.edu.cn), (mdai@xmu.edu.cn)

[2]Department of Earth and Ocean Sciences, University of South Carolina, Columbia, South Carolina 29208, USA (moore@geol.sc.edu)

We utilized 224Ra/228Th disequilibrium in the sediment to investigate the processes that regulate dissolved transfer across the sediment-water interface. Depth profiles of dissolved and surface-bound 224Ra and 228Th in the upper 0-20 cm sediment were measured using a delayed coincidence counter during a cruise to the Yangtze estuary from 15 to 24 August 2011. Along with 224Ra and 228Th, depth profiles of 234Th were collected to determine the bioturbation rate in the sediment. At most study sites, a marked deficit of 224Ra relative to 228Th was observed in the upper 0-10 cm sediment. In contrast, 224Ra was in excess with respect to 228Th in the upper 0-5 cm sediment at the river mouth, possibly due to redistribution of 224Ra from the mid-salinity region. By modeling the 224Ra profiles in the sediment using the general diagenetic equation, we demonstrated that in most cases molecular diffusion and bioturbation together can account for only ~20-30% of the measured flux of 224Ra. We concluded that other mechanisms, especially irrigation, must be invoked to explain the remnant 70% of the observed deviation of 224Ra relative to 228Th in the sediment. On the basis of the 224Ra/228Th disequilibrium in the sediment, we proposed an invaginated interface model to quantify the transfer rate of other dissolved species across the sediment-water interface. We have utilized the invaginated interface model to determine the benthic consumption rate of dissolved O2. The result reveals that O2 consumption is an important loss term of dissolved O2 in the Yangtze estuary and must be considered as one of the mechanisms that lead to hypoxia in this area.

The effect of zinc, nickel and cobalt on fluoride removal by low cost materials: Zeolite and calcite

QIANQIAN CAI[1]* BRETT TURNER[1], DAICHAO SHENG[1] KRISTIAN KRABBENHOFT[1] AND SCOTT SLOAN[1]

[1]Centre for Geotechnical and Materials Modelling, Civil Surveying and Environmental Engineering, The University of Newcastle, University Drive, Callaghan, N.S.W., 2308, Australia (*correspondence: Qianqian.Cai@uon.edu.au)

Spent Pot Lining (SPL) is a by-product of the electrolytic process in the smelting of aluminium. Historical disposal of SPL from the Hydro Aluminium smelter at Kurri Kurri, NSW, Australia has rendered the nearby groundwater contaminated as high as 2000 mg/L fluoride, which is far beyond the drinking water limitation of 1.5 mg/L. The excessive intake of fluoride, however, can lead to fluorosis. Since SPL leachate is in fact a complex chemical cocktail which also contains other contaminants like metal ions, it is necessary to understand how these chemicals will behave during the defluoridation process. This research aims to determine the effect of zinc, nickel, cobalt on the fluoride removal by zeolite and calcite. For this purpose, a range of "free-drift" kinetic tests have been conducted.

The tests were carried out at 20°C and a stirring rate of 200 rpm with <150μm zeolite or calcite. The initial concentration of synthetic fluoride solution was about 200 mg/L, which reflected the "average" concentration of fluoride contamination in groundwater at the Hydro Aluminium site. The fluoride solution was spiked with known amounts of either Zn, Ni or Co. Fluoride concentrations & pH were measured every 10 seconds using the respective ion-selective electrodes and spot checked by ion chromatography (IC). Selected samples were sent for ICPMS analysis for total metals.

Results show that the presence of metals can enhance the fluoride adsorption by zeolite with fluoride removal generally increasing with metal concentration. The best fluoride adsorption occurs with the addition of 100 mg/L Ni^{2+}. It exhibits an approximately 20% higher percentage adsorption than the blank (no metals). As for the calcite, the sample with Zn^{2+} exihibit the highest fluoride removal of around 90%, while the samples with the addition of Co^{2+} and Ni^{2+} are found to inhibit defluoridation compared with the blank. The kinetic study indicates that the experimental data are well fitted by the pseudo-second order kinetics model and Hill logistic model, with the latter resulting in a better fit overall.

Andesitic dyke swarms in the Araç-Boyalı foredeep basin, N Anatolia: Evidence for Eocene extension

R. EZGI CAKIROGLU[1]* M. CEMAL GÖNCÜOĞLU[1]
MICHELE MARRONI[2] AND LUCA PANDOLFI[2]

[1]Department of Geological Eng., Middle East Technical University, Ankara-Turkey
(*correspondance: ezgi.cakiroglu@metu.edu.tr)
[2]Dipartimento di Scienze della Terra, Università di Pisa, Italy

A number of dykes and sills have been investigated in the Araç-Boyalı Flysch Basin, a foreland basin formed on the platform of the Sakarya Composite Terrane following the closure of the Intra-Pontide Ocean during the Late Cretaceous – Late Paleocene. The andesitic dyke swarms, characterized by well-developed chilled margins, flow textures and elongated vesicles, intrude the basin sediments, among which massive and pillow lavas, as well as lava and pillow breccias are also found.

Major element data plotted on SiO_2 indicates plagioclase, pyroxene and biotite fractioation, as well Fe-Ti oxides in the samples, that are andesites and andesitic basalts of calc-alkaline character. Tectono-magmatic discrimination diagrams of lavas as well as the dykes are indicative for destructive plate margin volcanism. Lava and dyke samples display similar patterns in REE and Spider diagrams. A depletion of heavy REE, enrichment of LREE is observed, as well as a marked Nb-Ta trough, characteristic of arc magmas. Based on low Mg numbers, together with low compatible trace element concentrations and low Nb/La ratios, compositions of examined samples might have been modified by assimilation processes.

Geochemical characteristics of the volcanic rocks reveal that they are products of continental arc magmatism within the Sakarya Composite Terrane above the N-ward subducting Izmir-Ankara oceanic lithosphere of Neotethys.

Similarities in major, minor and trace element geochemistry are in favour of dykes being the feeders of the Eocene lava flows within the Eocene basins that formed as a result of post-collisional extention.

Environmental mineralogy: Bridging the gap from microscopic to macroscopic

G. CALAS, G. MORIN T.ALLARD L. GALOISY ,
F. JUILLOT G. ONA-NGUEMA[1] AND G.E. BROWN, JR.[2]

(georges.calas@upmc.fr)
[2]Dept. of Geological & Environmental Sciences, Stanford University, Stanford CA 94305, USA.

Minerals provide a large wealth of environmentally relevant information during their formation and further evolution, through their substituted trace/minor elements and structural -often radiation-induced- defects. A unified view of their behavior comes from the possibility to determine element speciation in fluids, minerals and mineral surfaces, atomic substitution processes in mineral lattices, using molecular-scale observations derived from structural, experimental and theoretical approaches.

The first focus will be on the structural evolution of nuclear glasses during aging (alteration, irradiation), showing the molecular-scale mechanisms that govern glass stability. Matrix stability relies on the synergy between glass/gel components, with a major role played by the competition for local charge compensation. Crystal chemistry considerations explain the differences observed in the leaching behavior during under-saturated and open conditions.

The second part is devoted to the mineralogical control of the distribution of heavy elements such as Zn, As, Pb or U in geochemical anomalies and sites contaminated through industrial/mining activities. Combining mineralogy and element speciation provides unique information on the behavior of heavy elements during low-T processes, showing the respective importance of low-solubility phases and sorbed species and illustrating the key mechanisms that inhibit short- and long-term contaminant dissemination. Trapping of heavy metals by Fe/Mn oxyhydroxides is an efficient natural attenuation process in acid mine drainage (AMD) waters. The dynamics of metal speciation and concentration in AMD systems provides an interesting picture of the complex interplay among source terms, geochemical conditions, hydrological fluxes, and bacterial activity

A last example will concern radiation-induced defects in minerals, used to trace short-lived uranium daughter elements. The high specific area of clays makes them sensitive to ground-level radiation doses, providing information on the past transfer of radionuclides in the geosphere, helping to model uranium-bearing fluid migration.

S burden in CFBs: A new approach

SARA CALLEGARO[1] DON R. BAKER[2], ANDREA MARZOLI[1] ANGELO DE MIN[3] HERVÉ BERTRAND[4] TINA GERAKI[5] CECILIA VITI[6] AND FABRIZIO NESTOLA[1]

[5]Diamond Light Source, UK; (tina.geraki@diamond.ac.uk)
[6]Università di Siena, IT; (cecilia.viti@unisi.it)

Most Phanerozoic Large Igneous Provinces (LIPs) are associated in age with, and may have triggered, major mass exctinctions. This is epitomized by the synchroneity of the Central Atlantic magmatic province (CAMP; c. 201 Ma) and the Deccan Traps (c. 66 Ma) with the end-Triassic and the end-Cretaceous biotic crises, respectively. However, LIPs not associated to mass extinctions are also recorded, as in the case of the Paranà-Etendeka (PE; c. 134 Ma). Although climatic forcing caused by huge emissions of volcanic gases such as SO_2 and CO_2 is now accepted, precise estimates of gas contents of the basalts and their gas emission masses and rates are still poorly constrained. The differences in environmental impact of these three LIPs may reflect their different gas outputs. Here we illustrate a new approach of estimating magmatic SO_2 emissions. First, the pyroxene/melt S partition coefficient coefficient was measured by micro-XRF (Diamond synchrotron, UK) and ion microprobe (WHOI, USA) on experimentally crystallized augites and basalts. S contents were then measured by in-situ micro-XRF in augite phenocrysts from representative rocks of the three considered LIPs. Selected natural clinopyroxene crystals were verified to be devoid of fluid or sulphide inclusions through Transmission electron microscopy (TEM, Siena) thus legitimating the aplicability of the partition coefficient and the extrapolation of S burden in primitive magmas starting from S measured on augites. S in the pristine magmas ranges between 100 and 1500 ppm, consistently with results obtained by Self *et al*. (2008) on melt inclusions from Deccan basalts. CAMP and Deccan magmas seem systematically richer in S than PE ones, an observation that correlates well with the severity of the associated biotic crises. Thus, emissions of S (along with other volatiles) appear as important factors for assessing the global environmental changes and may play a significant role in triggering mass extinctions.

Recycling of subducted crust in the source of within-plate CAMP basalts from southeastern North America

SARA CALLEGARO[1], HERVÉ BERTRAND[2] ANDREA MARZOLI[1] MASSIMO CHIARADIA[3] LAURIE REISBERG[4] CHRISTINE MEYZEN[1] AND GIULIANO BELLIENI[1]

[1]Università di Padova, IT; (sara.callegaro@unipd.it;) (andrea.marzoli@unipd.it;) (christine.meyzen@unipd.it;) (giuliano.bellieni@unipd.it)
[2]Univ. Ec. Norm. Sup Lyon, FR; (herve.bertrand@ens-lyon.fr)
[3]Université de Geneve, CH (Massimo.Chiaradia@unige.ch)
[4]CRPG-CNRS-UL Nancy, FR; (reisberg@crpg.cnrs-nancy.fr)

Basaltic dykes and sills of the Central Atlantic magmatic province (CAMP) were intruded between 202 and 195 Ma in southeastern North America (SENA) during Pangea break-up. We aim to constrain the mantle source of these magmatic bodies and their evolution path with new combined geochemical data (major and trace elements, Sr-Nd-Pb-Os isotopes). While Sr-Nd isotopic compositions for SENA rocks ($^{87}Sr/^{86}Sr_{200Ma}$ 0.70438-0.70880 and $^{143}Nd/^{144}Nd_{200Ma}$ 0.51251-0.51204) fall within the low-Ti CAMP field, Pb-Pb isotopes ($^{206}Pb/^{204}Pb_{200Ma}$ = 17.46-18.85, $^{207}Pb/^{204}Pb_{200Ma}$ = 15.54-15.65, $^{208}Pb/^{204}Pb_{200Ma}$ = 37.47-38.76) are peculiar for this area of the CAMP and span a wide range of compositions, notably extending towards low $^{206}Pb/^{204}Pb_{200Ma}$ values. Based on the generally unradiogenic Os isotopic compositions ($^{187}Os/^{188}Os_{200Ma}$ = 0.127-0.144) and the lack of correlation between these and other geochemical markers, the role of crustal contamination in the evolution of SENA tholeiites is constrained to be less than 10%. Hence, the isotopic variation is interpreted to reside within the mantle source and a process other than crustal assimilation was responsible for conveying the observed continental trace element signature (positive anomaly in Pb and negative anomalies in Ti and Nb) to these magmas. For this process, we hypothesize shallow recycling of subducted lower and upper crustal materials within the upper mantle. Pseudo-ternary mixing models show that a maximum of 10% recycled crust is enough to explain both the SENA dyke trace element patterns and their isotopic heterogeneity. Furthermore, though a thermal contribution of a mantle plume is not completely excluded due to the relatively high mantle potential temperatures (1430°-1480° C) calculated from SENA primitive olivines, its chemical contribution was negligible (less than 5%).

Effect of mineral structure and composition on carbonate clumped isotope measurements

DAMIEN CALMELS[1], MAGALI BONIFACIE[1], AMANDINE KATZ[1] AND JULIEN SIEBERT[2]

[1]IPGP, Sorbonne Paris Cité, Univ Paris Disderot, UMR 7154 CNRS, F-75005 Paris, France (calmels@ipgp.fr)
[2]IMPMC, Université Pierre et Marie Curie, UMR CNRS 7590, IPGP, 75005 Paris, France

Carbonate clumped isotope thermometry relies on the temperature-dependent extent of bounding of ^{13}C-^{18}O within CO_3^{2-} ion groups in solid carbonate minerals. The measure of the abundance of $^{13}C^{18}O^{16}O_2^{2-}$ ion groups cannot be performed on the carbonate mineral itself and requires Δ_{47} measurement of CO_2 extracted by phosphoric acid digestion (i.e., the excess of ^{13}C-^{18}O bonds in extracted CO_2 relative to a random distribution). Theoretical studies predict variations in the degree of ^{13}C-^{18}O clumping from one carbonate to another [1] and small but analytically resolvable differences in Δ_{47} of CO_2 extracted from various types of carbonates equilibrated at a given temperature [2]. In contrast, published calibrations of carbonate clumped isotope thermometer do not show distinguishable difference among the different types of carbonate investigated (mostly biogenic and inorganic calcite, aragonite and carbonate-apatite [3]). However, some coexisting carbonate phases supposed to have grown or been re-equilibrated at the same temperature show different Δ_{47} values (e.g., Bonifacie *et al*., same meeting).

We will present results from a series of experiments on a variety of natural and synthetic carbonate minerals. These experiments have been designed to investigate the possible effects of mineral structure and chemical composition on Δ_{47} values.

This study is relevant for key issues related to the use of Δ_{47}, and in particular in refining application of the Δ_{47} thermometry to the variety of carbonate minerals found in the geological record.

Carbon isotopic composition and flux variations of CO_2 emitted from the soil of Mt Etna

M. CAMARDA*, S. DE GREGORIO, R. FAVARA, F. GRASSA AND S. GURRIERI

Istituto Nazionale di Geofisica e Vulcanologia, sezione di Palermo, via Ugo La Malfa 153, 90146 Palermo, Italy. (*Correspondence: m.camarda@pa.ingv.it)

Since 1987, periodic soil CO_2 flux measurements on the south-western sector and on the eastern flank of Mt Etna have been performed to monitor volcanic activity. Many studies have demonstrated that soil CO_2 flux is closely related to the magma dynamics of Mt Etna. To further confirm this relationship and better understand the influence of rising magma on soil CO_2 emission, we periodically measured the $\delta^{13}C$ values as well as the soil CO_2 flux at several points in both areas of Mt Etna. The comparison between $\delta^{13}C$ values and soil CO_2 flux revealed two groups of data with different behaviours: (i) data arranged along mixing lines between organic and depth origins of CO_2; (ii) data with high soil CO_2 fluxes and $\delta^{13}C$ values with organic marker. The variations in $\delta^{13}C$ in (i) are temporally well correlated with the total amount of the soil CO_2 emitted in the areas. This result strongly corroborates the primary role played by magma dynamics in the control of soil CO_2 flux in the analysed areas. In addition, the values of flux of (ii), notwithstanding the organic marker, displayed synchronised variations with the total amount of the soil CO_2 emitted in the area and hence with the $\delta^{13}C$ values of group (i). The recorded synchronism suggests that the measurements in group (ii) are also to some extent influenced by magma dynamics. It can be supposed that: increase in flux in (i) is directly derived from the release of CO_2 from ascending magma, whereas the increase in soil CO_2 flux in (ii) is mainly due to the enhancement of stress linked to magmatic intrusion.

Evaluation of potential explanations for the offsets in Δ_{47} amongst various taxa of naturally occurring modern carbonate organisms

ROSEMARIE E. CAME

[1]Department of Earth Sciences, University of New Hampshire, Durham, NH 03824, USA (rosemarie.came@unh.edu)

For more than half a century, the $\delta^{18}O$ paleotemperature proxy has been applied with great success using marine carbonate fossils, yet progress has been limited because carbonate $\delta^{18}O$ is a function of both calcification temperature and the $\delta^{18}O$ of the water in which precipitation occurred, thereby requiring an assumption about past seawater $\delta^{18}O$. The recently developed carbonate "clumped isotope" paleothermometer (Δ_{47}) has the potential to circumvent this difficulty because the "clumping" of ^{13}C and ^{18}O atoms in a carbonate mineral lattice occurs independently of seawater $\delta^{18}O$ [1]. Furthermore, carbonate $\delta^{18}O$ and Δ_{47}-derived temperature are obtained simultaneously – in the same phase – allowing a calculation of seawater $\delta^{18}O$ using a single sample aliquot.

Initially, the relationship between Δ_{47} and calcification temperature was empirically derived using inorganic calcites that were grown at known temperatures [1]. Since that initial calibration study, several naturally occurring modern carbonates have been analyzed, and some yield Δ_{47} values that are consistent with the relationship derived for inorganic calcite (e.g., deep sea corals) [2], whereas others appear to be offset to values that are slightly higher (e.g. surface corals) [1] or slightly lower (e.g. otoliths) [3]. The differences observed between various taxa are not fully understood. Using both published and unpublished modern calibration data sets, several possible explanations for these offsets will be evaluated, including: "vital effects", mineralogical offsets, and differences in the sample preparation protocols of various Δ_{47} laboratories.

Nickel isotopic composition of modern seawater and rivers

V. CAMERON[1]* AND D. VANCE[2]

[1]Bristol Isotope Group, School of Earth Sciences, University of Bristol, UK (*correspondence: (glxvc@bristol.ac.uk)

[2]Institute of Geochemistry and Petrology, Department of Earth Sciences, ETH Zürich, Switzerland (derek.vance@erdw.ethz.ch)

The oceans are the most important repositories for the fallout from continental activities, such as weathering, mediating its flux of elements through a variety of processes including biogeochemical cycling. The abundances and stable isotopes of transition metals have been key tools in understanding and deciphering the totality of these processes through time and, certainly, ongoing development of isotopic systems will continue to reveal new insights into Earth processes. Here we present the first dataset for the Ni isotopic compositions of seawater and rivers.

Dissolved Ni was analysed in several major river systems, including the Amazon and Chang Jiang. In general, rivers exhibit substantial variability in both Ni concentration (2.2-35 nmol kg^{-1}) and $\delta^{60}Ni$ (0.29-1.34‰). Most of the rivers are isotopically heavy with the exception being two rivers that have isotopic compositions that overlap the lithogenic range observed for silicate rocks and sediments [1]. The variability noted in these data may be attributable to isotopic fractionation during chemical weathering or partitioning between dissolved and suspended load, both of which have been put forward to explain similar features in other isotopic systems. However, further studies will be required to resolve the detailed processes.

The range of seawater Ni concentrations was 3.1 nmol kg^{-1} at the surface to 11.2 nmol kg^{-1} at depth, confirming the surface to depth partitioning seen previously, and correlating with nutrient elements such as phosphate and silica. Seawater Ni isotopic data from the Atlantic and Pacific oceans produced three conspicuous outcomes: (i) relative homogeneity of all samples, with an average $\delta^{60}Ni$ of 1.44±0.15 (2σ); (ii) without exception, the Ni isotopic compositions are heavier than that of the dissolved riverine input; (iii) a missing light sink for Ni.

In-situ isotopic analysis of volatile fluids from subsurface carbon reservoirs

RICHARD CAMILLI[1] AND ANTHONY N. DURYEA[2]

[1]Woods Hole Oceanographic Institution, Dept. of Applied Ocean Physics and Engineering, Deep Submergence Laboratory, MS#7, Woods Hole, MA 02543, USA.
[2]Monitor Instruments Company LLC., 290 E Union Rd, Cheswick, PA 15024, USA.

Technological advances are moving analytical laboratory sensors into the field. This transition eliminates sample collection and transport requirements for offsite analysis, improving spatial and temporal resolution of data, while decreasing operations costs and latency. We present a miniaturized isotope ratio mass spectrometer (IRMS) for in-situ analysis of gases and volatile hydrocarbons from subsurface carbon reservoirs.

This new instrument, which uses a compact double-focusing mass analyzer is capable of rapid spectrum scans across a 2-200AMU range for quantitative characterization of a broad range of volatile compounds including hydrocarbons and reduced gases at concentrations to less than one part-per-billion. Its multiple fixed-cup collectors enable simultaneous isotopic ratio precision to better than one per-mil. This fully self contained IRMS requires less than 20W of power and displaces a volume of approximately 10 liters.

We present an overview of the IRMS design in two differing embodiements, a TETHYS configuration for marine operation on subsea robotic vehicles, and a configuration with integrated gas chromatograph (GC) for field applications such as logging-while-drilling. Results from laboratory testing of GC-IRMS confguration indicate isotopic precision of better than δ0.25‰ analysis of mixed natural gas with total cycle times of less than five minutes. Marine operations using the TETHYS configuration for real-time analysis of dissolved water column hydrocarbons and gases indicate sensitivities better than 1 part-per-billion and isotopic precision to better than δ1‰ with measurement cycle times of seconds. This provides an efficient method for locating and classifying biogenic and thermogenic seafloor seeps from subsurface carbon reservoirs.

A rheological and textural characterization of the fall-out phase of the large volume Pozzolane Nere mafic ignimbrite (Colli Albani Volcano, Rome)

S. CAMPAGNOLA*, C. ROMANO, A. VONA AND G. GIORDANO

Geological Science Department, University of Roma Tre, L.go S.L.Murialdo, 1 00146 Rome, Italy
(*correspondence: silvia.campagnola@uniroma3.it)

The Pozzolane Nere ignimbrite (PNR) represents one of the largest explosive events in the history of the Colli Albani volcano (407 ka, Vulcano Laziale period). The PNR is tephri-phonolitic in composition and is characterized by a basal scoria fallout deposit with an east-trending axis of dispersion overlain by a low aspect ratio ignimbrite, estimated at 30km^3 as bulk volume. Despite extensive studies on the deposits of the volcano, the mechanisms governing the explosive activity of these very undersaturated magmas are still poorly known. In order to improve our understanding on the origin of these high-energy eruptions (VEI 6), petrological and minero-chemical analyses of the five PNR fallout sub-layers were performed. Results from the VSD of the selected scoriae suggest an uneven distribution of nucleation events with VNDs (on the order of 10^8-10^9 cm^{-3}) higher than those observed in literature for mafic explosive eruptions and more comparable to VNDs pertaining to explosive eruptions of evolved composition. Textural and minero-chemical investigations of the samples have been combined with their rheological characterization. Low T measurements (690°C<T<800°C) were performed by micropenetration technique, while the high T viscosities of fully molten (1250°C<T<1569°C) and partially crystallized specimens (1100°C <T<1225°C) were measured at 1 bar in air with a concentric cylinder viscometer. Above the liquidus temperature, viscosity ranges from $10^{1.04}$ to $10^{3.64}$ in good agreement with the viscosity model by Giordano *et al.*[1]. In the subliquidus region, isothermal crystallization experiments allowed to quantify the role of crystals on the rheology of PNR magmas. The increase of apparent viscosity together with the onset of strain rate- and strain-dependent behavior could play a critical role during PNR degassing history, governing the elevated explosivity of these very undersatured magmas.

Evidence against a chondritic Earth

IAN H. CAMPBELL AND HUGH ST C. O'NEILL

Research School of Earth Sciences, The Australian National University, Canberra, ACT, 0200, Australia

The 142Nd/144Nd ratio of the Earth is greater than the solar ratio as inferred from chondritic meteorites, which challenges a fundamental assumption of modern geochemistry—that the composition of the silicate Earth is 'chondritic', meaning that it has refractory element ratios identical to those found in chondrites. The popular explanation for this and other paradoxes of mantle geochemistry, is an incompatible element hidden layer deep in the mantle, which must including 40% of the mantle's heat producing elements in order to explain the Nd anomaly. This requires the mantle plumes to carry at least 40% of the mantle's heat budget, which is inconsistent with constraints on the plume heat flux that put the this figure at less than 30%. Furthermore the sudden drop in the temperature of mantle plumes that occurred a ~2.5 Ga is interpreted to indicate that that D", which is commonly interpreted to be the hidden layer, did not form until that time. If the hidden layer (D") formed after the first 10 Myr of the Earth's evolution it cannot be responsible for the Earth's 142Nd/144Nd anomaly. Either the matter from which the Earth formed was not chondritic, or the Earth has lost incompatible elements rich matter by collisional erosion in the later stages of planet formation.

Mining, microbes, and models: Integrating microbal Fe(II) oxidation, hydrolysis, precipitation, and biogeochemical modeling, with application to acid mine drainage at Iron Mountain

KATE M. CAMPBELL[1], CHARLES N ALPERS[2], D. KIRK NORDSTROM[1], ALEX E. BLUM[1] AND MICHAEL B. HAY[3]

[1]U.S. Geological Survey, Boulder, CO, USA, (kcampbell@usgs.gov)
[2]U.S. Geological Survey, Sacramento, CA, USA
[3]ARCADIS U.S., Inc., Boulder, CO, USA

Acid mine drainage (AMD) is a major environmental concern because of high concentrations of acidity (low pH), sulfate, iron, and other elements. One important process affecting AMD chemistry is microbial Fe(II) oxidation. As Fe(II) oxidizes, a variety of Fe(III)-bearing minerals can precipitate, affecting the immobilization of elements such as Cu and Zn, as well as redox cycling of trace elements such as As and Sb. Precipitation can also cause costly management problems when it interferes with treatment efforts. An example of this problem occurred at the Iron Mountain Mine (CA, USA) where a pipeline carrying AMD to a treatment plant has developed scaling because of Fe(II) oxidation and Fe(III) precipitation inside the pipe. The scale accumulation has clogged flow and caused spillage of AMD, requiring expensive periodic cleaning of the pipeline.

Laboratory Fe(II) oxidation experiments were conducted using synthetic AMD with Fe(II)-oxidizing bacteria, and compared to experiments using natural AMD from Iron Mountain. Changes in pH, Fe(II), Fe(III), and trace elements were measured over time. The precipitates formed were characterized, and the micobial community was identified (16S rDNA). Water samples and scale collected from four locations along the pipeline also were characterized.

We developed a geochemical model to evaluate our understanding of coupled biotic and abiotic processes in AMD. Key processes included in the model are equilibrium reactions for all measured constituents, microbial Fe(II) oxidation kinetics, Fe(III) hydrolysis and polymerization, mineralogy, solubility, Fe(III) precipitation kinetics, and As(III) oxidation. This work highlights the utility of geochemical models as a means of improving quantitative descriptions of fundamental biogeochemical processes in AMD. Based on the geochemical model and laboratory experiments, we developed a potential mitigation strategy for the scaling problem that avoids costly pipeline maintenance.

Exploring the preservation of alkaline-carbonatitic extrusive rocks in relation to continent formation

L.S.CAMPBELL[1]* A. DYER[2] C. WILLIAMS[3] AND P.R. LYTHGOE[1]

[1]School of Earth, Atmospheric and Environmental Sciences, University of Manchester, Williamson Building, Oxford Road, Manchester M13 9PL. UK (*correspondence: L.S.Campbell@manchester.ac.uk)
[2]Department of Chemistry, Loughborough University, Ashby Road, Loughborough, Leicestershire LE11 3TU. UK
[3]School of Applied Science, University of Wolverhampton, Wulfruna Street, Wolverhampton, WV1 1SB. UK

Mineral reaction paths related to continental alkaline-carbonatitic extrusive rocks are examined in the context of a "zeolitic masquerade" hypothesis [1]. The hypothesis suggests that zeolitic alteration reactions are the first steps in a gradual stabilization of these bedded successions, as the highly reactive volcanic deposits change from glasses via zeolites to authigenic feldspars, clays and SiO_2 phases. Reported reaction progressions are suggestive of trends in which Si/Al increases with time as wider, Si-saturated fluids react with earlier-formed phases in continental environments. It is not known how trace elements such as the REE and HFSE behave at each stage of reactive progression as no systematic study of these elements has been made for wide occurrences of natural zeolites. But our preliminary data indicate that the first-formed, low-Si zeolites (e.g. phillipsite), reflect the REE patterns of the original volcanic glasses. Modifications to trace element signatures of altered successions are very likely to occur as reactions progress with exposure to wider crustal fluids. Some of these modifications will be dependent on the ion-selectivity properties of different zeolite minerals in the reaction paths, but fluid controls are certainly evident. A preliminary exploration of possible examples in the geological record, of recognition and stabilization of reactive successions, is discussed.

Sodium rich magmas parental to Catanda carbonatitic lavas (Angola): Melt inclusion evidence

M. CAMPENY[1]* V. KAMENETSKY[2] J.C. MELGAREJO[1] J. MANGAS[3], A. BAMBI[4] AND J. MANUEL[4]

[1] Faculty of Geology, University of Barcelona, Catalonia *(correspondence: mcampeny@ub.edu)
[2] CODES ARC, Univ. of Tasmania, Australia
[3] Dept. de Física, Univ. Las Palmas de Gran Canaria, Spain
[4] Dept. Geologia, Univ. Agostinho Neto, Luanda, Angola

Remains of highly eroded carbonatitic volcanic edifices occupy a region of 50 km^2 in the vicinity of the Catanda village, Kwanza Sul province, Angola. Carbonatitic lava flows and pyroclastic deposits are present in the area forming sequences of volcanic materials up to 600 metres in thickness.

We have studied the composition of the melt inclusions preserved in the primitive mineral phases of the lavas such as calcite, apatite, Na-rich cuspidine and spinel. Most inclusions are composed by calcium carbonates enriched in Na (up to 18 wt.%), K (up to 7 wt.%) and with significant S contents (Fig.1a). Alkaline chlorides such as sylvite and halite can be also found among daughter phases (Fig.1b), as well as periclase, olivine, monticellite and clinopyroxene. Na-rich apatite, perovskite and pyrochlore are also found in this assemblage, arguing for important role of alkalis and fluorine.

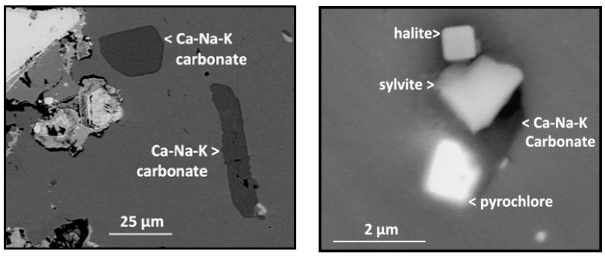

Figure 1: a) Calcium-alkaline carbonate included in calcite. b) Alkaline chlorides, carbonate and pyrochlore inside calcite.

The presence of alkalis in the melt inclusions hosted by main phenocryst mineral suggests that the parental magma compositions were Na- and K-rich. We consider that postmagmatic processes removed much of the alkaline elements from the Catanda lavas.

Gadolinium anomalies in Atibaia River water (SP, Brazil)

F. F. CAMPOS[1]* AND J. ENZWEILER[2]

University of Campinas - UNICAMP, Institute of Geosciences, Campinas, SP, Brazil
[1] *(correspondence: francisco.campos@ige.unicamp.br)
[2] (jacinta@ige.unicamp.br)

Stable synthetic chelates of gadolinium find wide use as contrast agents for magnetic resonance imaging (MRI). After administration to patients, the chelate is excreted in urine. Anthropogenic anomalies of Gd were measured in river water and groundwater samples by several authors, because the chelates are remarkably stable when passing wastewater treatment plants (WWTP) [1]. Despite that, even in densely populated areas small watersheds should be free of Gd anomalies in absence of discharge of raw or treated sewage.

In this work we studied three small sectors of Atibaia River, in São Paulo state, Brazil. River water was sampled, filtered through 0,22 μm syringe filters and acidified with distilled HNO_3 to pH < 2. Trace elements were measured by ICP-MS, without sample pre-concentration. The results of rare earth elements (REE) were normalized by the PAAS [2].

The first sector is the most pristine among the three. It is upstream, covers about 100 km of the river course and no Gd anomaly was detected in the water samples. The second sector comprises samples from Anhumas Creek, a tributary of Atibaia River, where it crosses an urban area and has two WWTPs. Gd anomalies were present even before the first WWTP, and their magnitude is comparable to anomalies described for some major German rivers [3]. Immediately after the WWTPs, Gd concentration increases reaching the same values of discharged effluents from WWTPs in Bremen (Germany) [3] and higher than those found in Berlin (Germany) [4] and in the Hérault watershed (South France) [5], but lower than in some other Berlin canals [4]. Anomalies calculated as Gd/Gd* [3] resulted in up to fifty-fold enrichment of Gd over background concentrations. The third sampled sector is Atibaia River where it crosses an industrial and urban area, before ending at a dam. In this area, the Gd/Gd* values were only useful to mark an anomaly at the discharge of a WWTP. The other samples showed strong influence of the industrial park, with enrichment in light REE, resulting in a poor Gd/Gd* anthropogenic signal.

C-, Cr-, Sr-isotope stratigraphies and rare-earth elements in carbonate and BIFs of the Neoproterozoic Jucurutu Formation, Seridó Belt, NE Brazil

M. S. CAMPOS[1], A. N. SIAL[1], C. GAUCHER[2], R. FREI[3], V. P. FERREIRA[1]*, R. C. NASCIMENTO[4] M. M. PIMENTEL[5] AND N. S. PEREIRA

[1]NEG-LABISE, Dept. Geology, UFPE, Recife, Brazil *(correspondence: valderez@ufpe.br)
[2] Fac. Ci., Univ. de la Republica, Montevideo, Uruguay
[3]Inst. Geogr./Geol., Univ. of Copenhagen, Denmark
[4] Dept. Geol., FUA, Manaus, Amazonas, Brazil
[5]Inst. Geosc., UFRGS, Porto Alegre, Brazil

The Jucurutu Fm. in the Seridó Belt, NE Brazil, encompasses fine- to coarse-grained amphibolites-facies marbles, locally with cross-bedding and stromatolite structures. BIFs of three localities in this belt comprise itabirites (actinolite- or cummingtonite-itabirite) and tremolite schist iron ores and are overlain by marbles of the Jucurutu Formation. Diamictites of uncertain stratigrahic position exhibit clasts up to 0.6 m long (augen-gneisses, quartzites and bi-gneisses) and a fine-grained clay matrix.

C-isotope stratigraphic pathways for the Jucurutu Fm. show negative $\delta^{13}C$ values at the base followed upsection by positive values. At the Ferro do Bonito Mine, values as low as -12‰ are found in carbonates just above the contact with underlying BIF, followed by values ~ -5‰ and then by positive values (+4 to +10‰) upsection. $\delta^{13}C$ values for carbonates that overlie BIFs at Riacho Fundo and at Serra da Formiga are all positive. The difference of $\delta^{13}C$ behavior between basal carbonates at Mina do Bonito (negative) and Riacho Fundo and Serra da Formiga (positive) localities results, perhaps, from different stages of BIF deposition. $^{87}Sr/^{86}Sr$ values for Jucurutu Fm. carbonates lie ~ 0.7074, a value commonly observed in late Cryogenian to early Ediacaran.

BIFs yield negative $\delta^{53}Cr$ values (-0.4 to -0.1 ‰), Ce/Ce* from -0.4 to 0.7 (17 among 21 samples support anoxic depositional environment) and were probably formed as accumulation of Fe^{+2} in an ice-capped anoxic ocean. Their deposition was followed by post-glacial cap carbonate deposition (Ce/Ce* from 0.4 to 0.5) in an oxic environment.

Evaluation of the influence of Radon Carried by Evapotranspiration of Equatorial Forests (northeastern of Brazil) in the Formation of Atmospheric Aerosols

T. CAMPOS[1]*, J.J. HOELZEMANN[2] AND R. PETTA[3]

[1]Federal University of Rio Grande do Norte, Brazil. *(correspondence☹thomascampos@geologia.ufrn.br)
[2]Federal University of Rio Grande do Norte , Brazil. (judith.hoelzemann@inpe.br)
[3] Federal University of Rio Grande do Norte , Brazil. (petta@ccet.ufrn.br)

Atmospheric aerosols cause great impact on climate, in this context and excluding the human activity, their production is closely related to the presence of ions in the atmosphere. These ionized molecules are formed both by the action of Cosmic rays from space, as the Gamma radiation from terrestrial materials, and even Alpha radiation from Radon gas, constituing an ionic groups with dimensions ≤ 1.5 nm and influencing the amount of atmospheric aerosols in a given region, mainly in areas of forests. This fact is due to the transport of radon gas into the air dissolved in groundwater by evapotranspiration of trees, since the alpha and Beta radiation from the disintegration of radon gas vented directly from soils and rocks has little power of penetration into the atmosphere [1]. This paper show our study about the ionic particulate correlation and variation with the radon emanations in an atmosphere of equatorial forest environment from the Atlantic Dune and Caatinga forests, respectively on the coastal plain and hinterland depression of the Rio Grande do Norte State.

The measurements of atmospheric ion clusters by a air ions counter (AlphaLab® system) and active-passive measurements of radon gas in the atmosphere, soil and water through emanometer (AlphaGuard ®, RADELEC® systems). The Alpha and Gamma regional radiation (RAD-7® system and RS-230® spectrometers). Based on these data, we will try to prove that climate change comes from deforestation also has to do with the reduction of radon gas in the atmosphere, which acts as an inductor of formation and clumps of ions, and not only with the decrease of aerosols from the biological activity of trees and plants, which both affect the formation of clouds.

Geochemical characteristics and tectonic significance of mafic cumulates in Kuluncak ophiolite (Malatya), SE Turkey

M. CAMUZCUOĞLU[1]* U. BAĞCI[1], J. KOEPKE[2] AND P. E. WOLFF[2]

[1]Mersin University, Department of Geological Engineering, 33343-Çiftlikköy-Mersin, Turkey (*correspondence: mcamuzcuoglu@mersin.edu.tr.)
[2]Institute for Mineralogy, University of Hannover, Callinstrasse 3, D-30167 Hannover, Germany

The regionally important Kuluncak (Malatya) ophiolite in the Eastern Tauride, composed of mantle tectonites, ultramafic-mafic cumulates, isotropic gabbros, a sheeted dike complex, plagiogranite, extrusives and pelagic cover sediments. The mafic cumulates of the ophiolite suite are observed in Hekimhan region, represented by olivine gabbro and gabbro, displaying mesocumulate and orthocumulate textures. The whole rock major and trace element geochemistry of the mafic cumulate rocks indicate that the primary magma generating the Kuluncak ophiolite is compositionally similar to those observed in modern island arc tectonic settings. The REE concentrations of the mafic cumulates exhibit spoon-shaped REE patterns, with La_N/Sm_N and Sm_N/Yb_N ratios ranging from 0.21 to 2.60 and from 0.68 to 1.36, respectively. The crystallization order for the cumulate rocks is olivine ($Fo_{63.7–86.9}$)±chromian spinel, clinopyroxene ($En_{41.01–55.43}$, $Fs_{4.2–14.29}$, $Wo_{35.84–48.2}$), plagioclase ($An_{73.4–93.67}$) and orthopyroxene ($En_{76.81–83.51}$, $Fs_{15.68–21.47}$, $Wo_{0.73–1.85}$). The cumulus and postcumulus minerals do not show significant zoning. The presence of anorthite-rich plagioclases ($An_{73.4–93.67}$) in the mafic cumulate rocks indicates hydrous conditions at the time of oceanic crust generation. Highly magnesian olivine ($Mg\#_{63.36–86.75}$), clinopyroxene ($Mg\#_{74.96–92.09}$), orthopyroxene ($Mg\#_{77.55–84.33}$) and their coexistency in the cumulate gabbroic rocks are indicative of suprasubduction zone environment. All the evidences suggest that the Kuluncak ophiolite were formed in a suprasubduction zone tectonic setting during the closure of the Inner Tauride in Late Cretaceous.

Supersolidus and subsolidus equilibria in indium-bearing magmatic-hydrothermal systems

P.A. CANDELA*, P.M. PICCOLIAND, S.M. KAYSER AND J.R. NANCE

Laboratory for Mineral Deposits Research, Dept. of Geology, University of Maryland, College Park, MD USA

Indium demand has increased due to its use as a capacitive sensor in touch screens. The metal is commonly a by-product of mining of VMS, granite-related, and other ores, wherein the most common host mineral is sphalerite. Murakami and Ishihara [1] report sphalerite analyses from indium deposits that range up to In/Zn ~ 0.006 by weight (0.35 wt % In). At current metal prices, the contribution of these two commodities to revenue are equal for In/Zn ~ 0.003; that is, in some cases, indium revenue can exceed zinc revenue. We suggest that deposits with significant indium require a suitable mineralogical host (e.g., zinc or tin sulfides), and higher temperatures of formation. Coupled substitution of Cu(I)+In(III) for 2Zn (defining $CuInZn_{-2}$, the roquesite (rq) exchange component) accounts for indium incorporation into sphalerite.

Defining the fugacity of In (metal) in the 5 component ore system Cu-Fe-Zn-In-S, the subsolidus low-variance assemblage:

$CuFeS_2$(Ccp) + FeS_2(Py) + In (System) = $CuInS_2$(Sp) + 2FeS(Po),

can be written in terms of chemical potentials at a given P&T. Consideration of the sulfur fugacity–dependence of the associated higher variance Po-absent, and Py-absent equilibria suggest that, for a given fugacity of In, increasing sulfur fugacity leads to increasing rq component in Sp. Incorporation of In into Po (FeS-Fe_2S_3 ss) is hypothesized to occur along the $InFe(III)_{-1}$ exchange vector, and, in Cu-bearing Po, as $Cu(I)In(III)Fe(II)_{-2}$.

Reconnaissance experiments have been performed to evaluate the behavior of In in the supersolidus and subsolidus realms. Cold-seal experiments were performed at 800ºC and 100MPa, durations of 5-15 days, and activity of In metal = 0.05 to ~1, to evaluate the partitioning of In between Po and rhyolite melt. Results of the experiments demonstrate the affinity of In for Po (i.e. sulfides) relative to silicate melts (D~ 2-20). Subsolidus experiments were performed in sealed silica tubes at T = 500ºC for the starting assemblage of pyrite, pyrrhotite, chalcopyrite, sphalerite and indium sulfide. Results are consistent with In concentrations: Sp > Ccp ~ Po, including wt % levels of In in Sp

Bo Barker Jørgensen has contributed more than anyone to uncovering the secrets of the microbial sulfur cycle, and this work provides the foundation for explorationing sulfur cycle evolution through time. Here, we report on the sulfur biogeochemistry of Lake Matano, South Sulawesi, Indonesia, whose low sulfate concentrations, clear waters and ferruginous conditions provide an analogue to the nature of ocean chemsitry during much of the Archean Eon (≥2.5 billion years ago). We focused in on the fractionations associated with sulfate reduction in the anoxic water column of the lake, using a newly developed MC-ICP-MS technique [1] to obtain sulfate $\delta^{34}S$ values at sulfate levels as low as 1 micromolar. Within the chemocline of the lake, the $\delta^{34}S$ of sulfate varied from 7 per mil to 40 per mil, yielding fractionations of >25 per mil at sulfate concentrations down to ≤ 5 micromolar. These fractions are greater than previously observed at such low sulfate levels. The $\delta^{34}S$ of sulfides in the chemocline varied from 7 per mil to -15 per mil, and this range is comparable to the range of values observed in shales from the Paleo- and Mesoarchean Eons. We conclude that seawater sulfate concentrations through this time were probably less than 20 microlar most likely < 5 micromolar based on independent modelling of the Archean sulfur cycle. There is an increase in the range of shale $\delta^{34}S$ values in the Neoarchean Eon, suggesting greater fractionations accompanying higher sulfate levels associated with mild oxygenation of the surface environment.

Geochemical signature of microbial activity during the deposition silica-stromatolite according to REE behaviour and Zr-Hf relationship

M. CANGEMI* AND P. CENSI[1]

Department of Earth and Marine Sciences, University of Palermo, Via Archirafi, 36 – 90123 Palermo, Italy
*(correspondence: mariannacangemi@gmail.com)

Interactions between organic and inorganic species during the deposition of silica-stromatolites and associated microbial mats under hydrothermal conditions have been highlighted according to geochemical REE behaviour coupled to Zr-Hf fractionations.

In the studied system, dissolved SiO_2 derived from the leaching of outcropping volcanic rocks during interactions with hydrothermal fluids represents the raw material allowing to the deposition of stromatolites under the effects of severe microbial activity. At the same time microbial colonies also produce large amount of extracellular polymeric substances (EPS) that compete against bacterial surface into fractionating REE, Zr and Hf with respect to dissolved phase. Onto bacterial cell membranes (enriched in stromatolites) both specific polyphosphate binding sites and non-specific carboxyl O-donor groups occur differently partitioning HREE and MREE, depending on the REE/bacterial surfaces ratio [1]. EPS (occurring mainly in microbial mats) behave similarly to humic substances with respect to dissolved REE, due the similar nature of their surfaces where phenolic and carboxyl binging sites occur [2]. As a consequence REE, mainly Ce, are removed by EPS from dissolved phase and strongly enriched onto microbial mats. This process involves positive Ce anomalies and REE enrichments in the latter materials and consequently reduce the REE/bacterial surface ratio in forming stromatolites that preferentially bind HREE onto polyphosphate groups. During these processes a preferential Y and Zr with respect to Ho and Hf leads to higher Y/Ho and Zr/Hf ratios in microbial mats than in stromatolites suggesting that these ratios could represent a suitable geochemical signature of microbial activity in hydrothermal systems.

Controls of microbial nitrate/ nitrite respiration in polar marine sediments and implications for global climate change.

A. CANION[1] AND J.E. KOSTKA[2]

[1]Florida State University, Tallahassee, FL, USA
[2]Georgia Institute of Technology, Atlanta, GA, USA

An estimated 50 to 70% of the global removal of marine N occurs in sediments, and N removal from continental shelves comprises approximately half of the total sediment contribution. Despite the importance of nitrate/ nitrite respiration to the marine nitrogen cycle, surprisingly few studies have addressed the significance of temperature as a physical control of nitrate respiration. We have been studying the mechanisms and controls of N removal in permanently cold sediments collected in the fjords of Svalbard, Norway, for the past five years. As for other biogeochemical processes, rates of denitrification and anammox in cold (1-2 ºC) Arctic sediments approach those measured in temperate marine sediments. Denitrifying bacteria were isolated and shown to follow a psychrotolerant to psychrophilic growth response. Both denitrification and anammox exhibited temperature response characteristics consistent with a predominately psychrophilic community, but microbes with the anammox pathway appeared to be more adapted to permanently-cold sediments. Long term (weeks) warming experiments indicated that increases in temperature of 5 to 10 °C above *in situ* temperatures had little effect on the temperature response of denitrification and anammox, but increases of 25 °C shifted denitrification towards a predominately mesophilic community and eliminated anammox activity. When compared to previous temperature response data for other respiration processes in permanently cold sediments, it is apparent that there is considerable variability in Topt and activation energy, Ea, which may be driven by substrate availability. These results suggest that the effects of low temperature are modulated by other environmental factors to control rates of N removal in these Arctic coastal sediments.

Most recently, we have investigated the temperature regulation of microbial communities that mediate nitrogen removal in nearshore sediments over a 50° latitudinal gradient at subtropical (Gulf of Mexico), temperate (Wadden Sea), and Arctic (Svalbard) sites. The apparent activation energy of denitrification was two-fold higher in subtropical versus temperate and arctic sediments, indicating a mesophile-dominated community. Results reveal adaptation of N_2-producing microbial communities to *in situ* temperatures.

B, Pb, Sr isotopic imprint of crustal and mantle rocks from the slab-mantle interface: The Cima di Gagnone example (Central Alps)

E. CANNAÒ[1]* S. AGOSTINI[2] M. SCAMBELLURI[1,2] AND S. TONARINI[2]

[1]DISTAV, Università di Genova, Corso Europa 26, 16132 Genova, Italy *(corrispondence: enrico.cannao@unige.it)
[2]IGG-CNR, Via G. Moruzzi, 1, 56124 Pisa, Italy

In subduction zones, the slab-mantle interface represents a key setting for tectonic mixing of slab- and mantle-derived materials and for fluid-mediated mass transfer from the slab to the overlying mantle. Element exchange between different lithologies and element release to fluids in this envronment can be traced by B, Pb, Sr isotopic systems. Here we focus on the Cima di Gagnone case-study, where pelitic schists and gneisses enclose peridotite lenses, like in a top-slab mélange [1]. The ultramafic rocks, hosting eclogitized and rodingitized MORB mafic rocks, derive from serpentinized oceanic peridotites that underwent subduction dehydration [1,2]. Serpentinization also occurred during prograde exchange with fluids derived from the host rocks, once the oceanic serpentinized peridotites were accreted to the mélange [3]. Potential precursors for Gagnone, e.g. Alpine HP serpentinized peridotites from Erro-Tobbio (ET), display high B (20 ppm), $\delta^{11}B$ (13-20‰), B/Nb > 140 [4] and scarce enrichments in radiogenic Pb, Sr. At Cima di Gagnone $^{87}Sr/^{86}Sr$ and $^{206}Pb/^{204}Pb$ ratios of ultramafites (0.7055-0.7109 and 17.7030-18.4939, respectively) indicate exchange with the host rocks ($^{87}Sr/^{86}Sr$ up to 0.7208; $^{206}Pb/^{204}Pb$ up to 18.9846). Negative $\delta^{11}B$ of ultramafic rocks (-1 to -10 ‰) point to a mixed effect of (1) dehydration of serpentinized precursors, leading to heavy ^{11}B loss into fluids and to light B isotopic compositions of residual rocks, combined with (2) exchange with fluids from the host crustal rocks. Several ultramafic samples with relatively low Pb and Sr isotopic ratios, like in the ET, and with low B/Nb (<45) and $\delta^{11}B$ (-9 ‰), may represent the dehydration products of serpentinized peridotites less affetcted by crustal exchange. These data document the rock and fluid compositions attained in a top-slab mélange and point to release to fluids of $\delta^{11}B$, radiogenic Sr and Pb, which may strongly affect mantle wedge meatsomatism and arc magmatism.

Source of magmas that generated eruptive products at Mt. Somma-Vesuvius and Campi Flegrei based on melt inclusions data

CLAUDIA CANNATELLI[1]* ROSARIO ESPOSITO[1] ANNAMARIA LIMA[1] BENEDETTO DE VIVO[1] AND ROBERT J. BODNAR[2]

[1]DISTAR, Università degli Studi di Napoli Federico II, Via Mezzocannone 8, Napoli, 80134, Italy (*Correspondence: claudia.cannatelli@unina.it), (rosario.esposito3@unina.it,) (anlima@unina.it), (bdevivo@unina.it)
[2]Department of Geosciences, Virginia Tech, 4044 Derring Hall, Blacksburg VA, 24061 USA

Mt. Vesuvius and Campi Flegrei volcanic systems are located in the Campanian Volcanic District, and are considered among the most hazardous volcanic areas in the world. They lie in the proximity of the densely populated area that comprises the city of Naples, with more than 3 million people at immediate risk if an eruption occurs. The goal of this study is to understand the origin of magmas that have generated the eruptive products of these volcanic systems, by studying the major and trace element systematics of melt inclusions trapped in phenocrysts.

Melt inclusions were selected based on host rock age and provenance, i.e. all of the eruptive products of Vesuvius (from 25ky to 1944AD), Campi Flegrei (18-0.5ky) and Campanian Ignimbrite (from 250ky to 39ky) have been investigated. Incompatible elements (Zr, Th, Hf, etc) show an inverse variation with MgO, in particular Th/Hf ratios show a constant trend, indicating a genetic link between the magmas over time. More evolved melt inclusions in Vesuvius pre-1631 products (first, second and part of the third cycle) show compositions that overlap with those of the most evolved melt inclusions in Campanian Ignimbrites. Less evolved magma compositions of Campi Flegrei (Solchiaro, Fondo Riccio and Minopoli 1) overlap with compositions of magma trapped in less evolved Campanian Ignimbrite-hosted melt inclusions and Vesuvius 1906-hosted melt inclusions eruptive products.

Similarities in the trace element systematics for the melt inclusions in Vesuvius, Campi Flegrei and Campanian Ignimbrites phenocrysts lead to the conclusion that these magmas likely originated from the same deep source.

Comparison of PFLOTRAN and TOUGHREACT numerical codes for reactive transport modelling of CO_2 storage in saline aquifers

B. CANTUCCI[1]* P. ORSINI[2] AND F. QUATTROCCHI[1]

[1]Istituto Nazionale di Geofisica e Vulcanologia, Via di Vigna Murata 605, 00143 Rome, Italy (*correspondence: barbara.cantucci@ingv.it)

[2]BLOSint Ltd, University of Nottingham Innovation Park, Triumph road, NG7 2TU (paolo.orsini@blosint.com)

CO_2 geological storage in deep saline aquifers needs specific requirements in terms of safe storage and enduring containment of injected gas.

In order to understand the behaviour of CO_2 and predict the effect of geochemical reactions on trapping meachanisms and porosity/peremability variations, numerical models are an important tool.

Due to the large time and length scales involved, realistic numerical solutions, including thermal, hydrologeological and geochemical effects, are computationally demanding and the use of parallel software is necessary.

In this work a large scale model of an Italian reservoir, potentially suitable for CO_2 storage, is used as case study to compare two reactive transport codes, TOUGHREACT [1] and PFLOTRAN [2]. Pflotran is an open-source, 3D reservoir simulator, for sub-surface multiphase, multicomponent reactive flows with parallel capabilities.

The simulation model consists of an offshore structure with an area of more than 100 km^2 and a vertical development of 3 km, hosting a thick carbonatic reservoir. Two simulations were performed at different scales, considering advective and diffusive transport of the considered species at non-isothermal conditions and mineral reactions kinetically controlled. The feedback between flow and geochemical reactions, implemented in PFLOTRAN, has been customised in order to comply with the model implemented in TOUGHREACT.

At the time of writing the Authours are finalising the comparison between PFLOTRAN and TOUGHREACT solutions. However, from the preliminary results, some divergences found are likely to be due to the different EOS used to compute the dissolution of supercritical CO_2 in brine. Grid sensivity analysis and boundary condition effects are also being investigated as part of the software comparison.

* correspondence: (eescjj@mail.sysu.edu.cn)

Last century, Kristiansson and Malmqvist put forward that element contents of material carried by the the naturally occurring ascending gas flow from earth interior were analyzed and the data can be used in exploration of metal deposits. [1] Many researchers studied the application effect in metal deposits of the method. [2] We proposed and studied that the concealed metal deposits were detected using the type, size, shape, structure, chemical composition of the particles carried by the ascending gas flow. [3]-[5] In the last few years, It's the first time that we proposed that release of a large amount of particles in gases from Earth's interior were caused by earthquake and the characteristics of the particles can be used in earthquake prediction.

We studied that the type, size, shape, structure, chemical composition of particles as well as gathering characteristic among the particles, which were carried by the ascending gas of ruptures generated by the “5.12” great wenchuan earthquake, using the individual particle analysis technology of a transmission electron microscopy. Similarities and differences in the particle characteristics of ascending gas between the ruptures generated by the “5.12” great wenchuan earthquake and the fault without earthquake occurrence were compared. Abnormal particles, which are rich in metals such as Pb, Hg, Cu, Os, were found in the ascending gas of ruptures generated by the “5.12” great wenchuan earthquake.

The particles offered the new data that derives from the depth for study on causes of earthquake. This research provided a new method for earthquake prediction. It can enrich theory of nanogeoscience.

Abiogenic Fischer-Tropsch synthesis of methane at the Baogutu reduced porphyry Cu deposit, western Junggar, NW-China

MINGJIAN CAO[12]* KEZHANG QIN[2]* GUANGMING LI[2]
NOREEN J. EVANS[3] AND LUYING JIN[12]

[1]Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O. Box 9825, Beijing 100029, China (*caomingjian@mail.iggcas.ac.cn)

[3]John de Laeter Center for isotope Research, Dept. Applied Geology, Curtin University, Perth WA 6845

Methane is widely developed in hydrothermal fluids from reduced poprhyry copper deposits (RPCDs; proposed by Rowins, 2000), but its origin remains enigmatic. The occurrence of methane in fluids at the Late Carboniferous Baogutu RPCD in western Junggar, Xinjiang, NW-China (our unpublished data; Shen *et al*., 2010), presents an excellent opportunity to address this problem. A systematic study including fluid inclusion microthermometry and Laser-Raman, hydrothermal mineral H-O isotope analyses was conducted to constrain the origin of CH_4 and CH_4-rich fluids.

The wide range of δD values (-86.7±11.2 ‰, n = 21) and $\delta^{18}O$ (+3.8±1.4 ‰, n = 21) for water within quartz most likely results from water-rock interaction with water/rock ratios (wt% in O) ranging from 0.25~3 and 0.2~1 for a closed system and open system, respectively, but not from mixing with meteoric water. Detailed Laser-Raman analyses indicate CO_2 in apatite included in granodiorite porphyry phenocrystic biotite records the early stage magmatic stages, whereas later hydrothermal fluids containing CH_4 with trace CO_2 are found in inclusions in vein quartz.

We propose that the magmatic CO_2 was reduced to CH_4 by Fischer-Tropsch type (FTT) reactions in the presence of H_2, which was probably generated during the early Ca-Na hydrothermal alteration with hydration of hornblende + clinopyroxene to actinolite + magnetite + sphene + albite. Therefore, the methane of fluids at the Baogutu RPCD was not produced via thermogenesis or bacteriogenesis but instead formed during late hydrothermal alteration by FTT reactions.

Molecular geochemistry as indicators of seal integrity and relevance to shale oil exploration

TINGTING CAO, MAOWEN LI, JIANG QIGUI AND ZHIMING LI

Sinopec Exploration and Production Research Institute

Recent development in unconventional shale petroleum production in North America has led to significant changes in the global energy outlook. Production of shale oil from organic rich source rocks has brought complex geochemical, geological and engineering challenges which are distinct from those related to conventional systems. This study compares the marine petroleum systems in the Devonian-Mississippian Bakken Formation of the Williston basin in North America and the lacustrine petroleum systems in the Eocene-Oligocene Shahejie Formation in the Zhanhua Depression of Bohai Bay Basin, China, to identify key geological controls for viable shale oil plays. In particular, we pay attention to the role of seal integrity in the retention of petroleum fluids within the mature source rock systems. In the Williston basin there are two opposing schools of thought that infer either the Bakken Formation or the Lodgepole Formation as the primary source rock for the Madison-reservoired oils in the Canadian Williston Basin. While there is geochemical evidence for significant mixing of Bakken and Lodgepole oils in the Madison reservoirs, multivariate statistical analysis of a large geochemical data set indicating that oil mixing appears to be geographically dependent and restricted by a northeast-southwest–striking zone, where fracture or fault systems are inferred to have provided high permeability zones allowing Bakken-derived oil to migrate upward across the Lodgepole Formation. The areas without significant fault or fracture systems favour either lateral oil migration along porous beds in the middle Bakken reservoirs or oil retention within the Bakken source rocks leading to overpressure zones. In the Zhanhua Depression, in contrast, molecular geochemical data suggest two contrasting hydrocarbon migration scenarios: dominant short-distance lateral migration in over-pressured central sag areas, and vertical migration along fault and fractures to the shallow reservoirs in the Guantao Formation. As oil production from the shale dominated intervals in the Zhanhua Depression show clear relationship between the production locations to the proximity of regional fault systems, delineating the relationship holds the key in the target selection of shale oil exploration.

A potential steel passivating layer: fe-saponite and chlorite growth on steel in high P,T engineered barrier experiments

F.A.CAPORUSCIO[1]* AND M.C.CHESHIRE [2]

[1]EES-14, LANL, Los Alamos, NM, 87545 USA (*correspondence:floriec@lanl.gov)
[2]EES-14, LANL, Los Alamos, NM, 87545

Experimental work for the US Used Fuel Disposition campaign has started to characterize the stability and alteration of a bentonite-based Engineered Barrier Systems (EBS) with different waste container materials in brine at higher heat loads and pressures.

Experiments were run at ~150 bar 300º C for 6 weeks. Unprocessed bentonite from Colony, Wyoming was used as the clay buffer. Redox conditions were buffered at magnetite-iron oxygen fugacity. A K-Na-Ca-Cl-based brine replicated deep groundwater compositions. The experimental mixtures were brine–clay-various steels with a liquid/clay ratio of ~9. Reaction mineralogy and aqueous geochemistry of each experiment was evaluated.

No smectite illitization was observed in these reactions. It would appear that illitization was retarded due to a limitation of K^+ in the closed-system. However, notable clay mineral reactions occurred at the steel surfaces. Authigenic chlorite and Fe-saponite grew with their basal planes perpendicular to the steel plate, forming a 10 – 100 μm thick 'corrosion' layer. The steel plates act as a substrate for chlorite/Fe-saponite growth. XRD and microprobe analyses of the silicate mantling on the low-carbon steel indicates the phase is a Fe saponite with a composition of $(Na_{0.09},Ca_{0.03})$ $(Fe_{2.20}Mg_{0.12}Al_{0.86})$ $(Al_{0.58}Si_{3.42})O_{10}(OH)_2$. Stainless steel (304) is mantled by a chlorite/Fe saponite mixture. This phyllosilicate mix is high in Fe (33.99 wt% FeO), Cr (1.35 wt % Cr_2O_3) and Ni (1.34 wt % NiO).

Mineral growth on the waste containers was influenced by the container, clay buffer, and fluid compositions, in addition to pressure and temperature conditions Results show that the waste container may act as a substrate for chlorite /saponite growth in response to corrosion and the chlorite /saponite can act as a passivating agent.

Biotite and phlogopite dissolution: Topographic observation by VSI

C. CAPPELLI[1]*, J. CAMA[2] F.J. HUERTAS[1], C. FISCHER[3] AND A. LÜTTGE[3]

[1]Instituto Andaluz de Ciencias de la Tierra (IACT), CSIC-UGR, Avenida Fuentenueva s/n., 18002 Granada, Spain (*correspondence: chiaracappelli@ugr.es)
[2]Institute of Environmental Assessment and Water Research (IDAEA), CSIC, Jordi Girona 18-26, 08034 Barcelona, Catalonia, Spain
[3]University of Bremen – Department 5 Geosciences, Bibliothekstraße 1, 28359 Bremen, Germany

The dissolution kinetics of two micas (biotite and phlogopite) was investigated by vertical scanning interferometry (VSI). Topographical data at the basal surface during dissolution at pH 1 and 2 (25 -100 ºC) of nitric and oxalic acid solutions were used to determine the micas' dissolution mechanisms.

Single biotite and phlogopite fragments of approximately 100 mm^2 were reacted in 250 mL of acidic solution up to 44 days. The cleavage surfaces were examined by VSI before and after the reaction.

On the one hand, the biotite dissolution in nitric acid was dominated by step-edge retreat together with a phenomenon of layer peeling at the step edges [1]. At longer reaction times dissolution channels developed, leaving mineral islands. In the presence of oxalic acid, biotite step-edge retreat was also observed. In addition, formation of rounded etch pits of different size and density, depending on the experimental conditions, took place by covering the surface rather uniformly. Moreover, some peculiar dissolution microstructures were found at the mineral-solution interface.

On the other hand, VSI images of phlogopite surface showed step-edge retreat and formation of triangular crystallographically controlled etch pits [2,3] of different size, being non-homogeneously distributed over the basal surface. In the presence of oxalic acid, the phlogopite dissolution features were similar to those observed in nitric acid, but higher etch pit density and etch pit alignment were observed.

Hence, as the mechanisms that control the dissolution of the different mica minerals depend on the presence/absence of oxalic acid, it is necessary to study the effects of the compositional factor and the presence of inorganic ligands on the dissolution kinetics of micas.

Fe-Si system: a potential major component of the Earth's core

RAZVAN CARACAS[1], MATTHIEU VERSTRAETE[2], REBECCA FISCHER[3] AND ANDREW CAMPBELL[3]

1) Laboratoire de Geologie de Lyon (LGLTPE) CNRS UMR 5276, Ecole Normale Supérieure de Lyon, France; (razvan.caracas@ens-lyon.fr)
2) University of Liege, Institut de Physique, Bat. B5, Liege, Belgium
3) Department of the Geophysical Sciences, University of Chicago, 5734 E Ellis Ave, Chicago, IL 60637, USA

We investigate the phase diagram of the Fe-Si system, the solubility limits of Si into hcp Fe, and the effect of Si on the thermal and electrical conductivities of iron. For this we perform first-principles calculations based on the density-functional theory and the density-functional perturbation theory.

First we build a series of hcp supercells; we replace some of the Fe atoms with Si in various amounts and configurations. In this way we mimic the dissolution of silicon into hcp and take into account a realistic solid solution. Silicon slightly increases the specific volume of iron, but the differences levels out at high pressures. We show that the density and seismic profiles of the core can be easily matched by Fe-Si alloys with small amounts of Si. Further phonon analysis suggests that stoichiometric Fe_3Si is dynamically unstable at high pressure. This results in decomposition into Si-bearing hcp Fe and Fe-bearing B2 FeSi. Then we follow the evolution of the Fe-FeSi immiscibility gap as a function of pressure.

Finally we compute the electrical and thermal conductivities of Si-bearing hcp iron at inner core conditions. We obtain that a relatively small amount of Si decreases the conductivity of iron, but then this quickly reaches saturation.

Based on these considerations we conclude that Si can be a major light element of the Earth's core.

Mantle-derived fluids in Central Mediterranean: Geochemical and geophysical constrains on sources of fluids and migration

CARACAUSI A[1], F. GRASSA[1], V. PENNINO[2], A. RIZZO[1], AND A. SULLI[2]

[1]Istituto Nazionale Geofisica e Vulcanologia, via Ugo La Malfa 153, 90146, Palermo, Italy. (a.caracausi@pa.ingv.it)
[2]University of Palermo, via Archirafi 36, 90123, Palermo, Italy.(attilio.sulli@unipa.it)

The geodynamics of the central Mediterranean is characterized by the interaction between the European plate and the African's. In this setting Sicily is a sector of the Appenine-Maghrebide accretionary prism, which is located between two areas affected by extensional tectonics (Sicily Channel to the south and the Thyrrenian back arc basin to the north).

Significant mantle-derived helium ($0.4<R/Ra<2.8$; $R=^3He/^4He$ in the sample, Ra in atmosphere) is found in the CH_4 and N_2-CO_2 rich fluids released in central western Sicily, a region without evidence of recent magmatism. CH_4-dominated gases are released from mud volcanoes localized in an area of both low heat flow and seismicity. On the contrary CO_2 is mainly associated to the thermal groundwater circulating mainly in Mesozoic limestone over an area characterized by high seismicity and heat flow anomaly. Total carbon dissolved in thermal water is a mixture of mantle-derived and crustal inorganic CO_2, while CH_4-dominated fluids show a mixing between a ^3He rich and CH_4-poor term and a CH_4-rich and ^3He-poor one typical of crustal reservoir of gases. The computed mantle derived He, much higher than stable continental areas, indicates that the transfer of fluids is controlled by tectonic mechanism through the crust. Finally, recent geophysical investigations discovered the occurrence of active lithospheric faults that could control the transfer of mantle derived fluids from the sources to the crust and throughout this towards the surface.

Magma dynamics at Mount Etna (Italy) inferred from geochemistry of gas emissions

CARACAUSI A., MARTELLI M., PAONITA A. AND RIZZO A.*

Istituto Nazionale di Geofisica e Vulcanologia – Sezione di Palermo, Via Ugo La Malfa 153, 90146 Palermo, Italy (*correspondence: a.rizzo@pa.ingv.it)

Since 2007 we have performed a geochemical monitoring of some fumaroles located in the rim of Voragine crater at Mount Etna. The acquired data have been integrated with those from peripheral gas emissions, monitored since 1996. As a first step, the gas mixtures have been quantitatively corrected for post-magmatic processes such as interaction with shallow aquifers. Then, the systematics of He-Ar-CO_2 allowed us to assess the degassing path of the emitted gases and the absolute pressures at which are released. As a result, peripheral gases are fed by volatiles exsolved from magma batches residing in a range of pressure comprised between 200 and 400 MPa, while summit fumaroles get also gases from lower pressures (~130 MPa). These pressures well agree with geophysical and petrological investigations that recognize ponding zone of magma at 5-12 km b.s.l. and at 2-3 km b.s.l.

In addition to pure magma degassing processes, also mixing of the volatiles exsolved at different pressures occurs and influences the chemical and isotope variations, especially of crater fumaroles. Indeed, temporal monitoring of $\delta^{13}C_{CO2}$ and He/Ar ratio showed that variable proportions of mixing as well as variable degassing pressure strongly depend on magma dynamics at depth. In particular, a progressively deep component seems to prevale during pre-eruptive phases reflecting magma recharge at depth, while the pure degassing component pertains to shallow volatile component prevaling during post-eruption periods.

Finally, long-term monitoring of $^3He/^4He$ ratios from both peripheral and crater gases has allowed us to sistematically recognize phases of increase of the isotope ratios, occurred months before the onset of eruptive activity at all the sampled emissions. Considering what above stated, these phases would be related to refill of the plumbing system by ^{3}He-rich magmas, being thus very primitive and rising directly from the mantle. Recently, this behavior has been also recorded before 2011-2012 and 2013 volcanic activities, which have been characterized by frequent episodes of fire fountains and lava flows from the New South East Crater (NSEC). We point out that the last phase of magma recharge at depth is still ongoing suggesting that the new eruptive period, started in early 2013, could be further fed in the following months.

μ-XRD, μ-XRF, and μ-XANES synchrotron analyses of heterogeneous mine-waste materials related to AMD processes

C. CARBONE[1], G. GIULI,[2] S. CONSANI[2] P. MARESCOTTI[2] AND G. LUCCHETTI[2]

[1]DISTAV, Corso Europa 26, Univeristy of Genova, Italy
[2]Scuola di Scienze e Tecnologie, Sezione di Geologia University of Camerino, Italy

In this work, we studied the mineralogical and chemical variations of some representative mine-waste samples from the Fe-Cu sulphide Libiola Mine, by means of combined synchrotron-based μ-XRD, μ-XRF, and μ-XANES analyses performed at ESRF beamlines (Grenoble). Mine waste is acid generating (Marescotti *et al*., 2010) and is characterized by a high amount of completely to partially altered sulphide-rich mineralizations. Other than acid generation, the major environmental problem is the mobilization of potential toxic elements (PTEs) that can be concentrated in waters and soils. We studied three different Fe-oxides and -oxyhydroxides rich samples representative of a) stratified crust formed by the ageing of soft precipitates formed from acid mine waters discharged at mine adits, b) partially altered massive pyrite-rich mineralizations which contain the transition from unaltered to completely alteres sulphide-mineralizations (Carbone *et al*., 2012), and c) partially altered stockwork pyrite-rich mineralizations.

In this study, we demonstrated that the combined use of micro-synchrotron-based techniques (performed at ID18f and ID21 beamlines) can be succesfully applied to monitor the alteration processes that occur betwwen sulphides and their oxidation products. In particular, the combined use of μ-XRD and μ-XRF highlighted a different behaviour of some ecotoxic elements, such as Zn and As, during the evolution of the alteration process. A quantitative analysis of the sulphide/sulphate ratio was performed using the μ-XANES S k-edge spectra, while the Fe k-edge spectra were used in order to obtain the distribution of Fe^{3+} between primary and secondary phases.

The summit activity at Mt. Etna from 1995 to 2001: A multidisciplinary approach to investigate the long-term processes of the magmatic plumbing system

D. CARBONE[1], R.A. CORSARO[2], F. GUGLIELMINO[3] AND G. PUGLISI[4]*

[1]INGV-OE, piazza Roma 2, 95125 Catania, Italy, (carbone@ct.ingv.it)
[2]INGV-OE, (corsaro@ct.ingv.it)
[3]INGV-OE, (guglielmino@ct.ingv.it)
[4]INGV-OE, (*correspondence: puglisi-g@ct.ingv.it)

The integration of volcanologic observations, petrologic data, microgravity and ground deformation acquired at Etna from 1995 to 2001, provided the opportunity to investigate the long-term dynamics of Mt. Etna during a period when the activity was restricted to the summit craters.

Temporal patterns of major and trace elements indicate that the variability of bulk rocks composition is due to fractional crystallization and mixing between residing and new intruding magmas. Microgravity data show that from late-1996 to mid-1999 and from late-2000 to mid-2001, strong gravity decrease occurred, centered on the upper southeastern sector of the volcano. The gravity decreases coincide with an increase in the rate of the seismic strain release**.** Ground deformation show, from 1994 to the onset of the 2001 eruption, an almost continuous expansion of the volcano mainly due to magma accumulation into the western sector of the volcano. Therefore, the anti-correlation between gravity and seismicity in the eastern flank is not strictly connected to movements of magma and/or change of its chemical and physical properties. Conversely, these data suggest an increase of micro-fracturing along the NNW–SSE structural trend, implying a local density (gravity) decrease coupled with an increase in the release of seismic energy.

From 1996 to 1999 the inferred increase in the rate of fracturing and acceleration of deformation in the volcano eastern flank led to the ascent of conspicuous magma volumes that promoted the reactivation of the South-East and Voragine summit craters, with sustained an intense explosive and effusive activity until the end of 1999. The increase of rate of fracturing from late-2000 to mid-2001 enhanced the formation of a preferential path for magma ascent to the surface and the onset of the July 2001 flank eruption.

Control of magma recharge and buoyancy on the frequency and magnitude of volcanic eruptions

LUCA CARICCHI[1] CATHERINE ANNEN[2] AND JON BLUNDY[2]

[1]Section of Earth and Environmental Sciences, University of Geneva, Rue des Maraîchers 13, CH-1205 Geneva, CH
[2]Department of Earth Sciences, University of Bristol, Wills Memorial Building, Queen's Road, BS8 1RJ, Bristol, UK

The frequency at which volcanic eruptions occur is inversely proportional to the volume of magma released in a single event. The basic requirements for a volcanic eruption to occur are that enough heat is supplied to the crust to assemble a body of eruptible magma and that overpressure is sufficient for the magma to reach the surface without solidifying. Starting from these basic principles we used thermo-mechanical calculations and Monte Carlo simulations to quantify the relative contribution of magma fluxes and the physical properties of the crust on likelihood and volume of volcanic eruptions. The calculations were performed considering the periodic input of magma in pulses of different size and shape injected at various frequencies The average rate of magma supplied to the upper crust over hundreds of thousands of years appears to control the volume of magma that can potentially be released during a single eruption, whereas the time interval between short-lived pulses of magmatism, affects the total duration of magma injection preceding an eruption. Our calculations reconcile the relationship between erupted volume and upper crustal magma residence times, and replicate the correlation between erupted volumes and caldera dimensions. Our modelling shows that relatively small and frequent eruptions are triggered by magma injection while buoyancy is important to trigger large eruptions. These calculations permit to identify the physical processes controlling the relationship between frequency and magnitude of volcanic eruptions and increase our capability of determining the temporal evolution of volcanic activity in different volcanic systems.

Systems biology studies on the stress response of perchlorate, chlorate oxidative and nitrosative stress in *Desulfovibrio alaskensis* G20

HANS K. CARLSON[12]* MARK R. MULLAN[1,2], ADAM M. DEUTSCHBAUER[2] MORGAN N. PRICE[2], ADAM A. ARKIN[13] AND JOHN D. COATES[123]*

[1]Energy Biosciences Institute, University of California, Berkeley, Berkeley, CA (*correspondance: jdcoates@berkeley.edu, carlsonh@berkeley.edu)
[2] Department of Plant and Microbial Biology, University of California, Berkeley, Berkeley, CA
[3] Lawrence Berkeley National Laboratory, Berkeley, CA

The chloroxyanions, perchlorate and chlorate, are potent inhibitors of sulfate-reducing bacteria, and as such are promising as treatments for biosouring in oil reservoirs. To understand the mechanism of inhibition, tagged transposon pools of the model sulfate-reducer, *Desulfovibrio alaskensis* G20 were stressed with the intermediates of respiratory perchlorate reduction: perchlorate, chlorate and oxygen.

The G20 mutant fitness profiles for (per)chlorate stress compared with other stressors such as nitrate, nitrite, nitric oxide and the reactive oxygen species hydrogen peroxide and hypochlorous acid reveal both overlapping and unique targets and mechanisms of resistance. Physiological, biochemical and transcriptomic studies were used to further define the cellular response to (per)chlorate. Taken together our results suggest that (per)chlorate toxicity appears to be a combination of oxidative stress alongside competitive inhibition of transport systems and enzymes involved in sulfate reduction. This work provides a starting point for developing new treatments to inhibit sulfate reduction in engineered ecosystems, including possible synergistic interactions between stressors.

Making Earth

RICHARD W. CARLSON

Carnegie Institution of Washington, Washington, DC, 20015 USA: (rcarlson@ciw.edu)

Our understanding of the steps involved in Earth formation have been transformed by huge improvements in the isotopic measurement techniques employed in geo/cosmochemistry. Modern techniques can: provide chronological precisions of well less than a million years on events happening over 4.5 billion years ago; allow the application of a wide variety of extinct radionuclides as chronometers and tracers that are sensitive to different key processes in planet formation and differentiation; and resolve isotopic variabililty in the Solar nebula that can provide clues to its structure and the origin of the building blocks of the terrestrial planets. The identification of an increasing number of stable isotope variations between meteorites and Earth has reopened the question of whether meteorites can be used to accurately infer the composition of the bulk-Earth. This basic compositional datum likely will have to come from direct measurement of Earth composition, for example the determination of bulk-Earth U and Th abundances via geoneutrinos. Improved chronological precision now allows clear resolution of many key steps involved in planet formation. Earth gained its characteristic depletion in volatile elements compared to chondritic meteorites within a few million years of Solar system formation. Ages for other events, however, must be interpreted in the context of a prolonged interval for Earth formation. For example, core formation on Earth is dated at 4.47-4.53 Ga, but this age range likely just reflects a mean age for a sequence of core forming events that occurred with each impact between a large planetesimal and the growing Earth. The last major impact into the growing Earth, likely the one responsible for Moon formation, appears to have occurred relatively late in Solar system history. The oldest reliably dated lunar crustal rocks give ages between 4.36 and 4.41 Ga, which overlap the I-Xe age of Earth's atmosphere, the U-Pb model age of Earth's mantle, the Sm-Nd and Lu-Hf model ages of the lunar mantle, and the oldest ages for zircons from western Australia and mafic metamorphic rocks from northern Quebec. Some Archean rocks derive from sources created in this early differentiation event, but mantle convection appears to have mixed away much of the evidence for this event in Earth's interior by 2.7 Ga. By ~4.4 Ga, Earth's surface and shallow interior had cooled to the point where liquid water was present on the surface and cycles of basaltic magmatism followed by hydration and remelting of the basalt to produce the felsic rocks typical of continental crust already had begun.

Preserving Fertile MORB Mantle in the Continental Lithosphere

RICHARD W. CARLSON[1] AND DMITRI A. IONOV[2]

[1]Carnegie Institution of Washington, Washington, DC, 20015 USA: (rcarlson@ciw.edu)
[2]PRES-Lyon & UMR6524-CNRS, 42023 Saint Etienne, France: dmitri.ionov@univ-st-etienne.fr

The shallow mantle beneath the Tariat region of central Mongolia is composed predominantly of fertile peridotite [1]. Of over 110 peridotite xenoliths recently collected from four localities in the Tariat region, over 90% are lherzolites. The remainder include subequal amounts of harzburgite and veined pyroxenite-peridotites. The median Mg#, Al_2O_3, and CaO contents of the Tariat collection are 89.4, 3.87 and 3.23, respectively. Modeling major element compositions indicate that most samples experienced 0-6% partial melt removal at 1 GPa [2]. Clinopyroxenes, on average, are moderately LREE depleted (average chondrite normalized La/Sm = 0.45). Most whole rocks show small, if any, depletions in Re and Pd compared to other HSE. $^{187}Os/^{188}Os$ for samples with more than 3.2% Al_2O_3 range only from 0.126 to 0.131. Samples with Al_2O_3 ranging from 3.1 to 1% Al_2O_3 define a correlation with $^{187}Os/^{188}Os$ suggesting an "alumichron" age of ~2 Ga. The most refractory samples, however, show no correlation with Os isotopic composition, with $^{187}Os/^{188}Os$ from 0.114 to 0.128; they also are commonly enriched in iron and LREE. In contrast to the indicators of fertility in most samples, new Sr, Nd and Hf isotopic data for acid-leached clinopyroxene separates from fertile lherzolites plot within the range of modern MORB with $^{87}Sr/^{86}Sr$ from 0.7021 to 0.7026 and εNd from +7.7 to +9.8, overlapping earlier results [3] and εHf from +13.3 to +18.5. One metasomatized harzburgite gives $^{87}Sr/^{86}Sr$ (0.7045) and εNd (+1.5), within the range seen for Cenozoic Mongolian basaltic volcanism [4], but retains a high εHf of +11.5, which suggests recent overprinting of Sr and Nd, but less so Hf, by melts similar to the regionally widespread basalts. The crustal section in this part of the Central Asia Orogenic Belt consists of various terranes mainly accreted in the Paleozoic [5]. The composition of the mantle lithosphere beneath at least the Tariat region suggests that a significant slice of fertile MORB mantle was accreted with the overlying crust, perhaps allowing an unusually clear look at a section of convecting asthenosphere less altered than typical of exposed abyssal peridotites.

Nitrogen in bivalve shell & soft tissues: Implications for N sequestration and cycling in coastal waters

RUTH H. CARMICHAEL*[12] D. JOE DALRYMPLE[12] P. BIANCANI [12], C. KOVACS[1], W. WALTON[3] AND E. DARROW12

[1]Dauphin Island Sea Lab, Dauphin Island, AL 36528, (*correspondence: rcarmichael@disl.org)
[2]University of South Alabama, Mobile, AL 36688
[3]Auburn University Shellfish Laboratory, Dauphin Island, AL 36528

There is growing interest in the role of bivalve shellfish in biofiltration, particularly with regard to N sequestration and removal from coastal waters. We quantified N assimilation into tissues of several bivalve species, linking N to anthropogenic sources for management, and defining timescales of N sequestration or removal that may affect ecosystem functions (particularly biogeochemical cycling). These data are important as urbanization and other human activities increasingly alter food supply and habitat for bivalves and we recognize historical global loss of commercial bivalves, due to combined habitat loss and over harvest. We found that N assimilated into bivalves largely depended on food quantity and quality, which determined growth (rate of N assimilation) and %N content in both soft tissues and shell. N assimilation rates & %N are at least affected by species-specific physiology, feeding habits, ontogeny and genetics, and cannot be generalized due to site-specific variation in food supply and environmental attributes. Similarly, biodeposition that allows N sequestration via burial or biogeochemical processes depended on food quantity and quality as well as environmental variation. Stable isotope analysis was used to successfully link biological responses to anthropogenic N sources across temporal and spatial scales, even when effects on growth or survival were not measurable. More data are needed to define timescales of sequestration, particularly in older reefs and for deposited shell. Ultimately these data can be combined from different regions to estimate global losses of N sequestration capacity through time due to bivalve depletion and predict capacity of sequestration or removal through restoration and farming activities. Interestingly, external N loading appears to have a positive influence on N removal capacity of bivalves by increasing growth rates and N storage in tissues, but external N loaded is greater than enhanced N sequestration and removal capacity in most cases, particularly in areas with increasingly limited available habitat.

^{40}K-^{40}Ca constraints on the source of dissolved Calcium in Himalayan rivers

G. CARO[1] AND C. FRANCE-LANORD[1]

[1]CRPG-CNRS, Université de Lorraine, 15, rue Notre Dame des Pauvres, Vandoeuvre-les-Nancy. (caro@crpg.cnrs-nancy.fr;) cfl@crpg.cnrs-nancy.fr

This study investigates the potential of the ^{40}K-^{40}Ca system for quantifying the contribution of silicate and carbonate lithologies to the Ca dissolved load of major Himalayan rivers. The ^{40}K-^{40}Ca decay scheme has geochemical properties similar to the ^{87}Rb-^{87}Sr system but its application as a tracer has been hampered by the analytical precision required to measure small variations on the large ^{40}Ca isotope (96.9%). This difficulty can now be overcome using the Finnigan Triton TIMS, which allows measurement of the ^{40}Ca/^{44}Ca ratio with external precision of 0.3-0.5 ε-unit [1]. Previous work showed that dissolved loads from the Ganga (in Patna) and Brahmaputra (in Guwahati) carry radiogenic ^{40}Ca excesses of +1.4±0.3 and +0.9±0.3 ε-units, respectively [1]. Since the ^{40}Ca composition of seawater remained constant and indistinguishable from the mantle value (ε^{40}Ca=0) for the past 3.5 Ga [1], radiogenic Calcium must originate from the weathering of felsic rocks, or, alternatively, from metamorphosed carbonates having experienced isotopic exchange with surrounding silicates, as previously documented for ^{87}Sr. In order to test these hypotheses, we performed high-precision ^{40}Ca analyses in bedload carbonates from rivers draining the major Himalayan rock units, and in whole-rock dolostones with highly radiogenic ^{87}Sr/^{86}Sr from the Lesser Himalaya. Our results show that whole-rock and bedload carbonates are characterized by an ε^{40}Ca=0 despite having highly variable ^{87}Sr/^{86}Sr ratios (0.71-0.86). A small excess (<1 ε-unit) was found in one dolomitic sample with ^{87}Sr/^{86}Sr≈0.86 but given its extreme ^{87}Sr/^{86}Sr signature, this marginal lithology is bound to have a negligible influence on the Himalayan riverine ^{40}Ca budget. Overall, it appears that the major carbonate units of the Himalaya were not significantly affected by metamorphic redistribution of ^{40}Ca. These preliminary results suggest that radiogenic signatures measured in the Ganga and Brahmaputra are derived from the weathering of silicate lithologies, and highlight the potential of the ^{40}K-^{40}Ca scheme as a tracer of silicate weathering in the Himalayan system.

Detoxification of milk contaminated by aflatoxin M1 using clay minerals and effects on milk quality

A. CARRARO[1], A. DE GIACOMO[2], M.L. GIANNOSSI, L. MEDICI[3], L. PALAZZO[2], V. QUARANTA[2], V. SUMMA[3] AND F. TATEO[1]

[2] Istituto Zooprofilattico Sperimentale della Puglia e della Basilicata, Foggia, Italy

[3] Institute of Methodologies for Environmental Analysis, National Research Council (CNR), Tito Scalo (PZ), Italy

Mycotoxines are widespread toxic substances produced by moulds in human and animal foodstuffs. Some of them, such as aflatoxin B1 (AFB1), are very toxic even in small amounts. The modern approach to the problem (and the link with public health) started in the 60s. After decades of studies, it appears that variations in nutritional habits and climatic conditions during the human history have emphasized epidemics and acute mycotoxin toxicity [1]. A main problem is the presence of AFM1 in milk and dairy products. The maximum amount in the European Union is 50ng/L (25ng/L for lactants). AFM1 is resistant to thermal and chemical treatments, so mineral sorbents are highly advisable. Clay minerals are suitable, but only a few data are available, as most studies deal with AFB1 which is absent in milk. To test the role of clay minerals in detoxifying milk, some bentonites and a kaolin were selected for the experimental work. The clay was added to milk and left to settle. Kaolin was less effective than bentonites, but was still able to detoxify contaminated milk, even using a little amount of kaolin (2.4% of the milk suspension). Among bentonites (beidellite-montmorillonite, ferruginous and saponite types), a saponite clay showed the highest sorbent capacity, in agreement with general theoretical consideration about its higher cell surface (available for AFM1) and less surface hydrophobicity. Fat, protein and lactose are slightly affected by clay treatments of milk; protein adsorption increases with the bentonite-milk ratio.

The climatic changes observed and predictably point to a wider diffusion of mycotoxines and health effects [1], and push toward the search for safe, cheap and accessible food treatments.

Arsenic anomalies in shallow groundwater and sediments (Venetian Plain, Italy)

A.CARRARO[1], P. FABBRI[2], A. GIARETTA[1] L. PERUZZO[1] F. TATEO[1] AND F. TELLINI[1]

[1]Institute of Geosciences and Earth Resources, National Research Council (CNR), c/o Department of Geosciences, University of Padova, Padova, Italy (peruzzo@igg.cnr.it)

[2]Department of Geosciences, University of Padova, Italy

A pilot area within the Venetian Plain was selected to assess the arsenic contamination of groundwater and sediments. The area represents a typical residential, industrial and agricultural organization of most western countries, and is also devoid of hydrothermal, volcanic or anthropogenic source of arsenic. The unconfined aquifer reservoir varies from a predominantly gravel composition in the north to a sandy and silt–clay composition further south, including peat layers. The hydrochemical features of groundwater are rather homogeneous, featuring low mineral content and a Ca-bicarbonate signature. In contrast, the redox state is highly variable: oxidizing conditions are predominant in the northern and coarse parts of the aquifer, whereas reducing potentials prevail in the southern and silt–clay parts. Several well waters contain arsenic in excess of drinkable limits (10 ppb), and most of these wells are located in the southern area. A large portion of the studied area has a high probability of containing nonpotable water (up to 150 ppb As). Remarkably, arsenic ''hot spots'' (As >300 ppb, up to 431 ppb) were identified at the transition from gravel to silt–clay sediments. Some private wells are used for farm activities and domestic purpose, especially where the public pipe network is absent. The analyses of sediments point out that the expected covariance of As and Fe (observed in many young sedimentary aquifers) is absent, whereas a regular increase of arsenic content and organic matter is detectable throughout all lithologies (sand, silt, clay and peats). The highest concentration of arsenic in peats is about 300 ppm, whereas the average in organic-poor sediments is 11 ppm (n = 10, std.dev. = 8.4, organic matter < 1%). The organic sediments in the area are a candidate source of arsenic in groundwater and this feature represents a prospecting tool in search of safe water. Another effective help in this task is the downhole decrease of arsenic in groundwater [1]: below 200m the average arsenic content in the area is 8 ppb.

Tracing Lead sources and chronologies in sediments and coral cores in Kuwait

CARRASCO, G. [1]* BOYLE, E.A.[1] ZHAO, N.[12], NURHATI, I.[3], GEVAO, B.[4] AND AL-GHADBAN, A.N.[4]

[1]Earth, Atmospheric and Planetary Sciences Department, Massachusetts Institute of Technology, Cambridge MA, USA (* presenting author).

[2]Woods Hole Oceanographic Institution, Woods Hole MA, USA.

[3]Singapore-MIT Alliance for Research and Technology, Singapore,

[4]Kuwait Institute for Scientific Research, Kuwait City, Kuwait,

The objective of this study was to reconstruct detailed input chronologies of Pb and other trace metals in the Kuwaiti marine environment, influenced by the Shatt-al-Arab River's load (SaAR), using seawater, and sediment and coral cores. Pb concentrations were determined by plasma mass spectrometry using resin preconcentration and isotope dilution (ID) for seawater, a "Graney leach" extraction and ID on sediments, and cleaning, dissolution and ID on corals. Pb isotopic distributions in seawater, sediments and corals were determined using multicollector magnetic sector plasma mass spectrometry after anion exchange purification of Pb.

Seawater Pb concentrations are high in the northern stations, including Kuwait Bay (KB). They show combined anthropogenic and riverine sources, while waters at a coral reef near Qaruh Island (QI) show high Pb.

Comparing the Pb concentration and isotopic fractionation in two sediment cores near KB and near the SaAR outflow with a coral core near QI helped us discern trends, potential sources, and some events for the past ~60 years in the region. The coral core shows more pointed events and trends, which resemble more the data from the anthropogenic-influenced station near KB than that from the lower-Pb concentration SaAR station. The QI coral core and the KB sediment core data suggest a decreasing trend in the Pb concentrations after 1990, possibly linked to Pb phase out in the Kuwait area, which agrees with the increasing Pb206/Pb207 ratios. The change of lead isotopic signal in the coral lags the change of lead concentration signal by 3-4 years.

Pb data from two more cores and surface sediments upstream the SaAR are currently being analyzed, and will be added to the current interpretation, as well as data for other metals (Cd, Cu, Ag, U) from the sediment and coral cores.

Mineralogy, Geochemistry and Metals content in tailings, sediments and soils next to some metallic ore deposits in east central Mexico

ALEJANDRO CARRILLO-CHAVEZ[1]* NORMA CRUZ[2], ERIK SALAS[2], CAROLINA MUÑOZ[1], ALICIA AUDIFRED[3] AND GILLES LEVRESSE[1]

[3]Faq. Quimica, Univ. Autonoma de Queretaro, Queretaro, 76200, Mexico, (audifred@uaq.mx)

Several metal sulfides ore deposits (epithermal veins and skarn type deposits) occur in the central east portion of Mexico (Sierra Madre). Historically, some of these deposits have been exploited since the 1500´s and 1600´s. Currently, there are millions of tons of mine waste material with high content of potentally toxic metals. The ore material contains stibinite, cinebar, realgar, chalcopyrite, galena, sphalerite, and minerals with Ag, Au and As. The mine waste material contains considerable amounts of Cd, Cr, Co, Cu, Ni, Pb, Hg, As, and Sb, posing a treat to the local population.

Some of the mine tailings consist of abundant metal oxides and metal sulfides. Redox reactions locally produce pH around 2 in leachates, and high metal content. Secondary mineralogy includes malachite, goethite, ferrihydrite, jarosite group minerals and gypsum, among others. The geochemical activity is controlled by the seasonal rains (from June to September), along with high evaporation rates. These factors produce acid mine drainage, metal leaching, redox and dissolution-precipitation reactions. Most important, high amounts of heavy metals and As are incorporated and transported in sediments, soil and surface water. As and metal content in tailings is up to 7 gr/Kg of As, 1 gr/Kg of Cu, 5 gr/Kg of Zn and 3 gr/Kg of Pb. River sediments concentrations are: As = 2.5 gr/kg, Cu = 0.146 g/Kg, Zn = 1 g/Kg, and Pb = 0.117 g/Kg. For agricultural soils (small patches of land along river terraces) As and metals concentrations are: As = 0.117 g/kg, Cu = 0.022 g/kg, Zn = 0.087 g/kg, and Pb = 0.037 g/kg. For surface water (seasonal mountain creeks) the As and metals concentrations are: As = 0.05 mg/l; Cu = 0.01 mg/l; Pb <0.017 mg/l, and Zn = 0.01 mg/l. The ultimate goal is to understand the geochemical controls of As and heavy metals in this environment. This work is financed by UNAM-PAPIIT Grant IN 112311.

Crystallization kinetics in hydrous magmas subject to decompression

C. AGOSTINI[1], F. ARZILLI[12], P. LANDI[3] AND M.R. CARROLL[1]

[1]School of Science and Technology – Geology Division, University of Camerino, Via Gentile III da Varano, I-62032 Camerino, Italy (correspondence: michael.carroll@unicam.it)

[2]SYRMEP Group, Elettra-Sincrotrone Trieste S.C.p.A., SS 14, Km 163, 5 in Area Science Park, 34012 Basovizza, Trieste, Italy

[3]Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Pisa, via della Faggiola 32, 56126 Pisa, Italy

Recent experimental work on crystallization kinetics in water-saturated magmas from Stromboli (Shoshonitic basalt) and Campi Flegrei (Trachyt-Phonolitic) provide insights into how magma decompression can significantly affect crystal abundances and thus melt physical properties during magma movement within the crust of the Earth.

Water-saturated samles of a primitive Stromboli basalt were subjected to isothermal (1075°C) decompression from 100 MPa to final pressures of 75 to 5 MP and samples were allowed to crystallize at the final pressure for times of 0.5 to 16 hr. Measured crystal growth rates show a strong dependence on time, varying from ~10^{-6} cm/s in the shortest experiments to ~10^{-8} cm/s in the longest experiments. The experimental results, combined with observations on natural samples, suggest timescales of hrs to several weeks for crystallization of small Plag crystals (<~200 microns, not showing resorption textures) in Stromboli scoria. Observed variation of Plag composition with P(H2O) suggest depths less than ~400 m for the upper part of the Stromboli feeding system.

Experiments on a trachytic composition from the Campi Flegrei (Naples) area studied the effects of decompression and cooling on alkali feldspar (Afsp) crystallization. Afsp is the main phase present in this trachyte and its abundance can strongly vary with small changes in pressure, temperature and water content in the melt, implying appreciable variations in magma physical properties and eruptive behavior. Results obtained show large variations with ΔT, time, and melt water content. In general, at small ΔT growth dominates crystallization, whereas at large ΔT nucleation dominates. Time also is important variable during crystallization, because long experiment durations involve more nucleation events. This is an important aspect to better understand magma evolution in the magma chamber and in the conduit, and consequent effects on magma rheology.

Geochemical and geomechanical influences on the permeability of wellbore cement fractures exposed to CO_2-rich brine

SUSAN CARROLL[1], STUART WALSH[1], HARRIS MASON[1], AND WYATT DU FRANE[1]

[1] Lawrence Livermore National Laboratory, Livermore, CA 94551 USA; (carrroll6@llnl.gov); (walsh24@llnl.gov;) (mason42@llnl.gov;) (dufrane2@llnl.gov)

The objective of this work was to quantify the relationships between chemical alteration, deformation, and permeability at the wellbore/caprock interface important to long-term geologic carbon storage through experiment and modeling. The core flood experiments span variable pCO_2, flow rate, and cement – caprock fracture apertures at 60°C and 24.8 MPa. We used x-ray computed micro tomography to spatially resolve the fracture surface and the extent of alteration, three dimensional digital image correlation to spatially resolve plastic deformation resulting from chemical alteration, and time dependent solution chemistry and pressure to track coupled evolution of chemical alteration and mechanical deformation. Coupled processes between chemical alteration and material compressibility were largely responsible for decrease in permeability despite measured porosity increase at the cement/caprock interface. CO_2-rich brines alter wellbore cement into distinct portlandite depleted, carbonate, and aluminum-bearing amorphous silicate layers and change the compressibility of cement at the wellbore/caprock interface. Dissolution of portlandite from the cement resulted in plastic deformation of the surface contacts restricting flow paths and lowering the overall permeability. Chemical alteration of the cement was controlled by ion diffusion through cement and its alteration layers, as well as calcite equilibrium at the carbonate/amorphous silicate boundary and analcime equilibrium at cement/caprock interface.

Uncertainties in global CCN and cloud drops: which aerosol processes are important?

K.S. CARSLAW[1]*, L.A. LEE[1], K.J. PRINGLE[1], C.L. REDDINGTON[1] AND G.W. MANN[1]

[1]School of Earth and Environment, University of Leeds, Leeds LS2 9JT, UK (*correspondence: k.s.carslaw@leeds.ac.uk)

Aerosol-cloud interaction has remained the largest uncertainty in the radiative forcing of climate through all IPCC assessments. Despite this persistent problem, very little research has been done to tackle the problem of uncertainty reduction directly. Here, we use new uncertainty analysis techniques to identify the leading causes of uncertainty in global CCN and cloud drop number (CDN) concentrations. The primary aims are to quantify a statistically robust "error bar" for these modelled quantities, to identify which parameters contribute most to uncertainty in different locations, and to ultimately direct research efforts towards model processes that have the greatest bearing on the uncertainty. By using Bayesian emulators we can perform a Monte Carlo statistical sampling of a complex global aerosol model across the entire space of dozens of parameters simultaneously – effectively performing many thousands of simulations for the cost of a few hundred. This approach then enables the model data to be analysed using variance decomposition so that a fraction of the uncertainty can be attributed to each parameter. We rank the importance of the parameters for CCN, CDN and first indirect forcing between 1750 and 2000. From among 28 parameters, the fraction of uncertainty caused by aerosol processes is approximately equal to that caused by emissions, but with very different spatial patterns. The parameters that are important for uncertainty in CCN and CDN are very different to those that are important for forcing, which is dominated by emissions that affect CCN under pre-industrial conditions. Finally, we introduce the Global Aerosol Synthesis and Science Project (GASSP), a community effort to reduce uncertainty in global CCN using extensive *in situ* measurements and model sensitivity and uncertainty fields.

[2]Paul Scherrer Institute, 5232 Villigen, Switzerland.
[3]CERN, CH-1211, Geneva, Switzerland.

Secondary organic aerosol (SOA) is one of the most challenging problems to solve in global aerosol-climate science, but how does it rank alongside other uncertainties in global models? Here, we perform a comprehensive uncertainty analysis of a global model to try to put SOA uncertainty in context. We quantify the uncertainty in modelled concentrations of CCN on a global scale due to 28 parameters related to aerosol and precursor gas emissions, aerosol processes and model structures. The unique approach, using emulation and variance analysis, enables the CCN variance in every grid box of the model to be decomposed into contributions from each parameter, including parameter interactions. The global production of biogenic SOA was perturbed between 5 and 360 Tg a^{-1}, and anthropogenic SOA between 3 and 160 Tg a^{-1}. The anthropogenic SOA uncertainty is ranked 7th out of 28 and accounts for about 5% of the global mean CCN uncertainty, somewhat higher than for anthropogenic SO_2 (although the latter emissions are assumed to be known to within ±50%, much better than for SOA). Biogenic SOA is only about half as important. Given the large assumed SOA uncertainty, these results suggest a rather low importance of SOA production to global CCN uncertainty. These results are based on the assumption that secondary organics do not contribute to nucleation, only to particle growth. However, the latest measurements suggest biogenic secondary organics need to be included in the nucleation rate expression. When such a mechanism is used in the model, we obtain better agreement with the seasonal cycle of particle concentration measurements and a much greater contribution of SOA uncertainty to the overall uncertainty in CCN. The sensitivity of CCN to SOA therefore depends on the extent to which organics control nucleation.

Changes in amino acid nitrogen isotopic composition patterns during phytoplankton degradation

D.CARSTENS[12]* C.J. SCHUBERT[2] A. DEEK[3] AND M.F. LEHMANN[1]

[1]University of Basel, Insitute of Environmental Geosciences, Bernoullistr. 30, 4056 Basel, Switzerland (*correspondence: doerte.carstens@eawag.ch)
[2]Swiss Federal Institute for Aquatic Science and Technology (Eawag), 6047 Kastanienbaum, Switzerland
[3]Trinationales Umweltzentrum, 79576 Weil am Rhein, Germany

The isotopic composition of organic nitrogen (N) in marine, estuarine and lacustrine sediments is often used to reconstruct paleoenvironmental conditions. Bacteria-mediated degradation and sedimentary diagenesis can modify the isotopic composition of the organic matter (OM). In order to study the biogeochemical mechanisms behind N isotope shifts in bulk organic N during early diagenesis, and to verify the robustness of algal amino acid (AA) $d^{15}N$ patterns during partial degradation, as well as the integrity of amino acid-based degradation indicators, we conducted incubation experiments, in which we simulated the decay of algal OM (*Fragilaria crotonensis*) under controlled oxic and anoxic conditions. During progressing decomposition, we monitored the concentration and N isotopic composition of bulk OM and of particulate amino acids (AAs).

Particulate N concentrations decreased during the 300 day experimental period from 4 mg L^{-1} to 1 mg L^{-1} in the oxic and to 2 mg L^{-1} in the anoxic set-up. In both experimental settings, the $\delta^{15}N$ values of the particulate N increased during simulated degradation. The $d^{15}N$ shift was more pronounced in the oxic (3.5‰) than in the anoxic (1.9‰) incubation. The total particulate AA concentrations decreased by 55% in the anoxic and by 46% in the oxic environment. Bacterial buildup, most pronounced in the initial degradation phase and under oxic conditions, was indicated by an increase in the concentration of D-glutamic acid (D-Glx), which is unique to bacteria. After two days of incubation, most AAs were enriched in ^{15}N relative to the fresh bulk diatom biomass, independent of the redox conditions. In the course of the experiments, however, both the AA composition and N isotopic composition showed trends that were distinctive for oxic versus anoxic degradation. Overall, our findings show that bacterial degradation and biosynthesis during early sedimentary diagenesis overprint initial diatom $\delta^{15}N$-AA patterns and contribute to the alteration of bulk N isotope signatures.

Evidences for a persistent link between Greenland climate and northeastern Pacific Oxygen Minimum Zone on millennial timescales under interglacial conditions

OLIVIER CARTAPANIS[1]* KAZUYO TACHIKAWA[1]
OSCAR E. ROMERO[2] AND EDOUARD BARD [1]

[1]Aix-Marseille Université, CNRS, IRD, Collège de France, CEREGE UM34, 13545 Aix en Provence, France (* present adress at McGill University, Montreal H3A 2A7, Canada, correspondence: olivier.cartapanis@mcgill.ca)
[2]Instituto Andaluz de Cs. de la Tierra (CISC-UGR), Ave. de las Palmeras 4, 18100 Armilla-Granada, Spain

The intensity and/or extension of the northeastern Pacific Oxygen Minimum Zone (OMZ) varied in phase with the high northern latitude climate on millennial timescale during the last glacial period, indicating the presence of atmospheric and oceanic teleconnection under glacial conditions. While millennial-scale variability during the last interglacial is well known from Greenland and northern Atlantic records, a possible relationship with the NE Pacific OMZ has not been yet demonstrated. Here, we present a new geochemical dataset for core MD02-2508 (23°27.91′N, 111°35.74′W, 606 m water depth), retrieved from the northern limit of the modern OMZ, spanning the last 120 ka. High-resolution XRF scanning measurements deliver information on terrigenous fraction, marine organic matter, biogenic opal and carbonates, alongside with biological productivity and redox sensitive trace element content (Mo, Ni, Cd). The geochemical proxies (opal content based on Si/Ti, Cd/Al and Ni/Al) show that high productivity occurred during the last interglacial. Highly-resolved opal reconstruction shows strong millennial-scale variability matching all Dansgaard-Oeschger interstadials throughout the last interglacial, while Mo/Al indicates reduced oxygenation during these events. Extremely high opal content during warm interstadials corresponds to high diatom productivity. Despite the different climatic and oceanic settings between glacial and interglacial periods, NE Pacific OMZ rapid variability seems to be tightly coupled to high northern latitude climate, mainly via atmospheric processes.

Anorthosite deposits: Fragments of early Mars

J. CARTER[1] AND F. POULET[2]

[1]European Southern Observatory, Vitacura, Santiago, Chile (jcarter@eso.org)
[2]Institut d'Astrophysique Spatiale, Université Paris-Sud, 91405 Orsay cedex, France (francois.poulet@ias.u-psud.fr)

We here report the detection of near-infrared spectral signatures indicative of the presence of a new rock type on Mars of anorthosite composition. On Mars, there are several reasons to explain why such rocks would not have been formed during its primordial differentiation (wetter mantle, sequestration of aluminum at depth in dense majorite and garnet phases and shallower pressure of plagioclase stability) (Elkins-Tanton *et al*., JGR, 2005)

We will then discuss the setting properties of these intriguing deposits. The few occurrences of anorthosite in comparison to the large number of other minerals (including mafic and alterated ones) suggest that the formation process of anorthositic rocks was likely rare on Mars and mainly restricted to early Mars. Their detection at several locations on Mars provides new constraints into magmatic (plutonic) evolution during early Mars.

Exploring a 60-year record of Mn deposition by comparing atmospheric dispersion models to soil chemistry profiles in Ohio (USA)

M.R. CARTER[1]* AND S.L. BRANTLEY[1]

[1]Geosciences Dept., The Pennsylvania State Univ., University Park, PA 16802 (*mcarter@psu.edu)

Atmospheric deposition of metals emitted by anthropogenic activities has been a significant source of metal loading into soils worldwide. A ferromanganese refinery, located in Marietta, OH, is currently the largest US emission source of manganese (Mn) into the atmosphere. Particulate emissions during production are up to 35% manganese oxide (MnO) by weight and predominantly range in diameter from 0.05 to 0.4 μm, making them both highly mobile and respirable. In order to assess the role of soils in Marietta as sinks for atmospherically-derived Mn, a series of soil cores were collected at a range of distances (1-45 km) from the refinery. The results show that enrichment of soil-surface Mn is 10 times that of the parent material and decreases in surface concentration as a function of increasing distance from the refinery. Total mass of Mn added to soils per unit land area integrated over the soil depth was calculated to be 75 mg Mn cm^{-2} near the refinery. In contrast, a net loss of Mn was found in soil profiles at a distance of 45 km from the facility. Enrichment of chromium (Cr) by more than a factor of 3 was also found in surface soils near the refinery, consistent with the production of ferrochromium at the Marietta plant. Mn deposition rates were also estimated with an atmospheric dispersion model (SCIPUFF) using recent meteorological data and emission rates for the refinery. When scaled appropriately, this model-derived deposition can reproduce the soil-derived value as long as deposition rates in previous decades were more than 3 orders of magnitude greater than today's rates. This model-soil discrepancy may be due to enforcement of air quality standards, such as the Clean Air Act. We are furthermore exploring other possible explanations for the discrepancy. These results suggest that coupling soil measurements with atmospheric dispersion modelling could help identify locations where deposition rates have changed dramatically.

Nb/Ta decoupling under low fo_2

C. CARTIER[1], T. HAMMOUDA[1], M.A. BOUHIFD[1], M. BOYET [1] AND J.L. DEVIDAL[1]

[1] Laboratoire Magmas et Volcans, UBP, CNRS UMR 6524, 5 rue Kessler, 63038 Clermont-Ferrand, France. Correspondence: (c.cartier@opgc.univ-bpclermont.fr)

The high field strength elements Nb and Ta are thought to behave like geochemical twins since they have similar ionic radii and the same valence (5+) and thus should not be fractionated during magmatic processes. As both elements are refractory, the bulk Earth is thought to have a chondritic Nb/Ta ratio (=19.9±0.6, [1]). However, and in contrast to Mars and other asteroids, lunar and terestrial rocks all display a subchondritic ratio (Nb/Ta=14±0.3 and 17.0±0.8 respectively, [1]). One way to explain this paradox is to invoke the incorporation of Nb by the core during a high pressure segregation (>25GPa) and moderately reducing fO_2 (IW-1.5), because in these conditions Ta is lithophile whereas Nb is moderatly siderophile [2].

Here we present new metal/silicate melt trace element partition coefficients obtained on enstatite chondrite material at 5 GPa and under variable oxygen fugacities (IW to IW-8). Experiments have been conducted in the multianvil apparatus between 1580 and 1850°C, using doped material. Trace elements were analyzed using laser ablation ICP-MS on metal and silicate liquid phases.

Our result show that below about IW-4 and at 5GPa, both Nb and Ta are siderophile. When plotted as a function of oxygen fugacity, metal/silicate partition coefficients display slopes that depend on the valence state of the element in the silicate liquid. Our results show that under extremely reducing conditions (<IW-4) Nb is changing from Nb^{5+} to Nb^{2+} and Ta is changing from Ta^{5+} to Ta^{3+} in the silicate melt. This valence contrast generates a fractionation of the Nb/Ta ratio in the silicate, that consequently presents Nb-depleted Nb/Ta ratios.

These results suggest that Nb and Ta can be extracted by metal/silicate separation at low pressure (5GPa) and fractionated in the silicate if the segregation occurs at low oxygen fugacity (<IW-2). Since proto-Earth probably created from differenciated small bodies before undergoing high pressure events, these new results should then be considered in the Earth's accretion models.

Re-investigating the nitrogen budget in the upper continental crust

PIERRE CARTIGNY[1], VINCENT BUSIGNY[1] AND ROBERTA RUDNICK[2]

[1]Laboratoire de Géochimie des Isotopes Stables, IPG-Paris, France, (cartigny@ipgp.fr), (busigny@ipgp.fr)
[2]Department of Geology, University of Maryland, USA, (rudnick@umd.edu)

Nitrogen in sediments primarily results from its original sequestration from the atmosphere by biological activity (as opposed e.g. to abiotic processes). After its cycling in ocean, burial, diagenesis, magmatism and/or metamorphism, some nitrogen will ultimately enter the continental crust where it can be stored over geological periods of time. Its amount and isotope composition remain however little constrained.

Upper continental crust N-budget has been estimated by various authors between 40 and 80 ppm NH_4 but all these studies rely on a same data compilation of Wlotska (1972). A value of ~80 ppm NH_4, means that a about 1/5 of atmospheric nitrogen is presently stored in the upper continental crust.

To better address this issue, we have initiated a re-investigation of the nitrogen content and isotope composition of the upper continental crust. Representative loesses and shales previously studied for major and trace elements (although Rb is commonly lacking) were thus considered.

Results illustrate substantial variations in N-contents from ~100 to ~ 1000 ppm NH_4, yet with little variability in $\delta^{15}N$-values (5.8 ± 1.2 ‰ vs. AIR, 1σ). The latter suggest that N-isotopes are little affected during processes related to shale formation sensu-lato. Contrasting with present day sediments and metasediments showing a strong positive correlation between N-contents with potassium and other large ion-lithophile elements, shales display inversely correlated relation with K-, Cs, or Nb/Cs contents.

Instead nitrogen contents show a striking positive correlation with the Chemical Index of Alteration (r^2 = 0.8), and therefore display positive relationship with e.g. Li-contents, SiO_2/Al_2O_3 and inverse relationship with K/U, etc...

Considering upper continental crust K/U-ratios leads to re-evaluate the budget of nitrogen in this reservoir by a factor from 2.5 to 5, suggesting that large amounts of nitrogen (up to 50%) of early atmosphere is presently stored in the upper continental crust.

[4]EPS and GEOTOP, McGill University, Montreal, Quebec, Canada (boswell.wing@mcgill.ca)
[5]ESER, Weizmann Institute of Science, Rehovot, Israel

The Wannaway komatiite-hosted Ni-PGE sulfide deposit is located in the Archean Ni-rich Kambalda Domain, Yilgarn Craton, Western Australia. This typical Type 1 orebody occurs at the base of a komatiite flow overlying sulfide-rich black shales and metabasalts and is characterized by a pyrrhotite-pentlandite assemblage with minor chalcopyrite and PGE-bearing Ni-Co sulfosalts. Detailed petrographic and minerochemical studies of a drillcore across the mineralized sequence were the basis for ion probe multiple S isotope analyses on pyrrhotite and pentlandite in basal massive to matrix/disseminated ore facies, and in black shales. Plots of $\delta^{34}S$ vs. $\Delta^{33}S$ can separate the effects of mass-dependent fractionation ($\delta^{34}S$ variability without $\Delta^{33}S$ variability) from mass-independent fractionation ($\Delta^{33}S$ variability). Non-zero values of $\Delta^{33}S$ fingerprint crustal S reservoirs in the Archean, characterized by intense photochemical reactions between S-bearing gases and unshielded solar UV rays [1]. In the $\delta^{34}S$-$\Delta^{33}S$ diagram, both komatiite-hosted ore and black shale samples plot at positive non-zero values of $\Delta^{33}S$, compatible with sulfur saturation of magma via assimilation of S-rich sediments. However, ore and black shales show different $\delta^{34}S$-$\Delta^{33}S$ patterns. Black shales possess remarkable dispersion in $\Delta^{33}S$, in contrast to the flat $\Delta^{33}S$ arrays for both ore-related pyrrhotite and pentlandite, which are in textural, chemical and isotopic equilibrium. Ore data for both phases display shifts in $\delta^{34}S$ values related to stratigraphy and sulfide mineralogy, and testify to progressive lowering of $\delta^{34}S$ signatures from basal massive ore upwards. Such a trend may correlate with intense isotopically heavy SO_2 outgassing of the lava [2], as proposed for similar isotopic imprints observed in other komatiite-hosted ores [3].

XMCD is an element-, site-, and symmetry-selective technique and allows determination of the site occupancies in iron oxides and oxyhydroxides and the magnetization associated with these ions. A number of unresolved questions related to the distribution of ions on magnetic networks in magnetic minerals of interest in Earth Sciences can be tackled with XMCD. We show three examples of such studies carried out at IMPMC. XMCD spectra of a well characterized synthetic sample of 6-line ferrihydrite, at both K and $L_{2,3}$ energy edges of iron, demonstrate unambiguously the presence of tetrahedrally coordinated Fe(III) in the mineral structure, which was a highly debated question. In a different study, N-type self-reversal magnetization in titanomaghemite from a sample of submarine basalt was identified as a reversal of the tetrahedral and octahedral magnetic subnetworks, because the XMCD spectrum at Fe K-edge of the N-type titanomaghemite at 20 K is a mirror image of the spectrum at 300 K. Finally, XMCD experiments carried out to compare the Fe^{2+}/Fe^{3+} ratio in nanomagnetite chemically produced from lepidocrocite and nanomagnetite biogenically produced by the Fe-reducing bacterium *Shewanella putrefaciens* show that the biogenic nanomagnetite contained a higher amount of Fe^{2+} than the abiogenic nanomagnetite.

The first comprehensive dataset of ^{236}U in the North Atlantic ocean

N.CASACUBERTA[13] M.CHRISTL[1] J.LACHNER[1] M.R.VAN-DER-LOEFF[2] P.MASQUÉ[3] AND H.-A.SYNAL[1]

[1]Laboratory of Ion Beam Physics, HPK G26, Schafmattstrasse 20, ETH-Zurich, CH-8093 Zurich, Switzerland.

[2]AWI-Geochemistry, Alfred Wegener Institut für Polar- und Meeresforschung, am Handelshafen 12, 27570, Bremerhaven, Germany.

[3]Institut de Ciència I Tecnologia Ambientals, Universitat Autònoma de Barcelona, 08193, Bellaterra, Spain..

Developments in accelerator mass spectrometry (AMS) allow determining very low levels of $^{236}U/^{238}U$ in Ocean waters. As a result, ^{236}U is emerging as a new anthropogenic tracer and its potential in oceanography is currently being explored [1,2]. In this study the first comprehensive dataset of $^{236}U/^{238}U$ in the North Atlantic Ocean is presented. ^{236}U was determined in 90 seawater samples (3 L each), collected during the GEOTRACES cruise GA02 in 2010 along the Northwest Atlantic Ocean. The cruise track was designed to follow the path of the North Atlantic Deep Water (NADW) from its formation region to the relatively deep parts of the western Atlantic Ocean basins. The sources of ^{236}U in the North Atlantic are (i) global fallout and (ii) releases of the European reprocessing plants in La Hague and Sellafield. The results show a broad variation of $^{236}U/^{238}U$ ratios, from $(44\pm15)x10^{-12}$ in the deep western equatorial Atlantic Ocean to $(1477\pm91)x10^{-12}$ in the overflow waters passing Denmark Strait, all ratios being significantly above the theoretical pre-antropogenic level of ocean water. This evidences that the whole transect (from 64ºN to 2ºN) in the North Atlantic Ocean is dominated by anthropogenic ^{236}U. The calculated inventories of ^{236}U increase by a factor of five from the southermost station to the North indicating that besides the fallout derived ^{236}U the water colum in the North Atlantic is already significantly influenced by releases from the European reprocessing plants. Seawater samples from the Arctic Ocean and the South Atlantic Ocean are currently processed, to get a more comprehensive picture of this isotope in the Atlantic Ocean.

Residence time analysis of active volcanic systems: Rb-Sr isotope study of Ischia and Pantelleria

M. CASALINI[1]*, R. AVANZINELLI[1] AND S. TOMMASINI[1]

[1] Dipartimento di Scienze della Terra, Università di Firenze, Italy (*correspondence: martina.casalini@unifi.it)

Numerous active and potentially high-risk volcanoes do occur in the Italian peninsula and therefore understanding their dynamics is crucial for volcanic hazard assessment. Here we present a study on the active volcanic systems of Ischia and Pantelleria, representing two high-silica volcanoes emplaced in subduction related and within-plate geodynamic settings, respectively.

Ischia is characterised by a continuous transition from trachy-basalt to phonolite. The geochemical and radiogenic isotope data of its volcanic products demonstrate a two-steps evolutive process: the first step, controlled by fractional crystallization plus crustal assimilation (AFC), drives magma composition from trachy-basalt to moderately differentiated trachyte; the second step, controlled only by fractional crystallisation (FC), drives the magma composition to the more differentiated products (phonolite) determining very low Sr (a few ppm) and high Rb (>500 ppm) contents due to extreme plagioclase and K-feldspar fractionation.

Pantelleria island displays a bimodal magmatism made up by alkali-balsalt and differentiated products, which evolve from trachyte to peralkaline ryolite (i.e. Pantellerite) through FC processes. Pantelleritic rocks also show extremely low Sr and high Rb contents.

The active volcanic systems of Ischia and Pantelleria, despite belonging to different geodynamic settings, are characterized by the occurrence of strongly differentiated products with anomalously high Sr isotope compositions that cannot be justified by the assimilation of crustal material.

This characteristic could be explained by ^{87}Sr in-growth in long-lived magma chambers, due to the high Rb/Sr of the most evolved rocks. To explore this hypothesis we carefully screened and selected a number of evolved samples: from these we separated the rock-forming minerals (sanidine and clinopyroxene) and groundmass/glass in order to determine Rb and Sr content by isotope dilution, along with Sr isotope composition. The extremely low diffusion coefficients of Sr in feldspar and clinopyroxene makes them suitable candidates to estimate the timing of crystallisation and, by inference, the magma residence time. The calculated crystallization times for the two islands are here compared and discussed in terms of the chemical and physical characteristics of the magmas.

Crystals modulate non-explosive gas transfer at Stromboli volcano, Italy

K. CASHMAN[1], A. RUST[1], I. BELIEN[2], J. OPPENHEIMER[1] AND A. SOLDATI[1]

[1]School of Earth Sciences, University of Bristol, UK (glkvc@bristol.ac.uk)

[2]Exxon Mobil Upstream Research, Houston, TX

Stromboli is best known for its eponymous frequent and mildly explosive eruptions. Most of Stromboli's gas loss (~ 90%), however, occurs by non-explosive mechanisms, either passively or via periodic small gas bursts known as "puffing". Passive degassing probably occurs across the entire magma surface beneath the crater terrace; puffing, in contrast, is focused into one or a few central vents that are stable over the short term but migrate with time. What, then, controls the spatial and temporal patterns of non-explosive gas loss? One clue comes from volcanic clasts ejected during normal Strombolian activity, which show that the near-surface magma has ~ 50% crystals. To explore the effect of crystals on gas migration, we have run experiments using 50:50 mixtures of golden syrup and rice (an anisotropic particle that is neutrally buoyant and approximates plagioclase in shape) fluxed by air; this allows us to investigate the effect of varying gas flux through static 'magma' columns. A first order observation is that, at steady state, the amount of gas retained within the column (the gas holdup) increases with increasing gas flux from below. Gas holdup is achieved by trapping small bubbles within the particle-melt suspension. Importantly, these small bubbles are created by interaction of the gas with the suspension by bubble splitting either around particles or by expansion after passage between two particles into a particle-poor space. At the same time, larger parcels of gas migrate though the suspension by creating transient fractures. The pressure increase required to fracture the suspension causes quasi-periodic gas release to the surface; the fracture is transient because of healing by viscous flow. These observations suggest physical mechanisms to explain both passive degassing and puffing. Passive degassing is best explained by the slow rise of individual bubbles through the crystal-melt suspension, with bubble size modulated by the size and spacing of crystals. Puffing activity is more analogous to quasi-periodic fracturing and gas release; healing of fracture paths explains the migration of puffing vents around the central crater terrace. The location of puffing in the center of the crater terrace further suggests focusing of the steady gas supply from depth at the center of the elongated shallow magma storage region.

Late-Variscan fayalite-bearing granites in Sardinia: The lower crust connection

L. CASINI[1]*, A. PUCCINI[1], S. CUCCURU[1], G. OGGIANO[1] AND G.SECCHI[1]

[1] University of Sassari, Department of Science of Nature and Environmental Resources, Via Piandanna, 4 - 07100 Sassari, Italy

The Variscan [340 – 260 Ma, 1] Corsica-Sardinia Batholith (C-SB) emplaced discordantly across the orogenic structure, from the roots zone to the Gondwana foreland. Despite the scarcity (< 5%) of mafic rocks, most pre-300 Ma plutons are peraluminous biotite granites derived from dehydration melting of pre-Variscan granitoids and subordinate metasediments [2]. Lower crustal granulites observed in the deeply exhumed section of the chain [3] are thought to have developed in consequence of extensive melt extraction. The post-300 Ma granites in south Sardinia [4], instead, display the following crustal characters: εNd from -6 to -12, δO^{18} between 7 and 12%, and $Sr_{i\ (290)}$ between 0.703 and 0.715. The rare but systematic occurrence of fayalite or pyroxene as Fe-buffering phase indicates that these A-type melts derived by partial melting of anhydrous, poorly evolved crustal material under high-T (> 900°C), low fH_2O and fO^2 conditions [5].

Nd_{DM} model ages of post-300 Ma granites in south Sardinia are in the range 1600 - 1700 Ma, about 1 Ga older than those calculated in Corsica [6]. This implies a older lithosphere, probably accreted at the northern margin of Gondwana (S Sardinia) in early Paleozoic. The observation that this part of the chain never reached a significant crustal thickness during the Variscan event (i.e., > 40 km) support the hypothesis that granulites formed before the Carboniferous.

A new hypothesis for the origin of HIMU and FOZO mantle end-members

PATERNO R. CASTILLO

Scripps Institution of Oceanography, Univ. of California, San Diego, La Jolla, CA 92093-0212 USA (pcastillo@ucsd.edu)

It is widely accepted that the bulk of intraplate magmas, best represented by ocean island basalts (OIB), originate from crustal materials that had previously been subducted into the mantle. It has also been proposed that after ~b.y. of residence, such subducted materials form a number of mantle source reservoirs, represented by end-members with extreme Sr-Nd-Pb isotopic compositions[1]. The first subducted material to be recognized was mid-ocean ridge basalt (MORB)[2], and this was later fine-tuned as having a long time integrated (~b.y.) high U/Pb ratio (HIMU) and producing OIB with the most radiogenic Pb isotopic ratios ($^{206}Pb/^{204}Pb$ >~19.0)[1,3]. However, it is becoming more evident that the compositional connection between subducted MORB and HIMU basalts is problematic[1,4]. As an alternative hypothesis, I propose that recycled Archaean calcium carbonate ($CaCO_3$) is the main source of the distinct Pb-Sr isotopic and major-trace element compositions of the "classical" HIMU and Proterozoic and younger carbonate for the "younger" HIMU or FOZO end-member. This hypothesis is consistent with some of the available observations, experimental results and inferences from these data. For example, the $^{87}Sr/^{86}Sr$ and K contents of carbonates are low in the Archean, but started to increase in the Proterozoic[5]. $CaCO_3$ subduction into the deep silicate Earth may also provide important clues to the seismic velocity structure and convection in the mantle. However, the carbonate recycling hypothesis is based primarily on qualitative data and the few existing analyses of Archaean carbonates, which are expected to have very high U/Pb if precipitated out of seawater in equilibrium, do not have original Archean seawater U/Pb ratios[6]. Future quantitative testing of the hypothesis can be done when analytical data for unmodified Precambrian carbonates become available.

C-isotope evidence for pCO_2 and volcanic forcing during the early Aptian OAE 1a – The Cau section (SE Spain)

J.M. CASTRO[1]* G.A. DE GEA[1] R.D. PANCOST
M.L. QUIJANO[3] AND B. DAVID A. NAAFS[2]

[1]Dept. Geologia, CEATierra, Univ. Jaén, E-23071. SPAIN
(*correspondence: jmcastro@ujaen.es)
[2]School of Chemistry, Univ. Bristol, BS8 1TS, UK
[3]Dept. Química Inorgánica y Orgánica, CEATierra, Univ. Jaén, E-23071. SPAIN

The Early Aptian Oceanic Anoxic Event (OAE1a) represents a major perturbation in the global carbon cycle and is linked to environmental, biotic and sedimentary changes. The isotopic signature of OAEs consists of a positive $\delta^{13}C$ excursion, interpreted as the result of massive deposition of organic matter and subsequent ^{12}C drawdown.

Most investigations consider that high atmospheric CO_2 concentrations related to volcanic outgassing [1] played a main role during OAE1a, but only few studies estimate pCO_2 during this time interval [2]. Here we test the use of the offset between the $\delta^{13}C_{carb}$ and $\delta^{13}C_{org}$ as a qualitative proxy for pCO_2 ($\Delta^{13}C$, [3]), which has been proved useful for the OAE2 [4].

We explore the temporal variations in pCO_2 from an expanded section of the OAE1a (Cau section, Spain). The high resolution study combining C-isotope stratigraphy and biostratigraphy, has led to a precise correlation with other well known sections from the Tehys domain.

Our results suggest that pCO_2 increased during the prelude of OAE1a. Intriguingly, it mantained stable high concentrations during most of the positive isotope excursion, despite a putative OM burial event, then droped in a relatively short time at the end of OAE 1a. This episode of high pCO_2 was punctuated by several short-lived cooling episodes [5], but high temperatures were rapidly recovered. This is consitent with a mantained volcanic forcing, demonstrated by Os isotope data [1, 6]. This study has proven the value of the $\Delta^{13}C$ as a pCO_2 proxy, and confirmed the link between volcanic outgassing and organic matter deposition in balancing the global climate change during OAE1a.

Advances in Our Understanding of the Noble Gas Thermometer in Groundwater - New Applications

M.C. CASTRO*, C.M. HALL, R.B. WARRIER AND K.C. LOHMANN

University of Michigan, Ann Arbor, Michigan 48105, USA
(*correspondence: mccastro@umich.edu)

Noble gases are conservative tracers and their concentrations in recharge areas of groundwater systems are a function of temperature, pressure, and excess air. Consequently, noble gas temperatures (NGTs) are regarded as robust indicators of past climate. Until recently, however, limited attention had been placed on processes taking place in the unsaturated zone and at the water table/soil air interface capable of impacting NGTs. In recent years, we highlighted the potential impact of O_2 depletion without corresponding CO_2 build-up in the unsaturated zone on noble gas partial pressures, leading to a bias to low NGTs. A recent study in Michigan showed, however, that recharge conditions can be significantly modified by large precipitation events such as Hurricane Ike and bring O_2 depleted soil air back to standard conditions.

Atmospheric noble gases were also measured in high-altitude springs in the Galapagos Islands. These revealed the presence of a unknown pattern with atmospheric He excesses and Ne, Kr, and Xe depletion together with relative Ar enrichment. A rainwater noble gas study was subsequently carried out in Michigan and revealed the presence of two patterns both with He excesses. The first one, associated with low pressure systems, presence of fog and light rainfall, displays a pattern remarkably similar to that previously identified in the Galapagos Islands. The second one, associated with the passage of frontal systems, displays a mass-dependent depletion pattern with respect to surface conditions. Precipitation is characterized by thunderstorms, heavy rainfall, and high cloud ceiling heights. This rainwater study suggests that noble gases dissolved in rainwater and in shallow aquifer systems where infiltration is rapid can be used to trace weather patterns.

The biogeochemical cycling of iron involves primarily the alternation of iron between oxidized and reduced forms. Recent work has shown that when microorganisms initiate such cycling a cascade of secondary abiotic processes occur through reaction of aqueous Fe(II) and solid Fe(II) oxide minerals. These reactions involve oxidative Fe(II) adsorption, electron transfer into or through the mineral solid, and atom exchange between dissolved Fe(II) and solid Fe(III) [1-3]. This results in mineral recrystallization that proceeds through a surface growth and dissolution mechanism [4]. The resulting dynamic surface transformations may affect the fate of iron oxide-associated trace elements and contaminants.

We have investigated the effect of dissolved Fe(II) on the repartitioning of elements adsorbed on or incorporated in goethite and hematite. Adsorbed As(V), which is structurally incompatible with iron oxides, is unaffected by the presence of Fe(II). In contrast, adsorbed Ni(II) and Zn(II) incorporate into iron oxide mineral structures in the presence of Fe(II). Fe(II) also induces the release of incorporated Ni and Zn back into solution; this is inhibited when insoluble elements co-substitute into goethite or hematite. Redox-active substituting elements, such as Cu(II), Co(III), and Mn(III/IV), undergo coupled reduction and repartitioning upon introduction of aqueous Fe(II). Preliminary stable isotope measurements show that Zn repartitioning during Fe(II)-catalyzed iron oxide recrystallization produces a fractionation distinct from that produce by Zn adsorption and that differs between goethite and hematite. These studies show that the effect of Fe(II) on the fate of trace elements and contaminants is dependent on the compatibility of these elements with the iron oxide structure. The observed element repartitioning demonstrates new pathways for contaminant entrapment and micronutrient release and suggests that iron oxides may not be reliable recorders of trace elements in the rock record.

Hydrothermal alteration of the products of transformation of cement-asbestos

M. CATALANO[1], A. BLOISE[1], N E. BELLUSO[2], C. B. CANNATA[1], E. BARRESE[1], R. DEROSA[1] AND A. F. GUALTIERI[3]

[1]University of Calabria, Arcavacata di Rende (CS), Italy

[3]University of Modena e Reggio Emilia, Modena, Italy

In some European countries the transformation products of cement-asbestos (CATP) can be recycled to produce stoneware tile mixtures, bricks, and concrete incorporated into mortars or to provide both refractoriness and reinforcement to other materials (e.g., road beds) [1]. Not recycled CATP materials must be moved in controlled landfill. An interesting study deals with the fate of the CATP placed in the landfill where solutions could percolate. Can the growth of fibers, perhaps asbestos, occur over a long period of time? The present work studies the experimental conditions involved in the transformation of the CATP and the resulting products. For two set of reactions, two different deeply characterized CATP mixtures (KC2S; KA) were used. KC2S contained ferrite, periclase, ternesite $Ca(OH)_2$, merwinite, wollastonite, yeelimite; KA contained akermanite, amorphous, merwinite, bredigite, wollastonite, quartz, calcite, magnetite. The CATP, after addition of H_2O as reactant, was hydrothermically altered in the following range conditions: temperature from 300 to 360 °C; pressure between 15 and 200 MPa; time from 168 to 504 h. Samples have been characterized in detail through XRPD, SEM-EDS and TEM-AEM. Some altered samples showed a large amount of Ca-inosilicate fibrous phases as hillebrandite, foshagite. Other products (i.e. Ca-garnet, brucite, monticellite) were also detected together with low amount of starting material relicts.

* (cates@colorado.edu)

The oldest compiled U-Pb zircon ages for the Acasta Gneiss Complex (AGC) in the Northwest Territories of Canada span about 4050-3850 Ma; yet older ca. 4200 Ma xenocrystic U-Pb zircon ages have also been reported for this terrane. The AGC comprises gneissic exposures across several large basement domes, but only a small portion (~5x5 km) of one such dome has been documented in the detail required to investigate a complex history. To better understand this history, ion microprobe $^{235,238}U$–$^{207,206}Pb$ zircon geochronology was combined with whole-rock (WR) and zircon rare earth element compositions ($[REE]_{zirc}$), Ti-in-zircon thermometry (Ti^{xln}) and ^{147}Sm-^{143}Nd geochronology for a subdivided ~60 cm^2 slab of Acasta banded gneiss comprising five separate lithologic components. Results were compared to other variably deformed AGC granitoid- and plagioclase-hornblende gneisses. Micro-sampling shows that different gneissic components host distinctive $[Th/U]_{zirc}$ vs. Ti^{xln} and $[REE]_{zirc}$, correlative with zircon age populations and WR compositions,but not with ^{147}Sm-^{143}Nd isotope systematics. Lattice-strain theory used to model D_{WR}^{zircon} [REE] reconciles the U–Pb zircon geochronology only for the ca. 3920 Ma age component, which also preserves strong positive Euanomalies. Modeling shows that the magmas which gave rise to the indigenous ca. 3920 Ma component formed at ~IW (iron-wüstite) to <FMQ (fayalite-magnetite-quartz) oxygen fugacities. Emplacement of the AGC was contemporaneous with the Late Heavy Bombardment (LHB Later superimposed Eoarchean events (3850-3720 Ma) are reminiscent of formation times for the Nuvvuagittuq Supracrustal Belt in northern Québec, and the Manfred Complex in Western Australia. Equilibration of the ^{147}Sm-^{143}Nd whole-rock chronometer occurred at the scale of individual components over the course of one or more of these later events.

Fe-serpentines to Fe-chlorites experimental synthesis: An iron metal- shale interaction between 60 and 300°C

M. CATHELINEAU[1], R. MOSSER-RUCK[1], I. PIGNATELLI[1], M.C. CAUMON AND L. TRUCHE[1]

[1]GeoRessources, CNRS, Universite de Lorraine, 54500, Vandoeuvre-les-Nancy, France

Interactions between a shale and iron metal have been studied experimentally at 90, 150 and 300°C, as well as at decreasing temperature from 90 to 50°C. These experiments simulate the mineralogical and chemical reaction of clays in contact with steel in high level nuclear waste repository, at the highest temperature to test the potential kinetic effects due to the rather short duration of the experiments with respect to the waste disposal time scale, and the experiments at decreasing temperatures to simulate the effects of the progressive cooling in the waste site due to decline of the radioactive heat (ANDRA research programme). The starting products are : a shale from the Callovo-Oxfordian series from the Paris basin (Quartz, illite and I/S rich in illite, calcite), a fluid which composition is close to the interstitial fluids of the geological formations, and iron metal added as plates or powder. The effects of the liquid on rock ratio (L/R), iron/ clay ratio (I/C) have been tested. The following mineral assemblages have been found as run products:

- di- sm > Fe-serpentine, so-called berthierine-like or greenalite for high iron/clay ratio or Fe rich di Sm + Fe rich tri-Sm for low iron/clay ratios (near neutral pH) at 90°C
- di-octahedral smectite (di-sm) > saponite at 150°C > trioctahedral Fe-chlorite + feldspar + zeolite (300°C).

New experiments at decreasing temperatures have produced other Fe-serpentines within the 60-80°C range such as cronstedtite. Thus, at each temperature, illite and I/S are unstable, and replaced by Fe-rich silicates at low temperature and Fe-Al silicates above 150°C. Within the range 60 -90°C, quartz is almost entirely dissolved as illite and I/S up to the total consumption of iron. Iron silicates are in competition with iron carbonates (siderite) and iron oxide (magnetite). Iron silicates are predominant near neutral pH when pCO_2 is not too high, and magnetite is found in most run samples but in low amounts, and iron/clay ratio >1. A thermodynamical modelling of the main mineralogical changes has been undertaken to interpret experimental data.

A framework for understanding the first and second rises of O_2

DAVID C. CATLING[1]

[1]Dept. Earth and Space Sciences/ Astrobiology Program, Univ. of Washington, Box 351310, Seattle WA, USA

Oxygenation of the atmosphere and oceans was determined by key source and sink fluxes of O_2. In terms of reductants, key fluxes are: (1) the escape of hydrogen to space F_E, (2) the 'net' flux of O_2 associated with the burial of organic carbon and sulfide derived from sulfate, F_B, (3) the flux to the atmosphere of aerial volcanic and metamorphic gases F_{VM}, (4) the continental oxidative weathering flux F_W, which depends on atmospheric pO_2, (5) reductants associated with seafloor volcanism F_{OV}, and (6) seafloor weathering F_{OW}. The last two fluxes connect seafloor redox to the surface environment. The seafloor weathering flux depends on pO_2 through downward mixing of O_2 and marine sulfate.

I propose a model where the relative magnitude of these fluxes determine three redox stages of Earth history with different mean states: I. anoxic (before 2.4 Ga), III. oxic (Proterozoic) and III. highly oxic (after late Neoproterozoic).

In state I, an anoxic atmosphere is relatively rich in hydrogen-bearing species, by definition, and so F_E is non-negligible. Thus, $F_B < F_{VM}$ and $F_E \approx F_{VM} + F_{OV}$. Since F_E is (to first order) proportional to the concentration of atmospehric CH_4, a model solution gives 100s to 1000s of ppmv CH_4 for reasonable $F_{VM} + F_{OV}$. The transition from I to II is reached when F_B exceeds F_{VM}. These two fluxes are small compared to gross biogenic gas fluxes, but the redox state of the atmosphere is set by small differences between large fluxes. In state II, enough O_2 allows continental weathering, and F_W is non-negigible. F_E (though persistent for probable mid-Proterozoic CH_4 levels) is small compared to other fluxes. A balance is $F_B \approx F_{VM} + F_{OV} + F_{OW} + F_W$. Seafloor volcanic and weathering fluxes buffer O_2 in the deep ocean to low levels. F_W depends on O_2 and a model solution in state II gives O_2 mixing ratios of 0.2-2% absolute. In state III, seafloor buffering is exhausted and the dominant balance is $F_B \approx F_{VM} + F_{OV} + F_W \approx F_W$, allowing Phanerozoic O_2 levels of 10-30%.

Driving state I to II are hydrogen escape [1] and possible geologic evolution affecting volcanic fluxes [2, 3]. The possible drivers of state II-III include hydrogen escape and sulfide burial and subduction [4].

Archaeological practices validating mineralogical and geochemical analyses in metal provenance studies. The gold mines from central Gaul (France) case study

B. CAUUET*[1], C.G. TAMAS[2], S. BARON[1] AND J. MILOT[1]

[1] TRACES-CNRS, 5, allées A. Machado, 31058 Toulouse Cedex 09, France. (*corresponding author: cauuet@univ-tlse2.fr)

[2] University Babes-Bolyai, 1, M. Kogalniceanu str., 400084 Cluj-Napoca, Romania

A quality protocol regarding the selection of materials used and/or formed during the chaîne opératoire from the ore of an Ancient mine to the produced metal is proposed. This protocol, based on many archaeological findings during the 90ies is applied here for Limousin (France) Au province exploited during Gaul times.

The Gaul mining in Fouilloux deposit (3rd to end of 1st c. BC) was focused on a quartz vein with native gold, electrum and sulfides (arsenopyrite, stibnite etc.) with a N60 strike and a dip of 62o to the NW. The exploitation started in an open pit with several benches going down to a depth of 20 m and afterwards continued in underground closely following the ore body on another 10 m depth. The underground stope follows the dip of the ore body and has 2 to 2.5 m width. Pillars have been preserved within the ore body by the Gaul miners for safety reasons. The pillars are high grade (around 90 g/t Au) and represent a certified archaeological ore occurrence which is used for metal tracing.

Ore treatment workshops were discovered nearby with remnants of the Ancient metallurgy (e.g. archaeological roasted ore) and remainders of the produced gold. A low open furnace for the gold metallurgy and a touchstone preserving golden traces was discovered in Fouilloux, as well as crucibles in Cros Gallet-Nord gold mine situated nearby. These artifacts allowed reconstitution of the various operations of the chaîne opératoire of gold production from La Tène in Limousin and will be used for metal tracing.

Archaeo-Metallurgical experimental operations using gold ore from a third Gaul mine, Laurieras allowed us to produce materials which will be also analyzed, i.e. raw ore, grilled ore, slags, and gold brought out directly from the crucible.

Mineralogical and geochemical analyses are ongoing on the materials obtained through experimental works on Au ore from Laurieras. The results obtained on experimental products will be compared with the results on archaeological materials discovered in Fouilloux and Cros Gallet-North Gaul mines.

Particulate carbonaceous matter (PCM) is a significant contributor to ambient particulate matter originating from intervening sources which contribution is difficult to resolve due to chemical complexity of PCM and often internal mixture of aerosol particles.

Carbon isotope analysis of stable and radioactive carbon offers a method for quantitative source apportionment of three principal sources of PCM due to their unique isotopic signatures: i.e. marine, continental (non-fossil) and fossil fuel sources [1] while additional specific tracers will allow splitting into more specific sources or primary and secondary sources [2]. AMS PMF analysis allows splitting into PCM property specific sources based on degree of oxigenation and fragmentation markers of OM. HNMR factor analysis is based on common chemical structures – aromatic, aliphatic, mono, di-acids - arising from typical sources.

All three methods were applied to resolve PCM sources over the Northeast Atlantic ocean during common sampling periods demonstrating their convergence on sources and suggesting a more reliable albeit complex approach to source apportionment.

An absorption method for porewater characterization in low-permeability sedimentary rocks

MAGDA CELEJEWSKI* AND TOM AL

University of New Brunswick, Earth Sciences
*(correspondence: m.celejewski@unb.ca
tal@unb.ca)

Determination of porewater geochemistry in low-permeability rocks is challenging due to small fluid volumes and the difficulty of extracting representative samples. Several porewater extraction techniques are available, but the ability of each to provide representative samples is suspect. The objectives of this study are to develop a method of extracting a representative sample of *in situ* porewater from low-permeability rocks using absorption into a cellulosic membrane, and to quantify porewater solute concentrations.

The feasibility of porewater extraction using absorption into cellulosic membranes has been demonstrated in trials with shale drill cores. Solute mass is measured with ICP-MS and water-content is measured with near infrared (NIR) spectrometry which together provide a measure of solute concentrations.

Interactions between the membrane and porewater solutes were investigated by assessing preferential adsorption of solutes to the membrane and the reversibility of solute leaching. The NIR spectrometer was calibrated to account for the influence of dissolved salt mass on the vibrational energies of H-O bonds in water. The method was tested by adding a known mass of synthetic porewater to membranes, and comparing the known solute concentrations to those determined from the leachable solute mass and the measured water-content.

Experimental results indicate that preferential adsorption of porewater solutes (Na, Cl, Mg, Ca, K, Sr, and Br) to the cellulosic membrane is statistically insignificant and that solutes are reversibly leachable. The relative error for NIR water-content based on the 95% confidence limits ranges from 2 to 7%. The relative difference in solute concentration between the known values and those calculated from solute-mass and water-content data range from 0 to 17%. The greatest relative differences occur when the measured water-content is very low and near the NIR detection limit.

Work to date has demonstrated that porewater can be extracted from low-permeability rock samples, and porewater solute concentration determinations are possible.

Calculated P-T paths for the blueschist-facies metapelites from the Ile de Groix (France)

STEPHEN CENTRELLA[12]* MICHEL BALLEVRE[2], PAVEL PITRA[2] AND PHILIPPE YAMATO[2]

[1] Inst. für Mineralogie, University of Münster, Corrensstrasse 24, 48149, Münster, Germany (*correspondence: s_cent01@uni-muenster.de)
[2] Géosciences Rennes, UMR 6118, Université de Rennes 1, 35042 Rennes, France

For a long time, the "Ile de Groix" has been the subject of many studies because it shows blueschist-facies rocks of Palaeozoic ages which are quite uncommon along the Variscan belt. Despite all these studies, there are still uncertainties on (i) whether peak P-T conditions vary or not across the island and (ii) how variations in the amount and causes of retrogression could control the apparent spatial zonation of the metamorphism. In order to check the different potential hypotheses, a detailed study of four samples of garnet-bearing metapelites has been performed.

In all samples, garnet preserves a growth zoning (core to rim bell-shaped decrease of Mn, increasing XMg), which, associated with the inclusions and the matrix minerals, allow to define the successive mineral parageneses. Calculated pseudosections using Thermocalc allow to define the prograde part of the P-T path, culminating in the eastern part at 22.5 kbar and 525°C. Decompression is nearly isothermal until the equilibrium between garnet and matrix was reached at 16.5 kbar and 515°C. A different P-T path is deduced for the western part of the island, where garnet growth zoning displays a more complex pattern, with bell-shaped Mn in the cores, but Mn-rich overgrowths observed in some samples. These patterns cannot result from differences in bulk-rock chemistry, but evidence differences in P-T paths.

Pressure-induced phase transitions in coesite

ANA ČERNOK[1]*, TIZIANA BOFFA BALLARAN[1], RAZVAN CARACAS[2], NOBUYOSHI MIYAJIMA[1], ELENA BYKOVA[1], VITALI PRAKAPENKA[3], HANNS-PETER LIERMANN[4] AND LEONID DUBROVINSKY[1]

[4]Photon Sciences, Deutsches Elektronen-Synchrotron (DESY), Notkestraße 85, 22607 Hamburg, Germany

High-pressure behavior of coesite was studied using diamond-anvil cells with neon as the pressure transmitting medium and applying *in situ* Raman spectroscopy and single crystal X-ray diffraction up to pressures of ~55 GPa. The experimental observations were complemented with theoretical computations of the Raman spectra under similar pressure conditions. We find that coesite undergoes two phase transitions and does not become amorphous at least up to ~ 52 GPa. The first phase transition (coesite I to coesite II) occurs at ~ 23 GPa and the second transition (coesite II to coesite III) occurs at ~ 35 GPa.

The *ab initio* calculations give an insight into the initiation mechanism of the first phase transition. Based on the unstability of phonon modes we imply that the phase transition is displacive in nature and related to shearing of the four-membered rings of SiO_4 tetrahedra upon compression. The transition to the lowest-symmetry phase, coesite III, is possibly a first order phase transition which leads to a very distinct structure. It was previously widely accepted that coesite undergoes pressure-induced amorphization at significantly lower pressures (30 GPa) and none of the metastable high-pressure polymorphs has been reported. We are currently analyzing crystallographic data of the high-pressure metastable polymorphs coestie II and coesite III.

Origin and burial of organic carbon depending upon the environmental setting in the southwestern East/Japan Sea

H.J. CHA[1]* AND M.S. CHOI[2]

[1]Chungnam National University/Research Institute of Marine Sciences, , Daejeon, Republic Of Korea (*correspondence: hcha80@chol.com)

[2]Chungnam National University/Department of Oceanography/Graduate School of Analytical Science and Technology, Daejeon, Republic Of Korea, (mschoi@cnu.ac.kr)

Box core sediment samples were collected from the southwestern part of the East/Japan Sea and analyzed for sediment chemical composition, organic carbon, C/N and C/P ratios and C and N isotopes ratios together with pore water dissolved species. The southwestern East/Japan Sea, consists of continental shelf, continental slope and deep ocean basin. Sediments of the southwestern East/Japan Sea, especially over the Ulleung Basin, are characterized in high organic carbon concentrations (0.3 to 4.1%) and very high organic carbon burial flux (2.7 - 11.5 gC. m^{-2}. yr^{-1}) considering that the sea is a hemipelagic sedimentary setting and there is no large river entering into the sea.

From C/N and C/P ratios and C and N isotopes of the sediments, sediments of the southwestern East/Japan Sea are thought mostly of marine origin except those over the Korean coasts and some volcanic islands. where C/N, C/P ratios and C and N isotopes show more or less terrestrial input.

After deposited, organic carbon is decomposed by both aerobic and anaerobic processes (reduction of Fe/Mn-oxides and/or sulfate depending upon the environmental setting). Even though the sediments of the southwestern East/Japan experience oxidation of organic carbon by sulfate reduction, burial fluxes of organic carbon is still very high in the sediment(2.7 - 11.5 gC. m^{-2}. yr^{-1}) compared to other areas with similar water depth.

The recovering of weathering propagation rates from the analysis of 238U-234U-230Th-226Ra nuclides in regoliths

FRANÇOIS CHABAUX, ERIC PELT, RAPHAEL DI CHIARA-ROUPERT, SOPHIE RIHS AND PETER STILLE

The potential of U-series nuclides for investigating weathering processes has been recognized since the 1960s. It results from the dual property of the nuclides to be fractionated during water-rock interactions and to have radioactive periods of the same order of magnitude as the time constants of many weathering processes. The recent progression in this field of research is clearly related to the analytical developments made over the last decades in measuring the 238U series nuclides with intermediate half-lives (i.e., 234U-230Th-226Ra). The majority of studies made in this field of research has been based up to now on the analysis of 238U - 234U - 230Th nuclides and the use of the three activity ratios (234U/238U) - (230Th/234U) - (230Th/232Th). They provided important theoretical elements for the determination of regolith production rates in weathering profiles (e.g., Dequincey *et al*., 2002; Chabaux *et al*., 2003; 2013 ; Pelt *et al*., 2007 ; Dosseto *et al*., 2008; Ma *et al*., 2010).

Here we propose to present the principle of the approach developed for recovering the regolith propagation rates from the analysis of U-series nuclides in a series of samples collected along the main weathering direction of the system. We will especially show how a simple modeling of U-series nuclides, based on mathematical formalism assuming a continuous gain and loss of the different U-series nuclides within a weathering profile, allows ones to recover such propagation rates. We will also highlight that the use of the 238U-234U-230Th nuclides together with the 226Ra nuclide allows for a better determination of the regolith production rate than together with the 232Th nuclide. Based on the results obtained by this approach it is suggested that the weathering and erosion processes in humid tropical or equatorial contexts are close to steady state, which would be not the case in area affected by important quaternary climatic variations (dry tropical or temperate context) or for soil systems significantly modified by human activity.

Making the planet Mercury: Constraining Mercury's core formation and composition through laboratory experiments

NANCY L. CHABOT[1]* E. ALEX WOLLACK[2], RACHEL L. KLIMA[1] AND MICHELLE E. MINITTI[1]

[1]Johns Hopkins University Applied Physics Laboratory, Laurel, MD, 20723, USA (*correspondence: Nancy.Chabot@jhuapl.edu)
[2]Princeton University, Princeton, NJ, 08540, USA

In 2011, MESSENGER became the first spacecraft ever to orbit Mercury and since then has returned a wealth of new data that is revolutionizing our understanding of the Solar System's innermost planet. Elemental composition information [1-3] has revealed that Mercury's surface is Fe-poor, but not Fe-free, and also S-rich. Gravity information [4] has led to new models proposed for Mercury's internal structure, notably with a large S- and Si-bearing metallic core with a top layer of solid FeS. Thus, the overall picture of Mercury is of a terrestrial planet very different from Earth, Venus, and Mars. As such, Mercury provides important constraints on planet formation in the inner Solar System.

In this work, we present results from an experimental study to understand the conditions and compositions involved during core formation on Mercury. Specifically, we use the Fe and S contents measured on Mercury's surface to constrain the amount of S and Si in Mercury's core. In total, 19 metal-silicate experiments were conducted at 1 atm and 1500°C, with varying amounts of S and Si in the metallic phases. We find that none of the experiments are able to match both the wt% levels of Fe and S measured on Mercury's surface, indicating a more complex history for the measured silicate compositions or that the Fe is meteoritic. To produce 2-4 wt% S in the silicate, as measured on Mercury's surface, our experimental results indicate core compositions with >3 wt% Si and a range of S and Si combinations. Nearly all of the determined S and Si core combinations yield bulk planetary Fe/Si and/or S/Si ratios that do not overlap with common chondrites, suggesting that Mercury formed from unique starting materials or is the remnant of a once larger body.

Biostimulation of silica and sulfur on crude oil biodegradation

SITI KHODIJAH CHAERUN[12] AND XIAO-LEI WU[1]*

[1] Department of Energy and Resources Engineering, College of Engineering, Peking University, Beijing, China (#Presenting author: (skchaerun@gmail.com); *(Correspondence: xiaolei_wu@pku.edu.cn)
[2] Laboratory of Environmental Biogeosciences and Mining Bioengineering, Division of Genetics and Molecular Biotechnology, Institut Teknologi Bandung, Indonesia

Clays have been used for stimulating oil spill bioremediation to prevent the eutrophication of the marine sites, showing that SiO_2 in the form of clays facilitates bacterial usage of hydrocarbon [1]. Likewise, sulfur (S), a component of crude oil, is reported to be a stimulator for oil biodegradation. Hence, in the current work, biostimulation of silica (Si) and S was employed for enhancing biosurfactant production by a novel species of *Pseudoclavibacter* sp. and *Dietzia* sp. DQ12-45-1b using the D-Daqing crude oil as sole carbon source for bioremediation purposes. Silica (in liquid form) enhanced bacterial growth and biosurfactant production for both strains. Interestingly, Si was capable of being stimulatory for an inactive cell of *Pseudoclavibacter* sp., thus shortening its lag phase. High S concentration did not inhibit or stimulate bacterial growth and biosurfactant production of both strains. Thus, dissolved Si derived from the Earth's crust is not inhibitory and even environmentally and economically beneficial for biosurfactant-producing bacteria. It can thus be concluded that the Si in liquid form could be considered to be a more eco-friendly and economical material source for the improvements in reliability, cost efficiency and speed of oil bioremediation.

K-feldspar geochronology: Not just ^{39}Ar

A.N. CHAFE[1], J.M. HANCHAR[1] AND I.M. VILLA[23]

[1]Memorial University of Newfoundland, St. John's, Canada; (a.chafe@mun.ca)
[2]Universität Bern, Switzerland; (igor@geo.unibe.ch)
[3]CUDAM, Università di Milano Bicocca, Italy

Bell-shaped Pb diffusion profiles are not found in U-Pb mineral chronometers; instead, patchy intra-grain age variations match heterochemical recrystallization [1]. Fluids most efficiently control micro-chemistry, micro-textures and the isotope record [2-5]. Is K-Ar different from U-Pb?

Some authors [6] propose that K-feldspar (Kfs) loses Ar in nature and the laboratory by the same mechanism, volume diffusion out of discrete "domains", so that a lab experiment can be inverted to yield a thermal history; they assume that ambient temperature alone uniquely controls Kfs ages.

We re-sampled and re-investigated the archetypal Kfs MH-10 [6]. We duplicated age spectra and Arrhenius trajectories of [6]; this is where agreement ends. The self-similarity of Arrhenian non-linearities demonstrates that "small domains", which were argued to be mathematically justified [6] even if physically untenable [7], are untenable mathematically as well. We characterized the sample by cathodoluminescence and electron microprobe, discovering at least 5 fluid-produced, heterochemical, diachronic mineral generations. This confirms [8]. Each diachronic Kfs generation has a different Ca/Cl/K signature. This confirms [9]. MH-10 records a geohygrometric history of fluid interactions; its laboratory staircase spectrum is an effect of degassing a mixture of unrelated Kfs generations. This forbids reconstructing its "thermal history". In the own words of [6], the insight gained from MH-10 must be extrapolated to all existing Kfs samples. Thus, no Kfs must be used as a "thermochronometer" unless it were to be proven to be unaffected by patchy recrystallization and to have an isochemical Ca/Cl/K signature. What Kfs is suitable for instead is a detailed reconstruction of the hygrochronology of a rock.

[5] Johannes Gutenberg-Universität Mainz, Mainz, Germany.

The focus of the present study is to characterize the effects of porosity clogging on the effective diffusivity of porous materials under geochemical perturbation. A systematic experimental approach was used, and coupled to pore network and reactive transport modeling.

The experiments were performed in diffusion cells composed of a column filled with synthetic silica spheres (SiLi beads) or purified sea sand and two reservoirs, containing a $SrCl_2$ and a Na_2SO_4 solutions. Prior to the mineral precipitation experiments the transport properties were characterized by means of conservative radiotracer (HTO) tests and revealed D_e values of $(4.79 \pm 0.24)\times10^{-10}$ m^2 s^{-1} and $(4.20 \pm 0.21)\times10^{-10}$ m^2 s^{-1} for SiLi beads and sea sand, respectively. The precipitation of celestite ($SrSO_4$) in the porosity and the subsequent evolution of the diffusivity were monitored by HTO and computed tomography (CT).

The CT resolution varied from 11 to 15 μm. The data were implemented into a pore network model (GEODICT) in order to estimate porosity and diffusivity of the materials, but also to monitor the precipitation processes in a non destructive way. The model was calibrated on a diffusion cell filled with SiLi beads of 400-600 μm particle size. The segmented CT porosity of 0.365 was comparable to 0.361 ± 0.047 for HTO radiotracer tests, giving confidence in the approach used. In addition, the porosity was cross-checked by mercury intrusion porosimetry measurements, which gave values of 0.389 and 0.413, in good agreement with the two precedent ones. In addition to the pore network modeling, a reactive transport model was developped to reproduce the data using Archie's law, in order to extend its applicability to very small effective porosities.

Rare-earth deposits in igneous rocks: A mineralogist's perspective

ANTON R. CHAKHMOURADIAN[1], ANATOLY N. ZAITSEV[2] AND EKATERINA P. REGUIR[1]

[1]Department of Gelogical Sciences, University of Manitoba, Winnipeg, Manitoba, Canada (correspondence: chakhmou@cc.umanitoba.ca)

[2]Department of Mineralogy, St. Petersburg State University, St. Petersburg, Russia

Globally, some 70% of advanced rare-earth exploration projects have focused their efforts on mineral deposits associated with igneous rocks (or their weathering products). Three groups of igneous deposits have attracted the most attention: (1) carbonatites; (2) peralkaline silica-undersaturated rocks; and (3) peralkaline anorogenic granites. The first two groups accounted for ~50% of the global production of rare earth elements (REE) prior to 1995. Deposits associated with carbonatites show the lowest levels of Y and heavy REE in their budget (Y/Nd ≤ 0.3) among the three groups, but are least depleted in Eu (Eu/Eu* = 0.7-1.1); these characteristics are in marked contrast to those of rare-earth ores in anorogenic granites (Y/Nd ≥ 0.8; Eu/Eu* ≤ 0.3). Postorogenic carbonatites associated with saturated alkali syenites have shown the greatest promise as a primary REE source (fluorocarbonates, monazite). Extreme enrichment of carbonatitic magmas in light REE cannot be explained satisfactorily with simple melting models. The presence of REE phases in their mantle source, low degree of contamination by crustal material, and fortuitous interplay between $a\mathrm{F}^-$ and $a(\mathrm{PO}_4)^{3-}$ appear to be prerequisite to the formation of a commercially viable deposit. In anorogenic carbonatites, appreciable REE mineralization commonly develops through breakdown of apatite, calcite and other primary low-grade REE hosts during their hydrothermal reworking (fluorocarbonates, ancylite, monazite) or lateritic weathering (monazite and other secondary phosphates). A variety of minerals forming large-tonnage deposits in peralkaline undersaturated rocks have been proposed as the ultimate solution to looming critical-metal shortages; however, only loparite has been extracted and processed industrially to date. It remains to be seen if any of the other REE-bearing minerals (e.g., eudialyte) are amenable to profitable metal recovery. These minerals crystallize from extremely evolved melts derived by protracted fractional crystallization of aegirine, feldspars and nepheline (± sodalite) from basanitic magma in anorogenic extensional settings.

Timescales of metamorphism: A Hierarchical distribution

SUMIT CHAKRABORTY [1]

[1]Institut fuer Geologie Mineralogie und Geophysik, Ruhr-University Bochum, Germany (Sumit.Chakraborty@rub.de)

Several tools now provide us information on the timescales of metamorphism: geodynamic modelling, spatially resolved isotopic dating, and diffusion modelling of compositional zoning are some of these. Using the different tools on the same set of rocks reveals processes that occur on a hierarchy of timescales. Geodynamic modelling as well as isotopic dating indicate that orogenies can last over hundreds of millions of years, spatially resolved isotopic dating and direct geological evidence indicates that individual metamorphic rocks go through their pressure-temperature cycles on timescales of a few million years, and individual reactions (e.g. melting) occur within a few hundred thousand years. Combination of the various tools can provide more detailed insights into thermal histories; these can be verified using thermomechanical modeling with realistic boundary conditions. For example, isotopic dating using systems with different closure temperatures provides absolute points along the T-t path of a rock and diffusion modelling helps to determine how these "dots" are connected. Diffusion modelling is now able to resolve non-linear cooling histories and it is found that cooling rates can vary (i.e. increase as well as decrease) significantly during cooling from peak temperatures, and the use of a single, average cooling rate to characterize metamorphic rocks is misleading. Moreover, cooling at high temperatures is not always associated with exhumation and other processes that may act as a thermal sink need to be considered. Finally, we find that regional metamorphic P-T cycles can be very short (e.g. ~ 3 m.y.) or relatively long (~ 20 m.y.), depending on the tectonic setting. Examples from the Himalaya and a UHT metamorphic sequence in the Central Indian Tectonic Zone will be used to elucidate these situations.

Neoarchean island arc magmatism and gold mineralization: Examples from eastern Dharwar craton, India

MANIKYAMBA, C*, ADRIJA CHATTERJEE LINGAMURTY, E. RAJANIKANTA SINGH, M.

National Geophysical Research Institute (Council of Scientific and Industrial Research) Uppal Road, Hyderabad 500 606 *(corresponding author email: cmaningri@gmail.com) (adrija.geo@gmail.com;) (elmgeology@gmail.com); (rajanimutum)@gmail.com)

Four linear arcuate greenstone belts dominate in the eastern Dharwar craton having variable proportions of gold mineralization along which Hutti is the only working mine at present. The Sandur greenstone terrane; the Ramagiri-Penakacherla-Hungund; Hutti-Jonnagiri-Kadiri-Kolar and Naraynpet-Gadwal-Velligallu linear, composite greenstone terranes of eastern Dharwar craton are evidenced with gold mineralization in different lithounits. The plume magmatism in the western sector has resulted in concentration of iron, manganese and other base metals deposits whereas the arc magmatism in the eastern sector contributed for the concentration of gold at some places. Subduction-accretion has been recognized as a predominent process in the growth of continental crust and its mineralization in eastern Dharwar craton. Most of the greenstone belts in eastrn Dharwar craton have a complete spectrum or a few litho units that represent intraoceanic island arc process. Sandur belt has komatiite-tholeiite sequences along with calc-alkaline volcanic rocks representing plume-arc accretionary process. Komatiites, oceanic island basalts, arc basalts, Nb-enriched basalts and adakites are present along the Ramagiri-Penakacherla-Hungund belt representing the dominance of island arc process where Penakacherla belt has abundant gold mineralization. Arc-back-arc baslats with adakites were reported at Hutti; high-Mg baslats along with arc basalts are preserved at Jonnagiri; arc basalts along with Nb-enriched baslats, adakites, Mg-andesites, dacites and rhyolites occur in Kadiri belt and Kolar has ultramafic rocks that reflect on mantle plume magmatism. In Narayanpet-Gadwal and Veligallu belts boninites are present at Veligallu and Gadwal which are associated with Nb-enriched basalts, arc basalts, Mg-andesites and adakites. The identification of the rocks deposited at Neoarchean convergent margins provide significant constraints on the island arc magmatism, plume-arc accretionary process and concentration of gold in few greenstone belts of eastern Dharwar craton.

Evolution of basaltic melt during mantle refertilisation at shallow depths of spreading ridges, through experimental studies of liquid compositions in equilibrium with plagioclase + spinel lherzolite at low pressures (0.75 and 0.5 GPa)

F. CHALOT-PRAT[1], T.J. FALLOON[2], D.H. GREEN[3] AND W.O. HIBBERSON[4]

[4]RSES, the Australian National University, Canberra, ACT0200, Australia

The presence of plag+sp lherzolites among ocean floor samples and in some ophiolite complexes invites speculation on their origin and relationships to processes of magmatism and mantle refertilisation beneath mid-ocean ridges. We have determined experimentally, in the (Cr+Na+Fe+Ca+Mg+Al+Si) system, the compositions of liquids and 5 co-existing minerals in the six phase assemblage [Liq+Ol+Opx+Cpx+Plag+Sp] at 0.5 and 0.75 GPa [1,2]. As compositions of mineral phases are pressure dependent, our results may be used to quantify the P-T and compositional evolutionary paths of both liquids and residues during mantle refertilisation at shallow depths. The major variations in liquid compositions are related to plagioclase composition. Liquid compositions, silica-oversaturated for An_{Plag} ≥40 but critically silica-undersaturated for An_{Plag} ≤25, are unlike natural MORB glasses, providing no support for MORB genesis by extraction of near-solidus melts from plag-lherzolite at low pressure. Comparisons with natural mineral compositions of plag+sp-refertilised lherzolites from the literature infer that the refertilisation process by reactive porous flow of magma within the oceanic lithospheric mantle took place at depths of up to 30 km (0.75 GPa≤P≤1 GPa) beneath the sea floor.

IBA quartz chemistry to track phase separation in intrusive rock

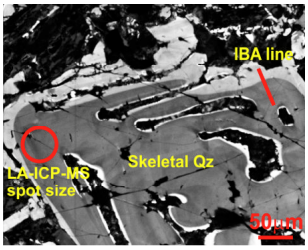
I. CHAMBEFORT[1], W.J. TROMPETTER[2] AND F. BEGUE[3]

[1]GNS Science, Wairakei Research Centre, NZ, (i.chambefort@gns.cri..nz)
[2]GNS Science, National Isotope Centre, NZ,
[3]Univ. of Canterbury, NZ,

Undercooling and fast crystallisation textures such as myrmekites, granophyric and dendritic and skeletal growths have often been associated with subsolidus crystallisation due to H_2O loss. The exsolution of the fluid phase initiates the nucleation of quartz, K-feldspar and plagioclase by quenching at the binary eutectic.

A combined study of cathodoluminescence imaging and detailed chemistry was applied to tonalitic intrusive rock from the Ngatamariki Geothermal Field, New Zealand. The intrusions underwent phase separation at an estimated depth of 1.6 km and produced a large phyllic alteration halo in the country rocks. The working hypothesis is that the last stage of the magmatic mineralogy has recorded the exsolution stage in their chemistry. Quartz phenocrysts in the tonalite are up to 8 mm in diameter and embayed. Also present are small (<2 mm) skeletal quartz grains cocrystallising with a myrmekitic / granophyric groudmass.

Cathodoluminescence on quartz, La-ICP-MS and Ion Beam Analysis (IBA) were done on rounded and skeletal quartz phenocrysts to track variations in Ti, Al, F, Li and B from core to rim in the different CL zones. The outer rims of the skeletal quartz and groundmass quartz are brighter in CL than the large phenocrysts, suggesting enrichment in Ti and other trace elements (figure). A 15 µm proton beam was raster scanned over the sample to produce elemental maps. Ti and Al were detected via X-rays; F via γ-rays, B and Li via (p,α) nuclear reactions. The IBA techniques give spatial precision to the micron scale and ppm LODs allowing detailed chemistry to track the volatile loss.



Acknowledgements: We thank Mighty River Power for the use of the rock sample. The project is funded by GNS Science CSA geothermal and ion beam inovations research programs, and the Royal Society of New Zealand Mardsen Fund GNS1203 to IC.

Combined diffusion studies in sanidine, quartz and orthopyroxene: Timescales of magma mixing in the Bishop Tuff

K.J. CHAMBERLAIN[1]*, D.J. MORGAN[2] AND C.J.N WILSON[1]

[1] SGEES, Victoria University of Wellington, PO Box 600 Wellington, 6012, New Zealand (*correspondence: katy.chamberlain@vuw.ac.nz; colin.wilson@vuw.ac.nz)
[2] SEES, University of Leeds, Leeds, LS2 9JT, UK (d.j.morgan@leeds.ac.uk)

The ~0.76 Ma Bishop Tuff (eastern California) is an archetypal product of a compositionally stratified magma chamber. A key issue regarding the evolution of the melt-dominant magma body that has arisen from recent studies involves understanding the nature and timing of late-stage mixing with a compositionally contrasting melt. This melt is reflected, for example, in the CL-bright rims on quartz and Sr- and Ba-rich rims on sanidine reported in ignimbrite samples erupted from vents along the northern caldera rim [1, 2, 3].

We use ternary feldspar thermometry combined with 1D diffusion models to calculate timescales for diffusion of key elements in three crystal phases of the Bishop Tuff. We show that Sr in sanidine, Fe-Mg in orthopyroxene and Ti in quartz all indicate mixing timescales of <150 yrs, in contrast to the ~2000 yr timescale from Ba in sanidine. The anomalously long timescales obtained from Ba diffusion in sanidine have implications for the application of this chronometer to low-T (~800 °C) rhyolitic systems. The short timescales modelled indicate that the "contaminant" magma causing the growth of these rims was a relatively transient feature in the ~ 70 kyr history of the melt-dominant magma chamber [4].

Melts in a single lava flow from a multiply subduction-modified mantle column below Central Italy

S. CHANEVA[1], I. NIKOGOSIAN[1], M.J. VAN BERGEN[1] P.R.D. MASON[1] AND MARTIN WHITEHOUSE[2]

[1]Department of Earth Sciences, Utrecht University, the Netherlands (simonachaneva@gmail.com)
[2]Swedish Museum of Natural History, Box 50007, SE104 05 Stockholm, Sweden

Latera stratovolcano, situated in the northernmost part of the Roman Magmatic Province (Central Italy), represents a late activity stage of Quaternary volcanism in the Vulsini complex. Lava compositions range between leucite-bearing ultrapotassic (HKS) and shoshonitic (SHO). We determined major-element, trace-element and Pb-isotope compositions of homogenized melt inclusions (MI) trapped in Fo-rich olivines (Fo_{91}-Fo_{87}) that were separated from samples of a voluminous lava flow with SHO affinity (Selva Del Lamone flow, SDL) and a HKS lava. Two populations of magmatic olivine, MI and spinel have been distinguished in the SDL lava, based on morphologies and compositions of host olivines and inclusions. A wide range in CaO contents of Fo-rich olivine points to crystallization from compositionally different primary melts. We infer that the SHO lava comprises two distinct mantle-derived alkali-rich melts: (1) "normal" SHO type, compositionally closest to the host rock; and (2) "low-CaO" high-Na_2O melt with lamproitic affinity. The MI from the SDL lava show an extreme Pb-isotopic diversity: $^{206}/^{204}$Pb = 18-19.2, $^{207}/^{204}$Pb = 14.6-16, $^{208}/^{204}$Pb = 36.5-40.5, each group being characterized by its own signature. The composition of the host lava appears to be a mixture of (at least) three isotopically distinct end-members. The MI form arrays between MORB-source-like mantle and various crustal/sedimentary end-members, including both upper and lower continental crust. Former Alpine and Adriatic subduction systems may have affected mantle sources of the SHO magma, whereas the HKS source was influenced by the Adriatic system, similar to the rest of the Roman Magmatic Province. A relatively recent thermal event, possibly promoted by detachment of the Adriatic slab, must have been responsible for the simultaneous melting of heterogeneous domains in the mantle column below the volcano that reflect superimposed imprints from multiple subduction systems.

Abnormal K-feldspars from the Lower Cambrian Hetang Formation in the Lower Yangtze Area: Implications for hydrothermal activities

CHAO CHANG[1], WENXUAN HU[12] AND XIAOLIN WANG[12]

[1]School of Earth Sciences and Engineering, Nanjing University, Nanjing, 210093, P.R. China
[2]Institute of Energy Sciences, Nanjing University, Nanjing, 210093, P.R. China

The Lower Cambrian black rock series are widely distributed throughout the Yangtze Platform in South China. At the lowermost part of the strata, there is a thin sulfide ore horizon rich in Cu, Mo, Co, Ni, PGE, Se, As, Hg, Sb, Ag, and Au. Based on geochemical characterization on certain segment of the strata, some researchers tried to figure out the formation mechanism of the horizon. However, no agreement on this question has been obtained yet, and the main argument is whether or not hydrothermal activities have played an important role in the formation process.

In this study, systematic analyses were carried out on the lithology and mineralogy of samples throughout the whole strata. Unexpectedly, abundant K-feldspars with abnormal composition were found. In terms of the electron probe microanalyses (EPMA), it is found that the K-feldspars can be subdivided into two types: Ba-rich K-feldspars and Ba-poor K-feldspars. The Ba-rich K-feldspar is characterized by high BaO content ranging from 1.34 % to 9.08 %; the K_2O and SiO_2 concentrations range from 7.24 % to 10.50 % and from 59.37 % to 69.70 %, respectively. The Ba-rich K-feldspar is found in veins, or occurs as thin rims of the Ba-poor K-feldspars in the matrix. The Ba-poor K-feldspar is depleted in BaO content ranging from 0.06 % to 1.08 %; the K_2O and SiO_2 content range from 5.22 % to 15.47 % and from 63.07 % to 73.13 %, respectively. The Ba-poor K-feldspar mostly occurs as anhedral grains in the matrix.

Furthermore, it is revealed that the plots of BaO and SiO_2 concentrations of the Ba-rich K-feldspar show a linear correlation, which is similar to those of hyalophane (or celsian). However, the K_2O-BaO relation is totally irregular. In addition, it is also observed that the K_2O-SiO_2 relation is basically linear, which shows that the K-feldspar could form in a continuous sequence from low K_2O content to high K_2O content; the endpoint could represent normal K-feldspars.

In conclusion, it is suggested that the K-feldspars were immature in composition and might precipitate from rapid cooling of hydrothermal fluids. We are searching for further evidence to support this new formation mechanism for abnormal K-feldspar.

Multiple controls on the geochemistry of early Cenozoic volcanism in Victoria, Australia

T-J. CHANG, J. HERGT, G. HOLDGATE, M. WALLACE AND D. PHILLIPS

School of Earth Sciences, The University of Melbourne, Parkville, Victoria, Australia, 3010

Early Cenozoic volcanism in Victoria (resulting in the so-called 'Older Volcanics' province) has received little attention compared to younger volcanic provinces in Australia. Magmatism occurred intermittently between ~20 to 40Ma and new trace element and isotope data for a number of subprovinces reveal wide geochemical variations both locally and regionally.

These rocks are dominated by alkali basalts and basanites, and all samples are reasonably fresh with typical mineral assemblages including olivine, clinopyroxene, and plagioclase, with or without nepheline. Mantle xenoliths have been observed in 4 samples. The MgO and SiO_2 contents range between 3.2-11.1wt% and 41.1-52.1 wt% respectively and the wide range in magnesium numbers (39-69) indicate that the magmas vary from primitive (perhaps even primary) to evolved in composition. Although trace element compositions broadly resemble those of modern OIB; in detail, mantle-normalised patterns show distinct differences between subprovinces. The transitions between subprovinces coincide with large-scale faults, that separate different structural zones in Victoria, indicating possible structural control over the magma chemistry. Ce/Pb and Nb/U ratios range between 11.4-33.3 and 23.8-60.9 respectively, with lower values reflecting the effects of crustal assimilation. Initial $^{87}Sr/^{86}Sr$ (0.70285-0.70507) and $^{143}Nd/^{144}Nd$ (0.512659-0.513021) ratios are corrected using new $^{40}Ar/^{39}Ar$ or $^{40}K/^{39}Ar$ ages. Isotopic compositions of the younger basalts (20-30Ma) form a distinct trend along the mantle array whereas the older basalts (~40Ma) scatter around Bulk Silicate Earth.Together, these new observations reveal that the earliest period of volcanism in the Older Volcanics province tapped a relatively homogeneous mantle source, and that magmas migrated to the surface without significant assimilation of continental crust. In contrast, the younger magmas interacted with and assimilated crustal material, modifying their compositions prior to eruption. The extent to which the mantle source rocks for this younger group may also have varied is under investigation. In addition, the role of the large-scale structures in chanelling magmas to the surface, and/or influencing their ability to interact with crust, is an important component of this study.

Characteristic Elements of Products of Designations of Origin selected from Yangchun in Guangdong Province, China

CHANG XIANG-YANG, LIU HUI, FU SHAN-MING, CHEN NAN, LI DONG-MEI AND ZHAO XIAO-FENG

School of Environmental Science & Engineering, Guangzhou University, Guangzhou 510006, China

Kaempferia Galanga L. which is the product of designations of origin was selected from Shuangjiao town, YangChun, Guangdong Province, China. The plants and soil profile samples were collected and the element content, element speciation, and lead isotope ratio were determined. Through the multivariate statistical analysis to ascertain the characteristic elements and multi-element group, and provide evidence for establishing the elements- isotope fingerprints of product identification system, the following conclusions:

A group of chemical elements in the plant could indicate the special effect from the special environment where the plants grown, with a closely relationship to the plants growth, those elements are called characteristic elements. According to the results of the analysis of weight, the characteristic elements of Kaempferia Galanga L. were Mn, Zn, Mg, Sr, Cu, Ni and Fe.

The factor analysis and cluster analysis were used for the purpose of the group of elements. The result of factor analysis showed that Cu, Co, Ni, Pb, Sr were the common element group in Kaempferia Galanga L. and soil. The cluster analysis showed that Co, Cr, Cu, Mg, Sr, Zn were the common element group in Kaempferia Galanga L. and soil. The results of the two methods can corroborated each other.

According to the results of the cluster analysis, Co/Ni, V/Co, Mg/Mn, Mn/Sr, Ni/Fe, Zn/Mn, Zn/Sr, V/Cr and V/Cu nine elements ratios was selected, and the change trend of consistent of elements ratios in the Kaempferia Galanga L. with corresponding soil profiles. The elements ratios could be identified as an important tracer tool.

The correlation analysis between elements speciation of soil and Kaempferia Galanga L. showed that effective state of element in soil had a significant relationship with the element content in Kaempferia Galanga L. The level of effective state of element of Fe, Mg, Mn, Pb and Zn in the research area was higher, but the level of Sr, Ti, V was lower.

Lead isotope ratios showed that the sources of lead in the soil profile and Kaempferia Galanga L. ware very stable, lead isotope ratios of Kaempferia Galanga L ware very close to the distribution characteristics of soil region. $^{206}Pb/^{208}Pb$-$^{206}Pb/^{207}Pb$ showed significant correlation further proves the product with soil were homology. Lead isotope could be used as the criterion of fingerprint identification of products of designations of origin.

The Project was supported by National Natural Science Foundation of China (Grant Nos. 40772201, 41073003).

Geochemical characteristics and petrogenesis of Cenozoic igneous rocks in the Georgian Caucasus

YU-HAN CHANG[1]*, SUN-LIN CHUNG[1], AVTO OKROSTSVARIDZE[2] AND ZURAB JAVAKHISHVILI[2]

[1] Department of Geosciences, National Taiwan University, Taipei, Taiwan (*correspondence: r01224107@ntu.edu.tw)

[2] Institute of Earth Sciences, Ilia State University, Tbilisi, Georgia

Cenozoic magmatism in the Caucasus-Iran-Anatolia (CIA) region can simply be divided into two main stages that pre- and post-date, respectively, the onset of the Arabia-Eurasia collision. The pre-collisional stage has been generally related to the Neotethyan subduction. The post-collisional stage has been ascribed to rollback and then breakoff of the subducted slab or other geodynamic processes such as delamination of thickened lithosphere. In Georgia, located ~500 km north of the Zagros suture zone, the pre-collisional rocks, with SiO_2 ranging from ~45-64 wt.%, are more heterogeneous in certain incompatible elements such as potassium and LREE than the post-collisional rocks, despite the latter show a wider range of SiO_2 (45-72 wt.%). Thus, in contrast to the post-collisional rocks that plot in the median- to high-K calc-alkaline suite, the pre-collisional rocks are dominantly of intermediate compositions ($SiO_2 \approx 60$ wt.%) and vary from low- to high-K calc-alkaline to shoshonitic in nature. However, rocks from both stages are characterized by the "arc signature" including enrichment in LILE (e.g., Rb, Ba) and depletion in HFSE (e.g., Ti, Nb, Ta). While isotopic determination is still in progress, Sr-Nd isotope data obtained so far from post-collisional rocks indicate that they have an isotopically uniform mantle source similar to other post-collisional magmas in the CIA region. We are also working on precise dating of the pre-collisional rocks. The result, together with geochemical and isotopic constraints, will hopefully help us better understand the petrogenesis that we suspect to have affiliated with a back-arc system.

Understanding controls on Ca isotopes in human blood and urine

M.B. CHANNON[1]*, G.W. GORDON[1], Q. SHOLLENBERGER[1], J.L.L. MORGAN[2], J.L. SKULAN[3], S.M. SMITH[2] AND A.D. ANBAR[1]

Calcium isotopes fractionate during bone formation, favoring light Ca isotopes. During bone resportion, Ca isotopes are released into the blood and soft tissue with little or no discrimination. This fractionation process may be a powerful biomarker for diseases that effect the skeletal system such as osteoporosis, multiple myeloma, and cancers that metastasize to bone. However, in order to translate this biomarker to a clinical setting, we must understand all the factors contributing to the Ca isotopic composition of blood and soft tissue in the body.

It was previously shown that Ca isotopic composition of urine reflects changes in bone mineral balance correlated to bone loss during bed rest [1-2]. The most recent study [2] involved 12 patients on bed rest for 30 days with a controlled diet. Both urine and blood were collected from participants throughout the study, as well as meal and beverage samples for isotopic analysis. This study showed that the Ca isotopic composition of urine becomes lighter as bed rest progresses, in correlation with bone resorption. Here we present new data of blood, meals, and additional urine analyses from this study.

We find variable Ca isotope ratios among meals that tend towards heavier values for breakfasts, lighter values for dinners, and intermediate values for lunches. We also find a large range within and between beverages. We investigate whether the compositional differences in meals is reflected in urine isotope ratios over a 24 hour period by measuring each urine void from the same participants for one full day of the study.

We also find that blood has a systematically lighter isotopic composition than urine. We explore the possibility of a renal fractionation [3] involving Ca-binding proteins that might explain the difference between the Ca isotope ratios of blood and urine. Nevertheless, blood tracks the same trend as urine during the progression of bed rest, and therefore the compositional difference between blood and urine does not obscure the signal of bone resorption.

Elastic wave velocities of polycrystalline $Mg_3Al_2Si_3O_{12}$-pyrope garnet to 24 GPa and 1300K

J. CHANTEL[1], G. MANTHILAKE[12], D. FROST[3], C. BEYER[3], Z. JING[4] AND Y. WANG[4]

[1] Universite Blaise Pascal, Laboratoire Magmas et Volcans, Clermont-Ferrand, France

[4] University of Chicago, Chicago, IL, USA

The most accurate method to investigate the mineralogy and chemistry of the mantle at depths greater than 150 km is through the analysis of compressional (*P*) and shear (*S*), seismic waves and comparison with the same velocities calculated for expected mineral assemblages. Regional variations in seismic wave velocities could originate from either chemical or thermal heterogeneities and experimental measurements of wave velocities of candidate phases at high pressures and temperatures are required to differentiate between these causes. In the transition zone, rocks formed from subducted basaltic crust are rich in garnet and its mineral proportion and chemistry differs from typical ultramafic mineral phases, which are dominated by olivine polymorphs wadsleyite and ringwoodite. Although the sound velocities of olivine polymorphs at relevant pressures have been well documented, those of garnet have not been investigated in its stability field.

We have successfully measured the acoustic wave velocities for synthetic polycrystalline pyrope garnet ($Mg_3Al_2Si_3O_{12}$) were to 24 GPa and temperatures up to 1300K by ultrasonic interferometry combined with energy-dispersive synchrotron X-ray diffraction in a 1000-ton press and a T-25 multi-anvil module (13ID-D, APS). Specimen lengths at high pressures (*P*) and temperatures (*T*) are directly measured by X-ray radiography methods, while elastic wave travel times and X-ray diffraction data were collected. Two dimensional (*P*-*T*) linear fittings of the present data yields the following parameters: K_{S0} = 168.5 (2) GPa, $\delta K_S/\delta P$ = 4.49 (2), $\delta K_S/\delta T$ = -19.9 MPa/K, G_0 = 88.5 GPa, $\delta G/\delta P$ = 1.59 (1) and $\delta G/\delta T$ = -8.9 MPa/K which is consistent with earlier results at lower pressures except for a significantly lower G_0 and $\delta G/\delta T$. Compressional (V_P) and shear (V_S) wave velocities as well as the adiabatic bulk (K_S) and shear (G) moduli exhibit monotonic increase with increasing pressure and decrease with increasing temperature, respectively. The observed linear pressure and temperature dependence in both V_P and V_S is in contrast to the non-linear behavior of V_P and V_S for majorite garnet with the pyrolite composition, in particular for V_S.

Stability of polycyclic aromatic hydrocarbons at upper mantle conditions

A.D. CHANYSHEV[12]*, K.D. LITASOV[1,2], A. SHATSKIY[12] Y. FURUKAWA[3] AND E. OHTANI[3]

[1]Sobolev Institute of Geology and Mineralogy, Novosibirsk, 630090, Russia
(*correspondence: chanyshev_90@mail.ru)
[2]Novosibirsk State University, Novosibirsk, 630090, Russia
[3]Tohoku University, Sendai, 980-8578, Japan

The origin of deep-seated hydrocarbons was widely discussed in relation to the study of C-O-H fluid. The estimation of fO_2 conditions in the deep mantle indicate that it can be in equilibrium with reduced fluids and fO_2 in mantle rocks can be fluctuated near that for the iron-wustite buffer at the depth below 300 km [1]. The calculations of fluid compositions at these conditions in the C-O-H system indicate the dominant CH_4-H_2O mixture, with subordinate H_2, and heavier hydrocarbons [1]. However, some theoretical calculations predict that heavy hydrocarbons, such as alkanes, alkenes, polycyclic aromatic hydrocarbons (PAH), can become stable in the mantle fluids at 300-600 km and deeper [2].

Here we determined stability and chemical reactivity of PAHs at upper mantle pressures. PAHs were selected according to abundance in natural samples [3] and meteorites. The starting materials were from naphthalene to coronene. The decomposition parameters were detected by *in situ* X-ray diffraction and laboratory multianvil experiments. In the pressure range of 6-9 GPa selected PAHs become unstable at temperatures of 873-1023 K. After experiments we analyzed products using matrix-assisted laser desorption/ionization method (MALDI). As a result, the formation of polymers of starting materials at 7 GPa and 773-873 K was determined. The polymers have atomic masses up to 5000 Da.

The P-T parameters for the PAHs stability field do not correspond to the upper mantle conditions; indicating that PAHs in diamonds and other mantle minerals [3] would have secondary origin. Indeed, data for PAHs stability is important for near-surface geodynamics of small and large planetary bodies as PAHs are widely observed in the Universe [4]. The work is supported by RFBR No 12-05-00841.

The variation of Sr isotopes ($^{87}Sr/^{86}Sr$ and$\delta^{88/86}Sr$) in river waters after Typhoon Morakot at a small catchment, southwestern Taiwan

H. C. CHAO[12], C. F. YOU[1]*, H. C. LIU[1] AND C. H. CHUNG[1]

[1]Department of Earth Sciences, National Cheng Kung University, Tainan, Taiwan, R.O.C. (*correspondence: cfy20@mail.ncku.edu.tw)

[2]Present Address: Department of Geography, National Changhua University of Education, Changhua, Taiwan, R.O.C. (ekman60@gmail.com)

Radiogenic Sr isotope ($^{87}Sr/^{86}Sr$) is a robust tool for provenance identification in hydrology, affected mainly by chemical weathering and climatic changes. Owing to technical improved MC-ICP-MS, stable Sr isotopes ($^{88}Sr/^{86}Sr$) in natural materials have become available recently. In this study, weekly river waters, bed loads and suspend particles were collected through dry and wet season from a small drainage catchment (161 km^2), Hou-ku River in southwestern Taiwan, to study effects of intense rainfall event (2000 mm/3 days, Typhoon Morakot). Dissolved major/trace elements, hydrogen, oxygen, and strontium isotopes ($^{87}Sr/^{86}Sr$ and $\delta^{88}Sr$) in river waters were measured to investigate changes on chemical and isotopic characteristics after the typhoon events. For a better constrain on the end member compositions, carbonate phases were chemically removed before acid digestion. Radiogenic and stable Sr isotopes in carbonate and residual phases were measured precisely. Dissolved major elements indicates that the watershed was predominated by silicate weathering, but trended toward carbonate weathering after the rainfall. This event causes all elemental concentrations to drop; however, respective element/chloride ratios were increased 2 to 10 folds. High dissolved $^{87}Sr/^{86}Sr$ was evident in dry season, but low ratio after the rainfall event. Both carbonate and residual phases show higher radiogenic Sr isotopes in the suspend particles (0.70987 – 0.71043 and 0.72591 – 0.72729, respectively) than the bed loads (0.70954 – 0.71013 and 0.72047 – 0.72134, respectively). Stable Sr isotopes show no significant variation ($\delta^{88}Sr$ = 0.24 – 0.31 ‰) after the event. However, all solids show lower $\delta^{88}Sr$ (0.05 – 0.17 ‰) than the river waters, preferential leached of heavier Sr. In summary, the extreme rainfall event did not alter Sr isotopes ($^{87}Sr/^{86}Sr$ and $\delta^{88}Sr$) in river waters; contain higher stable isotopes than the associated sediments.

Mg isotopes: Insights into weathering in a tropical volcaniclastic regolith

M. CHAPELA LARA[1]*, H.L. BUSS[1], P.A.E. POGGE VON STRANDMANN[2], C. DESSERT[3] AND J. GAILLARDET[3]

[1]School of Earth Sciences, Univ. of Bristol, Bristol BS8 1RJ, UK (*correspondence: M.ChapelaLara@bristol.ac.uk, h.buss@bristol.ac.uk)

[3]Institut de Physique du Globe de Paris, 75252 Paris Cedex 05 France (dessert@ipgp.fr, gaillard@ipgp.fr)

Mg is an important constituent of silicates and a major nutrient and its stable isotopes have been shown to fractionate during geochemical and biological reactions. Mg isotope ratios therefore hold promise as a useful tracer of (bio)geochemical processes in the critical zone. We present preliminary results on the Mg isotopic composition of porewater and stream water (baseflow and stormflow), along with elemental data from depth profiles (1.0 - 9.3 m) in bulk regolith and exchangeable cations taken at 4 sites along a topo-sequence in a well-constrained catchment over volcaniclastic bedrock at the Luquillo Critical Zone Observatory, Puerto Rico..

Mg and K concentrations corrected for rain input and evapotranspiration indicate weathering contributions to pore water solutes. Pore water concentrations are relatively invariant with time below 0.5 m depth (2.0 m depth in the deepest profile). Above these depths, Mg concentrations vary in space and time, with all profiles showing overall higher concentrations in the surface layers, suggestive of biological influence. In contrast, $\delta^{26}Mg$ values in the deepest profile show a clear trend towards heavier $\delta^{26}Mg$ with increasing depth (-0.83‰ to -0.18‰) suggesting mixing between atmospheric Mg at the surface and a dissolving, isotopically heavier phase at depth. An excursion towards heavier $\delta^{26}Mg$ at the soil-saprolite interface (-0.7‰, ~1m depth) indicates a change in controlling processes. A similar heavy excursion is present at the same depth in 3 of the 4 profiles.

Stream water at baseflow is isotopically heavier than the pore waters and becomes progressively lighter with increasing stage. These results may indicate that watershed export of Mg is dominated by deep-weathering processes during baseflow with contributions from rain and shallow soils during storms.

First Finding of Picrobasaltic Melts on Iturup Island, Kurile Island Arc

I. CHAPLYGIN, I. SOLOVOVA AND M. YUDOVSKAYA

Institute of Geology of Ore Deposits (IGEM RAS), 109117 Moscow, Russia (maiya@igem.ru)

Basaltic magmatism occurs extensively in the Kurile island arc, but more magnesian magmas (picrobasalts) were not previously reported. The subvolcanic picrobasaltic massif of Ksenolitnaya Cove, Iturup Island, contains xenoliths of olivine with rare clinopyroxene crystals. Primary melt inclusions were found in olivine from both the xenoliths and their host rock. The inclusions are surrounded by decrepitation haloes. Melting of daughter phases in the melt inclusions was observed at 1170-1225°C. The inclusions in the xenoliths and rock have similar compositions with low SiO_2 (up to 45 wt %) and high MgO (up to 12 wt %), CaO (up to 17.5 wt %), H2O (≥1 wt %), F (up to 0.3 wt %) and P2O5 (up to 0.4 wt %). A comparison of the whole-rock compositions of basic volcanics from the Kurile island arc and the obtained data for melt inclusions suggests that extremely primitive mantle melts with very high CaO contents were trapped in the inclusions. The similarity of major- and trace-element characteristics and temperatures of olivine-hosted melt inclusions from the picrobasalts and xenoliths suggests a cumulate origin of the latter during the crystallization of a primary mantle melt in a magma chamber.

This study was supported by the Russian Foundation for Basic Research and the Russian Program for the Support of Leading Scientific Schools.

Strontium isotopes map fluid flow in a natural CO_2 Reservoir, Green River, Utah, USA

HAZEL CHAPMAN[1]*, NIKO KAMPMAN[1], MIKE BICKLE[1], ANDREAS BUSCH[2] AND JAMES P EVANS[3]

[1] Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge CB2 3EQ, UK (*correspondence: hjc1000@cam.ac.uk)

[2] Shell Global Solutions International, Kessler Park 1, 2288 GS Rijswijk, The Netherlands

[3] Department of Geology, Utah State University, 4505 Old Main Hill Logan, UT 84322-4505

Strontium isotopes offer a powerful constraint in the study of subsurface fluids and are used here to map fluid transport in a natural CO_2 reservoir adjacent to a cold water CO_2-geyser and a CO_2-leaking extensional fault at Little Grand Wash, at Green River in Utah.

The strontium isotopic ratios with associated chemical data in this sequence of porous sandstone layers with intervening caprocks are used to constrain the CO_2-charged fluid sources, fluid-fluid mixing and mineral reactions caused by CO_2 migration within the fault damage zone. Carbonate and silicate fractions have been analysed in Wingate, Kayenta, Navajo and Entrada sandstones, gypsum rich layers, the low permeable Carmel caprocks and shale bands within the Entrada Sandstone. The mixing trends from deep brine, sandstone reservoirs and shale-rich cap-rock are well illustrated by 1/Sr versus $^{87}Sr/^{86}Sr$ ratios. The mineralogical changes enhance the sealing properties of cap-rocks for underground storage.

Molybdenum speciation and distribution in ancient euxinic shales by μXRF and μXANES spectroscopy

ANTHONY CHAPPAZ[1]*, JEFFREY P. FITTS[2] AND TAIS W. DAHL[3]

[1] Institute for Great Lakes Research – Dep. of Earth and Atmospheric Sciences, Central Michigan University, Mount Pleasant, MI 48859, USA
[2]Department of Civil & Environmental Engineering, Princeton University, Princeton, NJ 08544, USA
[3] Natural History Museum of Denmark, University of Copenhagen, DK1350 Copenhagen, Denmark.

Molybdenum is a redox sensitive metal used to investigate oxygen content in ancient oceans from sedimentary records. Specifically, Mo enrichment, Mo/TOC ratio and ^{98}Mo-isotopic signature in black shales are determined to characterize euxinic deposition, seawater Mo concentration, and global ocean oxygenation, respectively. However, these approaches are based on bulk rock analyses without a comprehensive understanding of chemical burial pathway(s). Here, we bridge this gap using μ-XRF and μ-XANES to investigate Mo speciation and distribution in drill core samples from the ~500 Ma Alum shale formation.

The Mo distribution in our shale samples demonstrates a homogenous enrichment (~100 ppm) relative to average upper crust (~ 1 ppm), superimposed by enrichments in 0.1 mm thick lenses within certain sedimentary lamina. The μ-XRF elemental maps show a consistent correlation of Mo and Fe abundance and that Mo-rich lenses are particularly poor in Rb (e.g. clay minerals) and Br (e.g. organic matter). However, the apparent decoupling between Mo and organic matter in the lenses is tentative and needs further validation. The Mo speciation was determined using μXANES spectra and compared to bulk XANES analyses of modern euxinic sediments where two types of Mo compounds were identified: Mo(IV)-S and Mo(VI)-O [1]. In our samples the Mo-rich lenses host both species, while the matrix contains only the Mo(IV)-S compound.

The Mo-Fe association is consistent with our previous study showing that both Mo species display an Fe atom in the second or third shell. Further, the reduced Mo(IV)-S compounds appear to be pristine precipitates from Cambrian seawater, whereas post-depositional oxidation cannot be ruled out for the oxidized Mo(VI)-O species. Conclusively, the pristine Mo(IV)-S in the matrix may serve as better targets for paleoredox investigations relative to bulk rock analysis.

Trace-gas measurements in firn and ice cores using CRDS instruments

J. CHAPPELLAZ[1]*

[1]LGGE/CNRS, BP 96, 38402 St Martin d'Hères, France (*correspondence : jerome@lgge.obs.ujf-grenoble.fr)

Ice cores and polar firn air provide a unique means to reconstruct polar temperature as well as atmospheric composition changes. They notably help to understand the feedbacks at work between natural climate variability and biogeochemical cycles controlling the atmospheric composition.

The iconic curves of greenhouse gas (CO_2, CH_4, N_2O) concentration changes over the last 800,000 years have been produced through painstaking discrete measurements over years of laboratory work. Stable isotopic ratios of the three greenhouse gases (used to better understand the causes of greenhouse gas concentration changes) are also investigated through discrete measurements. They typically require a full day work in the laboratory for acquiring one or two data points, and they are still far from reaching the time span and resolution of mixing ratio measurements.

Since four years, the availability of Cavity Ring-Down Spectroscopy (CRDS) instruments with enough sensitivity and precision for ice core applications, has largely changed the way firn air and ice core samples are handled. I will show and discuss the results recently obtained on firn air measured in the field and on different ice cores, the latter combining a continuous-flow analysis (CFA) extraction technique and a CRDS instrument, using either WS-CRDS (Picarro) or OF-CEAS (SARA) technology. Clear advantages of these new analytical settings are : speed of measurements, instrumental precision, saving of raw material, compatibility with field work, resolution of fine features along the core. But as with any new technique, there are drawbacks. Notably the difficulty to obtain accurate measurements with the coupled CFA-CRDS setup (calibration with discrete measurements is still needed), and the smoothing and possible drift of the CFA system.

I will also provide a short review on our current developments at the interface between laser physics and ice core / paleoclimate applications. This concerns the OF-CEAS measurements of trace-gas isotopic ratios, as well as an embedded OF-CEAS spectrometer for real-time *in situ* measurements of water isotopes and greenhouse gases inside an ice sheet.

Thermodynamic study of monoclinic pyrrhotite in equilibrium with pyrite by solid-state galvanic cell technique

DMITRIY A. CHAREEV*[1] AND EVGENIY G. OSADCHII[1]

[1] Institute of Experimental Mineralogy, Russian Academy of Sciences, Chernogolovka, Moscow District, 142432 Russia (*correspondence: chareev@iem.ac.ru)

The reaction $7FeS_2(cr) + 12Ag(cr) = 8Fe_{0.875}S(cr) + 6Ag_2S(cr)$ was studied by measuring the temperature dependence of the electromotive force (EMF) of the all-solid-state galvanic cell with common gas space:

(-) Pt | Ag | AgI | Ag_2S, Fe_7S_8, FeS_2 | Pt (+)

The measurements were carried out in the flow of argon at atmospheric pressure, and AgI was used as a solid electrolyte. As a result of the measurements of EMF as a function of temperature the nonlinear trend was obtained which characterize the equilibrium monoclinic pyrrhotite + pyrite (mpo+py). For these measurements, the lower temperature limit (490 K) corresponds to the equilibrium pyrite+metallic silver (EMF=0); and the upper temperature limit of linear part (565 K) is determined by the temperature of monoclinic pyrrhotite decomposition. From linear low temperature experimental results of this study and literature data for Ag_2S, the temperature dependence of the gaseous sulfur activity was determined in pyrite+monoclinic pyrrhotite (mpo+py) equilibrium:

$\log fS_2(\text{mpo+py}) = 14.08 - 14406 \cdot T^{-1}$,

$(490<T/K<565)$.

Radium Isotopes as Tracers of Boundary Exchange Processes Along the US GEOTRACES North Atlantic Zonal Transect

M.A. CHARETTE[1], P.J. MORRIS[12], W.J. JENKINS[1], P.B. HENDERSON[1] AND W.S. MOORE[2]

[1]Department of Marine Chemistry and Geochemistry, Woods Hole Oceanographic Institution, Woods Hole, MA 02543 USA

[2]Present addresss: School of Earth Sciences, University of Bristol, Bristol, BS8 1RJ, UK

[3]Department of Earth and Ocean Sciences, University of South Carolina, Columbia, SC 29208 USA

Radium isotopes are produced in sediments via the decay of thorium isotopes and are generally soluble in seawater. As such, the radium quartet (^{224}Ra, ^{223}Ra, ^{228}Ra, ^{226}Ra) has been used as tracers of ocean boundary inputs and mixing processes. We measured radium isotopes on the US GEOTRACES North Atlantic cruises in 2010 and 2011, which crossed a number of key ocean boundary features including the Mediterranean outflow, the Mauritanian upwelling and oxygen minimum zones (OMZ) along western Africa, a hydrothermal plume over the mid-Atlantic Ridge (MAR), and the broad continental margin of the northeastern US. Radium isotope features at these locations will be discussed in the context of their potential to quantify fluxes of trace elements and isotopes (TEIs) from common sources. Notable observations include: (1) evidence of substantial sediment-water interaction in the benthic boundary layer along the OMZ, (2) decoupling between ^{223}Ra and the other Ra isotopes over the MAR, and (3) significant contential inputs (e.g. submarine groundwater discharge) in the western Atlantic. Finally, we present results from an upper ocean 2-D mixing model based on our ^{228}Ra data along the OMZ, which can form the basis for interpreting the dissolved and particulate iron cycle in this region.

Compositional variability of ultramafic lavas on Mercury: Implications for surface mineralogy and mantle sources

B. CHARLIER[12], O. NAMUR[2] AND T.L. GROVE[1]

[1]EAPS, Massachusetts Institute of Technology, Cambridge, MA 02139, USA
[2]Institut für Mineralogie, Universität Hannover, Callinstrasse 3, 30167 Hannover, Germany

Measurements of major element ratios obtained by the MESSENGER spacecraft using x-ray fluorescence spectra are used to calculate absolute element abundances of lavas at the surface of Mercury. We discuss calculation methods and assumptions that take into account the distribution of major elements between silicate, metal, and sulfide components and the potential occurrence of sulfide minerals under reduced conditions. Available compositional data for the northern volcanic plains and for intercrater plains and heavily cratered terrain display significant variations although they share common silica- and magnesium-rich characteristics (basaltic komatiites to komatiites). The inferred mineralogy at Mercury's surface should be dominated by orthopyroxene, plagioclase, minor olivine if any, clinopyroxene (augite), and tridymite. Two compositional groups are distinguished based on mineral components, particularly by the presence or absence of clinopyroxene. Melting experiments at one atmosphere demonstrate that these compositional groups cannot be simply related to each other by any fractional crystallization process, suggesting differentiated source compositions and implying multi-stage differentiation and remelting processes for Mercury. Magma ocean crystallization followed by adiabatic decompression of mantle layers during cumulate overturn and/or convection would have produced adequate conditions to explain surface compositions. Thus, the surface of Mercury is not an unmodified quenched crust of primordial bulk planetary composition. Ultramafic lavas from Mercury have high liquidus temperatures (1450-1350 °C) and very low viscosities, in accordance with the eruption style characterized by flooding of pre-existing impact craters by lava and absence of central volcanoes.

New tricks with old tracers: Sr stable isotope variations in an evolved volcanic system investigated using an ^{84}Sr-^{87}Sr double spike

B.L.A. CHARLIER*[1], I.J. PARKINSON[2] AND C.J.N. WILSON[31]

Dept. Phys. Sci., The Open University, Milton Keynes, UK. (*correspondence: bruce.charlier@open.ac.uk)
[2]School of Earth Sciences, University of Bristol, UK. (ian.parkinson@bristol.ac.uk)
[3]SGEES, Victoria University of Wellington, New Zealand (colin.wilson@vuw.ac.nz)

Strontium is a refractory lithophile element with four stable isotopes, ^{84}Sr, ^{86}Sr, ^{87}Sr and ^{88}Sr . However, ^{87}Sr is also produced by the long-lived radioactive decay of ^{87}Rb, and this parent-daughter isotope system has long been a key pillar of geochronology and geochemical tracing. Conventional Sr isotopic measurements made using TIMS or MC-ICP-MS are corrected for instrumental mass fractionation assuming a value for the $^{88}Sr/^{86}Sr$ ratio of 8.375209. This internal normalisation permits the measurement of $^{87}Sr/^{86}Sr$ ratios to a very high precision. However, normalisation to a fixed $^{88}Sr/^{86}Sr$ ratio using a mass-dependent fractionation law assumes that the stable isotope ratio is uniform in natural samples and erases the possible signature of any mass-dependent natural variation in the $^{88}Sr/^{86}Sr$ and $^{84}Sr/^{86}Sr$ ratios. In this study, we present high-precision Sr stable and radiogenic isotope data (determined using a double spike and TIMS) along with trace element data for a suite of samples from a single evolved volcanic system (Huckleberry Ridge Tuff, Yellowstone). Strontium stable isotope values vary by up to ~0.5 ‰ and correlate well with Ba and Eu/Eu* variations in whole rocks and glass separates. Our data suggest that crystallisation of sanidine (± plagioclase) and/or mixing of melts that have experienced such fractionation is the main driver for the stable isotope variations. Sr-isotopic studies on volcanic rocks require re-evaluation.

Paleo-denudation rates at the Plio-pleistocene transition from *in situ*-produced cosmogenic ^{10}Be: Method and new results from the Tianshan and the Himalayas

J. CHARREAU[1], N. PUCHOL[1], P.-H. BLARD[1], R. PIK[1], R. BRAUCHER[2], L. LEANNI[2], D. BOURLES[2], J. LAVE[1] AND O. BEYSSAC[3]

[2] Aix-Marseille Université, CNRS-IRD UM 34 CEREGE, Aix-en-Provence, France, (bourles@cerege.fr)
[3]IMPMC, cc115, 75005 Paris, FRANCE (olivier.beyssac@impmc.upmc.fr)

Denudation that controls the mass transfer from the uplifting highlands to the lowlands basin and links climate and tectonics is a key factor governing the evolution of the Earth's surface. Quantitative records of past denudation rates are therefore critical, especially at the Plio-pleistocene transition, when the onset of Quaternary glaciations may have enhanced worldwide denudation rates.

To independently reconstruct denudation rates from sedimentary archives, we applied an innovative approach based on the analyses of in situ-produced cosmogenic ^{10}Be in ancient sediments. A pioneer study carried out in the Northern Tianshan (Central Asia) has shown a possible transient, from 4 to 2 Ma, increase in denudation rate in the drainage basin [1]. Continuing this work, we present here new cosmogenic paleo-denudation records from four different locations: three from both sides of the Tianshan range and one from the Surai section, in the Siwaliks (the southern piedmont of the Himalayas). While all these records have displayed local, and sometimes significant, variations of denudation rates since ~10 Ma, they do not show synchronous increase in denudation at the Plio-Pleistocene transition. These results challenge the paradigm of a worldwide increase in denudation rates that would be induced by the Quaternary climate variability.

Thanks to independent constraints: paleoelevation from oxygen and carbon isotopic records of paleosol carbonates, source tracking using new Raman spectra of graphite particles in the Surai section,,the inherent uncertainties of the method were reduced. However, a critical step is now to understand how the material is transferred to the basin and what are the main factors that control the distribution of current denudation.

Deglacial trends in the oxygen content of intermediate waters in the southwest Pacific

ZANNA CHASE*[1], ASHLEY TOWNSEND[2], HELEN BOSTOCK[3] AND HELEN NEIL[3]

[1]Institute for Marine and Antarctic Studies, University of Tasmania, 7000, Australia (*correspondence: Zanna.Chase@utas.edu.au)
[2]Central Science Laboratory, University of Tasmania, 7000, Australia (Ashley.Townsend@utas.edu.au)
[3]National Institute of Water and Atmospheric Research, Wellington 6421, New Zealand (Helen.Bostock@niwa.co.nz; Helen.Neil@niwa.co.nz)

Intermediate waters of the Southern Ocean – Antarctic Intermediate Water (AAIW) and Subantarctic Mode Water (SAMW) – ventilate a large portion of the intermediate depths of the ocean. They are important in the uptake of carbon dioxide from the atmosphere and they transport nutrients and oxygen to the low latitude thermocline. These processes are sensitive to climate change. Indeed, observations between 1970 and 1990 show that Southern Ocean intermediate waters have experienced the largest decrease in oxygen of any ocean region, driven by a decrease in the exchange of water between the surface and the interior [1].

Here we use redox sensitive trace metals to examine the response of intermediate water oxygenation to the most recent deglacial warming. Excess Re, U and Mn records from cores bathed by Antarctic Intermediate Water on the Campbell Pleateau (700 – 1200 m), southeast of New Zealand, suggest an increase in bottom water oxygen during the deglaciation. This trend is consistent with a rapid increase in benthic foraminiferal $\delta^{13}C$ at the start of the deglaciation at intermediate depth in the northern Tasman Sea, suggesting a ventilation event [2]. In contrast, redox-sensitive metals from the Chile margin, near the present-day locus of maximum AAIW production, indicate a decrease in intermediate water oxygenation upon deglaciation, a trend that has been interpreted to reflect a deglacial decrease in AAIW ventilation [3]. This presentation will examine intermediate water records from both sides of the Pacific in an effort to untangle the influences of biological productivity, ventilation and circulation.

Contrasted iron-speciation in obsidians and tektites: A spectroscopic study

CHASSÉ, M.[1]*, GALOISY, L.[1], LELONG, G.[1] AND CALAS, G.[1]

[1]Institut de Minéralogie et de Physique des Milieux Condensés (IMPMC), UPMC; 4, Place Jussieu, 75252 Paris Cedex 05, France.
(*correspondence : mathieu.chasse@impmc.upmc.fr)

Iron has long been known to play an important role in determining the properties of natural magmatic liquids. The determination of the sites occupied by ferrous and ferric cations in volcanic glasses may provide information on the physico-chemical conditions prevailing at the magmatic stage as well as on the cooling conditions of the magma. We discuss Fe speciation in calc-alkaline rhyolitic glasses (obsidians) and tektites, using optical absorption spectroscopy (OAS) and electron paramagnetic resonance (EPR). In obsidian, OAS reveals a major contribution of Fe^{2+} in a regular octahedral site, an unusual environment in synthetic glasses and tektites where this cation is mostly 4- and 5-coordinated [1], [2].

The presence of Fe-oxide nano-clusters, suspected since a long time from previous EPR studies [3], is confirmed by variable-temperature OAS in all obsidians investigated. By contrast, tektites do not show such contribution. Specific absorption bands, assigned to Fe-Fe and Fe-Ti intervalence charge transfers (IVCT), are characterized by a spectacular intensity dependence as a function of temperature over 1000 K (1000K-10K). This thermally-activated behavior shows an activation energy similar to that observed for IVCT in various minerals. The evidence of specific Fe^{2+} sites and of IVCT processes, indicate the presence of Fe-oxide clusters. These clusters, showing a local re-arrangement around Fe, are related to the cooling history of the glass, as they are not found in the medium range structure of synthetic glasses [4]. The existence of these clusters and their nature seem to be related to the conditions of formation of the investigated obsidians and they may clarify the information brought by these glasses about its magmatic history.

Thermodynamics and Kinetics of Fe(II)-Fe(III) Electron Transfer Across Interfaces

S. CHATMAN[1], P. ZARZYCKI[2], S. KERISIT[1], V. ALEXANDROV[1], C.I. PEARCE[1] AND K.M. ROSSO[1]*

[1]Pacific Northwest National Laboratory, Richland WA, USA (*correspondence: kevin.rosso@pnl.gov)
[2]Polish Academy of Sciences, Warsaw, Poland

Fe(II)-Fe(III) electron transfer is a key exchange in the biogeochemical cycle of iron. For most environmentally relevant conditions this exchange involves interaction between soluble ferrous iron and solid-phase iron (oxyhydr)oxides, with possible involvement of electrical conduction through the solid-state. This presentation addresses global thermodynamic limits and molecular-scale controls on the kinetics of this exchange from selected observations and simulations of Fe(II) interaction with hematite, goethite, and magnetite.

Single crystal single surface potentiometry and amperometry on hematite were used to examine the pH-dependence of surface electrical potential, the kinetics of protonation/deprotonation, and current flow from one crystallographic face to another, examining the effect of aqueous Fe(II) addition. The data reveal a pH-dependent energy band model with the iron redox couple in solution that is compatible with the magnitude and direction of face-to-face Fe(II)/Fe(III) current flow through the semiconductor bulk. Despite structural distinctions, in a similar fashion Fe(II) interaction with $Fe_{3-x}Ti_xO_4$ nanoparticles at various amounts of pre-oxidation shows a reversible topotactic Fe(II) uptake and release consistent with surface deprotonation and protonation, respectively. Synchrotron Fe L-edge x-ray absorption and magnetic circular dichroism spectroscopies are used to map Fe site occupancy and valence before and after pre-oxidation and Fe(II) recharge. Molecular simulations of Fe(II) adsorption and subsequent interfacial electron transfer with Fe(III) at hematite and goethite surfaces reveal the importance of surface net charge, the protonation state of bridging ligands, and proton coupled electron transfer to facilitate the electron exchange into the solid. Aspects covered will include thermodynamic energy requirements for bulk crystal conduction, including heat dissipation in the solid, and possible free energy sources sustaining bulk currents, Fe(II) adsorption energies and the kinetics of electron injection, and the structural dependence of Fe(II)-Fe(III) electron exchange through the crystal lattice, towards a new, more comprehensive mechanistic model for these systems.

Geochemical signatures of volcanic rocks from kadiri greenstone belt, Dharwar craton, India: Implications on gold mineralisation

ADRIJA, CHATTERJEE[1]*, LINGAMURTY, E[1]., RAJANIKANTA SINGH, M[1] AND MANIKYAMBA, C[1].

[1][National Geophysical Research Institute (Council of Scientific and Industrial Research)
Uppal Road, Hyderabad 500 606,
(adrija.geo@gmail.com,elmgeology@gmail.com)
(rajanimutum@gmail.com), (cmaningri@gmail.com)

The Neoarchean Hutti-Jonnagiri-Kadiri-Kolar composite greenstone terrane is the largest (~500km) unique belt with abundant gold mineralisation which is being mined at Hutti. Kadiri greenstone belt is situated in the south central part of this largest arcuate belt, consisting of a variety of island arc volcanic rocks such as arc basalts, Nb-enriched basalts, adakites, dacites and rhyolites resembling with Phanerozoic intraoceanic island arc volcanic rocks. In this linear belt, north of Kadiri, plume-arc accretionary processes have been established at Jonnagiri belt.

Arc basalts of Kadiri have moderate SiO_2 and MgO with slightly enriched LREE and flat HREE. Nb-enriched basalts resemble with arc basalts with high Nb content (7-10 ppm). Adakites of Kadiri have elevated Al_2O_3 (12-16 wt%), low Yb (0.77-1.25 ppm) with high $(La/Yb)_N$ (14.6-33.9 ppm), Zr/Sm (14-50) and low Nb/Ta (5.4-16.9) with positive Eu anomalies.

The enrichment of gold at the northern (Hutti) and southern end (Kolar) of this composite greenstone terrane with the occurrence of intraoceanic island arc rocks at Kadiri belt reflect on the island arc processes which appear to have deposited gold at Hutti and Kolar due to suitable structure and lithological conduits at these places. These plume-arc interaction also explains the crustal growth due to subduction accretion in the eastern Dharwar craton.

Nd-Hf isotopic composition of the upper continental crust

C. CHAUVEL[1], M. GARÇON[1], S. BUREAU[1], S. GALLET[2] AND B.M. JAHN[3]

[1]ISTerre, Grenoble, France; (catherine.chauvel@ujf-grenoble.fr)
[2]Geoazur, Nice, France
[3]Institute of Earth Sciences, Taiwan

Knowledge of the average composition of the upper continental crust is crucial to establish not only how it formed but also when. While well constrained averages have been suggested for its major+trace element composition (e.g., Taylor and McLennan, 1985; Rudnick and Gao, 2003), no value exists for its Nd and Hf isotopic compositions even though radiogenic isotopic systems provide valuable information on its average model age.

Here we present Nd and Hf isotopic data determined on a large number of loess deposits from several continents. We demonstrate that these deposits have very uniform Nd and Hf isotopic compositions and that these data can be used to establish an average Nd-Hf isotopic composition for the upper continental crust: ε_{Nd} = -10.3±1.2 and ε_{Hf} = -13.2±2. This average falls on the Terrestrial Array as defined by Vervoort *et al*. (1999, 2011) demonstrating that the two parent-daughter ratios are not decoupled during crust formation. Trace element data acquired on the same set of samples allow us to calculate an average $^{147}Sm/^{144}Nd$ ratio for the upper continental crust: 0.1193±0.0026, a value slightly higher than previous estimates. We estimate the average Nd extraction age of upper continental crust from the depleted mantle at $T_{DM}(Nd)$ = 1.82±0.07 Ga. This model age is entirely consistent with previous suggestions made for example by Goldstein *et al*. in 1984.

Assuming that the Hf model age of the upper continental crust cannot be younger than its Nd model age, we can suggest a value for the very poorly known $^{176}Lu/^{177}Hf$ ratio of the upper crust. Our estimate is $^{176}Lu/^{177}Hf$ = 0.0125±0.0005, a value significantly lower than commonly used values (0.0150 - 0.0159; Griffin *et al*. 2002, Goodge & Vervoort 2006, Hawkesworth *et al*. 2010) but higher than the Rudnick & Gao estimate (0.0083). Using our preferred value, the average Hf upper crust differentiation age is about 300 Ma younger than when using a ratio of 0.0159. The impact of our new $^{176}Lu/^{177}Hf$ ratio on crustal model ages of zircon populations is not simple to evaluate in detail but the Hf model ages calculated with this new Lu/Hf ratio could be younger by up to 500 Ma.

The halogen cycle in subduction zones: Insight from back-arc basin basalts

D. CHAVRIT[1]*, L. RUZIÉ[1], R. BURGESS[1], D.R. HILTON[2], H. SUMINO[3], J. SINTON[4] AND C.J. BALLENTINE[1]

[1]S.E.A.E.S., University of Manchester, Manchester, UK (*presenting author, deborah.chavrit@manchester.ac.uk)
[2]Scripps Institution of Oceanography, La Jolla, USA
[3]GCRC, University of Tokyo, Tokyo 113-0033, Japan
[4]University of Hawaii, Honolulu, USA

The extent to which the subduction process preserves the volatile elements signature of the downgoing slab and the mechanisms by which these elements are transferred into the mantle wedge are not well understood. Halogens (Cl, Br, I) are good candidates to trace these processes, due to their incompatibility and their relatively high concentrations in seawater and marine sediments. A technique developed at the University of Manchester [1] allows the high precision measurements of these elements on neutron-irradiated samples using noble gas mass spectrometry.

To better constrain the cycle of halogens in subduction zones, we analyzed the halogens in 15 volcanic glasses (BABB) from three back-arc basins which are known to contain slab-derived components *viz* Manus basin, Lau basin and Mariana trough.

The three back-arc basins have relatively constant Br/Cl weight ratios ($4.0\pm0.4\times10^{-3}$) which are 2x higher than the mid-ocean ridge basalts (MORB) value [2]. The I/Cl weight ratios (0.9 to 7.1×10^{-5}) range from values close to seawater to MORB values. These results suggest that the halogen composition of the BABB mantle source is affected by a slab-derived component. However, the I/Cl ratios positively correlate with Ba/Nb ratios that are between 5-33 (weight), which reflect the extent of the slab contribution. Thus, it indicates the presence of an unknown end member with a MORB-like Ba/Nb ratio and with low I/Cl and high Br/Cl ratios. It is notable that the halogen ratios of this component are similar to that of the fluid phases trapped in altered oceanic crust [3]. Another component with higher Ba/Nb, higher I/Cl and lower Br/Cl ratios, is consistent with the presence of a sedimentary-derived component. The possible origins of the signature of the halogen BABB mantle source will be discussed by comparing with the different components characterizing the subducted oceanic crust.

A new approach for LA-ICP-MS using a high sensitive mass spectrometer

R. CHEMNITZER[1]* AND M. HAMESTER[1]

[1]Bruker Daltonik GmbH, Fahrenheitstr. 4, 28359 Bremen, Germany
(*correspondence: Rene.Chemnitzer@bruker.com), (Meike.Hamester@bdal.de)

The geochemical characterization of samples includes the elemental distribution but also the isotopic composition for a broad range of elements. Laserablation coupled to an ICP-MS has become an indispensible method. New instrumental developments allow resolutions to single-digit μm spots and new ablation cells show improved transport characteristics.

With a high sensitive ICP-MS (Bruker auroraElite) these developments lead to a tremendous increase in information. The work presents results from a LA-ICP-MS setup that provides the highest sensitivity currently available and shows results of the quantitative and isotope ratio analysis of zircon samples and other minerals.

Different parameters were investigated:

Laser
- Spot size (Laser)
- Energy density

ICP-MS
- Sample introduction / plasma
- 3-D ion focusing
- Scan speed

The results verify that the considerable higher sensitivity leads to new alternative approaches in LA-ICP-MS, that will be discussed in detail.

Si isotope systematics of acidic alteration of fresh Kilauean basalts

S. M. CHEMTOB[12]*, G. R. ROSSMAN[2], E. D. YOUNG[3], K. ZIEGLER[4], J. M. EILER[2] AND J. A. HUROWITZ[5]

[1]Washington University, St. Louis, MO (*correspondence: chemtob@levee.wustl.edu)
[2]California Institute of Technology, Pasadena, CA; [3]UCLA, Los Angeles, CA; [4]U. New Mexico, Inst. of Meteoritics, Albuquerque, NM; [5]Jet Propulsion Lab, Caltech.

Silicon isotopes are fractionated by low-temperature aqueous processes, making them potentially useful as a weathering proxy. Previous authors have reported that secondary minerals like clays and opal are lower in $^{30}Si/^{28}Si$ than the dissolved reservoirs from which they precipitated [1-2]. Young basalts from Kilauea, on the big island of Hawai'i, frequently feature opaque amorphous silica coatings, 2-80 μm thick, that form *in situ,* apparently by acidic surface leaching [3]. Here we show that, in contrast to secondary minerals in other settings, these coatings have higher $\delta^{30}Si$ than their basaltic substrate (which is presumed to be the source of Si in the surficial solutions from which the coatings precipitate).

Silica coated basalt samples were collected from 1974 and 1998 flows along Kilauea's East and Southwest Rift Zones. We removed the coating material by scraping and then dissolved it in dilute HF and HNO_3 [4]. The resulting solutions were purified by ion-exchange chromatography and analyzed by MC-ICP-MS. Basalt glasses had $\delta^{30}Si$ = -0.10 to -0.24‰; silica coatings had $\delta^{30}Si$ = +0.92 to 1.36‰. These isotopic compositions are difficult to reconcile with previously reported fractionation factors (i.e. $\Delta^{30}Si_{solid\text{-}aqueous} < 0$‰). We hypothesize that the atypical direction of fractionation is a result of unusual aqueous Si speciation (e.g. fluoride, chloride and/or sulfate complexation).

Batch experiments in which fresh glassy basalt gravel was reacted in HCl or HF (0.1 or 1 M) at 60° C replicated Hawaiian amorphous silica layer morphology. The fluids preferentially mobilized Al, Mg, Fe, Na, and Ca, leaving behind amorphous silica residues up to 100 μm thick. In HCl-bearing experiments, reacted fluids were ^{30}Si-enriched (up to $\delta^{30}Si$ = 2.29‰). HF-bearing experiments produced ^{28}Si-enriched fluids, suggesting preferential incorporation of ^{30}Si into precipitated silica or volatilization of ^{30}Si. These results indicate that fluid chemistry influences the direction and magnitude of Si isotope fractionation during weathering.

First Tritium-Helium Dating Results of Groundwater in Central Taiwan

AI-TI CHEN[1] TSANYAO FRANK YANG[1] TSUNG-KWEI LIU[1] YUJI SANO[2] NAOTO TAKAHATA[2] KUAN-YU CHEN[3] AND YUNSHUEN WANG[4]

[1] Department of Geosciences, National Taiwan University, Taipei, Taiwan, R.O.C.
[2] Department of Chemical Oceanography, Atmosphere and Ocean Research Institute, The University of Tokyo, Tokyo 164-8639, Japan
[3] Industrial Technology Research Institute, Taipei, Taiwan, R.O.C.
[4] Central Geological Survey, MOEA, Taipei, Taiwan, R.O.C.

We applied Tritium-Helium (T-He) dating method (Clarke *et al*., 1976), for the first time, to obtain the ages of groundwater from central part of Taiwan as a case study. The groundwater wells are located on the recharge area of Jhoshui river basin and Beigang River. Three groundwater samples have been collected from different monitoring wells, which are artificial and all around 100 meters deep, and the altitude of them are less than 402 meters. Samples sent to University of Utah and University of Tokyo for further T-He dating analysis. We could obtain total helium-3 concentrations in groundwater samples, although they might contain different signatures other than radiogenic source from tritium decay. In order to obtain the radiogenic helium-3 concentration, we needed to eliminate helium-3 concentrations of air-saturated water and terrigenic source in spite of air contamination. In this study, we can successfully separate the radiogenic source of helium-3 from terrigenic (crustal) source, assuming no air contamination for the studied samples. After helium-3 corrections, we can obtain the age results ca. 7-25 years, which are consistent with each other from the analysis results of two independent labs. The result suggests that the T-He dating technique could be a good method for determining the age of young groundwater in Taiwan.

Origin of highly differentiated granites from South China: Implications for W-Sn deposits

B. CHEN*, X.H. MA AND Z.Q. WANG

School of Earth and Space Sciences, Peking University, Beijing 100871, China, (binchen@pku.edu.cn)(*presenting author)

Voluminous composite granite plutons occur in South China, accompanied by large-scale W-Sn deposits. Each composite pluton is composed of major phase granites and highly evolved late-stage granites. Traditionally, the late-stage granites are thought to be residual melts from the former via fractionation, and ore-forming materials and fluids are from granite magma itself. We propose a different model for the origin of highly evolved granites and related W-Sn mineralization, based on studies on the Qianlishan composite plutons that are composed of major phase coarse-grained biotite granites (163 Ma) and late-stage fine-grained granites (153 Ma). The major phase granites show features of normal granites, with LREE enrichment and medium negative Eu anomalies in the chondrite-normalized REE patterns. The late-stage granites are highly evolved, with non-CHARAC trace element features (very high K/Ba, and low K/Rb and Zr/Hf), and show HREE enrichment, huge negative Eu anomalies and typical "tetrad effect" in the REE patterns. We suggest that the late-stage granites were unlikely derivatives from the major phase granites via fractionation, but rather, derived from melting of the Proterozoic lower crust in a new tectono-thermal event, triggered by underplating of basaltic magma. Small amounts of basalts were involved in the source, as suggested by the higher $\varepsilon_{Nd}(t)$ values of the late-stage granites (-5.6 to -7) than the major phase granites ($\varepsilon_{Nd}(t)$ = -8). The late-stage granites show common occurrence of ilmenite, euhedral quartz enclosed in feldspar, and interstitial fluorite, suggesting a low fO_2, water-deficient and fluorine-rich feature for them. Addition of fluorine would significantly lower the solidus temperature and viscosity of magma, and thus prolong the process of magma evolution and facilitate fractional crystallization. Prolonged magma process would (1) enhance the interaction between granitic melt and meteoric water from country rocks, causing the formation of "tetrad effect" of REE patterns and non-CHARAC trace element features of the late-stage granites, and (2) heat and drive the circulation of meteoric water that subsequently, together with fluorine, extract ore-forming materials from country rocks through complexation, forming skarn-type W-Sn deposits in Ca-rich country rocks. So, the W-Sn deposits were genetically linked with the highly evolved granites.

Synthesis, toxicity and reactivity of several types of NZVI

JIAWEI CHEN

State Key Laboratory of Geological Process and Mineral Resources, China University of Geosciences, Beijing 100083, China.
Email(chenjiawei@cugb.edu.cn)

An emerging technology for the treatment of contaminated land and water is the use of nano-scale zero-valent iron (here after NZVI), which can rapidly dechlorinate chlorinated organics or immobilize heavy metals in contaminated groundwater [1-5]. The field demonstrations of applying nano-Fe0 technology for source remediation are promising.

Here, we report synthetic methods, surface property modification, mobility, toxicity and reactivity of several types of NZVI. These materials include commercial NZVI, fresh-made NZVI, NZVI supported on clay minerals, NZVI coated by CMC. It showed different bactericidal activity of these NZVI to Escherichia coli. The reactivity of these materials was also compared for Cr(VI) reduction and TCE degradation. Besides batch experiments and column test, in-situ remediation in a big sand-box was performed for iron and NZVI.

We paid more attention to the effects of pH, natural organic matter and ageing time on the reaction systems. During the process of water-pollutant-NZVI interaction, the different performance of several types of NZVI inferred that particle surface property is very crucial to NZVI application. Cost-efficient and long-term useful NZVI should be addressed more in the future.

This study was supported by Fundamental Research Funds for the Central Universities (2010ZD14, 2012123), China Geological Survey (1212011120288) and National Program of Control and Treatment of Water Pollution (2009ZX07424-002).

Petrogenesis and geochronology of the Xilushan granitic complex in the Bengbu Uplift: Constraint on the timing of the Yanshan Movement

JIE CHEN XIANG WANG*AND XIAOJUN WANG

State Key Latoratory for Mineral Deposit Research, Nanjing University, Nanjing 210093, China
(* correspondence: xwang@nju.edu.cn)

The Xilushan granitic complex in the Bengbu Uplift, southeastern margin of the North China Block (NCB), consists of a gneissic monzogranite and a porphyritic granodiorite.

The gneissic monzogranite shows fracturing, deformation and anatectic textures, indicating it has suffered post-crystallization migmatisation. It contains mainly two zircon phases: igneous zircon (IZ) and metamorphic zircon (MZ). IZ shows strong CL brightness and clear oscillatory zoning, and its contents of Hf, U, Th and REE are comparatively low. It yields a weighted mean age of 223.6±2.9 Ma, representing the intrusion age of the geneissic monzogranite. MZ shows extremely weak CL brightness, weak to absent oscillatory zoning, and its contents of Hf, U, Th and REE are high and variable. It yields a weighted mean age of 156.1±2 Ma, and this age is interpreted as representing the climax of compressional orogenesis of the Yanshan Movement.

The porphyritic granodiorite has low abundances of HREE and Y, high contents of Sr and resulting high Sr/Y ratios, reflecting that the magma derived from partial melting of the base of the thickened lower crust. It plots in the field of post-orogenic granite in the Rb vs. (Y+Yb) discrimination diagram. The zircon from this rock is generally of magmatic origin, showing strong CL brigheness, fine-scale oscillatory zoning and developed sector zoning, and relatively low contents of Hf, U, Th and REE. It has a weighted mean age of 133.6±1.3 Ma, considered to be the onset time of the post-orogenic calc-alkaline magmatism of the Yanshan Movement.

According to the two ages of metamorphic and magmatic events revealed by the Xilushan complex and the previous studies on the tectonics in the NCB, the Yanshanian movement in the NCB can be divided into three successively evolutionary periods: (1) Compressional orogenesis period (180-156 Ma); (2) Stress transformation period (156-135 Ma); (3) Extensional collapse period (135-125 Ma).

Iron isotopes in the suspended load of the Seine River (France): natural versus anthropogenic sources

JIUBIN CHEN[12], VINCENT BUSIGNY[2], JÉRÔME GAILLARDET[2] AND PASCALE LOUVAT[2]

[1] State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, CAS, Guiyang 550002, China.
[2] Institut de Physique du Globe de Paris, Sorbonne Paris Cité, Univ. UMR 7154 CNRS, 75238 Paris, France

The determination of fluxes and isotope compositions of Fe transported to the ocean is essential for understanding global surface Fe cycle. Fe isotope composition in anthropogenically-impacted rivers is poorly constrained up to now. We present the first Fe isotope data in suspended particulate matter (SPM) of the Seine River (France). Iron concentrations and isotope compositions (also major and trace elements) were measured for two sample sets: a geographic transect along the river to estuary, and a temporal series collected in Paris. While Fe concentration in SPM clearly increases downstream, Fe isotope composition shows a very slight decrease (δ^{56}Fe from 0.10 to -0.07‰). Calculation of Fe enrichment factor relative to Al points to the anthropogenic input (~17% higher than the natural background). Correlations between Fe concentration and isotopic compositions with those of Zn (from a previous study) confirm that Fe is mainly derived from a mixing of natural and anthropogenic sources. The natural sources are dominantly composed of clay materials, with minor carbonates and heavy minerals. Sulfides and organic matter may be the main anthropogenic Fe phases, and dominate during low-water and high-water stages, respectively.

Our data have two major implications. Firstly, although Fe flux from continents to ocean is significantly increased after anthropogenic input, polluted rivers bring a Fe isotope signature essentially indistinguishable from the natural detrital Fe flux. Secondly, the markedly positive δ^{56}Fe values measured in the Pacific Ocean (up to 0.6‰), which contrast with the mostly negative (or 0‰) δ^{56}Fe values in Fe sources to the ocean (hydrothermalism, rivers, marine benthic Fe flux, atmospheric particles), are unlikely to be produced by anthropogenic Fe input, supporting the explanation of Fe isotope fractionation related to phytoplankton assimilation processes.

Seawater derived sulfur contributions to the Archean VMS deposits: Multi-sulfur isotope evidences from the Neo-Archean Jaguar Deposits, Western Australia

M. CHEN[1 2], I. CAMPBELL[2]*, Y. XUE[2], W. TIAN[1] AND T.R. IRELAND[2]

1. SESS, Peking Univ., Beijing, China (mmchen@pku.edu.cn)
2. RSES, Australian National Univ., Canberra, ACT 0200, Australia (*correspondence: ian.campbell@anu.edu.au)

The contributions of seawater sulfate to Archean VMS deposits remain equivocal; do they resemble modern seawater in the role of contributing sulfur to modern black smokers? Additionally, in magnitude, how much sulfur seawater can contribute to form an Archean VMS deposit?

Seawater sulfate plays a key role in modern black smoker systems. Estimations based on MDF $\delta^{34}S$ of sulfur isotope are typically ranging from 10% to 40%, or even up to 80% [1, 2]. While for Archean VMS deposits, which have been widely believed to be the analogous of modern black smokers, the seawater contributions have been under-estimated. One case study in the Kidd Creek shows a small contribution of seawater sulfate down to ~3%, and this value therefore implies a very low seawater sulfur concentration [3]. For further investigation, we report *in situ* SHRIMP SI multi-sulfur isotopic analyses (^{32}S ^{33}S ^{34}S) of pyrites from Jaguar VMS deposits in the Yilgan Craton, Western Australia. Taking MIF $\Delta^{33}S$ features of ore sulfides as the mixing of magmatic sulfur and reduced seawater sulfate, we estimate the quantity of seawater contribution to the sulfur budget of Jaguar VMS deposits. The estimated result is 16%-21%, much higher than 3% in Kidd Creek case. Samples from other reported Archean VMS deposits, including Dresser formation, Agnew-Wiluna belt and Alexo greenstone belt, are also quantitively assessed. The assessment reveals that the magnitude of seawater sulfate contribution to Archean VMS deposits can be as much as that of modern sea-floor hydrothermal systems, while the case of Kidd Creek cannot represent a global-scale event for understanding the seawater derived sulfur contributions to Archean VMS deposits.

From diagenesis to metagenesis, geochemical changes of the late Paleozoic shale and mudstone, periphery of Songliao basin

SHUWANG CHEN[1]*

[1] Shenyang Center of Geological Survey, CGS, China (presenting author: sycswgeology@163.com)

With wide spread area of dark shale and mudstone occurred in the peripheral area of Songliao basin, NE China, the late Paleozoic terrane with abundant organic material has been considered as important target strata to evaluate regional potential of shale gas resources. How about the maturity of this shale and mudstone and what is the main factor to control it is more debatable. The contact metamorphism about the strata associated with the Mesozoic igneous activity is in the focus of this study, funded by China Geological Survey.

The shale and mudstone samples of outcrop and drill from different distance to the belt of contact metamorphism were collected. The intrusive and volcanic samples related to the Mesozoic activity were also collected. Analysis about the shale and mudstone are mainly of R_o, illite crystallinity, TOC and the content of absorbent gas. Analysis about the related Mesozoic igneous bodies includes the mineral manometer and the fluid inclusions.

All evidence indicates that contact metamorphism is an important factor to control the maturity of the shale and mudstone. Statistics of the analysis data of R_o and illite crystallinity indicates that the maturity ranges from diagenesis to metagenesis. The mineral manometer combined with homogenization temperature of fluid inclusions shows that some Mesozoic intrusive bodies characterized as hot sources have high crystallization temperature and great emplacement depth, while the others characterized as warm point have low crystallization temperature and low emplacement depth. The contact belt related to the hot intrusive bodies always presents as large scale and high metamorphism degree, while the belt related to cool intrusive bodies presents as small scale and low degree. The contact belt presents as small scale and low metamorphism degree associated with the Mesozoic volcanic eruption. The late Paleozoic shale and mudstone away from hot intrusive bodies and covered with Mesozoic volcanic rocks always possess catagenesis to diagenesis of maturity and have high TOC and high content of absorbent gas.

Late Quaternary Nd-Hf isotope evolution of the Weddell Sea and the abyssal Southern Ocean

TIAN-YU CHEN[1], MARTIN FRANK[1], RAINER GERSONDE[2] AND ANNE OSBORNE[1]

[1] GEOMAR Helmholtz Centre for Ocean Research Kiel, Germany

[2] Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany.

The Southern Ocean deep circulation has played a critical role in regulating the atmospheric CO_2 concentration over glacial-interglacial time scales. While Nd and Hf isotopes have been demonstrated to be effective tracers of water mass circulation and continental weathering inputs to the deep ocean, relatively little is known about glacial-interglacial Hf isotopic evolution in Southern Ocean or the Nd isotope evolution of waters fully bathed in Antarctic bottom water. We present Nd-Hf isotope time series from the Weddell Sea margin (PS1388-3, water depth 2526 m) and abyssal Southern Ocean (PS2082-1, water depth 4610 m, abyssal Agulhas Basin) over the last 250 kyr in order to better understand the deep circulation and weathering inputs.

Nd isotope signatures of sediment leachates of PS2082-1 are consistent with previously published records from the neighboring Cape Basin revealing less radiogenic signatures in interglacials and more radiogenic signatures in glacials. However, ε_{Nd} values of the last glacial maximum (LGM) in the Agulhas Basin are systematically more radiogenic by about ~0.7 ε_{Nd} units than the Cape Bain records, which may imply a higher Pacific contribution. In contrast, Hf isotope signatures of the same leachates show an opposite evolution trend compared with Nd isotopes (i.e., less radiogenic in glacials), implying the Hf isotopes may be controlled by high southern latitude weathering regime changes. All PS2082 leachate data of Nd-Hf isotopes are within the seawater data range constrained by surface scrapings of Fe-Mn nodules and modern seawater from the Southern Ocean, supporting a seawater origin for the leachate Nd and Hf isotope signatures.

Surprisingly, Nd isotope compositions of PS1388-3 leachates have nearly invariant signatures (ε_{Nd}: ~ -12.0) over glacial-interglacial times and are much less radiogenic than the abyssal Southern Ocean, while the Hf isotopes show radiogenic peaks (ε_{Hf} > +8.0) after deglaciations. The results indicate that these signatures have been controlled by Antarctic weathering inputs, while dissolution of fresh surfaces of minerals with high Lu/Hf after deglaciations may explain the radiogenic Hf peaks.

Pb isotope evidence from the Oka carbonatite complex for a distinct mantle reservoir

WEI CHEN[1]* AND ANTONIO SIMONETTI[1]

[1] Department of Civil & Environmental Engineering & Earth Sciences, 156 Fitzpatrick Hall, University of Notre Dame, Notre Dame IN, 46556 USA

(*correspondence: wchen2@nd.edu; simonetti.3@nd.edu)

Pb isotope data from young (<200 Ma-old) carbonatite complexes plot well within the fields defined by present-day mid-ocean ridge basalts (MORBs) and oceanic island basalts (OIBs). Thus, one interpretation is that carbonaties are derived from similar mantle components (i.e., HIMU, EMI, EMII, DMM) sampled by modern oceanic basalts. Here, we report new in-situ Pb isotopic data for calcite, nepheline, and melilite from various rocks types associated with the Oka carbonatite complex (Québec, Canada). Linear trends observed in Pb *vs*. Pb isotope diagrams (e.g., Fig. 1) reflect open-system behavior involving mixing of at least two distinct mantle reservoirs. However, the unradiogenic $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ ratios for given $^{206}Pb/^{204}Pb$ values (e.g., Fig. 1) for Oka and associated alkaline rocks from the Monteregian Igneous Province (MIP) are distinct, and point to the involvement of an unidentified (depleted) mantle reservoir. This unradiogenic $^{207}Pb/^{204}Pb$ isotopic composition may be attributed to U/Pb fractionation early in Earth's history. Moreover, in-situ Sr and Nd isotope compositions for apatite from Oka overlap those for basalts derived from "FOZO", which suggests derivation from a deep mantle source.

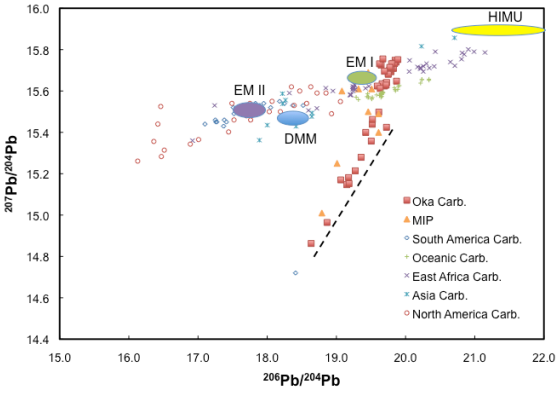

Figure 1 Pb isotope ratios for Oka and MIP intrusions.

Ultrasensitive portable multiple laser continuous-wave cavity-ringdown spectrometer for CH_4 isotope analysis

Y. CHEN[1], K.K. LEHMANN[2], P. MAHAFFY[3], V. HOLMES[3] P. MOREY[3] AND T. C. ONSTOTT[1]

[1] Princeton University, Dept. Of Geosciences, Princeton, NJ 08544, USA

[2] University of Virginia, Dept. of Chemistry, Charlottesville, VA, 22904, USA

[3] NASA's Goddard Space Flight Center, Greenbelt, MD 20771, USA

A portable NIR CW-CRD spectrometer was developed for stable isotope analyses of atmospheric CH_4 on Earth and Mars. The system consists of three DFB Laser diodes, two of which are tuned to the absorption peaks of $^{12}CH_4$ and $^{13}CH_4$ and the third of which is used to measure the baseline. A MEMS optical switch rapidly alternates the lasers feeding the cavity to measure absorbance of these two isotopic molecules of CH_4. This measurement scheme avoids the high uncertainty data usually measured when the wavelength being tuned at waist of absorption line shape and overcomes partially the long-term drifting of the traditional CRDS system, thus fulfilling the high precision requirement for isotope analysis of trace gas methane. The detection limit of this system is to $1.4x10^{-12}$ $cm^{-1}$with integration time of 5 minutes. For ambient air on Earth which contains 1.8ppm CH4, under 100 torr pressure, the 13CH4 absorbance is $1.8\times10^{-9}cm^{-1}$, thus the equivalent precision of the $\delta^{13}C$ will be less than one per mil for CH4 in the atmospheric concentration.

The structural analysis of Dunhua basin, China

S.Y.CHENG[1] AND Y.J. LI[2]

[1]School of Earth Sciences and Resources, Chang'an University, Xi'an,710054,Shaanxi Province, China (chengsanyou@126.com)

[2]Shaanxi Provincial Research Academy of Environmental Science, Xi'an,710061,Shaanxi Province, China (hkyliyingjie@126.com)

By means of two dimensional structure-stratigraphy interpretation of several seismic profiles and magnetic and gravity data, the paper analyzed the structural features and forming mechanism of Dunhua basin.

The results show that Dunhua basin perform as the two east-west trend fault depressions, the uplift between the fault depressions and the controling normal faults were intersected with Dunmi fracture in an acute angle, and the Dunmi main fracture also formed a deep fault depression. Consequently the northern fault depression and southern fault depression that are the two east-west trend fault depressions, are all typical dextral strike-slip and extension basins in which major strike-slip fault is the Dunmi fracture.

The seismic data shows that the Dunmi deep fault depression developed a large number normal faults that obliquely with the Dunmi fracture within the Lower Cretaceous stratum. Dextral strike-slip faulting began in Early Cretaceous, and the fault depressions were happened again in Paleogene. According to interpretation of the gravity and magnetic section, Dunhua basin was transformed by thrust fault between Cretaceous and Neogene, and the main thrust direction pointed to the north. The thrusting may be associated with tectonic inversion after the late Cretaceous in the northeast area, China, which resulted in sinistral transpression along the Dunmi fracture.

[4] IRD UMMISCO, Cameroun.

Soil microorganisms live in a complex 3-D framework which can cause a variety of micro-environments to develop that are more or less suitable for microbial growth, activity and survival. In particular, the soil pore system controls the accessibility of substrates and oxygen to microorganisms and the local moisture conditions. Experiments, in which the location of microorganisms and substrates and the soil structure were manipulated, showed how the heterotrophic soil respiration depended on the size of pores and on their connectivity. In turn we show how microorganisms may change substrate diffusivity at the scale of their habitat, by exuding EPS. In all, characteristics of the habitat seem to have more impact on heterotrophic respiration than microbial community structure. We present innovative models explicitly representing soil structure and how microhabitats control the activity of microorganisms and hence the fluxes of C in soil.

Geophysical evidences for eclogites beneath the West Siberian basin

YULIA CHEREPANOVA[1]* AND IRINA M. ARTEMIEVA[1]

[1]Oester Voldgade 10, DK-1350, Copenhagen, Denmark, (*correspondence: yc@geo.ku.dk)

The West Siberian basin is the world's largest intracontinental sedimentary basin. Its basement is formed through a number of collisional and accretional events during late Proterozoic-Paleozoic. The amalgamation, completed in the late Permian, was followed by a large-scale rifting and eruption of flood basalts in the Permian-early Triassic (ca 250 Ma). Active subsidence of the basin started in late Triassic with the main event only in Jurassic [1].

The West Siberian basin lacks surface topography, whereas the reliefs of the Moho and the top of the basement have amplitudes of ca. 20 km and 15 km, respectively [2]. The near-zero free air gravity over the basin indicates that it is in the isostatic equilibrium.

Assuming no effect of dynamic topography on basin subsidence, we examine the relative contributions of the crust and the lithospheric mantle to maintaining the surface topography. Lithosphere buoyancy is controlled by thicknesses and densities of the crust and the lithospheric mantle, composition, metamorphic state, and temperature. Crustal thickness and density are constrained by our new regional crustal model SibCrust, which is based on all existing seismic data [2]. Lithosphere thickness and temperature are constrained by the thermal model TC1 [3]. Our modelling shows large high-density anomaly (3.5 – 3.65 g/cm^3) in the upper mantle below the axial part of the basin along the major rift. This result is supported by the seismic velocity variation in the mantle along four ultra-deep reflection/refraction PNE profiles and by stretching factor. We propose that high density body in the mantle is caused by eclogitization and its presence can explain a substantial part of the subsidence of the West Siberian Basin.

$^{238}U/^{235}U$ variations in high- and low-temperature uranium deposits

I.V. CHERNYSHEV*, V.N. GOLUBE,
A.V. CHUGAEVAND A.N. BARANOVA

IGEM of Russ. Acad. of Sciences, Moscow 119017,
Staromonetny per., 35 (cher@igem.ru)

$^{238}U/^{235}U$ ratio was analysed by high-precision MC-ICP-MS method using ^{233}U-^{236}U double spike. Double spike was prepared from monoisotopes ^{233}U and ^{236}U and calibrated relative to CRM-112A standard in which $^{238}U/^{235}U$ value was accepted as 137.844±24 according to [1]. Long-term reproducibility (±2SD) of $^{238}U/^{235}U$ results estimated for three reference samples (total 87 analyses) is better then 0.07‰.

High-T U-deposits from some regions previously dated by U-Pb method were involved in this study. 1) Transbaikalia, Russia: the Streltsovsky, Octyabrsky and Antei deposits in volcanogenic Streltsovsky ore field (Mz); the Khadatkanda skarn deposit (Pz). 2) Erzgebirge, Germany: the Schlema-Alberoda granite-related deposit (Pz). 3) Tyan-Shan, Uzbekistan: the Chauli volcanogenic deposit (Pz). 4) Athabaska Basin, Canada: the Shea Creek and McArthur "unconformity" deposits (Prz). 5) Cage district, Canada: uraninite ore showing (Prz).

$^{238}U/^{235}U$ ratio was measured in pitchblende (more rarely in uraninite and coffinite) local microsamples of 10-50 μg weight separated directly from polished sections. $^{238}U/^{235}U$ values for listed deposits (total 44 analysed samples) yield 137.710-137.828 interval (i.e. 0.86‰) which only in part coincides with range for zircons 137.772-137.908 [2]. At the same time the individual deposits display 0.12-0.70‰ variations. Owing to analyses of local microsamples the distinctions of $^{238}U/^{235}U$ ratio up to 0.45‰ were documented for different pitchblende spherulites growth zones as well as for U-mineral phases formed during different periods of mineralization.

Ore samples from low-T U-deposits of "sandstone" (or "paleo-valley") type Dybryn and Khiagda (Vitim region, Russia) demonstrated wider range of $^{238}U/^{235}U$ values 137.738-137.881 (i.e. 1.0‰) which is statisticaly "heavier" as compared with high-T U-deposits. This data are in agreement with results obtained for 40 concentrates of "sandstone" type ores from USA, Canada and some other regions [3].

Near-infrared measurements of water speciation in hydrous $Na_2Si_2O_5$ melt using HDAC

NADEZDA CHERTKOVA[1]*

[1]Institute for Study of the Earth's Interior, Okayama University, Misasa, Japan
(*correspondence: nadezda@misasa.okayama-u.ac.jp)

In situ study of water speciation in silicate melts is important for the construction of water solubility models and prediction of physical properties of hydrous melts at high temperature and high pressure. Water speciation in $Na_2Si_2O_5$ melt (anhydrous NBO/T = 1, structural analogue of basaltic melt) was examined by FTIR spectroscopy in an externally heated diamond anvil cell (HDAC) [1]. Hydrous $Na_2Si_2O_5$ glass, containing up to 5.9 wt% water, was used as starting material without any additional pressure medium. Experimental pressure was monitored with the pressure- and temperature-dependent Raman shift of ^{13}C diamond [2].

At temperatures above 650 °C and at pressures above 1.6 GPa only a homogeneous melt phase was observed (Fig. 1a). Near-infrared specrta of this phase contain absorption peaks corresponding to molecular H_2O (at ~5200 cm^{-1}) and structurally bound OH groups (at ~4500 cm^{-1}). Assuming a constant ratio of molar absorptivities for these bands and knowing the total water content in the melt, concentrations of water species are estimated to be 2.0 wt% as molecular H_2O and 3.9 wt% as OH groups at 800 °C and 2 GPa.

Comparison of the OH/H_2O ratio in the quenched glasses at ambient conditions and in the melts at high temperature shows significant increase of OH species concentration with temperature. At this point, it is difficult to evaluate the effect of pressure on water speciation.

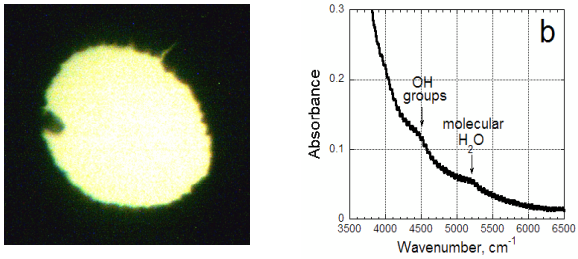

Fig. 1: (a) Sample chamber of HDAC with hydrous $Na_2Si_2O_5$ melt (5.9 wt% water) and ^{13}C diamond pressure marker. (b) Near-infrared absorption spectrum of the melt at 800 °C.

Chemical composition of Changjiang river sediments: Climate or lithology control?

B. CHETELAT[1], C-Q. LIU[1], Q. WANG[1] AND G. ZHANG[1]

[1]SKLEG, Institute of Geochemistry, CAS, 46 Guanshui Road, 550002 Guiyang, PR of China

We present major and trace elements data in particulate suspended matter (SPM) collected in the Changjiang main channel and its main tributaries. Suspended sediments are derived from a mafic source related to the Emeishan Large Igneous Province (ELIP) in the Upper Reach and from a more felsic source in the Middle/Lower Reaches. The difference in chemical composition between the two sources has a strong influence on the apparent weathering intensity. Although the apparent loss of soluble elements follows a climatic gradient from the Upper Reach to the Lower Reach, the co-variation of weathering indices with different proxies for igneous differentiation suggests that a lithologic control can not be ruled out. By taking into account the variability in chemical composition of the parent rocks, we show that river suspended sediments from the upper reach may have not experienced less intense chemical weathering than those transported by rivers from the Lower/Middle Reaches characterized by higher runoff and surface temperature. We argue that the relationships observed for different indices of weathering with climate might be an artifact and are partly driven by the change in chemical composition of the sediments parent-rocks.

U-Pb LA-ICPMS dating of common Pb-bearing accessory minerals using VizualAge / Iolite

D.M. CHEW[1]*, J.A. PETRUS[2] AND B.S. KAMBER[1]

[1]Dept. of Geology, Trinity College Dublin, Dublin 2, Ireland (*correspondence: chewd@tcd.ie, kamberbs@tcd.ie)

[2]Department of Earth Sciences, Laurentian University, Sudbury, Canada (japetrus@gmail.com)

Precise and accurate U–Pb LA-ICPMS dating of many U-bearing accessory minerals (e.g. apatite, titantite and rutile) is often compromised by common Pb. We present here a general approach to common Pb correction in U–Pb LA-ICP-MS dating using a modifed version of the VizualAge [1] U-Pb data reduction package for Iolite [2].

The approach was tested on apatite and titantite age standards (for which there are independent constraints on the U-Pb crystallization age) using a Thermo Scientific iCAP-Qc (Q-ICP-MS) coupled to a Photon Machines Analyte Excite 193 nm ArF Excimer laser. A 50 μm spot was used in all experiments. The Durango (31.44 ± 0.18 Ma) and McClure Mountain (523.51 ± 1.47 Ma) apatite standards yielded U-Pb TW concordia intercept ages of 31.97 ± 0.59 Ma (MSWD = 1.09) and 524.5 ± 3.7 Ma (MSWD = 0.72) respectively. The Fish Canyon Tuff (28.201 ± 0.046 Ma) and Khan (522.2 ± 2.2 Ma) titanite standards yielded U-Pb TW concordia intercept ages of 28.78 ± 0.41 Ma (MSWD = 1.4) and 520.9 ± 3.9 Ma (MSWD = 4.2) respectively, demonstrating the suitability of the common Pb correction approach.

The modified version of VizualAge / Iolite first applies a common Pb correction (using either the ^{204}Pb or ^{207}Pb methods) to the user-selected *age standard* integrations and fits session-wide "model" U–Th–Pb fractionation curves to the time-resolved U-Pb standard data. VizualAge / Iolite then applies this downhole fractionation model to the unknowns and sample-standard bracketing (using a user-specified interpolation method) is used to calculate final isotopic ratios and ages. In addition to live concordia diagrams which allow for visualising of data while adjusting integration intervals [1], the modified version of VizualAge incorporates a ^{207}Pb-corrected age channel calculated for a user-specified initial ^{207}Pb/^{206}Pb ratio. All other conventional common Pb correction methods (e.g. the ^{204}Pb method or intercept ages calculated from linear arrays on a concordia or isochron) can be performed offline.

Holocene Marine Reservoir Correction (ΔR) Variability in the Eastern Bay of Bengal

H.-W. CHIANG[1]*, Y. WANG[2], J. BRUCE H. SHYU[3] C.-C. WANG[3], LIN THU AUNG[4], PHYO MAUNG MAUNG[5] OO THAN[5], SOE THURA TUN[4] AND C.-C. SHEN[3]

[1]Earth Observatory of Singapore, Nanyang Technological University, Singapore (*correspondence: hwchiang@ntu.edu.tw)
[2]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, USA
[3]Department of Geosciences, National Taiwan University, Taipei, Taiwan, R.O.C.
[4]Myanmar Earthquake Committee, Myanmar Engineering Society, Myanmar
[5]Department of Meteorology and Hydrology, Myanmar

We present the regional marine reservoir corrections (ΔR) for the northeastern Bay of Bengal spanning two time periods, the past 300 years and the mid-Holocene. ΔR values were calculated using paired measurements of MC-ICPMS U-Th dating and AMS ^{14}C dating on 6 pristine fossil corals from Ramree and Cheduba Islands, western Myanmar.

The results show an average ΔR of 126±43 yr (1**σ,** n=3) for 175-278 years before AD 1950, which is significantly higher than the published modern values of 7±35 yr and 29±74 yr from the Andaman Islands [1] and the southeastern Bay of Bengal [2] separately. This ~100yr difference indicates that applying global marine reservoir age directly to younger-than-1000-years coral terraces might introduce errors to the calibrated ages. Our ΔR however is consistent with the mean of 158±68 yr from the western Indian Ocean [2]. It thus suggests the ^{14}C-depleted deep Indian Ocean water can influence as far east as the western coast of Myanmar; although large amount of fresh water from the Ganges River is believed to greatly reduce the vertical mixture. Less variation in the past 300 yrs inferred no major change in large-scale circulation. In contrast, ΔR dramatically fluctuated during 8.0-6.9 ka BP, from as high as 553±34 yr down to -35±32 yr.

This interval coincided with the period of strong Asian summer monsoon in mid-Holocene. Thus we believe the fluctuated ΔR values are resulted from (1) the stronger upwelling induced by strong monsoon wind and (2) the enhanced ocean-atmosphere gas exchange due to heavy rainfall and surface runoff.

Isotopic signature of naturally Cr(VI) contaminated spring waters from Western Tuscany (Italy)

L. CHIARANTINI[1]*, S. AGOSTINI[1], I. BANESCHI[1], M. GUIDI[1], C. NATALI[1], S. TONARINI[1] AND R. FREI[2]

[1]CNR-Istituto di Geoscienze e Georisorse, Pisa, Italy (*correspondence: laura.chiarantini@igg.cnr.it)
[2]Institute of Geography and Geology, University of Copenhagen (robertf@geo.ku.dk)

Weathering of serpentinites produces soils and sediments with high Cr concentrations. High Cr (VI) contents (up to 50 μg/l) have also been found in some spring waters spilling out from serpentinite bodies that outcrop in Western Tuscany. A section of a multidisciplinary research program (RESPIRA) is aimed to enhance the understanding of serpentinite rocks weathering processes in order to assess the mobility and bioavailability of Cr. Petrographic and minero-chemical analyses of both rocks and soil samples highlight the occurrence of minerals able to release Cr (III) containing significant Cr amounts, such as chlorites (Cr_2O_3 up to 8 wt%). The absence of Mn-oxides, permitting to rapid oxidise Cr(III), implies that local presence of Cr (VI) in waters have to be ascribed to other processes.

Sr-Pb isotopes of serpentinites suggest an interaction with recent, low-T, waters, whereas most soils display larger Sr-Pb isotopic ranges indicating a significant contribution of both elements from crustal sedimentary rocks. All spring waters display Mg-HCO_3 chemical composition and a Sr-Pb isotopic signature fitting within the serpentinites and soils range.

Cr isotopes are generally used to investigate Cr(VI) reduction occurred in contaminated ground waters, during biotic and abiotic processes, which produces a strong positive fractionation of residual unreduced Cr(VI) as well as a powerful tool for to reconstruct the redox state of ancient sea water. Nevertheless, little is know about fractionation effects accompanying Cr (III) oxidation although little positive fractionation has been experimentally demonstrated. The spring waters preliminary investigated for Cr isotopes are strongly positively fractionated (δ^{53}Cr values between +1 and +3‰) as observed in other naturally Cr (VI) contaminated ground waters [1]. The observed strong positive fractionation can be the result of both Cr oxidation and partial back reduction of soluble Cr (VI). Further investigations on serpentinite spring waters can contribute to better understand Cr isotopes behaviour during natural Cr redox reactions.

U-Pb geochronology and source constraints for late S-type Variscan magmatism related to Sn-W metallogeny: The Logrosán granite pluton (Central Iberian Zone)

E. CHICHARRO[1]*, C. VILLASECA[2], P. VALVERDE-VAQUERO[3], E. BELOUSOVA[4] AND J.A. LÓPEZ-GARCÍA[1]

[1] Department of Crystallography and Mineralogy. Complutense University of Madrid (*correspondence: evachicharro@ucm.es, jangel@ucm.es)
[2] Department of Petrology and Geochemistry. Complutense University of Madrid (granito@ucm.es)
[3] Spanish Geological and Mining Institute (IGME) (p.valverde@igme.es)
[4] Dpt. Earth and Planetary Sciences, GEMOC, Macquarie University. (ebelouso@els.mq.edu.au)

S-type tin-bearing granites intruded along the Central Iberian Zone (CIZ) during syn- and late-kinematic stages of the Variscan orogeny. The Logrosán cupola belongs to the Central Extremadura Batholith (CEB) which crops out within the epizonal domains of the CIZ. This granitic body intruded the Neoprotezoic Schist-Greywacke Complex (SGC). The Logrosán cupola is a felsic, perphosphoric, and strongly peraluminous (ASI=1.2-2) tin-granite (Sn=11-67 ppm). The most evolved facies are well-exposed in the topographic heights at the centre of the granitic cupola. Major and trace element geochemistry (e.g. CaO, Rb, Sr) shows no fractional crystallization trends suggesting the input of felsic batches derived from a deeper magma reservoir. Besides, the Sr-Nd and Hf isotopic signatures indicate that the Logrosán granite was derived by partial melting of heterogeneous crustal sources (initial $^{87}Sr/^{86}Sr$ ratios from 0.7134 to 0.7311; εNd between -4.3 and -4.0 and εHf(t) from 2.0 to -4.6 for Variscan zircons). An age for the granite emplacement of *ca*. 308 Ma (U-Pb Zrn & Mnz CA-ID-TIMS) indicates that the granite is coeval with other related plutons in the region. U-Pb LA-ICP-MS dating has identified a predominant group of Neoproterozoic inherited zircon with juvenile Hf-isotope composition (εHf up to +14.6; LA-MC-ICPMS data) similar to that of zircons from the SGC. This evidence suggests that the Logrosán granite was partially derived from melting a metasedimentary protolith similar to the Neoproterozoic SGC.

Microaerophilic biological methane cycling 2.6-2.1 billion years ago

We present a new and undescribed biogeochemical mechanism explaining the demise of the Archaean methane greenhouse atmosphere in the palaeoproterozoic using Cu, Fe, C_{org} stable isotope systematics and microbial culture experiments. Based on Cu-Fe chemistry, we infer that oceanic Cu levels, hundreds to thousands of scales above that of modern oceans, orchestrated the transition into a previously unknown Cu-resistant microbial ecosystem after the rise of atmospheric oxygen. The associated Neoarchaean emergence of Cu-dependent microaerophilic methanotrophy, ~2.8-2.5 Ga, provided a resilient biological filter against continuous catastrophic methane input into the Palaeoatmosphere, between ~2.6-2.1 Ga. Methane oxidation by this process peaked at ~50% increase by ~2.1 Ga, relative to the Neoarchaean. We propose that microaerophilic Cu-dependent methane oxidation was the second most important process for primary productivity after H_2-driven methanogenesis during the Palaeoproterozoic. It facilitated the accumulation of extremely low $d^{13}C_{org}$ isotopic excursions and was intensely active from the start to the end of the Huronian glaciation, facilitating biospheric oxidation.

^{15}N-Enrichment of amino acids for studying trophic structure and energy flow in food webs

YOSHITO CHIKARAISHI[1] NANAKO O. OGAWA[2] MASASHI TSUCHIYA[3] AND NAOHIKO OHKOUCHI[4]

Institute of Biogeosciences, Japan Agency for Marine-Earth Science and Technology, Yokosuka, JAPAN,
[1] (ychikaraishi@jamstec.go.jp), [2](nanaogawa@jamstec.go.jp), [3](tsuchiyam@jamstec.go.jp), [4] (nohkouchi@jamstec.go.jp),

To better understand the trophic linkages and energy flow in complex networks of ecosystems, we recently have employed compound-specific stable isotope analyis (CSIA) of amino acids as a relatively new tool. In particular, the CSIA has been used to estimate trophic position (TP) among animal species, using a following equation:

$TP = [(\delta^{15}N_{Glu} - \delta^{15}N_{Phe} + \beta)/TEF] + 1$

where β epresents the isotopic difference between glutamic acid and phenylalanine in aquatic algae (–3.4‰), and C3 (+8.4‰) and C4 higher plants (–0.4‰), and TEF represents trophic enrichment factor (7.6‰ = $\Delta\delta^{15}N_{Glu} - \Delta\delta^{15}N_{Phe}$) at each shift of trophic level (Chikaraishi *et al*., 2010). By using this CSIA, the estimation error on the TP has been suggested to be 0.12 unit as 1σ for aquatic (Chikaraishi *et al*., 2009) and 0.17 for terrestrial environments (Chikaraishi *et al*., 2011). Thus the CSIA of amino acids potentially reduces the uncertainty on the TP estimates compared to the traditional bulk isotope method by approximately 1/10 or more.

However, the validity of such estimates is dependent on the consistency of both β and TEF values. In the presentation, we will discuss whether the β value is universal among different producers and also whether the TEF value scales with trophic level, based on the experimental results for a number of organisms in our study and previously published literatures.

CO_2 and advective heat fluxes in central Apennine, Italy

CHIODINI G.[1], CARDELLINI C.[2], CALIRO S.[1], FRONDINI F.[2] AND CHIARABBA C.[3]

[1]INGV, sezione di Napoli, giovanni.chiodini@ov.ingv.it
[2]Università di Perugia, (carlo.cardellini@unipg.it)
[3]INGV, CNT-Roma,(claudio.chiarabba@ingv.it)

Carbon dioxide Earth degassing process affecting the Apennine belt was quantified on the base of the carbon mass balance of the regional aquifers. The deeply derived CO_2 resulted in ~ 2-2.5×10^{11} mol/a that represents ~10% of the estimated present-day total CO_2 discharge from the sub aerial volcanoes of the Earth. The groundwaters enriched in CO_2 systematically display a slight temperature anomaly, which becomes significant when the differences between the water temperatures at the springs and the temperature of corresponding recharging meteoric waters are compared. These temperature differences, together with the hydrogeologic parameters of the different aquifers, have been used to compute the total amount of heat by geothermal warming which results of ~ 2.1 × 10^9 J/s. This geothermal warming implies heat fluxes higher than 300 mW/m^2 in a large sector of the Apennines, i.e. values in average higher than those affecting the famous geothermal provinces of Tuscany and Latium. This finding is in some way surprising because so far the central Apennines is though to be a cold area. This high heat and CO2 flux opens a new vision of the Apennines belt and requires the existence, at depth, of a thermal and fluid source such as a large magmatic intrusion. Recent tomographic images of the area confirm the presence of such intrusion visible as a broad negative velocity of seismic waves. This study reveals how the investigations based on large groundwaters systems are important for a more reliable estimation of both deep CO_2 and heat fluxes in orogenes.

Entropy and reactive solute transport in porous media

G. CHIOGNA *[1], D. L. HOCHSTETLER [2], A. BELLIN [3], P. K. KITANIDIS[2] AND M. ROLLE [1,2]

[1] Center for Applied Geoscience, University of Tübingen, Sigwartstr. 10, 72076 Tübingen, Germany (correspondence: gabriele.chiogna@ifg.uni-tuebingen.de)
[2] Department of Civil and Environmental Engineering, Stanford University, 473 Via Ortega, CA 94305, Stanford, USA
[3] Dipartimento di Ingegneria Civile ed Ambientale, Università di Trento, via Mesiano 77, 38123 Trento, Italy

Mixing processes significantly affect reactive solute transport in porous media. Contaminant degradation in environmental aquatic systems can be limited either by the availability of one or more reactants, brought into contact by physical mixing, or by the kinetics of the (bio)chemical transformations. Appropriate metrics are needed to accurately quantify the interplay between mixing and reactive processes. The exponential of the Shannon entropy of the concentration probability distribution has been proposed and applied to quantify the dilution of conservative solutes either in a given volume (dilution index) or in a given water flux (flux-related dilution index). We propose using entropy-based metrics of mixing to reactive transport in porous media. Adopting a flux-related framework, we show that the degree of uniformity of the solute mass flux distribution for a reactive species and its rate of change are informative measures of physical and (bio)chemical processes and their complex interaction (Figure 1).

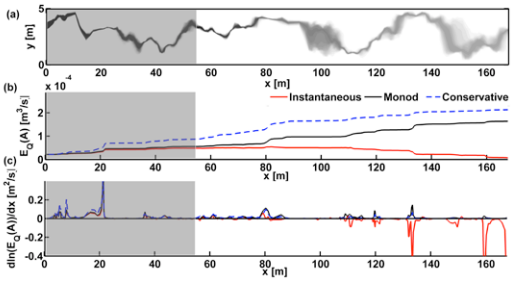

Figure 1: Steady-state conservative plume (a). Flux-related dilution index of compound A for the conservative and two reactive cases (b) and the spatial derivative of its natural logarithm (c) in a heterogeneous domain considering: instantaneous kinetics (red line), double Monod kinetics (black line) and conservative transport (blue dashed line).

Electrochemical investigation of iron monosulfide oxidation by hydrogen peroxide

P. CHIRITA[1]*AND C.A. CONSTANTIN[1] AND M.L. SCHLEGEL[2]

[1]University of Craiova, Department of Chemistry, Calea Bucuresti 107I, Craiova Romania (*correspondence: paulxchirita@gmail.com)
[2]CEA, DEN/DANS/DPC/SEARS//Laboratory for the Engineering of Surfaces and Lasers, F-91191 Gif-sur-Yvette, France (michel.schlegel@cea.fr)

Aqueous oxidation of synthetic iron monosulfide (FeS) by H_2O_2 in HCl solutions was investigated by electrochemical techniques. Corrosion current densities (i_{corr}) and corrosion potentials (E_{corr}) were measured as a function of [H_2O_2] (0.001 to 0.1 M) and pH (2 to 11) at temperatures from 30 to 45°C. Experiments were carried out in a conventional three electrode cell assembly with a Pt counter electrode and saturated calomel reference electrode.

It was found that, i_{corr} decreases (E_{corr} increases) from 0.27 mA cm^{-2} (-364 mV) down to 0.019 mA cm^{-2} (up to -57 mV) when pH increases from 2 to 5 (7). Thereafter they remain roughly constant up to pH 11. [H_2O_2] and temperature have a more complex effect on FeS oxidative dissolution. At pH 2.5 and 45ºC, i_{corr} increases from 0.16 mA cm^{-2} ([H_2O_2]=0.001 M) up to 0.35 mA cm^{-2} ([H_2O_2]=0.002 M), and then it decreases down to 0.2 mA cm^{-2} ([H_2O_2]=0.1 M). In similar conditions, E_{corr} increases when [H_2O_2] increases. At [H_2O_2]=0.005 M and pH 2.5, E_{corr} increases (i_{corr} decreases) from -348 mV (0.19 mA cm^{-2}) up to -304 mV (down to 0.16 mA cm^{-2}) when temperature increases from 30ºC to 40ºC (35ºC). Thereafter E_{corr} decreases (i_{corr} increases) to -372 mV (0.24 mA cm^{-2}).

The experimental results indicate that at low pH H_2O_2 is an effective oxidant of FeS. The complex effect of [H_2O_2] and temperature on mineral aqueous oxidation is likely the result of the several reactions. Among these reactions we note: FeS oxidation; [H_2O_2] decomposition and formed O_2 adsorption on mineral surface.

The authors greatly appreciate support from IFA-CEA Program (Project C1-04).

SHRIMP U-Pb detrital zircon ages for metasedimentary rocks from the Seosan Group at western margin of the Gyeonggi Massif, Korea, and their tectonic implications

DEUNG-LYONG CHO[1]

[1]Geological Resaech Division, Korea Institute of Geosciences and Mineral Resources, Daejeon, 305-350, Republic of Korea (dlcho@kigam.re.kr)

The Gyeonggi Massif (GM) located at the central part of Korean Peninsula is one of the major tectonic units where Precambrian basement rocks are widely exposed. Recent studies reveal that Precambrian rocks in the GM are mostly consist of Paleoproterozoic (1.89-1.82 Ga) para- and orthogneiss, and small bodies of Neoproterozoic (0.90-0.75 Ga) TTG and alkali pluton. Mesoproterozoic sedimentary succession and igneous activites in the GM, however, have not been well defined yet.

In this study, sensitive high-resolution microprobe (SHRIMP) U-Pb age dating is carried out for detrital zircons from metasementary rocks of the Seosan Group (SG) which unconformably overlies the ~1.87 Ga basement rocks at western margin of the GM. Samples are mica-schist (SS3) and quartzite (SS6) from the Sogeuri Formation, and biotite gneiss (Btgn) from Ibugri Formation of the SG. In cathodoluminescence image, most of the zircons show oscillatory zoning patterns, and rarely present core-rim structure. Zircon ages from the SS3, SS6 and Btgn have ranges of 3.15-1.86 Ga, 2.84-1.78 Ga and 3.02-1.82 Ga, respectively. In age spectra, they have distinct peaks at ~1.87 Ga and ~2.54 Ga, and minor peaks exist between these ages. Only a few of the ages are older than 2.75 Ga.

The youngest detrial zircon ages in this study constraint sedimentation of the SG after ~1.8 Ga, and the age spectra are very similar to those reported from Meso- to Neoproterozoic sedimentary succession in the North China Craton [1], that is Changcheng, Jixian and Qingbaikou Groups in ascending order, which deposited after the Lüliang movement at ~1.8 Ga. On these bases, it can be concluded that (1) protolith of metasedimentary rocks of the SG derived from Noth China Craton; (2) western margin of the GM is correlated with North China Craton.

Determination of ^{238}U, isotope Uranium($^{234}U/^{238}U$), ^{222}Rn and gross alpha in the ground water of the Goesan area in Korea

S.Y. CHO[1] WK. YOON[1] B.W. CHO[1], Y.Y.YOON[1]
K.Y. LEE[1]Y.C. KIM[1]AND M.H.KOO[2]

[1]KIGAM, Daejeon 305-350, Korea (sycho@kigam.re.kr),
[2]Kongju National University

Ground waters generally contains various amount of radio-activity. Measurement of natural occurring radionuclides in groundwater is important for environmental and public health studies.

The measurement of the activity concentrations of ^{238}U, isotopic Uranium($^{234}U/^{238}U$), gross alpha and ^{222}Rn in sample of ground water is very important in the general study of radionuclide migration that is the source of the radio-nuclides dissolved in the water. Liquid scintillation counting (LSC) is an effective technique for the determination of radionuclide and measurement of radio activity in water samples using LSC which is one of the most common screening techniques applied in ground water.

The activity concentrations of the ^{238}U, isotopic Uranium ($^{234}U/^{238}U$), gross alpha and ^{222}Rn are reported for 55 natural water samples collected from public wells in the sample area. This method is dependent on sample preparation procedures and the setup of measurement conditions, which are typically individual to each of counting laboratories. The aim of this project was to get an overview of the distribution of natural radionuclide activity concentration levls in the ground water sampled from the area. The study area is located in Goesan (36º 35´N, 127 º 37´E), korea. The ^{222}Rn could be extracted easily form the water sample(10mL) using a 10 ml commercial organic scintillant. Gross alpha activity was measured in the water sample using LSC method. The sample preparation in this methods was based on the evaporation of relatively small sample(200ml) and measurement in the LS spectrometer with alpha/beta discrimination feature. Determination of ^{238}U concentration using individual coupled plus mass spectrometry(ICP-MS) and partial sample are solvent extraction method which was utilized to measure isotopic Uranium($^{234}U/^{238}U$) content in the ground water. The ^{238}U, isotopic Uranium($^{234}U/^{238}U$), gross alpha and ^{222}Rn, major ion concentrations and physic-chemical parameters were also measured.

The results revealed that the concentrations of Gross alpha, ^{222}Rn and ^{238}U ranged from 0 to 174.9(pCi/L), from < 94 to 29,300(pCi/L), from < 0,1 to 293(ppb), respectively. The isotopic Uranium($^{234}U/^{238}U$) activity ratio varied between 0.39-1.75.

Development of an *in situ* K-Ar dating technique using LIBS-QMS combination

Y.CHO[1]*Y. N. MIURA[2] AND S. SUGITA[3]

[1]Dept. Earth & Planetary Scientce, University of Tokyo, Kashiwa, Chiba, 277-8561 Japan (*correspondence: cho@astrobio.k.u-tokyo.ac.jp)
[2]Earthquake Research Institute, Univ. Tokyo 113-0033 Japan
[3]Dept. Cmplx. Sci. & Engr., Univ. Tokyo, Chiba 277-8561, Japan

The age of a rock is one of the most critical parameters for understanding the nature of the sample. Age determination of some key samples not only reveals the history of the specific rocks but also enables us to determine the age of planetary surfaces. In fact, absolute age determination of the planetary surfaces relies on the correlation between crater number density and the ages obtained by Apollo and Luna missions (chronology function) [1]. However, the chronology curve has a 0.5-1 Gyr of uncertainty due to the lack of returned samples. Determining the shape of the chronology function is important not only for determining accurate age, but also for understanding the temporal variation of the impact flux to the Earth-Moon system. In-situ age measurements and/or sample-return mission(s) are crucial to resolving this problem.

We have been developing an in-situ dating method using K-Ar system for future planetary landing missions on the Moon or Mars. In our method, K and Ar in a sample are extracted by the laser ablation and measured with laser-induced breakdown spectroscopy (LIBS) and a quadrupole mass spectrometer (QMS) as well as an optical microscope to measure the volume of laser ablation pits [2, 3].

Using our instrument we obtained the model ages of three previously measured samples with known K concentrations and ages: 2.1±0.3 Ga for a hornblende (K_2O=1.12 wt%, 1.75 Ga), 1.8±0.2 Ga for a biotite (K_2O=8.44 wt%, 1.79 Ga), and 2.0±0.3 Ga for a plagioclase (K_2O=1.42 wt%, 1.77 Ga). Since the three samples have similar ages and different K concentrations, we should be able to construct a "virtual" isochron by plotting the concentrations of K and radiogenic ^{40}Ar. The slope of the isochron simulated with our experimental data yields 1.78 Ga of age. This value is in good agreement with known values of 1.79 Ga.

Functionalized Carbon Nanotube for Forward Osmosis Membrane: Fabrication and Desalination Application

HYEON-GYU CHOI[1] MOON SON[1] HOSIK PARK[1] AND HEECHUL CHOI[1]*

[1]School of Environmental Science and Engineering, Gwangju Institute of Science and Technology, 1 Oryong-dong, Buk-gu, Gwangju, Republic of Korea (hgstyle@gist.ac.kr, moons@gist.ac.kr, phosik@gist.ac.kr)
*(correspondence: hcchoi@gist.ac.kr)

Forward osmosis (FO) has huge potential to replace with reverse osmosis due to the fact that it operates with osmotic pressure difference and low fouling tendency [1]. In this study, we synthesized the functionalized carbon nanotube blended polymeric membrane and evaluated performance for desalination application. Firstly multi-walled carbon nanotubes (MWCNTs) were functionlized by acid treatment [2]. By blending the MWCNTs, cellulose acetate based composite membrane was synthesized using phase inversion [3]. To characterize the MWCNTs and the membrane, SEM, TEM, FT-IR, and contact angle measurement were utilized. Lab-scale forward osmosis system was operated to evaluate membrane performance for desalination application.

It was confirmed that the functionalized MWCNTs has carboxylic group by acid treatment [3]. The hydrophlic group increase the hydrophilicity of the membrane resulting in enhanced water permeated flux. After 6 hours operation of lab-scale FO system, 47% of water permeated flux increased by 1% CNT blended. Salt ion rejection was not hindered by the presence of CNT (99% when 0% CNT and 97% when 1% CNT blended repectively), marginal reduction in salt rejection was caused by thinner membrane thickness due to increased viscosity of the polymer solution by CNT blending [4],[5]. Even small amount of MWCNTs was blended (i.e., 1 wt%), water permeated flux dramatically incresased whereas the salt ion rejection of the membrane was not decreased much compared to bare cellulose acetate membrane. This study showed the capability of MWCNTs to increase forward osmosis membrane performances for desalination application.

Pb isotope ratios in stream sediment around two abandoned mines originating from one ore deposits

J-W. CHOI[1]* K. LEE[1] AND E-J. YOO W-S. LEE[1] AND J-S. HAN[1]

[1]National Institute of Environmental Research, Incheon, Korea (*correspondence: cjw111@korea.kr,) (panthallasa@korea.kr, ejyoo@korea.kr,) (boystone@korea.kr,) (nierhan@korea.kr)

Recently Pb isotope ratios have been successfully used for tracing sources and transports of pollutants from mine sites [2]. In addition, Pb isotope ratio data allowed to estimate relative contributions when there are more than two sources for Pb [3]. We measured Pb isotope ratios of stream sediment and soils around two abandoned mines, DJ and ID mine, originating from one ore deposits. Potential sources existed such as agricultural land, farm house and artificial pool near DJ mine, while no additional sources were found around ID mine. Pb isotope ratios determined in this study provided identification of the sources for Pb in the sediment and assessment of the contributions from those sources to neighboring areas.

The sediment samples collected in the main stream from each mine were commonly characterized by: 1) relatively high concentrations, 2) general decrease in concentrations depending on proximity to mine, 3) constant isotope ratios, and 4) distinguished isotopic compositions from those of tributary stream and downstream areas. This suggests that the Pb in the main stream sediment was affected by Pb pollutants from mines in both sites. The inversed Pb concentrations versus $^{208}Pb/^{206}Pb$ and/or $^{207}Pb/^{206}Pb$ ratios plots showed linear correlation between main stream sediment, tributary sediment and downstream sediment. According to binary mixing equation, the relative contributions of Pb from DJ and ID mines to corresponding downstream area were 35~36 % and 37~42 %, respectively. The relative contributions of each source to downstream area calculated by IsoSource program were 35~67 % for main stream, 17~65 % for tributary stream, 0~3 % for agricultural soil, 0~14 % for farm house and less than 1 % for artificial pool.

Stable Pb and Cd isotopes in the riverwaters and soils near the Zn-refinery, Korea

MANSIK CHOI[1]*, JONGKYU PARK[1], DONGJUN CHANG[1] SOJEONG PARK[1] AND JONGUOO CHOI[2]

[1]Chungnam National University, Daejeon, Korea (aska4332@naver.com,) (fightgood@naver.com,) (zzung1009@nate.com)
[2]National Institute of Environmental Research, Incheon, Korea. (cjw111@korea.kr)
*(correspondence: mschoi@cnu.ac.kr)

In order to estimate the contribution of refinery borne metals in riverwaters and soils near Zn-refinery and to differentiate them from mining borne metals [1,2], this study collected riverwaters and soils with distance from the refinery to the artificial lake far away 50km. Waste and discharged water, ore and sludge were also collected and analyzed for concentrations of Cu, Zn, Cd and Pb, and isotopes of Cd and Pb using MC ICP/MS.

High concentrations of Cu, Cd, and Pb in riverwaters and soils were observed even in far distance and were correlated with Zn. Based on Pb isotopes, the contribution of refinery borne Pb was identified only in riverwaters and soils within 5 km, which showed the Pb isotopes from imported ores, while samples far away 5 km showed the Pb isotopes from local ores [3] nearby the refinery. $\varepsilon^{114/110}Cd$, isotopic ratio normalized to NIST 3108, showed negative values in soils and positive in riverwaters which indicated the fractionation from ore through the evaporation during refinery. Although the definite decision of the mixing between refinery borne metals and background was not easy, it was evident that refinery borne Cd contributed substantially to samples within 5 km. Size sorting in soils and mixing of enriched heavy isotopes from carbonate deposits with refinery borne metals in riverwaters were responsible for the distribution of $\varepsilon^{114/110}Cd$.

This study was supported by Grant 2012M3A2A1050969 of the National Research Foundation of Korea under the Ministry of Education, Science, Technology, Korea.

Mineralogical and microtextural properties of soils by erosion during the rainy season in the Andong area, southeastern part of Korea

CHOO CHANG-OH[1], JEONG GYO-CHEOL[2]* AND NAM KOUNG-HOON[3]

[1]Andong National University, Andong, Korea (mineralogy@hanmail.net)
[2]Andong National University, Andong, Korea (*correspondence: jeong@andong.ac.kr)
[3]Andong National University, Andong, Korea (namsoil@naver.com)

Along with geochemical information on weathering properties, properties of mineralogy and microtexture of soils are helpful to better understand the causes and patterns of soil erosion and landslide[1]. A total of annual soil loss in the Andong area, the southeastern part of the republic of Korea, amounts to one million tons due to heavy rainfall. We analyzed soils on natural slopes using XRD and SEM.

The most common minerals in soil on natural slopes are quartz, feldspars, illite, kaolinite, vermiculite, and iron oxides. Based on XRD data, the content of quartz in sandstone areas varies from 53.3 to 80.2 wt% while it ranges from 13.6 to 23.2 wt% in gneiss areas. According to SEM observation, fine particles comprising soil vary in size and shape with different geology. They are generally subrounded or elongated with rough surfaces, moderately compacted with some voids. Quartz and feldspars in soils are relatively coarser and frequently densely coated with illite with submicron in size and amorphous iron oxides. Most feldspars show rough surface with dissolution cavities or etch pits. In the same site, the content of quartz and feldspars increases with increasing the rate of soil erosion. The differences in mineralogy and soil texture are attributed to different slope angles and lithology, together with erosion rates. The mineralogical and microtextural properties of soil on natural slopes are important for determining soil erosion by rainfall because fine particles such as clays have great specific surface area and expandability.

Anomalous isotope fractionation of sulfur (AIF-S) during thermochemical sulfate reduction by solid organic matter

A.P. CHORNEY[1] Y. WATANABE[1] AND H. OHMOTO[1]

[1]NASA Astrobiology Institute and Department of Geosciences, University Park, USA, (apc5060@psu.edu); (yxw129@psu.edu); (hqo@psu.edu)

Watanabe *et al*. [1] found distinct AIF-S signatures in the products of Na_2SO_4 reduction by glycine at 150-200°C: $\Delta^{33}S$ values up to +0.92 ‰ for H_2S and up to +2.06‰ for Cr-reducible S. Here we report the results of new series of experiments using various mixtures of alanine, glycine, Na_2SO_4, and H_2SO_4 at 200-300C.

We have found that the $\Delta^{34}S$ (= $\delta^{34}S_{prod} - \delta^{34}S_{init.SO4}$) and $\Delta^{33}S$ (= $\delta^{33}S - 0.515\ \delta^{34}S$) values greatly vary depending on the starting materials, presence of various reaction products (H_2S, S^0, Cr-reducible S, HCl-soluble S, and organic S), temperature, pH, and reaction time. For example, mixtures of the two amino acids and Na_2SO_4 generated H_2S with much larger ranges in $\Delta^{34}S$ (-10.6 to +15.5 ‰) and $\Delta^{33}S$ (+0.5 to +2.3 ‰) and more consistent $\Delta^{36}S$ fractionation (+.4 to +1.4‰) compared to the experiments using a single type of amino acid and/or H_2SO_4. Under some experimental conditions we also observe changes from positive to negative $\Delta^{33}S$ fractionation (+.21 to -.22) in H_2S with time when reduction rates were high. In the experiments where large fractions of the initial SO_4^{2-} were reduced, the residual $SO_4^{2=}$ possessed $\Delta^{34}S$ = -.27 to 7.85‰ and $\Delta^{33}S$ = -.15 to .01‰. These data suggest the AIF-S signatures resulting from TSR are dependent on the degree of polymerization/dehydration of the organic matter, which affect its surface characteristics.

Our experimental data on sulfides and sulfates are similar to those in more than 60 percent of the AIF-S signatures in pre-2.4 Ga sedimentary rocks. If we consider the additional isotope effects due to Rayleigh distillation and recycling, our data can explain all the data reported on natural rocks.

Our experimental data, therefore, provide strong supportive evidence for the hypothesis that most (if not all) AIF-S signatures in geologic materials were created during thermochemical sulfate reduction, rather than by atmospheric UV reactions of volcanic SO_2. This suggestion is also supported by the fact that large Archean AIF-S signatures are typically found in kerogen rich pyritic black shales and the recent discoveries of large AIF-S in post-2.2 Ga materials that have undergone high-temperature reactions between organic matter and sulfate.

Critical Zone Evolution by Jerks

J. CHOROVER[1], P. BROOKS[2], A. HARPOLD[2], M. LITVAK[3] J. MCINTOSH[2], J. PELLETIER[4], J. PERDRIAL[1], P. TROCH[2] AND C. RASMUSSEN[1]

[1]Department of Soil, Water and Environmental Science, University of Arizona, Tucson, AZ, 85721, USA
[2]Department of Hydrology and Water Resources, University of Arizona, Tucson, AZ, 85721, USA
[3]Department of Biology, University of New Mexico, Albuquerque, NM, 87131
[4]Department of Geosciences, University of Arizona, Tucson, AZ, 85721, USA

One challenge of Critical Zone (CZ) science is the effective prediction of internal structure formation (vegetation, soil, bedrock fractures) over geomorphic time scales. Another involves forecasting how evolved structure at any geologic time shapes CZ dynamic response (water, solute, gas, sediment) to contemporaneous pulses ("*jerks*") such as precipitation inputs to semi-arid systems or catastrophic wildfire. Dissipative products of reactions among oxidants, reduced carbon, water, and silicates include gases, solutes and sediments. The stoichiometry and speciation of efflux is dynamic and convolves upgradient processes. Models are needed to convolve how these coupled physical, biological and chemical processes respond to climate (e.g., EEMT) to enable better prediction of such CZ parameters as watershed chemical denudation rate, soil depth distribution, water transit time, and stream solute flux. An improved understanding of the mechanistic underpinnings of such predictions, however, and why they succeed or fail, requires direct observation of parallel data streams generated in situ, such as those produced by the Critical Zone Observatories (CZOs). Data from the Jemez-Catalina (JRB-SCM) CZO indicate that climatic forcing that varies significantly between years drives corresponding differences in dissipative element flux, speciation, and stoichiomety. The bimodal annual precipitation regime of AZ and NM implies that formation of observed porous geomedia structure, solid phase (bio)geochemical composition, fluid flowpaths, etc., occurs disproportionately during brief episodes of water and carbon throughflux and/or disturbance, and our measurements support this hypothesis. Sub-catchment locations with elevated reaction rates appear to control overall system behavior, and the type of precipitation input is key; snowmelt pulses contribute to CZ weathering at depth, whereas flashy summer monsoon rains during peak biological activity generate hydrochemical discharges enriched in organic ligand-metal complexes and nanoparticles from near surface flow paths.

Role of Black Carbon for Radioactive Iodine Sorption

SUNGWOOK CHOUNG[1] MINKYUNG KIM[1], MIN-GYU KIM[2] AND WOOYONG UM[1,3]

[1]77 Chumgam-lo, Nam-gu, Pohang, 790-784 Republic of Korea, (schoung@postech.ac.kr)
[2]77 Chungam-lo, Nam-gu, Pohang 790-784 Republic of Korea,
[3]Energy and Environment Directory, Pacific Northwestern National Laboratory, 902 Bartelle Bvld., P7-54, Richland, WA99354, USA

Natural organic matter (NOM) plays an important role in determining the fate and transport of iodine species such as iodide (I^-) and iodate (IO_3^-) in groundwater system. Although NOM exists as diverse forms in environments, prior iodine studies have mainly focused on sorption processes of iodide and iodate to humic materials. This study was firstly conducted to determine the iodide and iodate sorption potential for a particulate NOM (i.e., black carbon [BC]). A laboratory-produced BC and commercial humic acid were used for batch sorption experiments to compare their iodine sorption properties. The BC exhibited >100 times greater sorption capability for iodide than iodate, while iodide sorption was negligible for the humic acid. The sorption properties of both adsorbents strongly depend on the initial iodine aqueous concentrations. After sorption of iodide to the BC, X-ray Absorption Fine Structure (XAFS) spectroscopy results indicated that the iodide was converted to electrophilic species and chemically interacted with carbon atoms of polycyclic aromatic hydrocarbons present in the BC (Figure 1). The computed distribution coefficients (i.e., K_d values) suggest that the BC materials retard significantly the transport of iodide in environmental systems containing even a small amount of BC.

Niche partitioning in early Eocene mammalian faunas: New insights into a C3 ecosystem from tooth morphology, microwear, and stable isotopes

HILARY CHRISTENSEN[1]

[1]The Carnegie Institution of Washington, Geophysical Lab, 5251 Broad Branch Rd NW, Washington, DC 20036 (hchristensen@ciw.edu)

The stable isotopic composition of biological tissues can provide information about an animal's diet, and as preserved in crystalline tooth enamel can persist unaltered for millions of years. This makes stable isotope techniques very important tools in the study of life history and ecology in extinct animals. In such cases, however, the sources of isotopic variability are often difficult to pinpoint. The present study introduces a novel method for the evaluation of dietary signal in mammalian stable isotope ecology by combining stable isotope analysis with these independent dietary indicators. Phosphate $\delta^{18}O$ and carbonate $\delta^{18}O$ and $\delta^{13}C$ values from the tooth enamel of an early Eocene mammalian fauna exhibit a wide range of values, especially for an ecosystem composed entirely of C3 plants. Comparison with microwear and morphological results show that the ^{18}O variability in these animals stems from differential reliance on ^{18}O-enriched leaf water as a proportion of water intake (high-fiber herbivores= more leaf water, frugivores= more meteoric water), while the ^{13}C variability likely stems from feeding on plants growing in different microhabitats. The dietary information available from microwear and morphology allows the sources of stable isotopic variability to be addressed, providing a powerful tool to the interpretation of isotopic values in both fossil and living systems.

Unravelling sources of ground-level ozone in the intermountain western U.S. through Pb isotopes

JOHN N. CHRISTENSEN[1] PETER WEISS-PENZIAS[2], SHAUN T. BROWN[1] CHARLES MCDADE[3] DAN JAFFE[4] AND MAE GUSTIN[5]

[1]Lawrence Berkeley Natl. Lab.,(jnchristensen@lbl.gov)
[2]Univ. of California, Santa Cruz CA, (pweiss@ucsc.edu)
[3]Crocker Nuclear Lab., Univ. of California, Davis CA
[4]Univ. of Washington, Bothell WA, djaffe@u.washington.edu
[5]Univ. of Nevada, Reno NV, (mgustin@cabnr.unr.edu)

The Western United States (US) is subject to pollution transported across the Pacific from Asia. One component of aerosol pollution is lead (Pb), an element that can be readily traced back to sources using isotopic fingerprints Over the past decade China has emitted ~$7x10^9$ g/yr of Pb to the atmosphere with the principal source being coal combustion. The isotopic composition of aerosol Pb from China is distinct from sources in the Western US. In [1] it was shown, using data from Northern California, that the amount of Pb sourced in Asia/China (termed Trans-Pac Pb, ng/m^3) could be determined from the aerosol Pb isotopic composition. Here we explore the combined use of Pb isotopes and back-trajectory analyses to constrain the sources of ozone and its precursors to remote areas of the intermountain Western US. The EPA is considering lowering the ozone standard from 75 ppbv (MDA8= Maximum Daily 8-hour Average) to 60-70 ppbv. This will result in remote areas of the intermountain west being out of compliance, despite a lack of significant local sources. Sources suggested as culprits for ozone exceedance events in the remote west include long-range transport from Asia, regional transport from the Los Angeles/Las Vegas area, exchange/intrusion of stratospheric air to the surface, and wildfires. We used a combination of Pb isotope fingerprinting and back-trajectory analyses to distinguish sources of ozone to Great Basin National Park located in eastern Nevada. We found that during discrete Chinese Pb events (>1.1 ng/m3) trans-Pacific transported ozone was 4±5 ppbv above 15 year averages for those dates. In contrast, dates charaterized by regional transport from the Los Angeles and Las Vegas areas were 19±3 ppbv above the long-term averages, and those characterized by high-atitude transport were 21±5 ppbv above. The latter is indicative of long range free tropopshere transport, most of these samples had modest concentrations of Trans-Pac Pb (ave. 0.43 ng/m^3). Our data constrain the average background concentration of Asian sourced Pb in air to 0.3±0.2 ng/m^3 in the western US.

Speciation of phosphorus in soils peripheral to meltwater ponds in Victoria Land, Antarctica

HANNAH CHRISTENSON, JENNY WEBSTER-BROWN AND IAN HAWES[1]

[1]Waterways Centre for Freshwater Management and Gateway Antarctica, University of Canterbury, Christchurch, New Zealand (*correspondence: hannah.christenson@pg.canterbury.ac.nz), (jenny.webster-brown@canterbury.ac.nz), (ian.hawes@canterbury.ac.nz)

Meltwater ponds are the most common habitat for terrestrial biota on continental Antarctica. The productivity of benthic cyanobacteria (the dominant biomass) is considered to be limited by phosphorus (P) availability in inland areas, but sources of P and factors limiting its bioavailability are poorly understood. Consequently it is difficult to predict how productivity will be affected by climate change-induced increases in pond size and volume. As part of a larger research programme to determine the P biogeochemical cycle for meltwater ponds, this study has explored P concentration and speciation in the soils near the ponds to identify additional potential sources of P to the pond water during periods of increased temperature and meltwater volume.

Over three years (2011 – 2013), soils were collected (together with sediments, waters and biological material) from 15 ponds from 3 areas of the Dry Valleys, and from 7 ponds in the McMurdo Ice Shelf /Ross Island region in Victoria Land, representing inland and coastal meltwater environments respectively. Concentrations of P were up to an order of magnitude higher in the soils of coastal ponds (mean = 2.2 g/kg), compared to inland pond soils (mean = 0.32 g/kg). P speciation, determined using standard sequential extraction methods indicated that <3% of the P in the soils was in a form that might be readily released during flooding or during the seasonal anoxia that develops in meltwater ponds. However, up to 10% was in a form that could be released under alkaline conditions (pH>10), as can occur during period of intense photosynthesis during summer months in the ponds.

The remaining P (70 to 99%) is refractory and less likely to be readily dissolved during soil flooding, though weathering of apatite and/or dissolution of refractory oxide phases may release P in the longer term, particularly from the relatively P-enriched coastal soils. In coastal ponds on the McMurdo Ice Shelf, pond sediments had <25% of the readily exchangeable P concentration in adjacent soils, and <80% total P, confirming immediate *and* longer term release of soil P into pond water.

Green rust sulphate - making space for interlayer cations

B.C. CHRISTIANSEN[1], A. KATZ[1,2], N. BOVET[1], H.O. SØRENSEN[1], M.P. ANDERSSON[1], S. NEDEL[1] C. FRANDSEN[3] K. DIDERIKSEN[1] AND S.L.S. STIPP [1]

[1] Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark; (bochr@nano.ku.dk)

[2] Present address: Institut franco-allemand de recherches de Saint-Louis – ISL, Saint-Louis Cedex, France

[3] Department of Physics, Technical University of Denmark, Denmark

Green rusts (GR) are layered double hydroxides with brucite like Fe(II),Fe(III) hydroxide layers. The surplus charge from Fe(III) is balanced by incorporation of anions and in some cases also cations. GR can reduce a range of redox sensitive compounds, e.g. nitrate, chromate and chlorinated solvents. GR forms readily in the laboratory at ambient temperatures, neutral pH and slightly reducing conditions, can be stable under groundwater conditions, making it a good candidate for contaminant remediation

Although GR has been the subject of numerous studies, several structural aspects are poorly understood. Interlayer ions for example, define the interlayer spacing, which in turn impacts interlayer accessibility for redox sensitive compounds and thereby the reactivity of GR. We have investigated interlayer incoporation of a range of monovalent cations (Na^+, K^+, Rb^+ and Cs^+) in GR_{SO4}. Synchotron X-ray diffraction demonstrated that the interlayer spacing correlates with radius of the cations, showing that they intercalate.

X-ray photoelectron spectroscopy showed that interlayer incorporation differs greatly among cations and is correlated with the stability constant for the X^+-SO_4^- ion pairs. Infrared spectroscopy showed that sulfate symmetry was affected differently by the incorporated cations. If interlayer spacing limits anion or cation availability for reaction, our results indicate that the identity of the incorporated monovalent cation would also affect reaction rates.

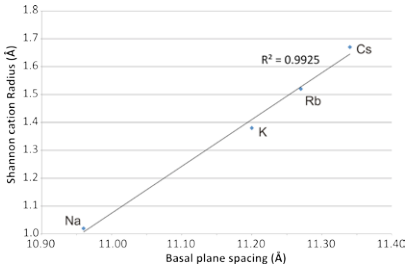

Figure 1. Correlation between GR_{SO4} basal plane spacing and ionic radius of cations in solution during formation.

Airborne *in situ* measurements of HDO/$H_2{}^{16}O$ confirm strong influence of convection on isotopic composition of upper tropospheric humidity

EMANUEL CHRISTNER*[1] CHRISTOPH DYROFF[1], SHAHROKH SANATI[1] AND ANDREAS ZAHN[1]

[1]KIT – Karlsruhe Institute of Technology, Institute for Meteorology and Climate Research, Karlsruhe, Germany (*correspondence: emanuel.christner@kit.edu)

Atmospheric water is an enormously crucial trace species. It is responsible for ~75% of the natural greenhouse effect [1] and carries huge amounts of latent heat. The isotopic composition of atmospheric water vapor is an elegant tracer for a better understanding and quantification of the extremely complex and variable hydrological cycle in Earth's atmosphere, which in turn is a prerequisite to improve climate modeling and predictions.

In this context, water-isotopologues (here the isotope ratio HDO/$H_2{}^{16}O$) can be used to study the atmospheric transport of water, as $H_2{}^{16}O$ and HDO are fractionated during several transport-related processes (evaporation, cloud condensation, rainout, re-evaporation, formation of ice).

During more than 20 long-distance flights across or close to the equator, HDO/$H_2{}^{16}O$ of convectively lofted air was measured *in situ* in the upper troposphere (UT). These measurements confirm the large impact of tropical strong convection on the isotopic composition of atmospheric water. In comparison to a Rayleigh model we find on average an enhancement of δD by more than 100 ‰ above three continents (Africa, South America, East Asia, Fig. 1). A meridional profile illustrates the transport of convectively lofted air to higher latitudes by Hadley circulation.

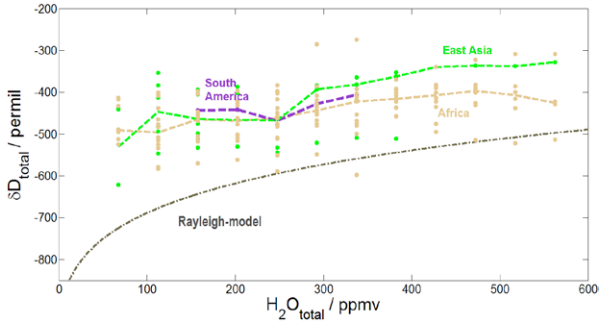

Figure 1: Enhanced tropical δD shows impact of convection on isotopic composition of humidity in the UT. Black line: Rayleigh model.

An integrated approach to build surface complexation models for chromate on iron oxides

MARIA CHRYSOCHOOU[1]* NADINE KABENGI[2] MICHAEL MACHESKY[3] CHAD JOHNSTON[1] AND JAMES KUBICKI[4]

[1]University of Connecticut, Storrs, CT 06268, USA (correspondence*: maria.chrysochoou@uconn.edu)
[2]Georgia State University, Atlanta, GA 30303, USA
[3]Illinois State Water Survey, Champaign, IL 61820, USA
[4]Pennsylvania State University, University Park, PA 16802, USA

This study presents Surface Complexation Models (SCMs) for chromate (CrO_4^{2-}) adsorption on ferrihydrite and hematite that were formulated and calibrated using complementary techniques to investigate the mechanisms and energetics of adsorption. Specifically, Attenuated Total Reflection – Fourier Transform Infrared (ATR-FTIR) and Extended X-ray Absorption Fine Structure (EXAFS) spectroscopies were applied to investigate the surface species formed under different pH, surface loading and ionic strength conditions; Flow Adsorption Calorimetry (FAC) analyses determined the enthalpies of adsorption and provide additional evidence for surface speciation; Density Functional Theory (DFT) calculations provided bond lengths, vibration frequencies and comparative enthalpy values. SCMs were formulated using the CD-MUSIC framework and calibrated taking both proton adsorption data and observed surface species distributions into account.

The results indicate that ferrihydrite and hematite present similar behavior in terms of the type of species formed, with some differences in the relative distribution and adsorption energetics that can be traced back to the mineral structure and properties. Monodentate complexes are dominant on both minerals at low chromate loadings and pH>5, while bidentate complexes are favored at acidic pH and high surface loading. No protonation of the surface complexes was observed under any conditions. More total heat of adsorption was observed on the ferrihydrite surface compared to the hematite.

The conditions at which bidentate complexes take over are dependent on ionic strength and on the presence of carbonate, as indicated by the ATR analyses and the SCMs, respectively. The calibration of the model also indicated that the distribution of the two species as a function of pH is very sensitive to the log K values. Overall, an improved fit to adsorption edges was obtained for both minerals compared to previously published models.

Magma components of the Gangdese batholith, southern Tibet: Decoded by zircon Hf and O isotopes

M.-F. CHU[1]* S.-L. CHUNG[2] X.-H. LI[3] H.-Y. LEE[2] AND S.Y. O'REILLY[45]

[1]Institute of Oceanography, National Taiwan University, Taipei 106, Taiwan (*correspondence: meifei@ntu.edu.tw)
[2]Department of Geosciences, National Taiwan University, Taipei 106, Taiwan (sunlin@ntu.edu.tw, haoyanglee@ntu.edu.tw)
[3]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China (lixh@gig.ac.cn)
[4]Australian Research Council Centre of Excellence for Core to Crust Fluid Systems and GEMOC, Department of Earth and Planetary Sciences, Macquarie University, North Ryde, NSW 2109, Australia (sue.oreilly@mq.edu.au)

The Gangdese batholith, southern Tibet is the largest of the Transhimalayan batholiths produced by the Neo-Tethyan subduction. Zircon U-Pb age data show that the emplacement of the Gangdese batholith occurred during ca. 200 and 40 Ma, and can be divided to the Jurassic, Cretaceous and Paleogene stages. Zircon Hf isotope data indicate that, in addition to the juvenile mantle signature observed in both of Mesozoic stages, the Paleogene Gangdese is characterized by significant Hf isotopic shift suggesting the involvement of old continental crust in the magma source, which we interpret as a result of Himalayan sediment subduction related to the advancing India. Here we report new zircon O isotope data measured by Cameca 1280 that, combined with published zircon Hf isotope data, identify four magma source components of the Gangdese bathoilth. These are (1) a depleted mantle [$\varepsilon_{Hf}(T)\approx +20$; $\delta^{18}O\approx +4.6$], representing the depleted mantle wedge of the Gangdese arc magma system; (2) an enriched mantle [$\varepsilon_{Hf}(T)\approx +8$, yielding crustal model age of ~600 Ma; $\delta^{18}O\approx +5.5$], resulting from subduction zone enrichment; (3) an old continental crust [$\varepsilon_{Hf}(T) < -5$; $\delta^{18}O$: up to +8.5], only in the Paleogene stage owing to the sediment subduction; and (4) a new component revealed in the Cretaceous and Paleogene stages that has high Hf and O isotope ratios [$\varepsilon_{Hf}(T)\approx +13$, yielding crustal model age of ~350 Ma; $\delta^{18}O$: up to +7.5]. The forth component, marked particularly with its high O isotope ratio, is interpreted to be derived from hydrothermally altered Neo-Tethyan oceanic crust and/or subducted arc-derived sediments.

Dynamic carbon cycle in the Ediacaran Yangtze Basin

XUELEI CHU[1]*

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China (*correspondence: xlchu@mail.iggcas.ac.cn)

Extraordinarily large fluctuation in the Neoproterozoic carbon isotope records implies strong perturbations of global carbon cycle. Rothman *et al*. [1] proposed a two-box dynamic model with intertwined pools of inorganic carbon (IC) and dissolved organic carbon (DOC) to explan the unusual carbon isotope excursions and their link to the early animal evolution. Decoupled carbon isotopes of sedimentary carbonate and organic carbon from the fossil-rich Doushantuo Formation (635–551 Ma) in the Yangtze area of South China may be explained by this dynamic model.

The Doushantuo Formation in the Yangtze area is divided into four lithostratigraphic members up section. Member I of ~6 m cap dolostone was the fast deposition in a nonsteady-state carbon cycle during the aftermath of Marinoan glaciation, which explains the irregular track of ε (isotope fractionation between carbonate and organic carbon) vs. $\delta^{13}C_{carb}$ plot. At member II of ~70 m with alternated organic-rich shale and dolostone, stable $\delta^{13}C_{org}$ values and $\delta^{13}C_{carb}$ fluctuations over 10‰ suggest a large DOC reservoir in the depth of the Yangtze basin during the earlier Ediacaran [2]. Bristow & Kennedy [3] and Jiang *et al*. [4] disagreed a large DOC reservoir on global scale. However, a large DOC pool is enough to influence the overlying IC reservoir in basin in a redox-stratified ocean [5]. The intercept of $\delta^{13}C_{carb}$ axis (-30.5‰) suggests that most DOC should be derived from the degradation of photoautotrophs. After the osciliation of sea-level at member III of ~70 m dolostone with imbedded chert and alternating limestone-dolostone, stable $\delta^{13}C_{org}$ values and variable $\delta^{13}C_{carb}$ values (~5‰) occurred in overlying 10~20-m-thick black shale (member IV) suggesting a still existing DOC reservoir in the deep water. Furthermore, an intercept of -40‰ indicates a large amount of DOC should be mostly derived from the degradation of heterotrophic organisms.

A comprehensive separation procedure for precise determination of Re, Ir, Ru, Pt and Pd in geological samples

Z.-Y. CHU[1]*, R. J. WALKER[2], J.-H. GUO[1], Y. YAN[1], Y.-H. YANG[1] AND Y.-B. ZHANG[1]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China, (*correspondence: zhychu@mail.igcas.ac.cn)

[2] Department of Geology, University of Maryland, College Park, MD 20742, USA

It is difficult to precisely determine Re, Ir, Ru, Pt and Pd in geological samples due to the low abundance of these elements. Moreover, the potential polyatomic interferences on Ru, ZrO interferences on Pd, and HfO interferences on Ir and Pt, make precise determination of these elements more challenging. In this study, we have developed a comprehensive method for separation of Re, Ir, Ru, Pt and Pd in geological samples based on anion exchange method, in order to realize reliable isotope dilution (ID) analyses of these elements.

The Re, Ir, Ru, Pt and Pd are firstly group-separated in Re-Ru, Ir-Pt and Pd by using 2 mL Biorad AG 1 X 8 (100-200 mesh) anion exchange columns. Subsequently, the Re-Ru is further purified using 0.25 mL Biorad AG1 X 8 (100-200 mesh) anion exchange columns. The Ru can also be further purified via a microdistillation method by using 50 μL of CrO_3-H_2SO_4 solution as an oxidant. The Ir-Pt and Pd are further purified using Eichrom-LN columns to completely remove potential HfO and ZrO interferences, respectively.

After this comprehensive separation procedure, the Re, Ru, Ir, Pt and Pd can be precisely measured by ID-MC-ICP-MS. The Ru further purified by microdistillation method can also be measured by ID-NTIMS method.

Finally, the USGS reference materials BHVO-2, BCR-2, BIR-1a and DNC-1 are measured and the analytical results of Re, Ir, Ru, Pt and Pd are in good agreement with the published values.

Thermodynamic potentials of Au-Hg binary solid solution

K.V. CHUDNENKO[1]* AND G.A. PAL'YANOVA[2]

[1]Vinogradov Institute of Geochemistry, SB RAS, Irkutsk, Russia (*correspondence: chud@igc.irk.ru)

[2]Sobolev IGM, SB RAS, Novosibirsk, Russia

Standard thermodynamic functions ($\Delta_f G^0$, S^0) of $Au_{1-x}Hg_x$ ($0 \le x_{Hg} \le 0.2$) solid solution have been calculated using the formalism of Redlich-Kister method [1]:

$$G^{ex} = x_1 x_2 ({}^0L + {}^1L (x_1 - x_2)) \quad (1)$$

Parameters of equation (1) were obtained by regression analysis of the data [2]:

$${}^0L \text{ (J/mol)} = 1500 + 4.05T$$

$${}^1L \text{ (J/mol)} = -7499.99 + 2.15T.$$

The excess entropy of solid solution was evaluated from equation [3]:

$$S^{ex} = -\left(\frac{\partial G^{ex}}{\partial T}\right)_P$$

Excess thermodynamic functions were used to calculate the standard thermodynamic properties of Hg solid solution in (Au) with mercury content 1-20 at. % (Table 1).

Solid solutions	$\Delta_f G^0$, J /mol	S^0, J/(mol•K)
Au0.99Hg0.01	-179	48.177
Au0.98Hg0.02	-319	48.752
Au0.96Hg0.04	-555	49.79
Au0.94Hg0.06	-750	50.745
Au0.92Hg0.08	-916	51.648
Au0.9Hg0.1	-1056	52.513
Au0.88Hg0.12	-1174	53.348
Au0.86Hg0.14	-1272	54.159
Au0.84Hg0.16	-1353	54.949
Au0.82Hg0.18	-1417	55.721
Au0.8Hg0.2	-1466	56.477

Table 1: Standard thermodynamic properties of Au-Hg solid solution

The obtained data can be used in different software packages for developing physicochemical models in natural and technological processes with participation of gold and mercury.

The work was supported by 12 and 48 Integration projects grants of SB RAS.

A contribution from radiogenic isotope study to metal source and timing of gold orogenic deposits: A case of Nezhdaninsky deposit, Yakutia, Russia

A.V. CHUGAEV* I.V. CHERNYSHEV, N.S. BORTNIKOVAND G.N. GAMYANIN

IGEM of Russian Acad.Sci., 35 Staromonetny, Moscow Russia (chug@igem.ru)

The relation of orogenic gold deposits to a magmatic activity is still yet controversial. The U-Pb and Rb-Sr (rock forming minerals) isotope ratio of the intrusive rocks associated with the Nezhdaninky world class gold deposit (NGD) (Au>470 t) hosted by the Permian carbonaceous-clastic sequence was studied [1]. The lamprophyre dikes has the concordant U-Pb zircon age of 121±1 Ma, (ID-TIMS) and the isochron Rb-Sr age of 121.0±2.8 Ma and are temporaly close to the auriferous veins aged at 119.0±4 and 132±12 Ma. The Kurum granodiorites and the Gel'dy stock quartz diorite aged at 94 ± 1 Ma and 92.6±0.8 Ma, respectively, postdate the NGD and were not parts of this mineral system.

A study of 62 galena samples from NGD and several ore occurrences and K-feldspar from intrusive rocks using high-precision (±0.02%) MC-ICP-MS method with $^{205}Tl/^{203}Tl$ normalization [2] showed that the predominant lead component at the NGD was derived from the Permian sedimentary host rocks. The subordinate lead was derived from Early Cretaceous magmatic rocks.

Thus, the NGD rocks formed within a time span of 25-28 Ma. This timing corresponds to two epochs of magmatic activity at the South Verkhoyansk Fold belt. The age of the NGD gold mineralization is not younger than 120 Ma [3]. The Nd-Sr-Pb isotope data on the igneous rocks and auriferous mineralization of the NGD [1, 2] suggest the Early and Late Cretaceous magma sources were formed in the Precambrian crust dated at ~1.8 Ga.

These data suggest the relation of the NGD to the lamprohyre and Early Cretaceous deep-seated crustal magmas and an ivolvement into the hydrothermal system of metals from underlying Permian clastic host rocks.

Surface area characterization of suspended sediment in glacial meltwater using "nano-BET"

P.M. CHUTCHARAVAN[1]*AND S.M. ACIEGO[2]

[1]Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI 48109, USA (*correspondence: petermch@umich.edu)

[2]Department of Earth and Environmental Sciences, University of Michigan, Ann Arbor, MI 48109, USA (aciego@umich.edu)

Suspended load is the greatest source of fluvial sediment flux to the ocean, on the order of 15-20 gigatons of material per year [1] and should have significant implications for global element cycling. However, the degree of element flux to the ocean is not solely dependent on the amount of material transported; the reactibility of the sediment grains must also be considered. Reactibility of sediment is primarily determined by two factors: mineralogical composition and grain surface area. Since surface area is directly related to reacitibility (i.e. more surface area means more sites for a reaction to potentially occur), it is a good overall estimate of element availability for a given sample.

Our study attempts to characterize the reactive surface area of suspended sediments in glacial meltwater. The hydrology of subglacial environments, consists of a complex "plumbing" system of channels that governs the flow of water under a glacier and the overall dissolved elemental flux. However, the surface area of the suspended load from glacial meltwater, and the relationship to subglacial geology and regional climate, remains uncharacterized due to the difficulty of measurements. Surface areas calculated by mineral shape and size underestimate reactive surface area by several orders of magnitude and conventional gas adsorption techniques require at least one gram of sample, often unattainable in the field.

Recent developments [2] have made it possible to measure the BET surface areas of miligram size samples with nano-scale precision. Using this new method, suspended sediment samples from two alpine glacier sites in Canada and Alaska were collected and analyzed. Results will demonstrate how the reactive surface area of suspended glacial sediments changes over the melt season and help provide better constraints for element availability in glacial meltwater.

The influence of frost weathering on the release of readily available ions from granite surfaces

THOMAS CHWALEK[A] NATASCHA TORRES [A], GERHARD FURRER [B] HELMUT BRANDL, BEAT MÜLLER [A] AND PETER C. HAUSER [D]

[a]Swiss Federal Institute for Environmental Science and Technology (EAWAG), CH-6047 Kastanienbaum, Switzerland
[b]Institute of Biogeochemistry and Pollution Dynamics, ETH Zurich, CH-8092 Zurich, Switzerland
[c]Institute of Evolutionary Biology and Environmental Studies, University of Zurich, CH-8057 Zurich, Switzerland
[d]Department of Chemistry, University of Basel, CH-4004 Basel, Switzerland

Hundreds of research studies concerning frost weathering of minerals were conducted during the last century. Regardless of a long history of inquiries, the quantitative insights of frost weathering products are still elusive. Frost weathering is mainly attributed to the increase of surface area without any chemical changes. This study represents the first attempt to evaluate readily available ions released by frost weathering with the use of capillary electrophoresis (CE) and a capacitively coupled contactless conductivity detection (C^4D) detector. An new easy-to-handle sampling technique called "Drop-on-Stone" (DoS) was used to sample rock surface areas. Aare Granite samples undergoing different amounts of freeze-thaw cycles were analyzed for a continuous increase of cations and anions. Particular attention was given to the first weathering steps. Complementary SEM pictures of the sampled areas were taken during the weathering experiments. The results illustrate the initial release of ions during the first few freeze-thaw cycles. This indicates that frost weathering is able to raise surface concentrations of readily soluble cations and anions. These ions serve as the primary nutrient source for organisms and are essential for initial soil formation in arctic and high altitude areas.

Geochemical atlas of Italian soils

D. CICCHELLA[1]* S. ALBANESE[2], E. DINELLI[3], L. GIACCIO[2], A. LIMA[2], P. VALERA[4] AND B. DE VIVO[2]

[1]Dipartimento di Scienze e Tecnologie, Università degli Studi del Sannio. Via dei Mulini 59/A, 82100 Benevento, Italy (* correspondence: cidom@unisannio.it)
[2]Dipartimento di Scienze della Terra, Università di Napoli Federico II. Via Mezzocannone 8, 80134 Napoli, Italy (bdevivo@unina.it)
[3]Dipartimento di Scienze della Terra e Geologico Ambientali, Università di Bologna. Piazza di Porta San Donato 1, 40126 Bologna, Italy (enrico,dinelli@unibo.it)
[4]Dipartimento di Geoingegneria e Tecnologie Ambientali, Università di Cagliari. Piazza d'Armi, 09123, Italy.

The geochemical Italian Atlas was carried out as part of GEMAS project whose objective was to characterize soils of rural areas of the whole Europe. Soil samples were collected at an average sampling density of 1 site per 2500 km^2. Two different sample types were collected: (1) 121 agricultural soils on regularly ploughed land to a depth of 20 cm and (2) 121 grazing land soils (land under permanent grass cover) to a depth of 10 cm. All soil samples were air dried, sieved to <2 mm, homogenised and finally split into 10 sub-samples. Both sample types (Ap and Gr) were analysed at the BGR in Berlin for a suite of 41 elements by WD-XRFS. The same samples were also analysed after AR and MMI extractions by a combination of ICP-AES and ICP-MS for 53 elements. In addition, other parameters were determined: pH, TOC, total carbon and total sulphur, LOI, CEC, Sr-isotopes, Pb-isotopes, MIR-spectra. By means of a GIS software, georeferenced data of the Italian territory were used to produce the geochemical maps of all the analysed elements for both agricultural and grazing land soils. Specifically, for each element and sampling media a map reporting interpolated data and graduated dots was produced; univariate statistics and graphs were also associated to each map. The Atlas also contain: 5 maps for regional variability of factor scores of elemental associations resulting from R-mode factor analysis and 15 land use maps for some selected elements (As, Be, Cd, Co, Cr, Cu, Hg, Ni, Pb, Sb, Se, Sn, Tl, V, Zn) following the intervention criteria established by Italian Law (D.L. 152/06).

Behaviour of mineral phases during combustion of coal waste dumps – experimental study

JUSTYNA CIESIELCZUK[1]

[1]University of Silesia, Będzińska 60, 41-200 Sosnowiec, Poland; (justyna.ciesielczuk@us.edu.pl)

Coal waste dumps can be affected by self-heating and self-combustion processes and became an environmental problem. These processes are widely investigated, but as every coal waste dump is unique and the factors which influence and modify the processes are so numerous, it is hard to predict the behaviour of deposited wastes in any individual case. The aim of the experiment was to reduce the number of influencing factors by heating, in an oven, samples of known mineral composition under known conditions. Samples were heated at 960ºC under oxidizing conditions for 74 hours in a pipe furnace (PRC 65M, Czylok). One sample (20W) comprised 53% coal, 24% kaolinite, 21% illite/muscovite and 3% quartz. A second sample (20B) contained 11% coal, 29% kaolinite, 22% illite/muscovite, 28% quartz, 2% feldspars and 1% siderite. Each sample was mixed 1:1 with siderite (containing 76% of the mineral siderite) and pyrite (containing 79% of the mineral pyrite).

After the experiment, sample 20W was more intensely cracked than 20B, less compact but homogeneous. The presence of siderite or pyrite made 20W more compact while burning, limiting oxygen access. Besides layers of varying hematite- and magnesioferrite contents were formed.

After heating, 20B contained half of the quartz originally present and 20W one third. There was also less quartz in samples mixed with pyrite than with siderite.

Twice as much mullite was produced in sample 20W than in 20B, although both primary samples contained similar amounts of clay minerals. Additionally, euhedral mullite needles formed only in 20W.

A small amount of diopside was produced in 20B samples mixed with pyrite or siderite. Much more diopside was produced in 20W with pyrite or siderite. There was no diopside in the original 20B and 20W samples.

The presence of coal matter accelerates changes in coexisting mineral phases. As it burns during the first stage of fire, coal matter provides moisture and the space for newly-formed mineral phases.

Preliminary data on the trace elements concentration in Moldova Nouă porphyry copper deposit (Romania)

CIOACĂ MIHAELA ELENA[1] MUNTEANU MARIAN[1], QI LIANG[2], COSTIN GELU[3] AND COSTEA CONSTANTIN[1]

[1]Geological Institute of Romania, Bucharest, Romania. (*mihaela.cioaca@igr.ro);

[2] Institute of Geochemistry, Chinese Academy of Sciences, Guiyang China;

[3]Rhodes University, Grahamstown, South Africa

Moldova Nouă porphyry Cu ore deposit is associated with the Suvorov quartz dioritic intrusion from Banat Mts (Romania). The copper mineralization esentially consists of chalcopyrite, pyrite ± magnetite, molybdenite, bornite and enargite as impregnations in intensely sericitized rocks. Trace elements (Au, Ag, Mo, Re, Te, In, Ge, PGE) from bulk rock samples in the porphyry type mineralization were analyzed using ICP-MS method. The results indicate mean values of 0.35 ppm Au, 0.29 ppm Ag, 52 ppm Mo, 0.26 ppm Re, 36.23 ppm Te, 0.11 ppm In, 1.43 ppm Ge, 4.18 ppm Se, 2.32 ppm Bi and ppm As 175. PGE shows very low values (~2 ppb in total). EMPA analyses show notable concentrations of Au in enargite, tennantite and pyrite (100-1300 ppm), Ag in covellite, enargite, tennantite, chalcopyrite (100-1300 ppm) and galena (1600-3000 ppm), Se in tennantite and enargite (300-2200 ppm), galena (800-4000 ppm) and in covellite, chalcopyrite and sphalerite (20-400 ppm), Bi in all sulfides (700-1000 ppm). Ge and In have been detected in some samples of chalcopyrite, galena and sphalerite.

U-bearing hematite: A tool for dating Iron Oxide Copper Gold systems?

C.L. CIOBANU[1]*, B.P. WADE[2], N.J. COOK[1], D. GILES[1], A. SCHMIDT-MUMM[1] AND J. CLEVERLEY[3]

[1] Deep Exploration Technologies Cooperative Research Centre, The University of Adelaide, Adelaide, SA 5005, Australia (*correspondence: cristiana.ciobanu@adelaide.edu.au, nigel.cook@adelaide.edu.au, david.giles@ adelaide.edu.au, asmumm@gmail.com)

[2]Adelaide Microscopy, The University of Adelaide, Adelaide, SA 5005, Australia (benjamin.wade@adelaide.edu.au)

[3]CSIRO Earth Science & Resource Engineering, 6102 WA, Australia (james.cleverley@csiro.au)

Hematite, the most abundant mineral in Iron Oxide Copper Gold (IOCG) deposits in the Gawler Craton of South Australia, may incorporate significant amounts of U, W, Mo and radiogenic Pb. These elements are concentrated in hematite grains which display either oscillatory and/or sectorial compositional zoning, or are porous. The presence of U and Pb raises the potential for novel geochronology applications aimed at constraining the timing of mineralization.

Meaningful preliminary age data were obtained for U-bearing hematite by LA-ICP-MS techniques on zoned grains. In the absence of suitable, matrix-matched standards, GJ-1 zircon was used as the primary standard. $^{207}Pb/^{206}Pb$ ages obtained on the zoned hematite (1590±7, 1583±3 Ma; Fig. 1) are statistically indistinguishable from ages for emplacement of the Gawler Range Volcanics and associated Hiltaba Intrusive Suite, and consistent with a major ore-forming event in the region at ~1.59 Ga.

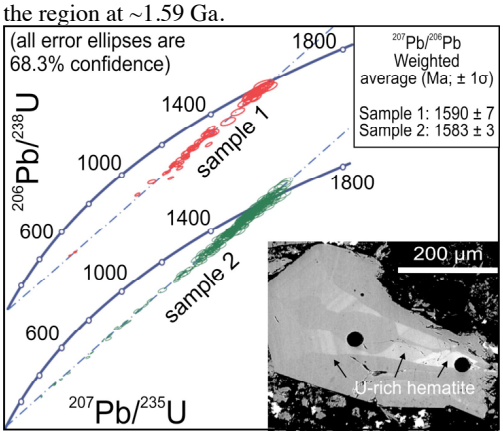

Fig. 1 U/Pb Concordia plots for dated U-hematite. All lower intercepts are at zero. BSE image shows typical zoning in dated grains.

Provided that matrix-associated mass fractionation can be constrained, and suitable standards are fabricated, the ability to date an abundant refractory mineral like hematite could represent a valuable tool for dating IOCG deposits and, potentially, other iron-bearing ores.

Subseafloor biosphere of the Canterbury basin

M.C. CIOBANU[1] G. BURGAUD[2], A. DUFRESNE[3], A. BREUKER[4] V. REDOU[2], S. BEN MAAMAR[1], F. GABOYER[1] O. VANDENABEELE-TRAMBOUZE[1] J.S. LIPP[5], A. SCHIPPERS[4] P. VANDENKOORNHUYSE[3], G. BARBIER[2] M. JEBBAR[1] A., GODFROY[1] AND K. ALAIN[1]*

[4]BGR, Hannover, Germany

[5]MARUM, University of Bremen, Bremen, Germany

The subseafloor microbiota is diverse and complex, hosting metabolically active communities down to depths of more than 1000 meters below the seafloor (mbsf), as revealed by molecular and metagenomic studies. It harbors representatives from the three domains of life, i.e., numerous endemic and/or as yet uncultured *Archaea* and *Bacteria*, in addition to bacterial endospores, protists and fungi belonging to *Eukarya*. Although background molecular data on bacterial and archaeal lineages inhabiting subsurface sediment above 1000 mbsf exists, most deep-subsurface microorganisms detected so far were refractory to cultivation. Deeply buried microorganisms form an almost untapped diversity, as sub-sea-floor prokaryotic culturability in most studies is less than 0.1% of all microscopically detected cells. So far, active prokaryotes have been discovered down to 1626 mbsf, and microeukaryotes down to 113 mbsf, but the lower limit of the deep subsurface biosphere remains elusive.

Here we report on the microbial prokaryotic and eukaryotic communities of a core of nearly 2 km collected in the Canterbury basin during IODP Expedition 317. A very stringent high-throughput 454-pyrosequencing approach targeting the 16S/18S rRNA genes for *Bacteria, Archaea* and *Eukarya*, along with real-time PCR analysis (genetic markers and functional genes), cell counts and cultures, were performed to assess microbial abundance, diversity and activity at different depths. Our results suggest that a diversity of microorganisms exists down to 1922 mbsf in the seafloor of the Canterbury basin and that this diversity is to a certain extent alive.

The opening phase of the 2010 summit eruption of Eyjafjallajökull volcano, Iceland: Contributions from morpho-textural and geochemical characterization of tephra

RAFFAELLO CIONI[1] MARCO PISTOLESI[2], LORELLA FRANCALANCI[3] ANTONELLA BERTAGNINI[4] CLAUDIA D'ORIANO[4] AND ELEONORA BRASCHI[5]

[1]Dip. di Scienze Chimiche e Geologiche, Cagliari, Italy; (rcioni@unica.it)

[3]Dip. Scienze della Terra, Università di Firenze, Italy
[4]Istituto Nazionale di Geofisica e Vulcanologia, Pisa, Italy
[5]CNR-IGG, Firenze, Italy

The 2010 summit eruption of Eyjafjallajökull volcano (Iceland) started on 14 April when the eruption melted its way through the ice-filled summit caldera. We focus on the opening phase of the event (first 15-17 hours), which represents a unique opportunity to investigate triggering mechanisms and pre-eruptive dynamics.

Tephra samples were collected from the pristine fallout deposits ~4.5 km east from the crater. On the whole, the juvenile components along the eruptive sequence show a large morphological and textural variability. The peculiarity of the products of the opening phase is the presence of abundant (40 vol.%) blocky, dense, obsidian-like, microlite-poor clasts. These features suggest important quenching effects of the first body intruded at the base of the ice cover immediately before the eruption onset. Major and trace element analyses on groundmass glass of this phase highlight the occurrence of clasts with a larger compositional variability than those of the products from the following phases. Similarly, $^{87}Sr/^{86}Sr$ ratios determined by microdrilling on single ash clasts revealed the presence of groundmass glass with large isotopic variability, ranging from the typical values recorded in Icelandic magma, up to much higher values ($^{87}Sr/^{86}Sr = 0.70668$), never found in Icelandic volcanics. Conversely, plagioclase crystals from the same phase of activity have low $^{87}Sr/^{86}Sr$ values. These compositional and isotopic data suggest that the very first erupted magma assimilated hydrothermally altered volcanic/epiclastic rocks with high Sr isotopic ratio, possibly in the immediately pre-eruptive phase. The results confirm the importance of studying the products of the opening phases of explosive eruptions in order to get a complete understanding of pre-eruptive conditions.

Zircon U-Pb ages and $\delta^{18}O$ in a 'contaminated' lower crustal metagabbro (Serre Massif, Calabria)

R. CIRRINCIONE[1], P. FIANNACCA[1]* AND I.S. WILLIAMS[2]

[1]Department of Biological, Geological and Environmental Sciences, University of Catania
(*correspondence: pfianna@unict.it)
[2]Research School of Earth Sciences, Australian National University

Previous dating of granulitic metagabbros from the base of a near-complete cross-section of Variscan continental crust exposed in southern Calabria has provided reliable ages of ~300-290 Ma for the late Variscan metamorphism, but less convincing ages of ~593-564 Ma for the original mafic magmatism [1,2,3]. Zircon extracted from a basal metagabbro to determine the age and nature of deep crustal magmatism has two main forms: moderately luminescent, weakly zoned overgrowths or whole grains with no core, and cores surrounded by an overgrowth. 53 SHRIMP U-Pb dates have a wide range from ~3.2 Ga to ~270 Ma. 35 cores are older than ~330 Ma, with weak clusters at 720±40, 620±35 and 560±25 Ma. The largest cluster, at 455±9 Ma (6 cores), is the youngest possibly pre-metamorphic group. Overgrowths and coreless grains (Th/U <0.3) all have dates ≤330 Ma, giving ~313 Ma as the maximum age for the youngest thermal event that produced zircon growth or recrystallization. All this zircon has high $\delta^{18}O$ (9.3–10.6‰), indicating crystallization in the presence of sediment related fluids. Several cores in the 330-500 Ma range have the same features. Older cores have lower $\delta^{18}O$ (6.1-9.2‰), but only three are <7.5‰. There is no preserved evidence for any zircon in the metagabbro being primary zircon crystallized from a mantle-derived magma. Instead, the oxygen isotopes have a strong sediment signature, consistent with the large amount of detrital zircon in the rock. Either the metagabbro is dominantly of metasedimentary origin, or prolonged granulitic evolution of a sediment-'contaminated' mafic magma in the deep crust has largely modified the zircon $\delta^{18}O$ and some U-Pb dates, making it hard to determine the gabbro emplacement age. If the 455±9 Ma zircon is detrital, however, the gabbro magmatism must be younger. These inferences now need to be tested using trace element and isotopic analyses of zircon and other minerals from the metagabbro and associated rocks.

Eoarchaean crust in the Dniestr-Bug region, Ukrainian Shield – Pb-Hf-O isotope constraints

S. CLAESSON[1]* L. SHUMLYANSKYY[1,2], E. BIBIKOVA[3] K. BILLSTRÖM[1] , M. WHITEHOUSE[1] AND T. ANDERSEN[4]

[1] Swedish Museum of Natural History, Stockholm, Sweden (*correspondence: stefan.claesson@nrm.se)
[2] Institute of Geochemistry, Mineralogy and Ore Formation, Kyiv, Ukraine
[3] Vernadsky Institute of Geochemistry & Analytical Chemistry RAS, Moscow, Russia
[4] Dept of Geosciences, University of Oslo, Norway

In the Ukrainian shield, enderbites of the Dniester-Bug Series contain zircons as old as c. 3.75 Ga with initial Hf isotope ratios indicating their derivation from mildly depleted sources. Most Dniester-Bug rocks are strongly tectonized and metamorphosed. We present here new U-Pb, Hf and O isotope results for zircon separated from enderbite, a supracrustal garnet-mica schist, and an assumedly clastic quartz-rich rock enclosed in enderbite.

Zircon from all these rocks yields variably discordant U-Pb ages up to c. 3.75 Ga. Hf isotope compositions for the oldest zircons indicate these crystallized from magmas with chondritic to slightly depleted isotope signatures at c. 3.75 Ga. The majority of zircons with younger U-Pb ages also appear to be ultimately derived from similar crustal sources. This supports that there was an important period of formation of continental crust at c. 3.75 Ga

$\delta^{18}O$(Zrc) for two enderbites range from mantle values to slightly more evolved compositions. $\delta^{18}O$(Zrc) up to 7.2‰ for the garnet-mica schist indicates this includes materials which in parts are derived from more evolved sources. $\delta^{18}O$(Zrc) for the quartz-rich rock stands out, with a few analyses as low as 7‰ or less, but the majority in the range 8-10‰. Few Archaean zircon crystals with such high $\delta^{18}O$(Zrc) values have been reported previously.

If the quartz-rich rock originally is a clastic sediment and the zircon has preserved its magmatic $\delta^{18}O$ signature, most of the source rocks had evolved O isotopic compositions. Secondary alteration of O in clastic zircon may also be a possibility. Alternatively, the quartz-rich rock may be heavily metasomatized enderbite and the O isotope composition of the zircons altered in a process which at the same time not has erased the original Hf isotope signature.

Clues to atmospheric evolution in Earth's ancient sediments

M.W. CLAIRE[1]

[1]Department of Earth and Environmental Sciences, University of St Andrews, St Andrews, Fife, KY16 9AL, Scotland, UK (m.claire@uea.ac.uk)

Sulfur isotopes are fractionated in a mass-anomalous fashion when SO_2 gas is subjected to ultraviolet light. Amazingly, the subtle fractionations (MIF-S) resulting from this process are preserved in sedimentary rocks of Archean age, but are absent in younger rocks. The MIF-S data provides direct constraints on the composition of the ancient atmosphere, and have been described as the "smoking gun" for an anoxic Archean atmosphere. In the thirteen years since their initial discovery (Farquhar *et al*. 2000), the database of Archean MIF-S has grown to include detailed temporal (and stratigraphic-level) changes in both sign and magnitude of $\Delta^{33}S$ and $\Delta^{36}S$, although our theoretical understanding hasn't advanced much beyond the notion of a 1ppm threshold concentration of atmospheric oxygen (Pavlov and Kasting, 2002). I will summarize my recent numerical modeling efforts made in conjunction with new geochemical data (Zerkle *et al*., 2012 ; Kurzweil *et al*., 2013 ; Claire *et al*., 2013), which reveal how MIF-S might constrain atmospheric methane levels, the presence of an organic haze, the widespread radiation of oxygenic photosynthesis, and changes in the redox-state of the atmosphere/hydrosphere/ geosphere prior to the Great Oxidation Event.

Anthropogenic radionuclides (RN) are generated by a wide range of industrial, medical and military activities. In a context of storage in deep geological formations or after their release in terrestrial environnements by accidents, it is of paramount importance to quantify their mobility, which is partly ruled by their interaction with the solid surfaces. Usually, experiments are conducted using radiotracers at various scale from laboratory to the field in order to measure retention and retardation parameters. Although this kind of experiment is fundamental to tackle this issue, understanding the natural speciation of stable isotopes as chemical homologues to RN brings useful additional information. In particular, it sheds light on RN isotopic exchange and "irreversible" trapping mechanisms. This approach has already been used successfully to gain a better comprehension of iodine fate in the far-field of geological disposals (Claret *et al*., 2010), which was debated in the litterature, due to conflicting experimental results (from no retardation to significant retardation, depending on the study). By careful quantification of iodine reservoirs in the Callovian-Oxfordian clay rock , it was possible to provide new insights into this aspect of the iodine problem. The relevance of such approach for Sr (Lerouge *et al*., 2010), Se and Ni, three elements with contrasted chemical beaviours and of interest for radwaste storage will be discussed based on new experimental results.

Interfacial chemistry viewed through the lens of network analysis

A. E. CLARK*[1] A. OZKANLAR[2] AND M. KELLEY[3]

Department of Chemistry, Washington State University
([1]a uclark@wsu.edu)
[2] (abdullah.ozkanlar@wsu.edu)
[3] (m.kelly@wsu.edu)

In prior work we have utilized a combination of density functional theory, classical molecular dynamics, and time-resolved laser-induced fluorescence to probe the surface sorption of trivalent lanthanides to various silicate minerals.[1-3] Those studies illustrated the utility and predictive capability of DFT and MD to obtain accurate bulk observable properties and average molecular scale speciation. However, interrogation of interfacial dynamics and time-dependent correlations between surface organization and reactivity have proven more difficult to quantify. Toward this end, we have recently demonstrated that the hydrogen bond network of water has many similarities to the complex and distributed networks found in computer science, and is thus amenable to new types of network information analyses that include degree distributions, network neighborhoods, and geodesic pathways.[4 – 7] Structural motifs can be elucidated within the network. The distribution of defect states and their evolution in time, in addition to a network entropy of the fluid can be also determined. Finally, hydrogen bond dynamics at the molecular and intermediate length scales (1-100's of Å) are readily quantified. In this work we re-analyze our prior MD studies of trivalent sorption to quartz through the lens of modern network analysis methods, deriving new insight into the role that interfacial organization and hydrogen bond dynamics has upon interfacial reactivity.

Garnet, zircon and monazite as monitors of high-temperature metamorphic events: How useful are they?

CHRIS CLARK[1]*

[1]Applied Geology, Curtin University, Perth, WA, Australia (*correspondence: c.clark@curtin.edu.au)

Value adding to the temporal information retrieved from the analysis of geochronometers, such as zircon and monazite, through the collection of rare-earth (REE) and trace element datasets and attempts to integrate their growth with thermodynamic datasets is a field that is rapidly evolving. This information when coupled with REE analyses of silicate minerals such as garnet, orthopyroxene and feldspar allows inferences to be made about the rates of heating, cooling and exhumation as well as the timing of partial melting experienced by rocks during orogenic cycles. Advances in anlytical capabilities (e.g. laser split streaming) now allow large datasets to be collected across entire terranes enabling age-mapping of orogens to be undertaken. However, in high-temperature metapelites that seem to have all the right ingredients for these processes to be constrained (e.g. they contain garnet, zircon, monazite and rutile, they've melted and experienced temperatures in excess of 900 °C) variations in the REE partitioning between zircon and garnet varies over the length-scale of a single thin section. This presentation seeks to highlight some complexities in the application of these undoublty useful techniques to high-temperature metamorphic rocks from a number of terranes and hopefully provide some useful comments on developing more effiecnet strategies to characterise the *P–T–t* evolution of high-grade terranes.

Combustion aerosol over marine stratus: Long range transport, subsidence and aerosol-cloud interactions over the South East Pacific

A. CLARKE[1]* S. FREITAG[1], J. SNIDER[2] J. KAZIL[3,4], G. FEINGOLD[4] R. BLOT[1] T. CAMPOS[5] AND V. BREKHOVSKIKH[1]

[1]University of Hawaii, Honolulu, HI, USA (*correspondence: tclarke@soest.hawaii.edu)
[2]*University of Wyoming, Laramie, WY, USA*
[3]CIRES, University of Colorado, Boulder, CO, USA
[4]NOAA, Earth System Res. Lab., Boulder, CO, USA
[5]NCAR, Boulder, CO, USA

The worlds largest stratus deck over the South East Pacific (SEP) was a study target for the VOCALS (http://www.eol.ucar.edu/projects/vocals/) experiment in October 2008. Aerosol-cloud interactions were one major goal of the 14 flights of the NCAR C-130 aircraft reported here. Each flight covered about a 1000 km range with multiple profiles and legs below, in and above the Sc deck.

Strong aerosol sources along the coast of Chile were expected and found to influence cloud condensation nuclei (CCN) in coastal clouds. However; "rivers" of elevated CO, black carbon (BC) associated with combustion aerosol effective as CCN at <0.3%S were also common in subsiding FT. These often lay above the extensive Sc deck for over 1000km offshore and included aerosol from sources over the western Pacific as well as South America. When present above cloud, this combustion aerosol increased available CCN and decreased effective radius compared to clouds in "clean" MBL air advected from the South Pacific. Observed aerosol entrainment appeared linked to turbulence localized near cloud that significantly exceeded mean estimated entrainment rates. Surface derived sea-spray aerosol (Dp>40nm) only accounted for about 20% of MBL CCN.

Pockets of Open Cell (POC) convection were consistently found in air with CO values lower than adjacent cloudy regions and similar to values over the remote South Pacific. As CO is not depleted by clouds or precipitation this suggests POC's are favored to form in clean SP air not impacted by entrained combustion aerosol. Preliminary LES model results indicate that such entrainment may help buffer MBL clouds against depletion of CCN by drizzle. The latter would delay transition of closed cell to open cell convection, potentially leading to increased lifetimes of Sc clouds. One case of entrainment of a strong "river" of pollution appears to have led to a transition from POC's back to a cloudy MBL.

Late Cretaceous sub-tropical Pacific Ocean clumped-isotope palaeothermometry

L.J. CLARKE[1]* I. MILLÁN[2] AND S.M. BERNASCONI[2]

[1]Division of Chemistry and Environmental Science, School of Science and the Environment, Manchester Metropolitan University, Manchester, M1 5GD, U.K. (*correspondence: l.clarke@mmu.ac.uk)

[2]Geologisches Institut, ETH, 8092 Zurich, Switzerland. (isabel.millan@erdw.ethz.ch), (stefano.bernasconi@erdw.ethz.ch)

Carbonate clumped-isotope palaeothermometry data are presented for the <38 micron coccolithophore-bearing fraction of Late Cretaceous (Campanian to Maastrichtian) sediments recovered from Shatsky Rise Ocean Drilling Program Site 1210, presently situated in the northwest Pacific Ocean. The predominantly coccolithophore composition of the sediments enables reconstruction of photic zone surface-ocean palaeotemperatures. Site 1210 occupied a sub-tropical palaeolatitude in the Pacific Ocean during the Late Cretaceous that resulted in relatively high sedimentation rates for an open-marine setting. Site 1210 Late Cretaceous sediments comprise nannofossil ooze that has not undergone sufficient sub-seafloor diagenesis to cause lithification and conversion into chalk or limestone, making these sediment cores ideally suited for novel application of clumped-isotope palaeothermometry. Clumped-isotope data were generated using the ETH automated mass spectrometry method of Schmid and Bernasconi [1].

The novel clumped-isotope dataset is discussed in terms of a number of critical palaeoceanographic objectives and interpretations: 1) determination of absolute Late Cretaceous sub-tropical Pacific Ocean palaeotemperatures and associated reconstruction of latitudinal palaeotemperature gradients, both via comparison to other published palaeotemperature data; 2) assessment of whether an orbital-forcing control on the sub-tropical surface ocean is evident within the clumped-isotope palaeotemperature record; and 3) use of clumped-isotope palaeotemperatures in combination with conventional $\delta^{18}O$ values in order to deconvolute a temporal seawater oxygen-isotope composition record, specifically to test the hypothesised occurrence of cryosphere development, and associated glacioeustatic sea-level change, proximal to the Campanian to Maastrichtian stage boundary.

Ocean redox dynamics during the end-Permian extinction and Early Triassic recovery

MATTHEW O. CLARKSON[1] SIMON W. POULTON[2], RACHEL A. WOOD[1] AND SYLVAIN RICHOZ[3]

[1]School of GeoSc., Univ. of Edinburgh, EH3 9JW, UK (*correspondence: M.O.Clarkson@ed.ac.uk)

[2]School of Earth & Env., Univ. of Leeds. LS2 9JT, UK

[3]Austrian Ac. Of Sc., c/o Univ. Graz, 26 8010, Austria

The Permian Triassic mass extinction is widely regarded as the most severe of the Phanerozoic extinctions. The event was associated with major carbon cycle disruption, not only at the Permian Triassic Boundary (PTB) but also for the entire Early Triassic. These disturbances are recorded in the $\delta^{13}C$ record of both carbonate and organic carbon, which show a series of positive and negative carbon isotope excursions (CIEs) throughout the Eary Triassic. These fluctuations are also linked to minor extinctions in the Early Triassic and a delay in total species recovery until the Middle Triassic. One leading hypothesis invoked to explain these changes is oceanic anoxia, which provides a kill mechanism that is also potentially linked to observed changes in the carbon isotope record. Multiple anoxic events have indeed been identified in various sections around the world. However the link between the globally recorded CIEs and the development of anoxia is not clear, with no consistent relationship emerging.

Here we present a new record of anoxia from the Arabian platform using Fe-S-C systematics. This mixed sequence of continental margin carbonates and clastics records a shelf to basin transect for the PTB and Early Triassic, which demonstrates the distinct CIEs mentioned above. The use of Fe-speciation in tandem with carbon isotopes places the local record of anoxia in a global context, thus helping elucidate the timing, development and stability of anoxia.

Initial data show sustained anoxic, non-sulphidic (ferruginous) conditions across the PTB for both slope and basin settings. Subsequently anoxia appears restricted to the positive CIEs. Here, non-sulphidic conditions were again dominant, which is in contrast to a growing body of evidence indicating euxinic conditions for the PTB. S-isotope systematics provide further insight into controls on the observed environmental conditions at this time. Together, our approach provides a detailed examination of ocean redox variability during this interval of extreme environmental disturbance, thus enabling a greater understanding of C-cycle feedbacks and biological consequences.

Halogen (Cl, Br and I) inventory of the primitive meteorites

P.L.CLAY R. BURGESS H. BUSEMANN L. RUZIÉ. B. JOACHIM AND C.J. BALLENTINE

The University of Manchester, SEAES, Oxford Rd., Manchester, UK, M13 9PL

The halogens (Cl, Br and I) are sensitive tracers of planetary processing (e.g., melting, differentiation, crust formation, etc.) due to their low abundance and incompatible nature. In order to further our understanding of the halogens response to these crucial aspects of planetary formation, extending our baseline knowledge of their concentration and distribution in the materials that accreted to form the planets (and planetesimals) is essential. The relative scarcity of halogen measurements, particularly Br and I, in the literature attests to the ultra low abundance of these elements in the primitive meteorites and thus their lack of suitability for measurement by traditional ion-and micro-probe techniques.

A systematic study of the halogens in the primitive meteorites (carbonaceous, ordinary and enstatite chondrites) was undertaken to extend the existing halogen database. Chlorine, Br and I were extracted from IR laser stepped-heating of 0.25 to 3.3 mg of neutron-irradiated samples and measured by noble gas mass spectrometry using the noble gas proxy isotopes $^{38}Ar_{Cl}$/Cl, $^{80}Kr_{Br}$/Br and $^{128}Xe_{I}$/I. The results of carbonaceous (CV), ordinary (H, L and LL) and enstatite chondrites (EH and EL) are given here. The ordinary chondrites have variable halogen concentrations (5–600 ppm Cl, 1–1650 ppb Br and 2–390 ppb I) and very low molar I/Cl (~10^{-6}) and Br/Cl (~10^{-4}) ratios, comparable to those measured in some terrestrial hydrothermal fluids [1]. The EH chondrites are overall the most *consistently* enriched in halogens (65–330 ppm Cl, 610–2290 ppb Br and 140–180 ppb I) and show near constant I concentration, regardless of petrologic type. The EL6 Daniel's Kuil is depleted in halogens (25 ppm Cl, 60 ppb Br and 9 ppb I), which could be due to loss during metamorphism on the EL parent body. Two of three Antarctic meteorite analyses (MIL 07139; EH3) show an extreme enrichment in halogens (e.g., 6700 ppb Br); this is likely a surface phenomenon related to terrestrial weathering [2] and are therefore not included in the above ranges. Forthcoming results from CI, CM and CR chondrites, as well as extension to other petrologic types for the above groups, will further elucidate the distribution of halogens in the most primitive solar sytem materials.

Li and Sr constraints on biogeochemical processes in a tropical andesitic watershed

CLERGUE C.[1,2]*, DESSERT C.[1,2], BUSS H.[3], DELLINGER M.[1], CRISPI O.[2], ROUSTEAU A.[4]GAILLARDET J.[1] AND BENEDETTI M.F.[2]

[1]Institut de Physique du Globe de Paris, UMR 7154, Université Paris Diderot (*correspondence:clergue@ipgp.fr)

[2] Observatoire de volcanologie et de sismologie de Guadeloupe et Observatoire de l'érosion aux Antilles, Institut de Physique du Globe de Paris

[3]School of Earth Sciences, Univ. of Bristol, Bristol BS8 1RJ, UK

[4]Laboratoire de biologie et physiologie végétale, Université Antilles Guyane

In this study, we analysed Sr and Li concentrations and isotopic compositions in the surface reservoirs (soils, rocks, plants, stream and rain waters) of a small forested andesitic watershed located in the tropical rain forest of Guadeloupe. Sr is used to identify the sources contributing to soil genesis and Li is good tool to describe weathering dynamic.

Our results show that the $^{87}Sr/^{86}Sr$ ratio of unweathered andesite is 0.704. Previous studies have shown that deposition of Saharan dusts with signature around 0.717 occurs in the Carribean. Most of soil samples Sr isotopes ratios (between 0.7086 and 0.7155) are intermediate between rainfall (0.710) and Saharan dust endmembers. That reveals the significant contribution of atmospheric deposition to soil composition and confirms previous study done in Puerto Rico (Pett-Ridge *et al*., 2009).

The δ^7Li signature of unweathered andesite and Montserrat dusts is around 4.5‰. Because of its origin, Saharan dust signature can be estimated around 1‰. In the soil, δ^7Li signature decreases from 3.0‰ to -10.5‰ between 0 and 1250cm. Many studies have shown that during chemical weathering Li isotopes are fractionated as ^6Li is preferentially retained in solid secondary phases whereas dissolved fraction are enriched in ^7Li. Here the decrease of δ^7Li reflects the increase of weathering intensity with depth.

In this tropical Caribbean context, with very thick and cation poor soil, Saharan minerals have strong impact on soil genesis. Because of thick saprolite layer, vegetation is isolated from primary minerals and those atmospheric inputs might constitute a significant nutrient supply for vegetation growth.

$^{16}O^{1}H$ signal as an indication of metamict O-contamination in zircon

J. CLIFF[1]*, R.T. PIDGEON[2] AND A.A. NEMCHIN[2]

[1]Centre for Microscopy, Characterisation and Analysis, University of Western Australia, Perth Western Australia (*correspondence: john.cliff@uwa.edu.au)

[2]Department of Applied Geology, Curtin Univ., Perth Western Australia

Although zircons are generally considered to be refractory with respect to oxygen isotope signatures, metamiction can make the mineral susceptable to O-isotope exchange. A variety of means are available to indicate metamict conditions, i.e. electron microscopy, common Pb contamination, Raman spectroscopy, α-damage etc., however, these methods may be inconvenient or may in some cases lead to the erroneous conclusion that the zircon is pristine. We introduce here a SIMS based technique that can provide evidence of metamiction and at the same time perform $\delta^{18}O$ analyses—namely the analysis of the $^{16}O^{1}H$ signal. The technique is particulalry well suited to multicollector instruments and can be utilized with little to no decrease in $\delta^{18}O$ precision. In a pilot study using the technique, we found that elevated $^{16}O^{1}H/^{16}O$ relative to a highly crystalline standard (CZ3; $^{16}O^{1}H/^{16}O = 0.00136 \pm 0.00006$; mean ± 1 SD) was correlated with apparent radiation damage and we interpret an increase in this signal to indicate excess H_2O in the mineral. Although $\delta^{18}O$ in these amorphous regions varied from -.7‰ to +8.5‰ (VSMOW; Fig. 1), regions with $^{16}O^{1}H/^{16}O$ values less than 6 SD above the CZ3 mean value were all interpretable as mantle $\delta^{18}O$ values. We found that the magnitude of the $^{16}O^{1}H/^{16}O$ on pristine zircons is dependant upon chamber vacuum and sample degasing and it is unclear if the zircon signal is detectable above background. However, at a given vacuum, four different standards gave statistically indistinguishable $^{16}O^{1}H/^{16}O$ values.

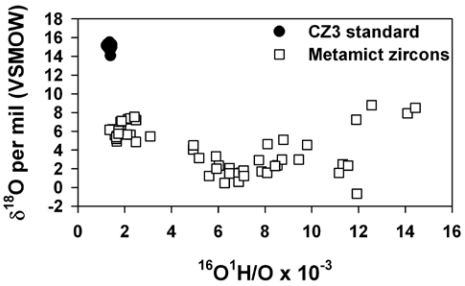

Fig 1. Comparison of $\delta^{18}O$ and $^{16}O^{1}H/O$ in the CZ3 standard and metamict zircons.

Doubly ^{13}C-substituted ethane

MATTHIEU D. CLOG[1]* JOHN M. EILER[1] JARBAS V. P. GUZZO[2] ERICA T. MORAES[2] AND IGOR V.A. SOUZA[2]

[1] Caltech, Pasadena, CA, USA (clog@caltech.edu, eiler@gps.caltech.edu)

[2] Petrobras R&D Center, Cenpes

Most natural gas reservoirs contain significant amounts of ethane (C_2H_6). Here we examine the geochemistry of multiple ^{13}C substitutions in this molecule. Several processes can plausibly influence the abundances of $^{13}C_2H_6$ in natural gases: inheritance from larger biomolecules in source rocks; kinetic fractionations associated with thermal degradation or organic matter; isotope exchange reactions at thermodynamic equilibrium; and/or mixing of gases with different bulk isotopic composition. There is little basis for a priori predictions as to which of these processes will dominate in nature. We present the mass spectrometric techniques for measurement of $^{13}C_2H_6$ at natural abundances, using a high-resolution gas source isotope ratio mass spectrometer (the Thermo 253 Ultra), and explore the chemistry of this species through experiments and initial results on conventional thermogenic natural gases.

The high resolutions of the Ultra (up to 27,000, M/ΔM) allow clean separation of obvious interferences (e.g., O_2 or CH_3OH at m/z=32). Most critically, we are able to discriminate the doubly-substituted isotopologues $^{13}C_2H_6$ from $^{13}C^{12}CDH_5$ at m/z=32. However, we find it is fastest and most precise if we analyse the sum of both singly-subsitiuted isotopologues at m/z=31, $^{13}C^{12}CH_6$ and $^{12}C_2H_5D$, and then calculate $\delta^{13}C$ based on a conventional measurement of δD. We report abundances of $^{13}C_2H_6$ as an enrichment relative to a stochastic reference frame: $\Delta^{13}C_2H_6 = 1000*((^{13}C_2H_6/C_2H_6)/(^{13}C_2H_6/C_2H_6)_{stochastic})-1)$.

Measurements of the $^{13}C_2H_6/^{12}C_2H_6$ ratio are limited by counting statistics down to ±0.15 per mil (1 s.e.). The corresponding precision in $\Delta^{13}C_2H_6$ is +/-0.2 per mil (1 s.e.), when one includes the small additional uncertainties in the 31/30 ratio and conventional δD measurements. Replicate extractions of natural samples are reproducible to better than ±0.5 ‰. Analyses of synthetic gas mixtures confirm that fragmentation/ recombination reactions in the ion source are not a major factor. Preliminary work on ethane from thermogenic gases showed a total range in $\Delta^{13}C_2H_6$ of 4 ‰. The expected range in $\Delta^{13}C_2H_6$ due to thermodynamic equilibrium alone at typical temperatures of natural gas generation and storage is only ~0.2-0.3 ‰. Thus, our results suggest that proportions of $^{13}C_2H_6$ in natural gases are largely controlled by inheritance from organic precursors and/or kinetic isotope effects associated with gas generation. This is an expected result because isotopic exchange of the C-C bond in ethane is likely slow under geological conditions.

Tephra interference during amorphous silica determination - A false environmental signal?

WIM CLYMANS[1]* NATHALIE VAN DER PUTTEN[1], STEFAN WASTEGÅRD[2], SVANTE BJÖRCK[1] AND DANIEL J. CONLEY[1]

[1]Department of Geology, Lund University, Sweden (*correspondence: wim.clymans@geol.lu.se)
[2] Department of Physical Geography and Quaternary Geology, Stockholm University, Sweden

Amorphous silica (ASi) is a widely applied environmental proxy that had ecological and hydrological interpretations. Volcanic eruptions can eject large amounts of igneous material to the atmosphere. The ash-outfall covers the landscape with continuous ash-deposits called tephra. The rapid weathering of tephra results in the formation of short-range ordered minerals (e.g. allophane, imogolite). The dissolution properties of short-range ordered minerals are believed to be similar to those of ASi. Soil and palaeo-environmental scientists have ignored its contribution during measurment. Nevertheless, evaluation of its exact contribution to ASi measurements or examining its dissolution behavior is lacking. We tested if tephra ASi contributes to ASi measurements during alkaline extraction, and how it interferes with sediment and lake records from the southern hemisphere.

We selected 25 well-known tephra covering a representative range of chemical composition, age, spatial provenance and sample type. A well-studied peat core from Kerguelen was used to verify its interactions with other ecological and hydrological proxies. Samples were analyzed for total ASi using the long-term sequential Na_2CO_3 (0.1M) and continuous NaOH (0.5M) method, as such obtaining detailed dissolution curves.

Amorphous Si content extracted from tephra ranged between 0.19 and 2.92 SiO_2 wt%. The extracted amount was independent of age and weakly related to its chemical composition. Detailed dissolution curves provided a distinct signature for pure tephra compared to other ASi fractions.

Palaeo-environmental studies using elevated ASi levels (> 10 SiO_2 wt%) to indicate environmental changes, encounter limited interference problems. However, our study does not exclude that increased diatom productivity could be caused by tephra weathering rather than a change in environmental conditions.

Metal behaviour during differentiation of subducted-related lavas (Hunter Ridge, SW Pacific)

GISELA COBENAS*[1], LEONID DANYUSHEVSKY[1] AND TREVOR FALLOON [1]

[11] CODES,ARC, Centre of Excellence in Ore Deposits, University of Tasmania, Hobart, Australia, gcobenas@utas.edu.au (* presenting author) (l.dan@utas.edu.au) (trevor.falloon@utas.edu.au)

The behaviour of key ore-forming metals during magmatic differentiation of typical island-arc lava suites from the Hunter Ridge (i.e. calc-alkaline and adakites) have been investigated using geochemistry of minerals and glass, petrographic observations, and quantitative geochemical modelling. The Hunter Ridge extends from the southern termination of the Vanuatu Trench to the Koro sea near Fiji. Calc-alkaline rocks record a protracted history of magma evolution from the very earliest stages of fractionation (i.e. before volatile loss) to eruption on the sea floor.

Metal partitioning behaviour in the principal magma components was examined (i.e. for olivine, clinopyroxene, plagioclase, magnetite, and melt). Mineral/melt partition coefficients (Ds) for Cu, Zn, V, Pb, Co and Sc were calculated directly from LA-ICP-MS analyses for phenocryst-groundmass/glass equilibrium pairs. For comparison purposes, modelling was also conducted using D values obtained from literature (where available). This approach allows us to examine, in detail, how magma ascent, crystallisation and degassing can lead either to the enrichment or depletion of ore-forming metals.

Our results provide evidence that i) Cu partitions into a H_2O-rich fluid at crustal levels as soon as volatile saturation occurs, ii) arc magmas are likely to exsolve a magmatic hydrothermal fluid before they are able to segregate an immiscible sulphide liquid, due to their higher oxidation states and volatile contents. Thus, a critical step in forming magmatic/hydrothermal ore deposits is concentrating and removing metals (i.e. Cu) from a magma before saturation of an immiscible sulphide liquid occurs. As Cu is incompatible in any of the early crystallizing silicates and oxides, it's concentration in the melt will progressively increase and it will be available to partition into an aqueous fluid phase. Zn and V are strongly controlled by magnetite fractionation. Co and Sc partition into olivine and clinopyroxene from the early stages of fractionation, and magnetite once it enters the liquidus. Pb behaves incompatibly and is concentrated in the melt during magmatic differentiation.

Phosphorus availability in agricultural soils of Wallonia (Belgium) – A modeling approach

FLORIAN COBERT[1] OLIVIER POURRET[2], MALORIE RENNESON[1] AND GILLES COLINET[1]

[1]Université de Liège, Gembloux Agro-Bio Tech. Unité Systèmes Sol-Eau, 2 passage des déportés. B-5030 Gembloux Belgique, (florian.cobert@ulg.ac.be) ; (gilles.colinet@ulg.ac.be) ; (malorie.renneson@ulg.ac.be)
[2] HydrISI Institut Polytechnique LaSalle Beauvais, 19 rue Pierre Waguet, F-60026 Beauvais Cedex, France, (olivier.pourret@lasalle-beauvais.fr)

A better understanding of Phosphorus (P) behaviour in soil is needed to adapt the ordinary practices of P fertilization to the requirement of reducing agricultural impact on the environment (eutrophication of surface water) without impairing crop yields.

The aim of this study was to identify the chemical parameters that actually govern the modelling of available P in agricultural soils of Wallonia with the PHREEQC geochemical model [1]. In a first step, the chemical parameters necessary in input data to have an optimal modeling of P available in Wallonia soils were defined. During this input data calibration, our results show that it is necessary to use soil pH_{water} rather than soil pH_{KCl} and $[Al]_{ox}$ (oxalate-extractable Al) rather than $[Al]_{total}$. For other parameters, this study shows that using total content is suitable enough. In a second step, sensitivity tests were performed to quantitatively evaluate the impact of input data variations on mean P available modelled. Results of these sensitivity tests show that only pH_{water} and $[Mg]_{total}$ variations significantly influence the modelling results (i.e. mean P available in agricultural soils of Wallonia). Indeed, mean P available modelled increases by a factor 3 when the soil pH_{water} is raised from 7.3 to 8.0. The modelled values decrease of 9% and 16%, respectively, when $[Mg]_{total}$ increases of 20 and 40%, at soil pH_{water} = 8.2. However, results show that mean available P is not sensitive neither to soil pH_{water} nor to $[Mg]_{total}$ variations, when soil pH ≤ 7.3.

This study has shown the high potential of PHREEQC modelling to predict available P and to estimate chemical parameters that govern P availability in Wallonia soils. As these input data parameters and PHREEQC model are calibrated, we will further try to predict the impact of various agricultural systems on the fate of P in soils.

Amorphous calcium carbonate (ACC) is thought to play a key role in biomineralisation processes in sea organisms. Very few structural studies have been performed on ACC, mainly due to its instability and tendency to crystallise into calcite. Magnesium-stabilised ACC has been prepared [1,2] with Mg:Ca ratio of 0.05:1, and has enabled neutron and x-ray diffraction measurements. The Empirical Potential Structure Refinement (EPSR) method has been used to make a model of Magnesium-stabilised ACC having good agreement with the experimental diffraction data. The model has well-defined CO_3 and H_2O molecules with an average calcium coordination of 7. The distribution of calcium in the model is homogeneous with a uniformly distributed Ca-rich network and no evidence of Ca-poor channels [3].

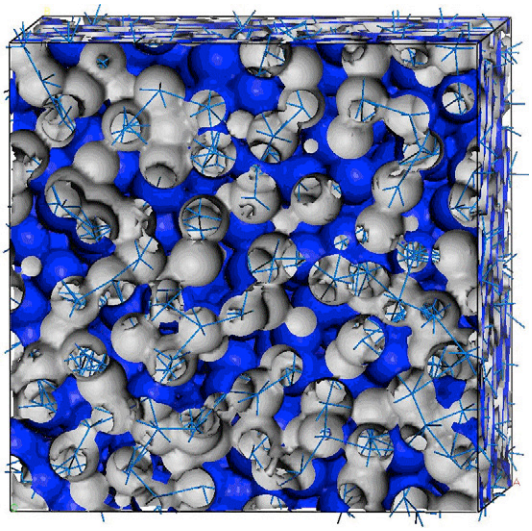

Figure 1: EPSR model of Mg-stabilised ACC with sticks showing the Ca-rich network (i.e. Ca–O–Ca)

The silicon isotopic composition ($\delta^{30}Si$) of water masses in the Atlantic

COFFINEAU N[1]* DE LA ROCHA C. L[1] SCHLOSSER C[2] AND WOLF-GLADROW D.A[3]

[1]UMR6539, LEMAR, IUEM, Université de Bretgane Occidentale, Technopôle Brest-Iroise, Place Nicolas Copernic, 29280 Plouzané, France (christina.delarocha@unib-brest.fr)

*(correspondence: nathalie.coffineau@univ-brest.fr)

Use of silicon isotopes ($\delta^{30}Si$) as a paleoceanographic proxy requires sound knowledge of the distribution and behaviour of silicon isotopes throughout the ocean. Over the past few years considerable efforts have been made to map the silicon isotope composition ($\delta^{30}Si$) of silicic acid (dissolved silicon, DSi) and biogenic silica (BSi) throughout the ocean.

We present here new data for the $\delta^{30}Si$ of DSi of water masses in the South Atlantic and eastern North Atlantic. These data include transects from the Drake Passage to the Weddell Gyre, through the Antarctic Circumpolar Current, and through the oxygen minimum zone in the tropical eastern North Atlantic. Seven surface to deep profiles (~4000m) span the southern section of the study from the Drake Passage across the Weddell Sea and then up along the prime meridian. These samples were taken as part of the GEOTRACES Zero & Drake campaign. An additional 5 CTD profiles were taken during a tracer release experiment (MSM10/1) from Ponta Delgada in the Azores to Mindelo, Cape Verde.

These profiles add to a growing dataset from which we are building a comprehensive picture of the distribution of Si isotopes in major Atlantic water masses. This exploration of the evolution of the $\delta^{30}Si$ of water masses such as Antarctic Bottom Water, North Atlantic Deep Water, and North Atlantic Intermediate Water, enables the identification and to some extent quantification of the biogeochemical and mixing processes controlling the isotopic composition of the water masses observed at our stations.

A statistical approach to the Nd isotopes distribution in the oceans

ANTOINE COGEZ[1] CLAUDE ALLÈGRE[1], LAURE MEYNADIER[1] AND ÉRIC LEWIN[2]

[1]Équipe de Géochimie et Cosmochimie, Institut de Physique du Globe de Paris – Sorbonne Paris Cité, UMR 7154, Université Paris Diderot
[2]Équipe de Géochimie 4D, Institut des Sciences de la Terre, Université Joseph Fourier, Grenoble

The reliability of neodymium (Nd) isotopes (ε_{Nd} notation) to trace past ocean circulation and continental erosion builds upon our understanding of the present Nd budget in the oceans. Ocean circulation models have been used for the past decade to test the ability of different processes to explain the present Nd isotopic compositions and concentrations of the oceans. The increasing amount of ε_{Nd} data in seawater now allows a first statistical approach: we used Lacan *et al*. (2012) seawater data compilation, completed with sediment core tops and ferromanganese nodule and crusts data. We used different statistical methods, all contributing with relevant and eachother coherent informations for the understanding of the present ocean Nd behaviour.

First, the ε_{Nd} variogram shows a mean correlation distance of 3500 km for the global ocean, which gives the space scale of the mixing dynamics for this element. This distance is then used to build an interpolated map of the Nd isotopic composition, using least squares method. It reveals global and regional features linked to some of the main continental sources and ocean circulation patterns.

Second, we studied the shape of ε_{Nd} distributions: their interpretation is based on the central limit theorem which implies that mixing processes produce gaussian distributions. After a weighting of the ε_{Nd} distributions by data uncertainties (analytical, sample type) and data densities in each ocean area, we compare it to the Laplace-Gauss distribution. We find that the global distribution is clearly asymetric and multimodal, reflecting the autonomous behaviour of the different oceans and the importance of the Nd inputs in each ocean. Moreover separate ocean distributions suggest rather a better mixing inside each ocean, with distribution tails for the area of Nd inputs. Finally the Antarctic clearly reflects a mixing between the different oceans and constitutes a barrier for a direct mixing of the different oceans with one another.

Third, a box model solved with global inversion techniques let us draw some conclusions about the residence and mixing times in the different oceans and their distributions (confirming the previous remarks), the input and internal processes, and the current limitations about the interpretation of the Nd budget in the oceans.

^{186}Os mantle evidence of Hadean crust formation

JUDITH A. COGGON[1]* AMBRE LUGUET[1], GEOFFREY M. NOWELL[2] AND PETER W. U. APPEL[3]

[1] Steinmann Institut, Universität Bonn, Poppelsdorfer Schloss, 53115 Bonn, Germany (*correspondence: jude@uni-bonn.de)
[2] Department of Earth Sciences, University of Durham, South Road, Durham DH1 3LE, UK.
[3] Geological Survey of Denmark and Greenland, Øster Voldgade 10, DK-1350 Copenhagen K, Denmark.

Crust-mantle differentiation events are recorded by the radiogenic signatures within crustal rocks and minerals and in their mantle counterparts. While the crustal record has been extensively studied and exhibits a peaked distribution of ages up to 4.38 Ga (detrital zircons) [1], corresponding statistical peaks of the mantle record only extend back to 3.3 Ga [2]. The oldest recorded mantle melting ages were measured in a single sulphide inclusion (3.9 Ga) within a xenocrystic olivine from the Lac de Gras kimberlite (Slave Craton) [3], and in two detrital, Os-rich platinum group minerals (PGM) (4.1 and 3.9 Ga) from the Witwatersrand sedimentary basin [4]. However, Eoarchean-Hadean Re-Os sulphide model ages have not revealed any statistically significant peaks.

The ^{190}Pt-^{186}Os isotope system is demonstrably less sensitive to crustal contamination and alteration than the Re-Os isotope system. We measured whole-rock ^{186}Os/^{188}Os and highly siderophile element (HSE) (Os, Ir, Pt and Re) compositions of Earth's oldest known chromitites, from the >3.811 Ga Ujaragssuit nunât intrusion, Southwest Greenland to provide the first ever mantle evidence of Hadean crust-mantle differentiation. Pt-Os model ages fall into two distinct groups, reflecting the dominance of either primary or secondary PGM (e.g. alloys) in each sample aliquot. Primary PGM preserve Hadean Pt-Os ages that cluster around 4.1 Ga, with individual ages as old as 4.36 Ga. These Hadean mantle depletion ages from Greenland are consistent with the oldest zircon ages from Australia (~4.0-4.38 Ga), suggesting that global crust-mantle differentiation events occurred on Earth within the first 300 million years after accretion. These findings suggest the existence of an Os-rich mantle, similar to that observed today, by 4.1 Ga. Our study therefore supports occurrence of the "late veneer bombardement" at least 0.2 billion years earlier than previously proposed.

Geochemical Windows on Coral Calcification: Cellular Mechanisms and Impacts of Climate Change

ANNE L. COHEN[1,]* THOMAS DECARLO[1], GLENN A. GAETANI[1] AND MICHAEL HOLCOMB[2]

[1]Woods Hole Oceanographic Institution, Woods Hole MA 02543 USA; (*acohen@whoi.edu)
[2]University of Western Australia, Crawley, WA 6009 Australia

Coral reefs exist because rates of calcium carbonate ($CaCO_3$) production by coral reef calcifying organisms exceed rates of $CaCO_3$ dissolution and export. Tropical reef-building corals are critical components of the reef $CaCO_3$ budget, producing aragonite crystals a hundred times faster than abiotic precipitation could occur under ambient seawater conditions. The ability of corals to maintain such high rates of $CaCO_3$ production under ocean warming and acidification is therefore critically important for the future of coral reefs worldwide. This presentation focuses on the application of geochemical and petrographic tools to uncover the fundamental mechanisms of coral calcification. Such tools provide unprecedented opportunity to probe an inaccessible, nano-sized space beneath the coral animal, revealing the origins and composition of the calcifying fluid and the ability of corals to manipulate fluid composition to induce crystal nucleation and growth on a tightly controlled diurnal schedule. Compositional and structural features of abiotic crystals grown in controlled aragonite precipitation experiments provide the crucial framework for interpreting compositional variability in coral skeletons. Application of this framework to populations of wild corals growing across natural gradients of temperature and ocean acidification is allowing us to assess the potential for corals to manipulate the composition of the internal fluid and maintain elevated rates of calcification under global climate change.

The Potassium-Argon Laser Experiment (KArLE) for *in situ* geochronology

B. A. COHEN[1]* J. S. MILLER[1,2] AND Z.-H. LI[1,3]

[1]NASA Marshall Space Flight Center, Huntsville AL 35812 (Barbara.A.Cohen@nasa.gov); [2]Qualis Corporation, Jacobs ESSSA Group; [3]University of Alabama Huntsville.

Absolute dating is essential in establishing planetary geologic history, including crystallization, magmatic evolution, and alteration. Radiometric geochronology has only been accomplishable in terrestrial laboratories on returned samples and meteorites, but there is more to be gained by geochronology than money for missions to return samples. We are addressing this challenge by developing the Potassium (K)–Argon Laser Experiment (KArLE) for *in situ* dating [1,2]. KArLE ablates a rock sample, determines the K in the plasma state using laser-induced breakdown spectroscopy (LIBS), measures the liberated Ar using quadrupole mass spectrometry (QMS), and relates the two by optically measuring the volume of the ablated pit. We have constructed a full breadboard of the KArLE concept using commercial off-the-shelf parts with flight-equivalent performance [3,4] to verify measurement capabilities and operations.

We conducted end-to-end measurements on the Fish Canyon Tuff, a well-characterized Ar dating standard. Our preliminary results yield a K concentration of 8-10 wt% and ^{40}Ar yield of 5×10^{15} mol for 500-μm diameter pits (200 laser shots). An isochron constructed with these measurements gives an age of 20.6 Ma, within 25% of the accepted age of 28 Ma, and readily identifies a trapped terrestrial air component. The largest sources of uncertainty are related to procedural blanks, data analysis routines, and calibration curves, all of which we are currently improving.

In addition to achieving an *in situ* age measurement, each KArLE component conducts analyses common to planetary surface missions (e.g. elemental composition, volatile analysis, microimaging). The dual-use components make KArLE an attractive way to integrate geochronology into a payload capability. The components' flight heritage suggests that the experiment will fit on landers and rovers to Mars, the Moon, asteroids, or any rocky surface. Upcoming flight opportunities for KArLE include Curiosity 2020, Discovery, and New Frontiers missions.

Dynamical Mean Field Theory and Insulator to Metal Transitions in FeO and other Iron-bearing Minerals

R.E. COHEN[1] AND K. HAULE[2]

[1]Geophysical Laboratory, Carnegie Institution of Washington, Washington, D.C. 20015 USA (rcohen@carnegiescience.edu)

[2]Dept. of Physics, Rutgers University, Piscataway, NJ, USA (haule@physics.rutgers.edu)

Experiments and theory show that FeO metallizes at high temperatures (~2000K) and pressures (~80 GPa) [1]. Here we use DFT+Dynamical Mean Field Theory (DMFT) with continuous time quantum Monte Carlo (CTQMC) to study the origin of the metallization. We find with increasing pressure in paramagnetic FeO in a cubic lattice a high-spin low-spin transition, with a wide transition region between characterized by intermediate occupancies of the t2g and eg states between. We find that at 300K cubic FeO remains insulating to a factor of two compression (over 600 GPa), except for a small region of high spin metal. However, at high temperatures (e.g. 2000K) a metallic state is found under compression. The metallization occurs from thermal fluctuations among different multiplets representing high- and low-spin states. We are now studying the AFM ground state, the Néel transition, and (Mg,Fe)O solid solutions. The behaviour of other transitions metal oxides such as MnO will also be presented and compared with the behaviour of FeO. This work is supposed by NSF.

Mineralogical, geochemical characteristics and mass changes in the alteration zone at the Elmaalan (Trabzon) VMS mineralization in NE Turkey

L. COL[1]* AND N. TUYSUZ[2]

[1]Dept. of Geol. Eng., Gümüşhane Univ., 29100-Gümüşhane, Turkey (*correspondence: colleyla@gmail.com)
[2]Dept. of Geol. Eng., Karadeniz Tech. Univ., 61080-Trabzon, Turkey (ntuysuz@ktu.edu.tr)

Elmaalan (Trabzon) volcanogenic massive sulfide (VMS) mineralization lies primarily within the immediate footwall of mineralized Upper Cretaceous dacitic pyroclastics, and overlain by barren dacite and pyroclastics at hanging wall in the northern zone of the Eastern Pontide Orogenic Belt in Northeastern Turkey. Main ore minerals are pyrite, chalcopyrite, sphalerite, galena, fahlers, bornite and in less amount chalcosine and covellite together with digenite; quartz, barite, carbonates and clay minerals, sericite and gypsum are exist as gangue.

The footwall dacitic pyroclastics exposed to extreme hydrothermal alterations. The observed alterations of silisification, sericitization, Ca/Mg-rich carbonation, Fe/Mg-rich chloritization and smectization with minor scale hematization and limonitization extend outward from ore zone. The hydrothermal alteration is divided into five zones for mass change calculation toward the ore zone. The mass change calculations of these zones show that, carbonation has 13% mass loss, sericitization-carbonation (Mg)-chloritization 9% mass gain, sericitization 21% mass loss, sericitization-silisification 29% mass gain and silisification 62% mass gain. According to these results, both mass gain and mass loss occurred in footwall dacitic pyroclastics during the hydrothermal alteration. The mass change results indicate that the rate of Si, Fe, and K elements increases, whereas that of Ca, Na and Al decreases toward the ore zone.

The δ18O values of solutions equilibrated with quartz, illite and chlorite vary between -0,3‰ and +5,7‰ and that of with illite/simectit and simectit are in between +24,6‰ and +26,5‰. Illite/simectit and simectit values are supposed to form low tempature and surface conditions, but quartz, illite and chlorite values may indicate that fluids become effective on mineralazition and hydrothermal alteration are magmatic in origin and affected with dilution of surficial water.

[3] Dept. Mineralogy and Petrology, University of Granada, Spain.(gervilla@ugr.es)
[4] Geological Institute, Bulgarian Academy of Sciences, Sofia, Bulgaria. (thomas@geology.bas.bg)

The ultramafic massifs of Yakovitsa and Dobromirtsi contain chromitites hosted in dunites-harzgurgites are affected by amphibolite/greenschist-facies metamorphism. These massifs are interpreted as portions of a meta-ophiolitic mantle, now widespread within the crustal units of the Central and Eastern parts of the Rhodope Crystalline Massif (SE Bulgaria). Although their age is still unknown, it is very likely that the massifs were thrust over Paleozoic (570 Ma [2]) para-gneisses with flysch characteristics during the Jurassic (>170-160 Ma [1]).

We report LA-ICP-MS analysis of unaltered chromite cores in chromitites from these massifs. Minor- and trace-element (Ga, Ti, Ni. Zn, Co, Mn, V, Sc) patterns of these cores from Yakovitsa and Dobromirtsi are similar to other well-characterised Cr-rich chromites in chromitite bodies hosted in the mantle sections of ophiolites. This supports (1) the ophiolitic origin of these ultramafic bodies, (2) a genetic link between the Yakovitsa and the Dobromirtsi massifs. The trace elements of the chromites strongly indicate that the chromitites crystallised from melts that originated in an arc setting. The similarity of the nature of their parental melts suggest that these massifs probably correspond to two fragments of the same portion of oceanic lithosphere developed in a back-arc setting . We plan to investigate Hf-isotope data on zircon and Os-isotope data from platinum-group minerals in the chromitites of both massifs to provide additional tests of this hypothesis.

Rare earth elements as indicators of hydrothermal processes within the East Scotia subduction system

C.S. COLE[1]* R.H. JAMES[2] D.P. CONNELLY[2] AND E.C. HATHORNE[3]

[1]Ocean and Earth Science, University of Southampton, Southampton, SO14 3ZH, UK (*correspondence: catherine.cole@noc.soton.ac.uk)
[2]National Oceanography Centre, University of Southampton Waterfront Campus, Southampton, SO14 3ZH, UK
[3]GEOMAR, Helmholtz Centre for Ocean Research, Kiel, Germany

The East Scotia subduction zone, located in the Atlantic sector of the Southern Ocean, hosts a number of hydrothermal sites in both back-arc and island-arc settings. High temperature (> 353 °C) 'black smoker' vents have been sampled at three locations along segments E2 and E9 of the East Scotia back-arc spreading ridge, as well as 'white smoker' (< 212 °C) and diffuse (< 40 °C) hydrothermal fluids from within the caldera of the Kemp submarine volcano. The composition of the endmember fluids (Mg = 0 mM) is markedly different, with pH ranging from 0.8 to 3.4, [Cl^-] from 88 to 536 mM, [H_2S] from 6.7 – 200 mM, [F^-] from 35 to 1000 μM) and [Li] from 18 to 606 μM. All of the vent sites are basalt-hosted, providing an ideal opportunity for investigating the geochemical controls on rare earth element (REE) behaviour.

Hydrothermal fluids from E2 and E9 have total REE concentrations ranging from 7 – 127 nmol/kg, and chondrite-normalised fractionation patterns are either light REE-enriched (La_{CN}/Yb_{CN} = 12.9 – 30.0) with a positive europium anomaly (Eu_{CN}/Eu^*_{CN} = 3.51 – 59.4), or mid REE-enriched (La_{CN}/Nd_{CN} = 0.61) with a negative Eu anomaly (Eu_{CN}/Eu^*_{CN} = 0.59). By constrast, fluids from the Kemp Caldera have almost unfractionated REE patterns (La_{CN}/Yb_{CN} = 0.8 – 2.2; Eu_{CN}/Eu^*_{CN} = 1.0 – 2.2).

We will demonstrate that the REE geochemistry of fluids from the back-arc spreading ridge is variably influenced by ion exhange with host minerals, phase separation, competitive complexation with ligands, and anhydrite deposition, whereas fluids from the Kemp submarine volcano are also affected by the injection of magmatic volatiles which enhances the solubility of all the REEs. We will also show that the REE patterns of anhydrite deposits from Kemp differ from those of the present-day fluids, potentially providing critical information about the nature of hydrothermal activity in the past, where access to hydrothermal fluids is precluded.

Plutons are texturally modified primary igneous liquids, not cumulates

DREW S. COLEMAN[1]* RYAN E. FRAZER[1], RYAN D. MILLS[2] ALLEN F. GLAZNER[1] AND JOHN M. BARTLEY[3]

[1] Department of Geological Sciences, University of North Carolina, Chapel Hill, NC 27599-3315, * (correspondence dcoleman@unc.edu); (frazer@live.unc.edu; afg@unc.edu)
[2] ARES Directorate, NASA-JSC, Houston, TX 77058, (ryan.d.mills@nasa.gov)
[3] Department of Geology and Geophysics, University of Utah, Salt Lake City, (john.bartley@utah.edu)

Existing data support a model in which chemical patterns of both shallow plutonic rocks and volcanic rocks mainly reflect melt generation in the deep crust with minimal differentation in the upper crust. Field and petrologic features of shallow plutonic rocks reflect incremental assembly of evolving lower crustal melts, overprinted by significant textural modification. Homogeneous granodiorites reflect slow accumulation of compositionally uniform magmas that were likely feeding chemically similar, small (10^1 km^3) eruptions. Zoned intrusions reflect evolution of melt composition fed from the lower crust on time scales of 10^5 to 10^7a, with limited upper crustal differentiation. If so, plutonic rocks are as rich a source of information about chemical evolution of the crust as volcanic rocks, and plutonic rocks provide a more complete record than volcanic rocks because they are better preserved through geologic time.

In contrast to small eruptions, magmatism related to large ignimbrites (>500 km^3) may be scarcely represented in the plutonic rock record. The abnormally high magma flux necessary to generate an ignimbrite results in effective evacuation of the source. Comparable volumes of plutonic rocks that preserve such high fluxes remain unrecognized. In the Southern Rocky Mountain volcanic field, two examples are identified where the only intrusive rocks temporally equivalent to ignimbrites are dikes and ring dikes of roughly the same composition as the ignimbrite. We take this to indicate that the magmas were transported efficiently from deep sources to the surface without protracted storage in the upper crust.

Altogether, the data support a model for plutonic/volcanic rock connections in which both dominantly reflect melt generation processes with minimal overprinting by shallow crustal processes. Hypothetical links between plutonic and volcanic rocks that rely on significant shallow differentiation fail field, geophysical, geochemical and geochronological tests and should be reexamined.

Impact of curiosity-driven research on oil production through *Problem awareness*

MAX COLEMAN

NASA Jet Propulsion Laboratory, Caltech. Pasadena, CA 91109 USA (max. coleman@jpl.nasa.gov)

Much effort is applied to the process of *Technology Transfer*, whereby research is commercialised, but it appears that much less attention is given to its counterpoint and possible precursor, *Problem Transfer*. This paper describes one example of how curiosity driven research, performed in the ambience of problem awareness, by chance, had considerable impact on oil production technology. Although it happened by chance it points to the need for greater dissemination of possibly soluble problems.

A major, but relatively little known, problem of the oil industry is the cost of coproducing water with oil, including that injected into the reservoir to increase oil production. A second and also expensive problem is precipitation of mineral "scale" in the well and near-wellbore region, reducing production flow. For example, in offshore wells sulfate present in injected seawater reacts with barium in the formation water precipitating barium sulfate. The problem is ameliorated by addition to the injected water of just the right amount of a relatively expensive scale inhibitor compound.

While setting up a new stable isotope laboratory in an oil company lab and seeking materials to test, a set of water samples was analysed. This produced two surprises. Isotopic analyses of samples from a well in which chemical compositions indicated presence of injected seawater (sulfate) allowed that contribution to be quantified from a cross plot of H and O isotopes. However, the isotopes (which characterise the whole water) showed that the seawater amount had been under-estimated by a factor of two! Excitingly, those wells with no seawater contribution formed a never previously seen anti-correlation of H and O isotopes, which proved to be mixtures of underlying aquifer brine and residual water in the oil zone, with very different chemical compositions. This was significant because estimates of oil reserves involved use of the resistivity of oil zone water, until then believed to be the same as that of the underlying aquifer. Subsequently, we developed a method to analyse oil zone water by extracting it from produced, “dry” oil. The Ph.D. student involved in developing the method formed an SME to undertake this service commercially as soon as he got his degree.

Thus, curiosity-driven research, serendipity and problem awareness delivered great economic impact and indicates the need for a better managed process of *Problem transfer*.

Calibration of Raman spectroscopy to determine water contents in lunar silicate glasses

A. COLIN*[1], GR. DAVIES[1] J.H. HOOIJSCHUUR[1] A.R.L. NICHOLS[2] N. RAI[1] AND W. VAN WESTRENEN[1]

[1] VU University Amsterdam - the Netherlands (correspondence : a.colin@vu.nl)

[2] IFREE, JAMSTEC, Yokosuka - Japan

Recent lunar sample analyses and remote sensing data suggest that the Moon is probably not as dry as initially thought (e.g. [1-2]). The presence or absence of water in the Moon’s interior has potentially dramatic consequences for the chemical and physical properties of lunar rocks and melts during lunar evolution. It is thus critical that techniques that are able to determine the water content of lunar soils directly on the lunar surface are developed for use during future lunar lander missions. In addition, in order to establish how water influences lunar melt properties, we need to be able to measure accurately the water content of lunar melts/glasses in experiments.

Raman spectroscopy can be used to quantify reliably the water content of both silicate glasses and minerals. Raman analyses are quick, non destructive and do not require any sample preparation, contrary to more classical techniques like FTIR, SIMS or Karl-Fischer titration. Thus we are calibrating the Raman technique to quantitatively measure water content in lunar glasses. Using a piston cylinder apparatus we synthesised a range of lunar glass compositions (as identified by Apollo missions), doped with different amounts of water (0-6wt%). We confirmed that the water content is homogeneous in our standards by imaging the water content by Fourier Transform Infrared spectroscopy, and determined the absolute water content by Karl Fischer titration. We analysed the samples by Raman and found that the ratio between the water peak area at high frequency and the silicate network peak areas at low frequency, calculated according to [3] is proportional to the water content. Above 0.4wt% water the accuracy is comparable with FTIR.

We are also determining the Raman detection limits for water, using a miniaturised Raman instrument previously designed for the ExoMars mission (e.g. [4]). We are testing this instrument in an in-house vacuum chamber to simulate the extremely low pressure conditions on the lunar surface.

Eclogitized serpentinites from the Rhodope Massif: Exploring the fate of serpentinites in the deep mantle

DAVID COLLINGS[1]*J IVAN SAVOV[1], NIKOLAY BONEV[2] AND KATHRYN ECCLES[3]

[1]School of Earth & Environment, Univ. Leeds, LS2 9JT (*ee09dac@leeds.ac.uk)
[2] Univ. of Sofia, Dept. of Geology & Paleontology, Sofia
[3]Department of Earth and Environment, Boston Univeristy

We report eclogitic mineral assemblages from the Avren serpentinite body on the Bulgarian-Greek border in the E. Rhodope Massif (RM). We have mapped and sampled extensively this 4×1 km body, and discovered thin bands of garnet-CPX bearing assemblages throughout the entire body. The serpentinites have variably melt-depleted protoliths and hydration history as is revealed by their wide ranges in bulk rock MgO (ave. ~31 wt%), CaO (ave. ~ 5 wt%) and Al_2O_3 (ave.~ 7 wt%). Texturally, enstatite-diopside–Cr-spinel symplectites are common and in agreement with proposed exposures to deep mantle wedge conditions (T ~650ºC and P up to 15kbar; [1]). Depending on the T and P, there are several important dehydration reaction paths recorded in the serpentinites:1)Srp→Ant→Ol+OPX+Sp+Grt→Hbl; 2)Srp→Ant→Tc+Chl→Tr/Act→Hbl. Importantly, in association with the garnets we have discovered vesuvianite, which has been shown to be an important H_2O carrier in dewatering serpentinites in subduction zones [2]. Bulk rock trace element variations are in the range of typical mantle wedge serpentinites with Li = 0.5 ppm; Cr = 1115 ppm; Ni= 1355 ppm and $[Nd/Yb]_N$ ~ 1. LA-ICP-MS results indicate garnets with $[Nd/Yb]_N$ ~ 0.05 and $[La/Sm]_N$ ~ 0.07. The EPMA data indicates that the garnets are $Py_{59}Gross_{12}Alm_{23}$ and the CPX are diopsides with $Wo_{46}En_{46}Fs_3$. The recrystalized olivines have high Mg# (~ 89). Based on Sm-Nd dating of garnets from the eclogite bands we report that the serpentinites were exposed to HP/UHP conditions during a Late Jurassic- Early Cretaceous subduction event. This timing is in agreement with metamorphic ages (U-Pb zircon rims) from adjacent parts of the RM [3,4]. Finding remnants of deeply subducted serpentinites on the surface may be rare [2, 4], but understanding their composition may shed light on the elemental fluxes associated with dewatering slabs under arc volcanic fronts. Such rocks may hold the answer for the anomalous (Vp/Vs) layers characteristic for many Western Pacific arcs (IBM, Japan, Aleutions, Kuriles)[6].

Record of Subduction Zone Carbon Cycling in HP/UHP Rocks, W. Alps

COLLINS, N.[1]* BEBOUT, G.[1] COOK-KOLLARS J.[1] AND KUMP, L.[2]

[1]Department of Earth and Environmental Sciences, Lehigh University, Bethlehem, PA, USA. *(nac211@lehigh.edu)
[2] Department of Geosciences, Pennsylvania State University, University Park, PA, USA.

Studies of volatiles in HP/UHP metamorphic suites can inform models of cycling among surface and deep-Earth reservoirs, including those focusing on C fluxes contributing to atmospheric CO_2 concentrations. Depending on the magnitude of the poorly constrained C flux in ultramafic rocks, on a global basis, sediments and altered oceanic crust (AOC) together deliver 70-95% of the C currently entering subduction zones (Bebout, 1995; Jarrard, 2003; Dasgupta and Hirschmann, 2010). We are investigating extents of retention and metamorphic release of C in deeply subducted AOC and carbonate-rich sediment represented by HP/UHP meta-ophiolitic and metasedimentary rocks in the Italian Alps. Study of metapelite devolatilization in this suite (Bebout *et al*., 2013, Chem. Geol.) provides a geochemical framework for study of C behavior along prograde P-T paths similar to those experienced in most modern subduction zones. Our results for sediments and AOC indicate impressive retention of oxidized and reduced C to depths approaching those beneath arc volcanic fronts. In metasedimentary rocks, extensive isotopic exchange between the oxidized and reduced C reservoirs results in varying shifts toward mantle values. Much of the carbonate in metabasalts has $\delta^{13}C$ overlapping with that for carbonate in AOC, with some HP/UHP metamorphic veins showing greater influence of organic C signatures from metasedimentary rocks.

Carbon retained through forearcs is available for return in volcanic arcs (perhaps via partial melting) or for entrainment into the deeper mantle. On a global basis, imbalance between subducted C input and C return flux by magmatism (excluding ultramafic inputs, ~40±20% of subducted C return via arcs and ~80±20% by all magmatism; Bebout, 2013, Treat. Geochem.) indicates net modern C return to the mantle, perhaps a reversal of Archean net outgassing (despite more rapid subduction). Modern C subduction flux is largely influenced by carbonate-rich sediment sections entering only a few margins, and future C cycling will be affected by the duration of C subduction pulses in these regions and any new subduction in carbonate-rich ocean basins. Global C cycle models predict that a relatively small change in the subduction/volcanic C flux could significantly affect atmospheric CO_2 levels and thus global climate.

Theoretical calculations on the thermodynamics and kinetics of U(VI) homogeneous reduction by Fe(II)

RICHARD N COLLINS[1] AND KEVIN M ROSSO[2]

[1]School of Civil and Environmental Engineering, The Univ. of New South Wales, Sydney, NSW 2052, Australia (*correspondence: richard.collins@unsw.edu.au)

[2]Chemical and Materials Sciences Division, Pacific Northwest National Laboratory, Richland, WA 99354, USA (kevin.rosso@pnnl.gov)

As uranium in the (VI) oxidation state is orders of magnitude more soluble than (IV), there is intense interest in promoting the (bio)reduction of uranium in remediation settings. Fe(II) is an environmentally ubiquitious reductant, however, inconsistencies have been experimentally reported on the thermodynamics and kinetics of U(VI) homogeneous reduction by Fe(II) [1,2].

Here, as a foundation for understanding its heterogeneous reduction behavior, we report on theoretical calculations of the thermodynamics and kinetics of the one electron reduction of monomeric U(VI) (hydrolysis) species by $Fe(H_2O)_6^{2+}$ in homogeneous solution. NWChem [3] was used to optimise the structures of the U and Fe monomers as well as inner- and outer-sphere complexes, pre- and post- electron transfer, by spin-unrestricted Kohn-Sham Density Functional Theory (DFT) and using the COSMO continuum solvation model. In addition to structure and free energy prediction, explicit calculation of the electronic coupling interaction was also performed, to estimate the electron transfer kinetics as defined by Marcus theory.

Calculations indicated that electron transfer via either an inner- or outer-sphere mechanism was only thermodynamically favourable for the second hydroysis species $UO_2(OH)_2(H_2O)_4^0$. However, in both cases, electron transfer proceeded via a coupled electron-proton transfer mechanism – an immediate indication that electron transfer would be inhibitively slow. These results suggest that the homogeneous reduction of U(VI) by Fe(II) is either thermodynamically unfavourable or kinetically limited at environmentally relevant U and Fe concentrations at pH values < 7.

A generic approach to geochemical multi-surface modelling of the leaching of contaminated materials

ROB N.J. COMANS[1] J.J. DIJKSTRA[2] AND A. VAN ZOMEREN[2]

[1] Department of Soil Quality, Wageningen University, The Netherlands, (rob.comans@wur.nl)

[2] Energy research Centre of the Netherlands (ECN), Petten, The Netherlands

Geochemical modelling is increasingly being used in both scientific research and environmental risk assessment of contaminated materials. In this presentation an overview will be given of the development of a generic multi-surface geochemical modelling approach, to describe the speciation and solid/liquid partitioning (leaching) of major and trace elements in both soils and waste materials. The approach is based on the premise that the major reactive organic and mineral surfaces that are being considered, play a generic and determining role in the speciation and leaching of elements in these different materials.

The geochemical modelling approach is based on individual adsorption models for which generic binding parameters have been published for a wide range of elements. It currently includes reactions for aqueous speciation and mineral solubility, combined with sorption to organic matter (NICA-Donnan model), Fe/Al-(hydr)oxides (Generalized Two-Layer Model) and clay (Donnan model). As such, the model is fully based on published generic thermodynamic parameters for these different types of processes and used without any parameter fitting. Methods for the estimation of essential modelling parameters such as the potentially available/reactive fraction of elements of interest, and the type and amounts of reactive mineral and organic surfaces will be discussed. The performance of this modelling approach has been tested for a range of different elements and contaminated materials, particularly by comparing measurements and model predictions of the solid/liquid partitioning of elements over a wide pH range.

Examples will be presented of different model applications, illustrating similarities and differences in controlling processes and element speciation. These applications suggest very similar properties and contributions of the considered reactive mineral and organic surfaces in the speciation and leaching of elements among very different waste and soil materials. Finally, an outlook will be given on current work and ambitions to further develop and improve this modelling approach.

The baric behaviour of Bloedite at low and high *T*: A contribution to the study of icy satellites

P. COMODI[1]*A V. STAGNO[2] A. ZUCCHINI[1] Y. FEI[2] AND V. PRAKAPENKA[3]

[1]Earth Sciences Department, University of Perugia, Italy (*correspondence: comodip@unipg.it)
[2]Geophysical Laboratory, Carnegie Institution of Washington, US
[3]Argonne National Laboratory, University of Chicago, US

Bloedite [$Na_2Mg(SO_4)_2{\cdot}4H_2O$], $P2_1/a$ space group, is a common constituent in evaporitic sedimentary environments and it has been suggested to be stable on icy satellites (Europa, Ganymede). The knowledge of the release of water from its structure as a function of pressure and temperature is of great interest to planetary scientists since it can be used to explain the presence of a deep ocean under the icy crust, and to understand the cryovolcanism phenomena observed from Voyager data. However, to date, there are no available data to predict possible structural modifications of bloedite (*i.e.* dehydration conditions) as a function of pressure, particularly at low temperature.

We performed *in situ* synchrotron X-ray powder diffraction experiments on natural bloedite at pressures up to 10 GPa and temperatures from ~100 K to ~570 K using diamond anvil cell technique at GSECARS, Advanced Photon Source (Argonne, USA).

The resulting negative linear thermal expansion coefficients from ambient pressure and low-*T* experiments are: $\alpha_c = 4.4(4){\cdot}10^{-5}$ K^{-1}, $\alpha_b = 1.4(3){\cdot}10^{-5}$ K^{-1}, $\alpha_a = 0.7(2){\cdot}10^{-5}$ K^{-1}, and $\alpha_V = 5.8(7){\cdot}10^{-5}$ K^{-1}. From high-*T* runs, the calculated thermal expansion coefficients are: $\alpha_c = 3.7(1){\cdot}10^{-5}$ K^{-1}, $\alpha_b = 2.5(3){\cdot}10^{-5}$ K^{-1}, $\alpha_a = 2.5(3){\cdot}10^{-5}$ K^{-1}, and $\alpha_V = 8.3(6){\cdot}10^{-5}$ K^{-1}. Non-linear thermal expansion coefficients for *a* and *V* parameters and linear for *b* and *c* were measured at 10 GPa up to 570 K. Both compression and expansion behaviours of bloedite are strongly anisotropic with *a* parameter more deformed with respect to *b* and *c*, in good agreement with Comodi *et al*. 2013 [1] where a strongly anisotropic compressibility was observed under H*P* at room temperature.

Thermogravimetric analyses were also performed at ambient pressure showing three endotherms at 410 K, 500 K and 1000 K, with weight losses of approximately 11%, 11% and 43% related to partial dehydration, full dehydration and sulphate decomposition, respectively. However, no evidence of dehydration were observed up to 570 K and 10 GPa.

Measurements of the lattice parameters of bloedite at the experimental conditions would suggest that pressure can stabilize the water molecules in the bloedite structure with implications for the extent of a thick icy crust.

K- and La- doped smectite under high pressure and temperature conditions: Implication on mantle metasomatism

ROMMULO V. CONCEIÇÃO[1]* LARISSA C. CARNIEL[1],VICENTE STEFANI[2], FLAVIA SCHENATO [3], FREDERICO ALABARSE[4], NAIRA M. BALZARETTI[2] AND ANA M. XAVIER [4]

[1]1Instituto de Geociências, Univ. Federal do Rio Grande do Sul (UFRGS), Porto Alegre, Brazil. (*correspondence: rommulo.conceicao@ufrgs.br)
[2]Programa de Pós-Graduação em Ciências dos Materiais, UFRGS, Porto Alegre, Brazil.
[3]Comissão Nacional de Energia Nuclear (CNEN), Rio de Janeiro, Brazil.
[4]Synchrotron Soleil, L'Orme les Merisiers, Saint Aubin – BP48, 91192 Gif sur Yvete, France.

The lithospheric mantle is depleted in incompatible elements and basically anhydrous or nearly anhydrous. This region can be rehydrated and re-enriched in these elements through subduction processes that brings, among others, pelagic material. In subduction zones, smectite is one of the most important minerals that could bring together water and trace elements into the mantle. In order to test the influence of smectite in the mantle metasomatism, we are developing phase diagrams under high pressure and temperature (HPHT) in K- and La-doped smectite. Our results show that La-smectite is stable under pressures of 2.5GPa, 4.0 and 7.7GPa at temperatures up to 250°C, ~300°C and 350°C, respectively, above which they transform into a muscovite-like structure, being irreversible in such conditions. K-smectite, however, is stable at temperatures around 250° C, independently of any pressure. Above this temperature, it transforms into a I/S structure previously to changing into a muscovite structure at ~450°, 350° and ~300°C, under 2.5, 4.0 and 7.7GPa, respectively. These results show that pressure does not affect the stability of K-smectite, which remain stable up to 250°C under pressures up to 7.7GPa. On the other hand, higher pressures enlarge smoothly the La-smectite stability field in a very limited extension. Transformation of La-smectite into muscovite occurs directly, but K-smectite transformation occurs via I/S structure. When our results are compared to water/ice stability, we observe that La-smectite/muscovite transformation is in perfect agreement with ice/water transformation. Once ice became water, La-smectite became muscovite. However, K-smectite does not have such straightforward influence on ice/water transformation due to the existence of the I/S stability field.

Experimental melting of phlogopite-peridotite at 1 GPa – Implications for potassic magmatism

P. CONDAMINE[1]*, E. MEDARD[1], D. LAPORTE[1] AND F. NAURET[1]

[1]Clermont Université, UPB/CNRS/IRD, Laboratoire Magmas et Volcans, 5 rue Kessler, 63038 Clermont-Ferrand, France (*correspondence : p.condamine@opgc.univ-bpclermont.fr)

Phlogopite has been recognized as a common phase in the subcontinental lithosphere, where it forms by percolation of ascending deeper fluids/melts. This hydrous phase is also assumed to be present in subduction zones as a result of mantle wedge metasomatism following slab dehydration. As a water repository, phlogopite could thus play a key role during partial melting in such settings and imprints peculiar trace element signatures in magmas. However, the stability of phlogopite in a natural mantle composition, as well as its fluid-absent melting reactions have never been determined.

We conducted piston-cylinder experiments at 1 GPa to determine the stability of phlogopite in both lherzolite and harzburgite under water-undersaturated conditions. Accounting for the effect of F in natural peridotites, we show that phlogopite and melt coexist over 150°C above the solidus (1015°C) at moderate degrees of melting (up to 11.5 %). The melting reactions have been quantified and appear continuous and incongruent – e.g. for lherzolite:

1.00 phl + 0.95 cpx + 0.89 opx + 0.1 sp = 0.93 ol + 1.98 melt

Low-degree melts are silica-saturated (from trachyte to basaltic andesite with increasing degrees of melting). Their K_2O content is buffered by the presence of phlogopite, depending on the source fertility, from ~4 wt% in lherzolite to ~7 wt% in harzburgite. We also determined the trace element partition coefficients between phlogopite and such hydrous, silica-rich melts.

Our data show that magmas with less than 4 wt% K_2O cannot be in equilibrium with residual mantle phlogopite. Conversely, magmas containing more than 7 wt% K_2O cannot come from a phlogopite-peridotite source. Potassic post-collisional lavas (e.g., from Tibet) exhibit a wide range of silica contents (60 – 45 wt% for Mg# > 0.65), with constant K_2O values (~4 wt% for southern Tibet). Such major element trends are in agreement with a phlogopite-bearing mantle source in post-collisional settings, an argument also supported by trace element partitioning models.

EARLYTIME: An initiative to evaluate and improve U-Pb and Pb-Pb dating of meteorites

J.N. CONNELLY[1]*, Y. AMELIN[2], T. BLACKBURN[3] AND D. CONDON[4]

[1]Centre for Star and Planet Formation, University of Copenhagen, Copenhagen, Denmark;
[2]Research School of Earth Sciences, Australian National University, Canberra ACT, Australia;
[3]Carnegie Institution for Science, USA,
[4]NIGL, Keyworth, England.

Understanding the formation of the Solar System in detail requires an accurate chronological framework for meteorites with precision and accuracy of at least several 100,000 years. Only the absolute Pb-Pb chronometer, with supporting U-Pb data and uranium isotopic composition, provides assumption-free dates with this resolution. However, constructing a timeline for the first ca. 10 Myr of the Solar System using this method requires comparing dates derived from diverse materials from different laboratories and analytical methods, instrumentation and data reduction schemes.

We propose a cooperative, community-based initiative that would start with a systematic evaluation of the compatibility of U-Pb and Pb-Pb data generated by different laboratories and then seek means to improve and standardize methods to the extent possible. An important first step will be the production, distribution and analyses of synthetic standard Pb solutions mixed to replicate a typical 4.56 Ga Pb-Pb data array to test the compatibility of different mass spectrometry approaches and data reduction schemes. This will be coupled with isotopic analyses of a synthetic U solution to be used in the "age" calculation. The results of this phase will be presented as a blind test of the consistency of results from participating laboratories.

The initiative will further prioritize: 1) developing software that would standardize data reduction and presentation, 2) exploring and establishing means to reduce Pb blanks in the sample handling, dissolution and chemical separation of meteoritic materials, 3) obtaining and distributing suitable natural material(s) that will test the full analytical procedures of participating laboratories, 4) working with the well-established EARTHTIME community to evaluate the feasibility of making more ^{202}Pb and ^{205}Pb such that a Pb double spike would be widely available to the community for meteoritic work, and 4) building a consensus on the variation or consistency of the U isotopic ratio(s) of inner Solar System materials. Information about the initiative, that we propose be called "EARLYTIME", will be made accessible via a dedicated website.

Isotope tracking of microbial sulfate reduction in oil reservoirs

MARK E. CONRAD[1], CHRISTOPHER G. HUBBARD[1], ANNA ENGELBREKTSON[2] AND JOHN COATES[1,2]

[1] Earth Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA, USA; (msconrad@lbl.gov)
[2] Department of Plant and Microbial Biology, UC Berkeley, Berkeley, CA, USA

Seawater injection as a secondary oil recovery technique is considered to stimulate microbial sulfate reduction in oil reservoirs, leading to reservoir souring. Souring leads to major issues with oil production and refining. Several techniques to remediate souring have been tried, with the most common being addition of nitrate to the injected seawater. Tools are needed to monitor the onset of souring and track the efficiency of treatment options. Microbial sulfate reduction is known to impart large, characteristic shifts in the sulfur and oxygen isotope compositions of the residual sulfate and byproducts of the process that can be distinguished from other processes that may be occurring in the reservoir including precipitation of sulfate and/or sulfide minerals, dilution or sorption onto reservoir materials. In this contribution, we present preliminary experimental results designed to explore the use and sensitivity of isotopic signatures of sulfate and sulfide to monitor reservoir souring.

Two sets of column experiments to simulate reservoir souring and treatment with nitrate have been conducted. In the first set, seawater with and without nitrate was introduced to columns. Appearance of sulfide in the effluent from the untreated columns was observed after 5 days, but measurable shifts in the $\delta^{34}S$ of the effluent sulfate were observed after only 2 days, indicating that sulfate reduction had already begun. In the nitrate columns, sulfide in the effluent was not observed until 3 weeks after the experiment began, but a shift in the $\delta^{34}S$ of the sulfate was observed after only 1 week. In the second set of experiments, the columns were allowed to go sour before nitrate was added. Effluent sulfate dropped to less than 5% of the influent concentrations. The $\delta^{34}S$ of the residual sulfate was ~60‰ higher and the $\delta^{18}O$ was ~15‰ higher. After nitrate addition, sulfide disappeared and both the $\delta^{34}S$ and $\delta^{18}O$ values of the effluent sulfate returned to baseline after ~10 days. With time, the $\delta^{34}S$ of the sulfate dropped to 2‰ less than the influent values indicating re-oxidation of sulfide precipitates in the columns. These results indicate that isotopic monitoring of microbial sulfate reduction is highly sensitive, potentially providing early indicators of reservoir souring processes. Future work will include isotopic monitoring samples from oil reservoirs and incorporation of isotopic effects into reservoir reactive transport models.

Evaluation of precipitation isotope variability across the tropical Pacific in SWING2 simulations and observations

JESSICA L. CONROY[1,2]* KIM M. COBB[2] AND DAVID NOONE[2]

[1]Department of Geology, University of Illinois Urbana-Champaign, IL, USA (*correspondence:jconroy8@mail.gatech.edu)
[2]School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta, GA, USA
[3]Department of Atmospheric and Oceanic Sciences, and Cooperative Institute for Research in Environmental Sciences, University of Colorado, Boulder, CO, USA

Isotope-equipped global climate models (GCMs) enable simulations of the stable isotopic composition of precipitation, but isotope simulations from different models may vary because of differences in hydrologic and isotopic fractionation schemes. However, different isotope model simulations are rarely considered together, allowing assessment of the distribution of simulated precipitation isotope variability relative to observations. Here we present an evaluation of tropical Pacific precipitation isotope variability in GCMs participating in the second Stable Water Isotope Intercomparison Group (SWING2) experiment and in observations. The tropical Pacific is an important target for such model-data comparisons, as it plays a key role in shaping global hydroclimate variability, and is home to many water isotope-based proxies of paleoclimatic change. We present examples highlighting variability in the strength of the isotopic 'amount effect' across the tropical Pacific. The models that best capture mean annual precipitation in the tropical Pacific are not the models that best simulate the mean annual stable isotopic composition of precipitation, suggesting precipitation amount is not the only influence on precipitation isotope variability in the tropical Pacific. The strength of the relationship between precipitation and precipitation $\delta^{18}O$ values varies between the western, central, and eastern equatorial Pacific. In the western equatorial Pacific, there is more variability among simulations, but precipitation $\delta^{18}O$ values have a stronger relationship with basin-wide precipitation relative to local precipitation. In the central and eastern equatorial Pacific, precipitation $\delta^{18}O$ values are strongly correlated with regional precipitation across most simulations. In many simulations of the eastern tropical Pacific, precipitation has a more spatially expansive relationship with basin-wide precipitation compared to precipitation $\delta^{18}O$ values.

Cold marine Patagonia waters and stable isotopes and trace elements from Quaternary mollusk shells

I. CONSOLONI[1]*. G. ZANCHETTA[1]. I. BANESCHI[2]. L. DALLAI[2], M. D'ORAZIO[2], M. GUIDI[2] AND M. TIEPOLO[3]

[1]Dipartimento di Scienze della Terra, Università di Pisa, Via S.Maria 53, 56126, Pisa, Italy (*correspondance: consoloni@dst.unipi.it)
[2]I.G.G., C.N.R, Via Moruzzi 1, 56124, Pisa, Italy
[3] I.G.G., C.N.R, Via Ferrata 1, 27100, Pavia, Italy

Most of the Atlantic coast of Patagonia is dominated by the cold Falkland (Malvinas) current, whereas further north the upper level coastal circulation is characterised by the interaction with the saltier and warmer Brazil current.
The front of these currents changes seasonally and its position has probably been changed over a longer period of time.
Stable isotopes ($^{13}C/^{12}C$ and $^{18}O/^{16}O$ ratios) and trace elements (Ba/Ca, Sr/Ca, Mg/Ca) have been used on mollusk shells preserved in fossil beach ridges for tracing past changes in the position of these two currents.
In particular, oxygen isotopic composition of *Mytilus edulis* collected from a Holocene beach ridge dated at ca. 6300 yr BP along the Bahia Camarones coast (Chubut Province, Argentina) is consistently different from the modern specimens and from Mytilidae samples collected from younger Holocene beach ridges and shell middens. On the contrary, the carbon isotopic values remain fairly homogeneous throughout the Holocene up to the present.
The changes in the oxygen isotopic composition of the shallow marine mollusk shells are consistent with changes in water temperature/salinity possibly related to fluctuations in the relative position between the Brazilian and Falkland currents, with a stronger influence of the warm and saltier Brazil current along the study area during the middle Holocene.
This is substantially confirmed by Mg/Ca ratio indicating an increase of the sea surface temperature during the middle Holocene in the Bahia Camarones area. It also found support on mollusk palaeontological data.

The effect of some new organic inhibitors on the oxidative dissolution of iron monosulfide (FeS)

C.A. CONSTANTIN[1]*, P. CHIRITA[1], C.E. BADICA , L.M. BIRSA[2], E. MATEI[3], I. BALTOG[3] AND M.L. SCHLEGEL[4]

[1] University of Craiova, Department of Chemistry, Calea Bucuresti 107I, Craiova Romania (*correspondence: cristina_a_constantin@yahoo.com)
[2]"Al. I. Cuza" University of Iasi, Department of Chemistry, 11 Carol I Blv. , Iasi 700506, Romania (lbirsa@uaic.ro)
[3] National Institute of Materials Physics, Lab. Optical Processes in Nanostructured Materials, P.O. Box MG-7, Bucharest, R077125, Romania (ibaltog@infim.ro)
[4] CEA, DEN/DANS/DPC/SEARS//Laboratory for the Engineering of Surfaces and Lasers, F-91191 Gif-sur-Yvette, France (michel.schlegel@cea.fr)

The effect of some new organic inhibitors on the oxidative dissolution of synthetic FeS at 25 ºC in air-saturated HCl solutions (pH 1.3) was investigated by polarization and Electrochemical Impedance Spectroscopy (EIS) methods. The studied organic inhibitors were: 4-(5-bromo-2-hydroxyphenyl)-5-methyl-2-(morpholin-4-yl)-1,3-thiazol (Pr01); 4-(2-hydroxyphenyl)-2-(morpholin-4-yl)-1,3-thiazol (Pr02) and 1-(5-bromo-2-hydroxyphenyl)-1-oxaethan-2-yl-*N*,*N*-diethyldithiocarbamate (Pr03). The used concentration of the inhibitors was 1 mM. The inhibition eficiency (IE) was computed by the following formula:

$$IE=(1-i_{corr}/i_{corr}^{0})\cdot 100$$

where i_{corr} and i_{corr}^{0} are the corrosion curent densities in the presence and absence of the inhibitor, respectively.

The best IE was observed for Pr01 (54 %). The other inhibition efficiencies were: 13% (Pr02) and 31% (Pr03). The interaction between FeS and the inhibitor with the best IE was analyzed by Raman spectroscopy, and the surface of reacted FeS was inspected under Scanning Electron Microscope (SEM).

This work was supported by a grant of the Romanian National Authority for Scientific Research, CNDI–UEFISCDI, project number 51/2012.

The role of carbon dioxide from recycled sediments in the genesis of ultrapotassic magmas from lithospheric mantle

S. CONTICELLI, R. AVANZINELLI AND E. AMMANNATI

Dipartimento Scienze Terra, Università di Firenze, Italy

The central-western Mediterranean is one of the most important areas on Earth for studying subduction-related potassic and ultrapotassic magmatism derived from partial melting of lithospheric supra subduction mantle. In the circum-Tyrrhenian area leucite-free (i.e., lamproite) and leucite-bearing (i.e., kamafugite, leucitite, and plagioleucitite) ultrapotassic rocks occur in association with shoshonites and high-K calc-alkaline volcanic rocks. Four different magmatic associations are then recognised. Eastward and then south-eastward migration of magmatism with time occurred following rollback of the subducting plate. Leucite-free silica-rich lamproite are restricted to the early stages of magmatism, associated with shoshonites and high-K calc-alkaline volcanic rocks. Present day volcanic activity is restricted to the Neapolitan district where ultrapotassic rocks with contrasting geochemical and isotopic characteristics occur. Ultrapotassic rocks are strongly enriched in incompatible trace elements with variable fractionation of Ta, Nb, and Ti with respect to Th and Large Ion Lithophile Elements. Mafic ultrapotassic rocks are also variably enriched in radiogenic Sr and Pb and unradiogenic Nd. The main geochemical and isotopic signatures result from sediment recycling within the upper mantle via subduction. Selected trace element ratios suggest that high temperatures are required to generate sediment-derived melts. Recycling of carbonated pelites play an important role in the Roman province controlling the genesis of leucite-bearing magmas.

Large volumes of a metasomatic component are predicted to be accommodated within a vein network in the sub-continental lithospheric mantle. Partial melting of the pure vein mineralogy is likely to generate ultrapotassic magmas of either lamproitic or kamafugitic nature. Over time, increased interaction between the metasomatic vein lithology and the surrounding mantle dilutes the alkaline component producing shoshonites and high-K calc-alkaline rocks. The addition of a further subduction-related component shortly before magma generation is required to explain the isotopic composition of rocks from the Neapolitan district. In the last phases of circum-Tyrrhenian evolution, a within-plate component appears within south-eastern Italy. This component is evident at Vulture volcano, in the Lucanian Magmatic province (SE Italy) and at Ustica Island (SW Tyrrhenian Sea).

Sources of Fe to the North Atlantic: Insights from Fe isotopes

TIM M. CONWAY[1]* AND SETH G. JOHN[1]

[1]Dept. Earth and Ocean Sciences, University of South Carolina, USA

*Presenting author (correspondence: tconway@geol.sc.edu)

Iron (Fe) is an important micronutrient in marine biogeochemical cycles, with dissolved Fe concentrations significantly influencing both nitrogen fixation and photosynthesis by phytoplankton throughout the surface ocean. Constraints on the marine iron cycle are therefore key to our understanding of the global carbon cycle. Dissolved Fe isotope measurements (δ^{56}Fe) are a new parameter which provide a unique opportunity to discriminate between the various sources, sinks and processes controlling Fe distribution within the oceans, in a way that is not possible with measurements of Fe concentration alone.

Utilising a new method for the simultaneous extraction of dissolved Fe, Zn and Cd from seawater, followed by analysis by double-spike plasma mass spectrometry, we present the first basin-scale study of δ^{56}Fe. Multiple high-resolution depth profiles from the GEOTRACES A03 North Atlantic Zonal Transect (Lisbon to Woods Hole, via Cape Verde) allow us to isotopically fingerprint different sources of Fe and assess the relative contribution of each to the dissolved Fe pool in the North Atlantic.

Close to the Mauritanian margin, where a pronounced oxygen minimum is present at depth, light δ^{56}Fe values (~0 to -0.5 ‰) provide evidence for a small but significant contribution of light reduced sedimentary Fe to the dissolved Fe pool, mixed with heavy Fe (+0.5 to +0.7 ‰) released from dissolving aerosols under the Saharan dust plume. Relatively homogenous heavy δ^{56}Fe values (+0.3 to +0.5 ‰) throughout the water column in the deep western basin suggests that dissolution of aerosol Fe is the dominant source of dissolved Fe to the North Atlantic ocean. The homogeneity of δ^{56}Fe values lends support to the idea that ligand-controlled exchange between the dissolved and particulate pools is important in controlling both dissolved Fe concentration and δ^{56}Fe in the North Atlantic.

We also present the first direct measurements of dissolved δ^{56}Fe in a buoyant hydrothermal plume, where values from the TAG Mid-Atlantic Ridge site (-1.3 ‰) indicate that hydrothermal vents are a source of isotopically light Fe to the oceans.

Does the redox cascade apply to permeable sediments?

PERRAN L.M. COOK[1]*, VICTOR EVRARD[1], MICHAEL BOURKE[1] AND RONNIE N. GLUD[2]

[1]Water Studies Group, School of Chemistry, Monash University, Melbourne, Australia (*perran.cook@monash.edu)
[2]Nordic Center for Earth Evolution, University of Southern Denmark, Odense, Denmark.

The redox cascade is a well-established paradigm that allows us to describe the sequential use of electron acceptors by microbial communities to oxidise organic matter. Sediment redox environments can be highly variable ranging from aerobic to anaerobic and back to aerobic on the timescale of minutes. The redox environment in permeable sediments is likely to be particularly variable, driven by sediment movement (re-suspension) and varying currents which can oscillate redox conditions on the timescale of minutes, hours and days. There have been no studies on the latent capacity of microbial communities or their short-term (hours –days) shifts in metabolism as the redox environment changes.

Understanding this dynamic is particularly important because it has implications for key redox reactions of global importance such as denitrification. In this talk we present the results of flow through reactor experiments on the ability of microbial communities to mineralize carbon and use electron acceptors other than oxygen over time scales of hours to days. Of key interest, our results have shown that microbial communities are able to rapidly switch to denitrification on times scales < 1 h, however this pathway can only account for a small fraction of the electron sink required for the observed rates of carbon mineralisation, pointing to the importance of the simultaneous use of other electron acceptors.

The role of natural organic matter in membrane perturbation: A model biomembrane system approach

R.L. COOK[1]* AND L.M. OJWANG'[1]

[1]Department of Chemistry, Louisiana State University, Baton Rouge, LA, 70803, USA (*correspondence: rlcook@lsu.edu)

Natural organic matter (NOM) is an important component of earth's ecosystems. It is known to play a major role in biogeochemical (including redox) processes and pollutant bioavailability (and subsequent toxicity), to name just two. There are conflicting reports in regards to the ability of NOM to either lower or raise the bioavailaibility of pollutants. To understand these conflicting findings a mechanistic understading is needed in terms of how NOM interacts with biomembranes. In order to make the system as simple as possible, only passive processes will be studied using of phospholipid vesicles. Our initial studies focused on the effects of pH, NOM concentration, and temperature on the ability of different humic acids to perturb the model biomembrane systems by utilizing fluorescence leakage experiments. Subsequently, wideline ^{31}P NMR was employed to investigate how the model biomembrane was being perturbed [1]. From these studies a two-step adsorption/absorption mechansim was proposed by which NOM induced biomembrane perturbation. This proposed mechanism was then further tested by kinetic studies which, in addition to supporting the proposed adsorption/absorption mechanism, also indicated two distinct components of the absorption step. Finally, the chemical components within the humic acids responsible for the perturbation of the model biomembrane system were investigated with the aid of chemically modified humic acids.

Computer Modeling of Pb Apatites and their Potential for Reducing Pb Levels in Drinking Water

DAVID J COOKE AND JEREMEY HOPWOOD[1]

[1]Department of Chemical and Biological Sciences, University of Huddersfield, UK email: (d.j.cooke@hud.ac.uk)

Due to its resistance to corrosion and maliability lead was the material of choice for water pipes from ancient times until the 20th centurary and many domoestic water supplies are still reliant on legacy lead piping. Over time lead will leach from the pipes into the water supply and if left unchecked can cause Pb levels in drinking water to become dangerously high. Consequently water companies the world over are investigating methods for reducing the levels of Pb present in a safe and economic way that can be applied even when pipes are inaccessable.

One solution being explored is to promote the crystalisation of lead phosphat minerals in the water pipes by adding additional phosphates to the water supply. Here we report on a combined modelling and experimerimental study exploring the Pb-apatite system.

The computer models are based on the atomistic potentials previously fitted by de Leeuw and co workers [1] to study a range of apatite minerals, which we have extended to incorporate the Pb^{2+} ion and were fitted so they reproduce the structure of $Pb_5(PO_4)_3F$ and $Pb_5(PO_4)_3Cl$ as well as $PbCO_3$, $PbCl_2$, PbF_2 and $Pb(OH)_2$ to within 1% of the experimentally determined parameters.

Initially we considered the effect on the unit cell of varying the Pb:Ca ratio and compared this to structure of crystals grown in the lab and found excellent aggreement between the experimental and simulated lattice parameters, thus giving us confidence to use the computer model as a predictive tool and probe how the Pb an Ca will arrange in the structure as a function of Pb content.

Our current work is focused in two main areas. Firstly we are considering the surface properties of the minerlas and whether segregatiuon of Ca or Pb is preferable. Secondly we are probing the mineral water interacebyconsidering the competative adsorption of lead and calcium on calcium and lead rich chloro and fluoro apatitie surfaces.

Magmatic-hydrothermal sutures and clusters of giant porphyry Cu-(Au-Mo) deposits

DAVID R COOKE AND JOSE PIQUER[1]

[1]CODES, the Australian Research Council's Centre for Excellence in Ore Deposits; d.cooke@utas.edu.au

Porphyry deposits are the world's major sources of Cu, Mo and Re, and important sources of Au and Ag. They typically form in compressional orogens, either during or after subduction. The transition from extensional tectonism and widespread calc-alkaline volcanism, to a compressional tectonic regime causes inversion of the extensional structural architecture, crustal thickening and shutdown of volcanism, promoting the growth of mid- to upper-crustal intermediate-to felsic magma chambers at major structural intersections. Fractional crystallisation within the magma chamber, possibly coupled with mafic magma underplating, thermal destabilisation and volatile addition, leads to eruptions of hydrous melts and mineralising fluids from the roof of the pluton, producing elongate 'spires' of porphyry that intrude to paleodepths are surrounded and overprinted by of 1-3 km and magmatic-hydrothermal alteration and mineralisation.

Both geochemical and structural processes are fundamental to the formation of clusters of giant porphyry deposits. Several of the world's largest deposit clusters, in terms of contained metal, were localised on major suture zones that developed due to the interaction of arc-parallel and arc-oblique fault systems in the overriding plate. The Eocene—Oligocene Chuquicamata cluster of deposits in northern Chile (Chuquicamata, Radomiro Tomic, Mina Sur, Ministro Hales, Opache and the Toki cluster) was localised along a 25 km corridor controlled by the NNE-trending Mesabi fault and equivalent structures, at its intersection witth the Calama-Olacapato-El Toro NW lineament. The district contains over 93 Mt of fine Cu. In the case of the world's largest porphyry Cu-Mo district, Rio Blanco-Los Bronces (> 200 Mt of fine Cu), at least seven porphyry deposits formed during the late Miocene-early Pliocene along a 12 km long, NNW-trending suture zone, with mineralised centres localised at the intersections between the major NNW-trending structures and cross-cutting NE-trending fault systems. The Paleozoic Oyu Tolgoi district in Mongolia contains at least 1749 t Au and 45.5 Mt Cu in a cluster of eight porphyry Cu-Au deposits aligned along a NNE-trending, 26 km long structural corridor. In each of these examples, conditions that promote repeated magmatic-hydrothermal activity in major upper-crustal sutures were essential for the formation of giant porphyry deposit clusters.

Thermal histories from crystal records

KARI M. COOPER[1]* AND ADAM J.R. KENT[2]

[1]Department of Geology, University of California Davis, Davis, CA 95616, USA
(*correspondence: kmcooper@ucdavis.edu)
[2]College of Earth, Ocean and Atmospheric Sciences, Oregon State University, Corvallis, OR 97330, USA

Many volcanic eruptions, including some of the largest ever, involve crystals stored in magma reservoirs within the crust for significant periods (10's to 100's ka) prior to eruption. Knowledge of the conditions of magma storage are critical for efforts to understand the processes that lead to initiation of eruptions and eruption dynamics, but these remain surprisingly poorly known [e.g., 1,2]. Eruption of homogeneous crystal-rich magma is often argued to reflect the mobilization of magma stored at near solidus conditions, but in other cases these are considered to reflect storage of magma at significantly higher temperatures for extended periods prior to eruption [3,4]. What has been heretofore lacking in this debate is clear observational evidence linking the thermal (and therefore physical) conditions within a magma reservoir to time scales of storage - i.e., thermal histories. We present a novel method for constraining pre-eruptive thermal histories of magmas by combining estimates of crystal residence time based on U-series systematics, textural information, and trace-element zoning in crystals.

At Mt Hood, Oregon, andesitic magmas are formed by mixing of silicic and mafic endmembers, with CSDs showing two populations of plagioclase [5]. The large (silicic-derived) population has cores >21 ka with rims that crystallized near eruption, yet preserve disequilibrium concentrations of Sr. By combining the ^{238}U-^{230}Th-^{226}Ra crystal age data with diffusion calculations and with crystal growth times based on CSDs, we show that only a small fraction of the total storage duration (<<5%) has been spent at temperatures above the critical crystal fraction of 40-50%, where the magma body is easily mobilized. Partial data sets for other volcanoes suggest that similar conditions of magma storage are widespread, which predicts that largely-liquid bodies that could be imaged geophysically will be ephemeral features.

Analytical chemistry, natural organic matter and climate change: Linking chemical signatures and microbial communities that affect carbon cycling in northern peatlands

W. T. COOPER[1], M.M. TFAILY[1], J.P. CHANTON[1], J.E. KOSTKA[2], X. LIN[2] P. CHANTON[2], J.M. STEINWEG[3]AND C.W. SCHADT[3].

[2]Georgia Institute of Technology, Atlanta, GA, USA
[3]Oak Ridge National Laboratory, Oak Ridge, TN, USA

Global peatlands sequester half as much carbon as that contained in the atmosphere. However, the response of these large carbon reservoirs to global warming remains uncertain. In this presentation the results of experiments designed to identify the reactive and refractory dissolved organic matter (DOM) pools from peatlands in the Marcell Experimental Forest, northern Minnesota, will be described, along with accompanying differences in microbial communities. These experiments included advanced analytical techniques[1] (ultrahigh resolution (UHR) mass spectrometry, PARAFAC-modeled 3-D excitation-emission matrix [EEM] fluorescence spectroscopy) and a combination of next generation sequencing and metagenomics.[2] Surface peat (0-10 cm) was characterized by high DOC concentrations and relatively low aromaticity. In more decomposed layers at 30-50 cm depth, UHR mass spectra identified distictly different reactive and refractory DOM pools, as well as the appearance of lipid-like compounds of apparant microbial origin. PARAFAC-modeled EEM revealed fluorescent components (products and reactants) that were consistent with microbial processing. Below 75 cm, results indicate slower degradation of organic matter under anaerobic conditions and stable enzymatic activity. Microbial community structure corresponded strongly to the vertical stratification of dissolved organic matter (DOM) quantity and composition. Atmospheric pressure photoionization was used to selectivly observe mass spectra of dissolved organic nitrogen (DON), and changes in DON were correlated to nitrogen-specific enzymatic activity in the solid phase peat. These results have important implications for predicting the fate of carbon storage in peatlands, since warming may lead to an increase in deposition of more labile DOM and enhanced phenol oxidase activity, the net effect being a release of a significant store of soil carbon to the atmosphere.

The potential of platinum stable isotopes of Fe-Mn nodules and crusts as a paleoceanographic tracer

L. CORCORAN[1]*, M.R. HANDLER[1], J. BAKER[2], T. SEWARD[1], J. CREECH[1] AND V. BENNETT[3]

[1] School of Geography, Environment and Earth Sciences, Victoria University of Wellington, New Zealand (*correspondence: Loretta.Corcoran@vuw.ac.nz)
[2] School of Environment, University of Auckland, Private Bag 92019, Auckland, New Zealand
[3] Research School of Earth Sciences, Australian National University, Canberra, ACT 0200, Australia

Fe-Mn nodules and crusts are slow-growing chemical sediments that form by direct precipitation from seawater, resulting in a record of changing seawater chemistry. In the modern oxic marine environment these sediments are also the primary sink for platinum: 80 times enrichment over pelagic sediments and up to 1300 times over UCC concentrations[1,2], resulting in concentrations that make them amenable to Pt stable isotopic analysis.

Platinum is a non-bio-essential siderophile transition metal with six naturally occurring isotopes (^{190}Pt, ^{192}Pt, ^{194}Pt, ^{195}Pt, ^{196}Pt, ^{198}Pt) with a range of oxidation states (Pt^0, Pt^{2+}, Pt^{4+}). The dominant oxidation state of platinum in seawater is thought to be Pt^{2+}, with Pt^{4+} also present to an unknown degree[1,3]. Variations in ocean redox state, together with changes in source fluxes to the oceans, may lead to small variations (< ±1‰) in the stable isotopic composition of marine platinum. We will present the first investigation into the Pt stable isotopic composition of marine Fe-Mn (hydroxy)oxide sediments, to investigate its potential as a paleoceanographic tracer.

A method has been established using MC-ICPMS to precisely measure Pt isotopic compositions using a ^{196}Pt-^{198}Pt double spike to correct for instrumental mass bias[4]. Pt is separated from the Fe-Mn oxyhydroxide component of the sediments by means of anion exchange chemistry, with ≥ 80% yields and ≥ 85% purity, as determined for three natural nodule standards and a Pt standard. Preliminary results from bulk nodules from different ocean basins are indistinguishable within uncertainties but have a measurable isotopic offset from the IRMM standard and three other Pt metal standards[4] and the suggestion of offsets from other terrestrial reservoirs.

Mafic lavas constrain the chemical variability of the Society plume

C. CORDIER[1]*, C. CHAUVEL[1] AND M. GUILLET[1]

[1] ISTerre, Université Joseph Fourier, Grenoble, France. (*correspondence: carole.cordier@ujf-grenoble.fr)

Geochemical investigation of ocean island lavas has shown that in some archipelagoes, lavas are organized in distinct chemical and geographic trends, attributed to sampling by mantle plumes of distinct chemical reservoirs located deep in the mantle [e.g., 1-2].

Here, we present new trace element and Sr-Nd-Hf-Pb isotopic compositions of 40 mafic alkaline shield-building lavas (MgO>8 wt.%) from the main islands of the Society Archipelago (French Polynesia): Mehetia (<1 Myr), Moorea (ca 1.5 Myr), Raiatea and Huahine (ca 2.5 Myr), Bora Bora (ca 3.5 Myr) and Maupiti (ca 4.5 Myr). Isotopic compositions of the mafic lavas cover the entire range known for the Society lavas (^{87}Sr/^{86}Sr = 0.703894 to 0.706053; ^{143}Nd/^{144}Nd = 0.512613 to 0.512898; ^{176}Hf/^{177}Hf = 0.282849 to 0.283042; ^{206}Pb/^{204}Pb = 18.77 to 19.55).

Recently, Payne *et al*. [3] distinguished two groups of islands along the Society chain using the relationship between published Ba/Nb and ^{143}Nd/^{144}Nd data . Our new data do not support this interpretation and show a continuum of compositions rather than two distinct groups. For instance, Maupiti and Huahine, assigned to different groups, not only have similar geochemical signature but also the data points for both islands are spread over the two groups. The geochemical structure of the Society plume is thus complex and the model of two parallel trends reflecting its location with respect to the DUPAL anomaly [3] needs revision.

Our dataset shows that FeO, TiO_2 and CaO decrease and SiO_2 and K_2O increase with ^{87}Sr/^{86}Sr. These correlations do not result from shallow-level processes but from changing melting depths and lithologies within the plume conduit. They also cover the entire range of major element compositions of ocean island mafic lavas [4] (e.g. SiO_2 = 42-48 wt.%, K_2O/TiO_2 = 0.1-0.7 and CaO/Al_2O_3 = 0.7-1.1). Thus, using average archipelago compositions to discuss mantle end-member lithologies leads to underestimate the internal plume variability. In the Society chain, low ^{87}Sr/^{86}Sr melts derive from deeper melting and/or from silica-poor sources (e.g., CO_2-bearing peridotite or eclogite) while high ^{87}Sr/^{86}Sr melts derive from shallower melting and/or from sources richer in SiO_2 (e.g., volatile-free peridotite).

Deformation mechanisms of olivine compressed at 300 MPa and 800-1100°C

PATRICK CORDIER[1], SYLVIE DEMOUCHY[2], ALEXANDRE MUSSI[1] AND ANDREA TOMMASI[2]

[1] Université Lille 1 & CNRS, UMR 8207 Unité Matériaux et Transformations, 59555 Villeneuve d'Ascq, France
[2] Université de Montpellier 2 & CNRS, UMR 5342 Geosciences Montpellier, 34095 Montpellier. France

Rheology of mantle rocks at lithospheric temperatures remains poorly constrained, since most experimental studies on creep mechanisms of olivine single crystals ($(MgFe)_2SiO_4$, *Pbnm*) and polycrystalline olivine aggregates were performed at high-temperatures (T >> 1200°C). In this study, we have performed deformation experiments on oriented single crystals of San Carlos olivine and polycrystalline olivine aggregate at temperatures relevant of the uppermost mantle (ranging from 800 to 1090°C) in tri-axial compression. The experiments were carried out at a confining pressure of 300 MPa in a high-resolution gas-medium mechanical testing apparatus at various constant strain rates (from 7×10^{-6} s^{-1} to 1×10^{-4} s^{-1}). Mechanical tests yield differential stresses ranging from 88 to 1076 MPa. All samples were deformed at constant displacement rate and for finite strains ranging from 4 to 23 %, to provide insight into possible effects of hardening, softening or stick-and-slip. The single crystals were compressed along several crystallographic directions to test the possibility of activating different slip systems (*e.g.* [100](001), [001](100), [001](010) and [100](010)). We will present the characterization of the dislocation microstructures performed in the TEM. In particular, we present some slip plane characterizations for [001] dislocations based on electron tomography.

The disposal of spent nuclear fuel: The effect of high energy surface sites on dissolution rate

C. L. CORKHILL*, D. J. BAILEY, S. THORNBER, M. C. STENNETT AND N. C. HYATT

Immobilisation Science Laboratory, Department of Materials Science and Engineering, University of Sheffield, Sheffield, UK. (*correspondence: c.corkhill@sheffield.ac.uk)

High energy surface sites, including grain boundaries, step edges and naturally occurring surface defects are expected to play a role in the dissolution of mineral surfaces. Spent Nuclear Fuel (SNF), composed primarily of ceramic UO_2, has grain boundaries and oxygen vacancy defects as a result of high temperature annealing within a nuclear reactor. In the safety case for the geological disposal of nuclear waste, the release of radioactivity from the repository is controlled by the dissolution of the SNF in groundwater, therefore the dissolution characteristics arising from surface features must be determined.

In this study, we demonstrate the effect of high energy surfaces sites on the dissolution rate of CeO_2, a SNF analogue, which approximates as closely as possible the characteristics of fuel-grade UO_2. Due to the highly refractory nature of CeO_2, dissolution was conducted at 90 °C and pH 2 (nitric acid). CeO_2 was powdered to several different size fractions and subject to dissolution. It was found that large size fractions exhibited a greater dissolution rate than small size fractions (0.81×10^{-4} g m^{-2} d^{-1} for 75 – 150 μm compared to 0.45×10^{-4} g m^{-2} d^{-1} for 25 -50 μm). Annealing the powders at high temperature removed some of the high energy surface sites and resulted in a less rapid dissolution rate (0.21×10^{-4} g m^{-2} d^{-1} for 25 -50 μm). Monolith samples of CeO_2 were subject to dissolution and analysed periodically by AFM and ICP-MS. Initially, grain boundary dissolution was rapid (460 nm increase in grain boundary depth over 7 days), concurrent with a rapid dissolution rate (0.57 ppm d^{-1}). The dissolution rate decreased (0.15 ppm d^{-1}) when there was no longer any change in the grain boundary depth. CeO_2 powders were annealed under reducing conditions (H_2/N_2), forming non-stoichiometric $CeO_{1.93}$, concurrent with the formation of oxygen vacancy defects. The dissolution rate of these powders was three orders of magnitude greater than for CeO_2 powders. These results demonstrate that high energy surface sites are important in controlling the dissolution rate of SNF and provide quantitative information to reduce uncertainty in the safety case for SNF disposal.

Si isotope and Ge/Si ratios record successive cycles of dissolution/precipitation of pedogenic clay minerals

J-T. CORNELIS[1,2]*, D. WEIS[1], J. BARLING[1], L. LAVKULICH[3] AND B. DELVAUX[2]

[1]Department of Earth, Ocean and Atmospheric Sciences (PCIGR), University of British Columbia, 2207 Main Mall, Vancouver BC, V6T 1Z4, Canada
[2]Earth and Life Institute, Université catholique de Louvain, Croix du Sud 2, 1348 Louvain-la-Neuve, Belgium (*correspondence : jean-thomas.cornelis@uclouvain.be)
[3] Soil Science, University of British Columbia, 127-2357 Main Mall, Vancouver BC, V6T 1Z4, Canada

Pedogenic clay minerals provide the most significant and reactive surface area in soils and as such largely govern biogeochemical processes at the interface between lithosphere and biosphere. Deciphering the mechanisms governing clay formation is therefore of the utmost importance to understand how soils will evolve and how they control the Earth's biogeochemical cycles. Pedogenetic transformations governing the dynamic of clay minerals in soils are however still not fully understood.

Compared to the original geochemical signature of clay-size minerals in the deepsoil Bw horizon of a Podzol ($\delta^{30}Si$ = -0.49±0.01‰; Ge/Si = 3.8±0.17μmol/mol), we document increasing enrichment of ^{28}Si and Ge in clay-size minerals produced during podzolization by the mobilization, transport and precipitation of carbon, metals and silicon. Partial dissolution of clay minerals previously enriched in ^{28}Si isotope and Ge in the eluvial E horizon ($\delta^{30}Si$ = -0.57±0.05‰; Ge/Si = 8.59±0.22μmol/mol) is the only process that could account for the occurrence of even lighter Si and greater enrichment of Ge in aluminosilicates in the illuvial Bh/Bs horizon ($\delta^{30}Si$ = -1.14±0.15‰; Ge/Si = 10.1±0.32μmol/mol).

This study provides consistent evidence for previously unrecognized cycles of (partial) dissolution and precipitation of pedogenic clay minerals during podzolization, leading to tertiary and quaternary silicate neoformation. This challenges the concept that pedogenic clay minerals would be the stable end soil-product in equilibrium with soil-forming factors and suggests that they are reactive over time depending on soil physico-chemical conditions. Si isotope and Ge/Si ratios record a "mineral memory" of the soil-forming processes, and as such provide a powerful tool for the understanding of biogeochemical processes governing soil formation.

Geologic evolution of the Cerro Quema Au-Cu deposit, Azuero Peninsula (Panama)

I. CORRAL[1], M. CORBELLA[1], À. CANALS[2] , A. GRIERA[1], D. GÓMEZ-GRAS[1], D. NAVARRO-CIURANA[1] AND E. CARDELLACH[1]

[1]Departament de Geologia, Universitat Autònoma de Barcelona, 08193 Barcelona. Spain
(*Corresponding author: Isaac.Corral@uab.cat)
[2]Facultat de Geologia, Universitat de Barcelona, 08028 Barcelona. Spain

Central America hosts a variety of metallic mineral resources including Au, Cu, Ag, Pb, Zn, Ni, Co, Sb, W, and Al, spanning a broad range of deposit types. In Panama, Au and Cu are the most economically important metals, and they are mainly related to epithermal and porphyry copper systems.

Cerro Quema is a high sulfidation epithermal deposit located in the Azuero Peninsula (SW Panama), it is constituted by serveral mineralized bodies named from W to E: La Pava, Cerro Quemita and Cerro Quema. Estimated Au resources are 7.23 Mt with an average gold grade of 1.10 g/T. Cerro Quema is located in the fore-arc basin of the Panamanian Cretaceous volcanic arc. It is related to an E-W trending regional fault system, and is hosted by the dacite dome complex of the Río Quema Formation (Campanian to Maaastrichtian in age).

Hydrothermal alteration consits of an inner zone of nearly pure quartz (vuggy silica alteration), with local quartz-alunite and pyrophyllite alteration (advanced argillic alteration), enclosed by a kaolinite, illite and illite/smectite-bearing zone (argillic alteration), grading to an external halo of propylithic alteration.

Gold occurs as disseminated submicroscopic grains and "invisible gold" within the pyrite lattice. Copper is associated to Cu-bearing phases such as chalcopyrite, enargite, tennantite, covellite and chalcocite.

Cerro Quema was formed by fluids derived from the emplacement of an underlying porphyry copper intrusion emplaced along E-W trending regional faults located in the Cretaceous fore-arc basin, during Paleogene times. The proposed geologic model suggests that high sulfidation epithermal deposits are not exclusive of volcanic edifices or volcanic domes related to subduciton zones. This deposits can also occur in fore-arc basins, associated with acidic intrusions located between the volcanic arc front and the subduction trench. This should be taken into account for exploration in geologically similar terranes.

[4]Second University of Napoli,Via Roma 29, 81031, Aversa (CE), Italy (valeria.direnzo@ov.ingv.it)

A geochemical study comprehensive of major elements, trace elements and Sr-Nd isotopes in the bulk rock, coupled to noble gases analyses from fluid inclusions retained in minerals, was performed. The studied samples (basalts, trachybasalts and basanites) represent some among the most primitive products of Etnean history. The variable composition measured in trace elements (i.e. Zr/Nb=2.81–4.98, Ce/Yb=35.02–66.90, La/Yb=15.36–35.52, Th/Y=0.17–0.43) was modeled as due to varying degrees of melting of a common mantle source. We numerically simulated the process by MELTS code to calculate a melting percentage for each product and we accordingly estimated the pristine trace-elements content of their mantle source. This latter resulted to be common to all of the investigated samples and evidenced a close affinity between Etnean and Hyblean mantle. The observed coupling between trace elements and noble gases allowed us to better define the Etnean mantle, which resulted compatible with a peridotitic matrix veined by 10% of clinopyroxenites. The geochemistry of the Sr-Nd-He isotopes ($^{87}Sr/^{86}Sr$= 0.703321–0.703910, $^{143}Nd/^{144}Nd$= 0.512836 – 0.512913 and $^{3}He/^{4}He$= 6.7–7.6 Ra) confirmed the relation existing between Etnean and Hyblean mantle and evidenced that mantle contamination by crustal-like fluids occurred at a variable extent in our products. The $^{87}Sr/^{86}Sr$ ratio appears correlated to the estimated degree of melting for each product, therefore the metasomatic fluids probably refertilized some portions of the mantle and promoted partial melting. In contrast, the observed decoupling between $^{3}He/^{4}He$ and $^{87}Sr/^{86}Sr$ ratios could be related to shallower processes, as magma aging or a contribution of shallow fluids, able to decrease the primitive $^{3}He/^{4}He$ of some samples.

Modeling water-gas-rock interactions using CHESS/HYTEC

JÉRÔME CORVISIER[1]

[1]Centre de Géosciences, MINES ParisTech, Fontainebleau FRANCE (jerome.corvisier@mines-paristech.fr)

Numerous applications of reactive-transport codes within the field of Geosciences require handling water-gas-rock interactions. Some strong but convenient assumptions could be made to simplify the problem: infinite gas source, dissolved gases, perfect gas approximation… Nevertheless, in many cases, such approaches lead to significant errors and the gaseous phase has to be more accurately represented in models.

Specific gas modules incorporating classical cubic equations of state (Redlich-Kwong, Peng-Robinson…) and their appropriate analytic solver have been developped [1,2] and implemented in the geochemical code CHESS [3] and the coupled reactive-transport code HYTEC [4].

These improvements allow the modeling of complex water-salt-gas-rock systems in various conditions. CHESS can, for example, be used to study the geochemical impact of impurities captured and possibly co-injected along with CO_2 for its geological storage. As an illustration, the code is able to reproduce the measured solubility and co-solubility of gases including gas mixtures such as CO_2-N_2 mixtures.

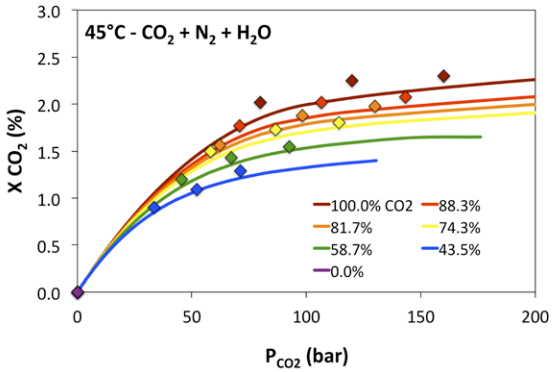

Figure Aqueous CO_2 molar fraction vs. pressure for CO_2-N_2-H_2O system (symbols correspond to measurements [5] and solid lines to CHESS simulations).

$^{87}Sr/^{86}Sr$ in gypsic soils of hyperarid settings as an altitude proxy: Results for northern Chile (19-24ºS) and paleoaltimetry applications

N. C. COSENTINO* AND T. E. JORDAN

Earth and Atmospheric Sciences, Cornell Univ., Ithaca, NY 14853, USA (*correspondence: njc58@cornell.edu)

Quantification of uplift of a continental surface relative to sea level is challenging. We have developed a new altimeter proxy based on the $^{87}Sr/^{86}Sr$ ratio of incipient soils in hyperarid settings like those present in the Atacama Desert. The proposed altimeter is based on the first order topographic control on the extent of coastal fog [1]. Atmospheric advection brings offshore-generated stratocumulus clouds to the continent, generating fog that on geologically recent timescales (10^3-10^4 yrs) has averaged base and top altitudes of 300 and 1150 m.a.s.l., respectively. In the hyperarid desert, calcium sulfate accumulates on the surface, progressively forming saline soil [2]. Samples of Atacama's incipient soils reveal $^{87}Sr/^{86}Sr$ values clustering in two altitudinal domains (Figure 1); seawater $^{87}Sr/^{86}Sr$ (0.70916) is distinctively higher than the ratio for Atacama's incipient soils outside of the fog zone (0.70733).

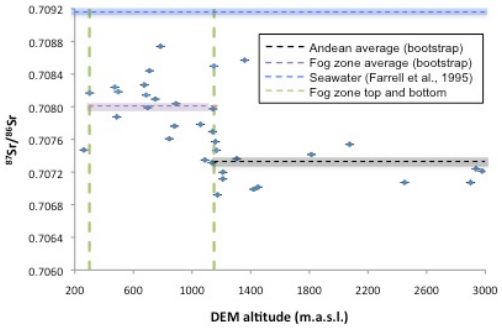

Figure 1: Northern Chile (19-24ºS) modern accumulations of salts' $^{87}Sr/^{86}Sr$ and altitude of formation. Translucent color boxes represent the uncertainty in each domain's $^{87}Sr/^{86}Sr$ mean ratio. Samples from [2] and this study (N = 36).

We are investigating the use of this relationship to deduce late Miocene-Pliocene topographic history of the Nazca/South America forearc. Based on results of dated paleosols in the study area we reach a preliminary interpretation: ≥ 400 m local uplift has occurred since 5 Ma.

The origin of geochemical anomalies in top soils of Eastern-Central Peloritani Mountains (Sicily, Italy)

COSENZA A.[1]*, AYUSO R. A.[2], FOLEY N.[2], ALBANESE S.[1], LIMA A.[1], MESSINA A.[3] AND DE VIVO B.[1]

[1]DISTAR, Università di Napoli Federico II, Via Mezzocannone 8, 80134 Napoli, Italy (*correspondence: antonio.cosenza@unina.it)

[2]U.S.G.S., National Center, Mail Stop 954, Reston, VA 20192, US (rayuso@usgs.gov)

[3]Dipartimento di Fisica e Scienze della Terra, Università di Messina, Salita Sperone 31, 98165 Messina (antonia.messina@tiscali.it)

The Peloritani Mountains extend across the Southern Sector of the Calabria-Peloritani Arc, in NE Sicily. The arc consists of a stack of nine continental crust tectonic units *Aspromonte*, *Mela*, *Piraino*, *Mandanici*, *Alì*, *Fondachelli*, *San Marco d'Alunzio*, *Longi-Taormina Capo Sant'Andrea*, including Pan-African and Variscan crystalline basements and remnants of Meso-Cenozoic sedimentary covers.

In this study, we focused on 122 top soils samples collected over an area of 300 km^2, from the Ali to the Bafia villages (Eastern-Central Peloritani Mts.). The concentrations of 53 elements Mo, Cu, Pb, Zn, Ag, Ni, Co, Mn, Fe, As, U, Au, Th, Sr, Cd, Sb, Bi, V, Ca, P, La, Cr, Mg, Ba, Ti, B, Al, Na, K, W, Sc, Tl, S, Hg, Se, Te, Ga, Cs, Ge, Hf, Nb, Rb, Sn, Ta, Zr, Y, Ce, In, Re, Be, Li, Pd and Pt including potentially harmful metals, have been determined by ICP-MS after Aqua Regia acidification. Geochemical data have been georeferenced and interpolated geochemical maps show distribution patterns of 15 elements for which the Italian environmental law (D. Lgs 152/2006) establishes trigger limits based on geogenic values that differ for land use.

Regarding both residential and industrial/commercial land use, Pb, As and Cd concentrations in these soils often exceed the corresponding trigger limits as established by Italian law. To discriminate between anthropogenic and geogenic origin of Pb, we determined Pb isotopic compositions ($^{206}Pb/^{207}Pb$ and $^{208}Pb/^{207}Pb$) of galena hand-picked from bedrock and of soils (leach and residues) collected in the studied area. The Pb isotopic compositions of the samples indicate that the origin of most contamination is likely geogenic. This interpretation is consistent with widespread occurrence of small sulphide deposits in the area.

The presence of different heavy metal anomalies in top soils represents an interesting new finding, which could be useful for mineral exploration follow up survey, at least for commodity like Au and Ag.

Bacterial formation of Fe-phosphates in the water column of meromictic ferruginous Lake Pavin (Massif Central, France)

JULIE COSMIDIS[1,2], KARIM BENZERARA[1], GUILLAUME MORIN[1], VINCENT BUSIGNY[2], DIDIER JEZEQUEL[2], OANEZ LEBEAU[2], VINCENT NOËL[1], GABRIELLE DUBLET[1] AND GUILLAUME OTHMANE[1]

[1] Institut de Minéralogie et de Physique des Milieux Condensés – Université Pierre et Marie Curie
[2] Institut de Physique du Globe de Paris – Sorbonne Paris Cité – Université Paris Diderot

Lac Pavin (Massif Central, France) is a deep (~92 m) stratified crater lake with anoxic and ferruginous conditions developing in the water column below ~60 m depth. Previous geochemical studies have shown that dissolved Fe(II) and phosphate (PO_4) are present at high concentrations in the anoxic monimolimnion (resp. ~1200 µM and 300 µM) and predicted the formation of vivianite ($Fe(II)_3(PO_4)_2 \bullet 8(H_2O)$) in this layer [1,2]. We performed a detailed characterization of the mineralogy of the settling particles in the water column, and determined the potential role of anaerobic bacterial communities in Fe and P cycling in the lake. Bulk x-ray diffraction and x-ray absorption spectroscopy analyses were used to characterize the mineralogical composition and Fe redox state of Fe-bearing particles collected at different depths in the water column and sediments deposited at the bottom of the lake. In the oxygenated layer of the lake, Fe is hosted by phyllosilicates and Fe-(oxyhydr)oxides (FeOOH). Amorphous Fe-phosphates form close to the redoxcline, whereas vivianite becomes dominant in the monimolimnion. FeOOH are preserved throughout the water column and undergo reductive dissolution at the surface of the sediments, where vivianite becomes the main Fe-bearing phase. These results were confirmed by electron and scanning transmission x-ray microscopies, which showed heterogeneities in the composition and Fe redox state of the particles at the submicrometer-scale. Fe-phosphates were moreover observed to encrust microbial bodies. Based on comparisons with laboratory experiments [3], we propose that the precipitation of Fe-phosphates results from the activity of Fe-oxidizing bacteria. Polyphosphate-accumulating microorganisms could also participate in the formation of Fe-phosphates by concentrating PO_4 in the monimolimnion.

Mass specific magnetic susceptibility as a proxy to differentiate soils within the humid subtropical region

C. S. DA COSTA[1]*

[1]Universidad Estadual de Maringá. Dep. Agronomia. Av. Colombo 5790. Maringá-PR. Brazil 87020-190. (*correspondence: acscosta@uem.br)

Magnetism (χ_{LF}) In Soils

Mass specific magnetic susceptibility (χ_{LF}) data were used to differentiate soils within the humid subtropical region of Brazil. Soils with different degree of weathering and formed under different edaphoclimatic conditions had very different magnetic behabior.

Data collected in the fine earth and clay size fraction of soils from a 200.000 Km^2 area of Paraná State-Brazil shows χ_{LF} values ranging from zero to more than 10.000 10^{-8} m^3 kg^{-1}. Coarse grained multidomain magnetites were present in the sand and silt fractions of the soils while maghemite was detected in the clay size fraction. Higher magnetite contents were found in soils developed from basalts in Latosols/Oxisols. The χ_{LF} values observed for the the soils with poor drainage conditions were low (< 100 x 10^{-8} m^3 kg^{-1}) but not all magnetite from the coarser fractions were reduced and dissolved. In the clay size fraction quantification of the iron oxides [1] shows that maghemite is the iron oxide responsible for the χ_{LF} values and detailed X-rays diffraction data that soil maghemites have extended degree of Fe for Al isomorphous substitution that decreases with increasing soil pH and less intense weathering conditiions (lower average rainfall and temperature) [2]. Important bioavailable metals such as Cu, Mn, Zn and Co presented strong correlation with the χ_{LF} values specially with the magnetite content..

Bromine in basaltic volcanic systems: Experimental study on fluid/melt partitioning coefficient

MICHELA COSTA [1]*, ALESSANDRO AIUPPA [1,2], GIADA IACONO MARZIANO [3] AND ANTONIO PAONITA [2].

[1] [Dipartimento delle Scienze della Terra e del Mare – DiSTeM – Palermo (*correspondance: michela.costa@unipa.it)]

Volcanic halogens play a central role not only in magmatic systems processes but also in atmospheric chemistry, since they have been shown to participate in reactions implicated in tropospheric O_3 destruction [1, 2]. Unfortunately, our current state of knowledge concerning Br behaviour in magmatic systems is still rather poor so a quantitative model of the mechanisms controlling volcanic Br degassing is currently impossible. A fundamental step is understanding Br fluid/melt partitioning coefficient ($D_{Br}^{f/m}$), which has not been investigated yet in basaltic melts. Our work has been mainly aimed to experimentally investigating the distribution of Br between a basaltic melt (Mt. Etna, Italy) and a coexisting fluid phase containing H_2O and known concentrations of Br. Experiments were carried out at ISTO-CNRS of Orléans using rapid-quench autoclaves (T~1200°C; pressure range 500-1000 bar; ~ NNO buffer). Major element in final glasses were measured by EMPA whereas bromine measurements were performed by LA-ICP-MS. In our experiments, Br was found to strongly partition into the fluid phase. This is in agreement with what Bureau *et al*. (2003) reported for an albitic composition and it means that volcanic Br contribution to the atmosphere may be significant. Since no experimental data on $D_{Br}^{f/m}$ in basaltic melts have ever been obtained so far, our study contributes to fill the lack of knowledge concerning Br. In fact, coupling together our experimental results with gas data of Mt. Etna volcanic plume and with information from melt-inclusion, our work can constrain the true Br contents dissolved in Etnean magmas and thus hopefully open the way to constraints Br behaviour during volcanic degassing paths.

Frontiers in Laser Ablation U-Th/Pb Petrochronology

JOHN M COTTLE[1]*

[1] Department of Earth Science, University of California Santa Barbara, CA 93106-9630, USA, cottle@geol.ucsb.edu (* presenting author)

Since the first Laser Ablation ICP-MS U-Th/Pb dates were published ~20 years ago, the field has expanded significantly, becoming a key technique for rapidly measuring spatially resolved in-situ isotopic dates. LA-ICP-MS geochronology is now integral to a broad range of studies - from determining sedimentary provenance to quantifying the timing and duration of tectonic processes. Drawing on examples from ongoing research projects at UCSB and elsewhere, this presentation will highlight recent advances and potential future directions *in situ* U-Th/Pb accessory phase geochronology. Specifically, I will focus on four key avenues of progress: 1) improvements in laser and mass spectrometry instrumentation that increase both the precision with which measurements can be made and the spatial resolution at which dates can be measured; 2) development and application of novel data acquisition and reduction methods to interrogate data and produce the best quality dates possible; 3) concomitant analysis of trace elements (Ti, Y, Zr, REE etc.) and/or other isotope systems (e.g. Sm/Nd, Lu/Hf, Li) of petrologic importance along with U-Th/Pb isotopic analysis in order to integrate dates with structural, pressure-temperature, phase relationhips and geochemical data and; 4) development of campaign-style geochronology methods to elucidate the spatial and temporal scale of geologic processes at scales ranging from single crystals to entire orogens.

Redox heterogeneity in MORB as a function of mantle source

E. COTTRELL[1,*] AND K. A. KELLEY[2]

[1]NMNH, Smithsonian Inst., Washington, DC 20560, USA (*correspondence: cottrelle@si.edu)
[2]GSO, Univ. of Rhode Island, Narragansett, RI 20882 USA

Mantle oxygen fugacity (fO_2) has a first-order effect on the geochemical evolution of Earth's mantle and is predicted to influence several geophysical observables [1], yet systematic variations in mantle oxidation state at mid-ocean ridges have not previously been reported. We use XANES spectroscopy to provide $Fe^{3+}/\Sigma Fe$ ratios of submarine mantle-derived basalts from mid-ocean ridges (MORB) as a proxy for fO_2 [2]. $Fe^{3+}/\Sigma Fe$ ratios of MORB, far from plumes, decrease with indices of mantle enrichment such as $^{87/86}Sr$ and $^{208/204}Pb$ (n=22). In primitive glasses (MgO>8.5wt.%, n=19), $Fe^{3+}/\Sigma Fe$ ratios decrease strongly with increasing trace element enrichment, such as the Ba/La ratio. The strong inverse relationship between upper mantle fO_2 and enrichment recorded by MORB glasses globally contrasts with the positive relationship hinted at by abyssal peridotite oxybarometry, and with the prediction of a positive correlation born of the expectation that Fe^{3+} can be treated as more incompatible than Fe^{2+} during mantle melting.

These data unequivocally link upper mantle oxidation state to mantle source enrichment. Further, because the data require ancient fractionation of radiogenic parent-daughter pairs, the factors that lead to variation in mantle oxidation state must be preserved on plate tectonic time scales.

Reduced lavas share isotopic and trace element signatures with low-degree carbonatitic and/or kimberlitic melts of peridotite. These include EM-1 isotopic flavor, Hf depletion relative to Nd, and strong enrichment of highly incompatible elements. Because upper mantle carbon may act to simultaneously reduce iron [3] and generate melts that share geochemical traits with our reduced samples, we propose that variations in mantle carbon lead to magmas that are reduced and enriched. Estimates of mantle carbon concentration from Siqueiros and 'popping rock' support this interpretation, though other processes that might link enrichment to reduction, such as ancient subduction of reducing sediments or mobilization of reduced fluids at depth, cannot be ruled out.

Volcanic degassing of the Gunbarrel large igneous province and its environmental repercussions

GRANT COX[1], GALEN HALVERSON[2], MATT HURTGEN[3], ANDRE POIRIER[4], LUCIE THEOU- HUBERT[5] AND BOSWELL WING[6]

[1] (grant.cox@mail.mcgill.ca)
[2] (galen.halverson@mail.mcgill.ca)
[3] (matt@earth.northwestern.edu)
[4] (poirier.andre@uqam.ca)
[5] (lucie.hubert-theou@mail.mcgill.ca
[6] (boswell.wing@mail.mcgill.ca)

It has long been known that large volcanic eruptions have the capacity to influence the global environment (McCormick *et al*., 1995; Payne *et al*., 2008; Self *et al*., 2008). Five principal mechanisms exist through which volcanic activity can perturb the environment: 1) cooling due to loading of atmospheric sulfate (McCormick *et al*., 1995); 2) warming due to loading of atmospheric CO_2; 3) ocean acidification through elevated levels of oceanic CO_2 (Fraile-Nuez *et al*., 2012; Hall-Spencer *et al*., 2008); 4) ocean anoxia caused by an enhanced weathering flux of reduced volcanic material to the oceans (Sinton and Duncan, 1997); 5) ocean anoxia caused by an increased delivery of bio-limiting nutrients to the oceans (Frogner *et al*. 2001, Sinton & Duncan 1997).

Due to their size and duration, Large Igneous Provinces (LIP) have often been implicated in global environmental catastrophes, such as mass extinctions (e.g.. Wignall, 2005; Wignall, 2001). However, this simple relationship between eruptive size and environmental impact is complicated by the fact that unlike typical volcanic eruptions, which occur over short time intervals (i.e. days), the eruption of LIP occurs over a few million years.

The compilation of marine carbonate isotope ratios ($d^{13}C$) for the Neoproterozoic suggests a major perturbation to the global carbon cycle at ~780 Ma, coinciding with the eruption of the Gunbarrel LIP. We have use $d^{34}S$ and [S] from volcanic rocks associated with this LIP along with trace element geochemistry of coeval marine carbonates to assess what impact, if any, the Gunbarrel LIP may have had on the surface environment during the Neoproterozoic.

Nucleogenic neon-21 production rates for geochronology

STEPHEN E. COX[1]*, KENNETH A. FARLEY[1] AND DANIELE J. CHERNIAK[2]

[1]Division of Geological and Planetary Sciences, California Institute of Technology, Pasadena, CA 91125 (correspondence: scox@caltech.edu)

[2]Department of Earth & Environmental Sciences, Rensselaer Polytechnic Institute, Troy, NY 12180

The (U-Th)/Ne chronometer is a potentially powerful technique for dating minerals that contain U and/or Th and oxygen and/or fluorine. For example, zircon, hematite, and apatite have sufficiently high nucleogenic neon fractions that ^{21}Ne chronometry is practical. Because neon is produced via α particle capture by oxygen and fluorine, dating accuracy depends on reaction cross sections and the calculated α stopping power in the material being studied. Despite being derived from the same cross section data, published ^{21}Ne production rates vary by tens of percent [1,2]. To reduce this uncertainty we implanted α particles in two materials with very different stopping powers, quartz and barium tungstate, to measure the production rate of ^{21}Ne from α particles in the ^{238}U, ^{235}U, and ^{232}Th decay series.

We find production rates that agree with predicted rates following the production model in [1], with uncertainties of 2-5%. Uncertainties are ~4% for ^{21}Ne/^{4}He ratios extrapolated to other minerals and are <2% for ^{21}Ne concentrations measured by isotope dilution, so (U-Th)/Ne age uncertainties will be <5% when nucleogenic fractions are high.

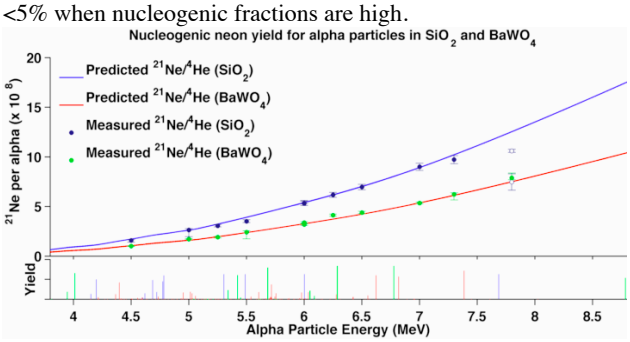

Figure 1: Ratios of nucleogenic neon to implanted helium in samples of quartz and barium tungstate compared to predicted yield following the approach of [1]. Open symbols showed evidence for helium beam contamination during implantation and are low for that reason. The lower plot shows alpha yields of the ^{238}U (blue), ^{235}U (red), and ^{232}Th (green) decay chains.

Which age is the true age? Unravelling within-flow ^{40}Ar/^{39}Ar age variations in Faroe Islands basalt lavas

E.L. CRAMER[1]*, S.C. SHERLOCK[1], A.M. HALTON[1], S. BLAKE[1], T.L. BARRY[2], S.P. KELLEY[1] AND D.W. JOLLEY[3]

[1]Dept. of Environment, Earth and Ecosystems, The Open University, Walton Hall, Milton Keynes, MK7 6AA. UK. (*correspondence: Elizabeth.Cramer@open.ac.uk)

[2]Dept. of Geology, University of Leicester, University Road, Leicester, LE1 7RH. UK.

[3]Geology and Petroleum Geology, School of Geosciences, University of Aberdeen, Meston Building, Aberdeen, AB24 3UE. UK.

Previous dating of basaltic igneous rocks from the Faroe Islands by radiometric techniques (Ar/Ar and K/Ar) has proved problematic [1].

The Ar/Ar technique assumes that the rapid cooling rates of lavas is sufficient to close the argon system uniformly, preventing any loss or gain of argon from the lava during cooling. Therefore, an Ar/Ar age for a basalt should be independent of where in the lava a sample is collected. However, in practise, within-flow age variations of more than 10% have been found.

Forty-eight samples were collected from vertical transects through five basalt lavas from the Faroe Islands and radiometric ages were obtained by Ar/Ar step-heating analysis of whole-rock basalt, taking care to pick only visually fresh material and avoiding any signs of alteration (e.g. vesicle fills).

Surface exposure samples from two lavas yield average plateau-ages of ~46 Ma and ~51 Ma respectively (with individual samples ranging from 35 Ma to 55 Ma). Drill core samples from three lavas yield average ages of between ~56 Ma and ~57 Ma. The spread of ages for lavas analysed using drill core is considerably less than that for the surface exposure samples, suggesting that the highly variable Ar/Ar ages may reflect the effects of surface weathering.

We have performed a suite of geochemical analyses on all these samples which will ultimately allow evaluation of these post-emplacement alteration effects on the Ar/Ar system.

While we use a case study from the Faroe Islands Basalt Group, our results are important for accurately interpreting Ar/Ar ages from any basaltic system.

Characterisation of depleted uranium munitions residues by synchrotron X-ray microanalysis

D.E. CREAN[1,2], F.R. LIVENS[2], M.C. STENNETT[1], D. GROLIMUND[3], C.N. BORCA[3] AND N.C. HYATT[1]*

[1]Department of Materials Science and Engineering, University of Sheffiled, UK
(*correspondence: n.c.hyatt@sheffield.ac.uk)
[2]School of Chemistry, University of Manchester, UK
[3]Swiss Light Source, Paul Scherrer Institute, Villigen, Switzerland

The testing and use of depleted uranium (DU) munitions has resulted in the contamination of a number of sites worldwide. Interaction of DU munitions with armoured targets on impact produces particulate residues mainly composed of uranium oxides [1]. Atlhough these residues are well characterised on formation, there is uncertainity surrounding their long term fate in the environment.

Using a complementary suite of synchrotron X-ray microanaylses, we have characterised a set of ~30 yr. environmentally aged DU particles recovered from soils at MOD Eskmeals, UK. Two areas of the site were sampled, an surface soil and a disposal pit for contaminated timbers.

Particles in surface soils had a distinctive spherical morphology and were composed of uranium oxides, U_3O_7 and U_3O_8. X-ray diffraction (μ-XRD) and X-ray absorption spectroscopy (μ-XAS) mapping were used to resolve distribution of these phases and corresponding U oxidation states, revealing distinct domains of each oxide. These data are consistent with DU particles as formed, and indicate that, at this site, primary morphology and U speciation are persistent in the environment.

In contrast, U in disposal pit soils was speciated mainly as U(VI) phosphate hydrate phases such as meta-ankoleite ($K(UO_2)(PO_4)\cdot 3H_2O$). A combination of X-ray fluorescence (μ-XRF), μ-XRD and μ-XANES mapping was used to resolve domains of U_3O_7, likley residual primary particles, surrounded by a widespread distribution of U(VI) phosphate hydrates, suggestive of a substantial alteration layer.

This study indicates that the environmental stability of DU munitions residues is highly variable and sensitive to deposition environments. Additionaly, the utility of high spatial resolution synchrotron X-ray microbe techniques to resolve micron-scale heterogenitiey in U chemistry in complex environmental samples was demonstrated.

[3]Centre for Star and Planet Formation, Natural History Museum of Denmark, University of Copenhagen, DK-1350 Copenhagen, Denmark

The platinum group elements (PGEs; Ru, Rh, Pd, Os, Ir, Pt) are highly siderophile and strongly sequestered into metallic cores during planetary differentiation. However, PGE abundances in Earth's mantle are higher than predicted from low-pressure metal–silicate partitioning experiments. These relative excesses are reconciled in models by considering either late addition of chondritic material or very different physical conditions during core formation. The Pt stable isotope system represents a novel tool for investigating this problem.

Using recently developed methods for highly precise measurement of Pt stable isotopes by double-spike MC-ICPMS [1] and chemical separation of Pt from geological materials [2], we have characterised the Pt stable isotopic compositions of iron meteorites (as a proxy for Earth's core) and chondrites (as a proxy for the undifferentiated Earth as well as proposed late veneer material) and compare these with data for samples of Earth's mantle. Pt is concentrated in iron meteorites (ca. 3–40 ppm; [3]) compared with undifferentiated meteorites (ca. 0.7–5.0 ppm; [4]), and core formation is thus expected to produce a fractionation in Pt stable isotope ratios, particularly if changes in redox state are involved (Pt^{2+} versus Pt^0). The composition of such materials are expected to be isotopically distinct from undifferentiated meteorites. By identifying these isotopic fingerprints in Earth's mantle, it should thus be possibile to constrain the potential sources or processes responsible for the PGE distribution in Earth's mantle.

Microbial Metabolism in Serpentinite Fluids

M. CRESPO-MEDINA[1]*, W. J. BRAZELTON[1], K. I. TWING[1], M. D. KUBO[2] ,T.M. HOEHLER[3] AND M. O. SCHRENK[1]

Serpentinization is the process in which ultramafic rocks, characteristic of the upper mantle, react with water liberating mantle carbon and reducing power to potenially support chemosynthetic microbial communities. These communities may be important mediators of carbon and energy exchange between the deep Earth and the surface biosphere. Our work focuses on the Coast Range Ophiolite Microbial Observatory (CROMO) in Northern California where subsurface fluids are accessible through a series of wells. Preliminary analyses indicate that the highly basic fluids (pH 9-12) have low microbial diversity, but there is limited knowledge about the metabolic capabilities of these communties. Metagenomic data from similar serpentine environments [1] have identified Betaproteobacteria belonging to the order Burkholderiales and Gram-positive bacteria from the phylum Clostridiales, as key components of the serpentine microbiome.

In an effort to better characterize the microbial community, metabolism, and geochemistry at CROMO, fluids from two representative wells (N08B and CSWold) were sampled during a recent field campaign. The wells selected can be differentiated in that N08B had cell counts ranging from 10^5-10^6 cells mL^{-1} of fluid, and abundance of the Betaproteobacterium *Hydrogenophaga*. In contrast, fluids from CSWold have lower cell counts (~10^3 cells mL^{-1}) and an abundance of *Dethiobacter*, a taxon within the phylum *Clostridiales*. Geochemical characterization of the fluids includes measurements of dissolved gases (H_2, CO, CH_4), dissolved inorganic and organic carbon, volatile fatty acids, and nutrients. Microcosm experiments were conducted with the purpose of monitoring carbon fixation and metabolism of small organic compounds, such as acetate, while tracing changes in fluid chemistry and microbial community composition. These experiments are expected to provide insight into the biogeochemical dynamics of the serpentinite subsurface at CROMO and represent a first step for developing RNA based Stable Isotope Probing (RNA-SIP) experiments to trace microbial activity at this site.

Despite the large number of studies reporting individual minerals dissolution rates, less is known about the dissolution rates of whole rocks. This lack of data motivated this study of the dissolution kinetics of a metabasalt from the Mt. Reventino area (Southern Italy). Experiments were performed on crushed and sieved metabasalt at 25°C using mixed-flow reactors. The interpretation of our experiments takes account of the contributions of the dissolution of each distinct mineral to model the chemical evolution of the aqueous phase. Individual mineral surface areas were estimated by distributing the total crushed rock BET surface area among the different minerals present in the metabasalt (chlorite, amphibole, epidote, albite, and phengite) as a function of their modal abundances. Then, by adopting the literature dissolution rate of epidote [1], the temporal evolution of cation concentrations were used to retrieve the dissolution rates of the other minerals. Dissolution rates for chlorite, amphibole, albite, and phengite retrieved from the pH 2 experiments are within an order of magnitude from each other. This observation contrasts with corresponding rates reported in the literature and suggests that mineral dissolution rates are affected by presence of other minerals in multi-phase rocks.

The Paleoproterozoic Zaonega Formation, Onega Basin, Russian Karelia represents a deep-water, mixed siliciclastic-carbonate depositional system in a magmatically active basin. It is characterized by rocks extremely enriched in organic matter. FAR-DEEP drillholes intersecting Zaonega Formation hold lithological evidence for one of the earliest generations and spilling of oil/asphalt onto the sea floor, with part of the hydrocarbons being generated due to syn-sedimentary magmatic activity. Geochronologic maximum-minimum constraints of 2.09±0.07 and 1.98±0.02 Ga for the Zaonega Formation indicate its deposition partially overlapped with and/or post-dated the 2.22-2.06 Ga Lomagundi-Jatuli positive carbon isotope interval.

High $\delta^{13}C_{carb}$ (up to +10 ‰) suggest that the Zaonega Formation records the end of the Lomagundi-Jatuli Event. However, synsedimentary magmatic activity, and petroleum generation together with extensive post-depositional alteration of carbonates, poses challenges in using these carbonates for interpretations of global environmental changes.

We report new data to assist with interpreting the conditions under which the carbonates precipitated. Carefully characterized carbonate samples were analyzed for REE and Sr isotopes. High $^{87}Sr/^{86}Sr$ ratios suggest alteration by post-depositional fluids. Variable REE profiles and changes in magnitude of the Eu anomaly imply that most carbonates were considerably influenced by hydrothermal fluids, but carbonates with sea-water geochemical characteristics are also present. *in situ* REE data show that this complexity is visible both in possibly primary and clearly later carbonate phases and that hydrothermal fluids were important during some carbonate precipitation and during later burial. Contribution from organic diagenesis remains to be evaluated. Whole rock data from these rocks should be therefore viewed cautiously with respect to assessing the Paleoproterozoic carbon cycle.

Reactive Oxygen Species (O_2, O_2^- and H_2O_2) control Manganese redox cycling in the euphotic zone: role of reactive intermediates

P. L. CROOT[1], M.I. HELLER[2] AND K. WUTTIG[3]

[1]Earth and Ocean Sciences, School of Natrual Sciences, National University of Ireland, Galway (NUI Galway), Galway, Ireland (peter.croot@nuigalway.ie)
[2]University of Southern California (USC), Los Angeles, California, USA (miheller@usc.edu)
[3]GEOMAR, Helmholtz Centre for Ocean Research Kiel, Kiel, Germany (kwuttig@geomar.de)

Manganese (Mn) is an essential element for oceanic phytoplankton as it plays a critical role in photosynthesis, through its unique redox chemistry, as the active site in photosystem II and in enzymes that act as defences against reactive oxygen species (ROS), most notably for protection against superoxide (O_2^-), through the action of superoxide dismutase (SOD), and against hydrogen peroxide (H_2O_2) via peroxidases and catalases. The distribution and redox speciation of Mn in the ocean is also strongly controlled by reactions with ROS. Here we examine the connections between ROS and dissolved Mn species in the upper ocean using a combination of field data from the Tropical Pacific and Atlantic, with laboratory data under controlled conditions. We find that reactions with Mn are a significant pathway for the dismutation of O_2^- in the Tropical Atlantic in surface waters where Mn concentrations are elevated due to Saharan dust input. Modelling of our data suggest it is unlikely that significant concentrations of Mn(III) are produced in the euphotic zone, as in the absence of evidence for the existence of strong Mn(III) ligands in seawater, Mn(II) reacts with O_2^- to form the short lived transient manganous superoxide, MnO_2^+, which may react rapidly with other redox species in a similar manner to O_2^-. Experiments with the strong Mn(III) chelator, desferrioxamine B (DFB), in seawater indicated that Mn(III) species are unlikely to form significant concentrations via oxidation of the the pre-cursor Mn(II) complex, as this species is only a minor species under natural ambient conditions due to the high side reaction of DFB with Ca.

Oxygenic photosynthesis 3 billion years ago

SEAN A. CROWE[1,2], LASSE N. DØSSING[3,1], NIC J. BEUKES[4], MICHAEL BAU[5]. STEPHANUS J. KRUGER[4], ROBERT FREI[3] AND DONALD E. CANFIELD[1]

[5]Dept. of Earth and Space Sci., Jacobs Univ., Bremen, Germany

Prior to the evolution of oxygenic photosynthesis, life on Earth was dominantly anaerobic with an estimated activity level of 1000 times less than today[1]. With the evolution of biological oxygen producers, oxygen became available to fuel aerobic metabolisms, increasing the abundance and activity of the biosphere and changing the dominant modes of metabolism. The first long-term oxygenation of the atmosphere took place around 2.3 billion years ago (Ga) during the Great Oxidation Event (GOE)[2] and oxygenic photosynthesis must have evolved by this time. Geochemical proxies, however, suggest transient atmospheric oxygenation dating back to 2.6-2.7 Ga[3,4,5], while molecular clocks indicate the possible evolution of oxygenic phototrophs as early as the Mesoarchean[6].

We examined the distribution of Cr isotopes and redox-sensitive metals in the approximately 3 billion year old Nsuze paleosol and in the near-contemporaneous Ijzermyn iron formation from the Pongola Supergroup, South Africa. These measurements reveal atmospheric oxygen concentrations of some 10^{-4} of present day levels. This mid-Archean oxygenation of Earth's atmosphere implies that oxygenic photosynthesis evolved at least 3 billion years ago, more than 600 million years before the GOE. Despite possible fluctuations in oxygen levels, oxygenic phototrophs have likely fueled Earth's aerobic biosphere since at least 3.0 Ga.

Geochemical changes in wet dune slacks: natural or anthropic driven?

A. CRUCES[1]* S. MOREIRA[1] M.C. FREITAS[1] M. LEIRA[1], M.R. CARVALHO[1], C. ANDRADE[1], T. FERREIRA[1], L. CANCELA DA FONSECA[2] AND M.C.R. SILVA[1]

[1]Universidade de Lisboa, Fac. Ciências, Departamento de Geologia, Centro de Geologia. 1749-016 Lisboa, Portugal (*correspondence: a.cruces@fc.ul.pt)

[2]Universidade de Lisboa, Centro de Oceanografia. 1749-016 Lisboa, Portugal

Lagoa da Sancha (LS) and Poço do Barbaroxa de Baixo (BB), located in the Portuguese SW coast, are smaller than 0.4km^2 wet dune slacks including shallow (<1m) open-water bodies, which occasionally dry out in summer. Both environments are part of a Natural Reserve since 2000. BB is a blind depression, whereas LS collects inputs from a 35km^2 watershed. Bottom sediments are $CaCO_3$-free organic muds, LS materials being peculiar in comparison to BB due to hyperacidity, lower organic and higher heavy metals contents.

Field surveys conducted since 2002 show that BB is an oligohaline to freshwater (0.2 -3.8‰) and slightly acidic to slightly alcaline (pH 5.9-7.6) environment, with DO of 3-7mg/l and low values of Eh (environments near reducing conditions: -110 to +150mV). The water chemistry shows that BB has medium to high mineralization (0.060 meq/l).

In the late 1980's, LS shared similar environmental parameters: salinity (2.5-5‰, exceptionally up to 12‰ due to overwash or evaporation), dissolved oxygen (3-12mg/l) and pH (6.0-8.0). It hosted diverse macrobenthos, ictyo and avifaunas. However, surveys performed after 2001, show a drastic change in this system, with almost complete elimination of those organims. Although LS waters remain mainly subsatured to satured (DO 2.8-9.5mg/l), all the other parameters are substantially different. The LS hydrossome became strongly oxidant (Eh:+315 to +546mV), acidic (pH: 2.7 to 3.8), the salinity dropping to 0-4.3‰. Also, it shows lower mineralization (0.026 meq/l), but the heavy metals content is up to 3 orders of magnitude higher than in BB (17mg/l Fe, 1.8mg/l Mn, 3.4ug/l Cu, 57ug/l Co, 83ug/l Ni, 18ug/l Cu). Such values resemble the composition of waters associated with acid mine drainage or metalliferous leaching.

Until present the extreme changes at LS have been interpreted as related to sulphide oxidation, a meteorological-driven hardly reversible consequence of prolonged bottom exposure during dry years. However, the recent discovery of an illegal industrial waste disposal proximal to LS opens a new hypothesis for that dramatic change related to anthropic contamination conveyed through groundwater circulation.

Harvesting, storage and saving of energy using microporous minerals

G. CRUCIANI[1]*

[1]Dept. of Physics and Earth Sciences, Univ. of Ferrara, 44100, Ferrara, Italy (*correspondence: cru@unife.it)

Given that up to 40% of energy demand in Europe (up to 80% in North America) is used in buildings, the R&D of sustainable technologies for heating and cooling of residential buildings is a key priority in many countries. Among the most promising technological solutions are the heat pumps, in particular those using adsorption (Adsorption Heat Pumps, AHP). The typical working cycle of these machines, encompassing three temperature levels, utilizes a low temperature heat source (e.g. solar or geothermal) to evaporate the working fluid (e.g. water) or activate (i.e. dehydrate) the adsorbing material. In the triggered thermodynamic cycle, heat is released to the environment at an intermediate temperature by the (exothermic) adsorption process by the fluid condensation, while the heat is taken form the environment at the highest T level during the endothermic desorption process.

Zeolites and related microporous minerals are among the most suited adsorbing materials both due to their efficiency and sustainability. The exothermic enthalpy of hydration, thermodynamically stabilizing the otherwise metastable anhydrous zeolite structure [1], explains the endothermic nature of the dehydration phenomenon in these minerals. Therefore, the H_2O desorption from zeolite at low T (e.g. T = 130-150°C from evacuated solar collectors) can be exploited to store heat which can be released to the environment during the next vapour adsorption. The thermal stability of several zeolite topologies [2] makes the ad/desorption cycle fully reversible. In AHPs and Solar Coolers, one evaporator and one condenser are connected to zeolite tanks which can be dehydrated at low T by solar or geothermal heat. Double tanks, cyclically operated in antiphase, allow to make use of both the release to (heating) and the subtraction from (cooling) the environment of the adsorption and condensation heat. Use of natural zeolites for solar cooling has been reported since 80-ties in USA for the chabazite from Bowie, and for chabazite and clinoptilolite in Italy [3].

Solar Heat Storage (SHS) systems can be designed by coupling the physisorption on zeolites to the chemisorption related to transformation between different hydration state(s) in crystalline phase(s) higher energy density (e.g. sulphates).

Sulfide Sites in the Arctic Ocean: Jan Mayen and Loki's Castle

M.I.F.S. CRUZ[1,2]*, A.F.A. MARQUES[1], A.S.C.A. DIAS[1,3], R.B. PEDERSEN[3], J.M.R.S. RELVAS[1] AND F.J.A.S. BARRIGA[1]

[1] Creminer FCUL LARSyS, Department of Geology, University of Lisbon, Portugal, (*correspondence: micruz@fc.ul.pt)

[2] Centre for Geobiology, Department of Earth Science, University of Bergen, Norway

[3] University of St Joseph, Macau, China

There is a growing consensus on the need of exploiting the resources of the ocean floors. High latitude oceans, and ocean floors, are not easy to study, for ovious reasons,.but the recent discoveries of hydrothermal vents in the Arctic Ocean openned new ground for exploration for metal resources. Jan Mayen and Loki's Castle on the Mohns Ridge are two known sites of interest [1].

The Jan Mayen hydrothermal field was discovered in 2005 at ≈71°N; it is located at water depths ranging from 550 to 700 m and the mesured temperatures reached 270°C. It is composed of two separate vent fields, set 5 km apart, named Trollveggen and Soria Moria, respectively. Host rocks tend to be alkaline basalts [2].

The Loki's Castle hydrothermal field was discovered in 2008 at ≈73.30°N, at a water depth of 2400m and with a maximum recorded temperature of 317°C. Host rocks are mainly MORB, although some ultramafic rocks are exposed nearby [3].

At both sites, ROV collected samples of chimney fragments and their surrounding deposits revealed pyrite, chalcopyrite and sphalerite as the main sulfides present. Jan Mayen's whole rock analyses for the chimney fragments depict maximum metal contents for Fe of 6.5wt%, for Zn 39.9wt% and for Cu 1wt%; while Loki's Castle samples contain a maximum of 31wt% Fe, 5.4wt% Zn and 2.4% Cu.

The dominant sulfide phase at Jan Mayen is sphalerite followed by pyrite, while at Loki's Castle pyrrhotite and pyrite predominate. Predominant non-sulfide phases at Jan Mayen are barite and silica, while Loki's non-sulfide phases are composed mainly of talc/serpentine and anhydrite.

	Fe (wt%)		**Zn (wt%)**		**Cu (wt%)**	
	Max	Avg	Max	Avg	Max	Avg
Jan Mayen	6.5	4.9	39.9	18.2	1.1	0.4
Loki's Castle	31	9.9	5.4	0.1	2.4	0.6

Samples from both these hydrothermal systems are currently being studied in order to understand their genesis, and better constrain their metal content and possible economic interest.

Geodynamic kinetics: Metamorphic reaction rates in subduction zones

ALICIA M. CRUZ-URIBE[1] AND MAUREEN D. FEINEMAN[1]

[1]The Pennsylvania State University, University Park, PA 16803 (amc472@psu.edu, mdf12@psu.edu)

Existing models of fluid release due to dehydration reactions in the subducting slab are based on the assumption that reactions approach equilibrium on timescales comparable to the rate of subduction. Yet there are no field-based measurements of the rates of prograde reactions in subducting slabs, making it difficult to assess the applicability of equilibrium thermodynamics in petrologic models of fluid release. The best constrained field-based metamorphic reaction rates are from regional metamorphic settings and describe a relatively robust relationship between temperature (T) and reaction rate (R_{net}):

$$\log R_{net} = 0.0077T - 12.1$$

Here we assess the applicability of regional reaction rates to fluid-producing reactions that occur during prograde metamorphism of subducting slabs.

We estimate the degree of reaction completion within a dynamic subdution setting by integrating the temperature dependence of regional reaction rates with a thermal model of a cold subduction zone (North Honshu) [1], assuming a subduction rate of 39 mm/yr. Our models show that regional reaction rates are considerably slower than subduction rates at temperatures below ~600˚C, such that subduction would significantly outpace the progress of metamorphic reactions in the slab. In order to create the assemblages exhumed in subduction channels (e.g., blueschist, eclogite), either (1) grain sizes must be very small; for instance, on the order of 100 μm or less, or (2) the kinetic environment of the subducting slab is fundamentally different than in other regional metamorphic settings. We propose that the dynamic nature of subduction zones (high dT/dt) results in conditions that are far from equilibrium (large ΔG_{rxn}), driving faster reaction rates in these systems. The dramatic increase in dT/dt at ~80 km slab depth due to slab-mantle coupling would then drive dehydration reactions in a race to "catch up" to the thermal state of the slab, the result of which would be a pulse of fluid released at around this depth. Thus even continuous reactions could run to completion over a relatively short depth interval, explaining the pulse-like fluid release inferred from some arc magmas and exhumed subduction terranes.

Interrelation between tuffs and organic rich source rock in Chang7 Formation, Triassic, Ordos Basin, Central China

CUI JINGWEI[1]*, ZHU RUKAI [1,2], WU SONTAO[1,2] AND BAI BIN[1,2]

[1]Reasearch institute of petroleum exploration and development, PetroChina, Beijing, China

[2]State key laboratory of enhenced oil recovery,Beijing, China (*corresponding author: jingwei.cui@126.com)

Organic rich source rocks development modles and controlling factors were summarized. Modles is including black sea molde, the upwelling molde, and hydrotherm modle. The controlling factors are primary production, anoxic enviroment, and sedimentation rate. Interrelation between organic rich sedimentation rate and tuff in the Ordos basin was reported rarely and tuff may erupted by the active of Qinling mountain orogeny and Sublacustrine hydrothermal activity. We used organic geochemistry and inorganic trace mentals to analyzed the source rock and tuff of T_3y, Ordos basin, central China after core fine description.

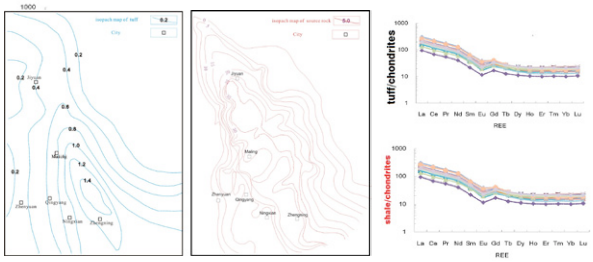

Fig.1 Comparisons of the distibution and REE of Tuffs and source rocks

Interrelation of tuffs and high quality source rocks determinted by the following evidences,

1) The tuffs were interbed the Chang7 high quality source rock and have the same distribution in the Ordos Basin, especially in the Chang7^3 oil subformation.

2) Tuffs and the source rocks have the same Rare earth element (REE) distribution, which indicate the same source. Tuff contribute nutrient elements (P, Fe and N) for organic rich shale developemnt.

3) Paleo-depth and paleo-salinity analyses indicated the water is fresh and the maximum water depth are below 120m.Organic rich shale development mode is tuff simulation the mass plankton growth, which lead to high TOC.

$\delta^{13}C$ record of black carbon in Daihai Lake sediments, northern China: An indicator of terrestrial environmental changes

LINLIN CUI[1] AND XU WANG[1] AND JULE XIAO[1] AND ZHONGLI DING[1]

[1]Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O. Box 9825, Beijing, 100029, China; (cuilinlin@mail.iggcas.ac.cn)

We measured the carbon isotope ratio of black carbon (BC) from the Daihai Lake sediment core (DH99a) in northern China to examine the effectiveness and sensitivity of the $\delta^{13}C$ values of BC ($\delta^{13}C_{BC}$) as a potential indicator of terrestrial environmental changes. We first performed a statistical study on the available data regarding carbon isotope fractionation (CIF) during the conversion of C3 and C4 vegetation to BC and observed that the mean CIF for BC produced from C3 plants is -0.3‰, whereas that for BC from C4 plants is -1.7‰. The $\delta^{13}C_{BC}$ record in the DH99a sediment core spanning the last ca 10,000 years displayed large variations from -23.7‰ to -29.2‰, which suggests that C3 plants dominantly occupied the Daihai Lake region during the Holocene. The most negative $\delta^{13}C_{BC}$ peaks coincided with high values of tree percentages and grain sizes, which occurred under relatively wetter climatic conditions during the middle Holocene (ca 6500-3200 cal. yr BP) and an interval between 1700 and 1350 cal. yr BP. In contrast, the least negative $\delta^{13}C_{BC}$ values corresponded to low values of tree percentages and grain sizes during relatively drier phases of the early and late Holocene. The generally negative correlation of the $\delta^{13}C_{BC}$ values with the tree percentages and grain sizes was thought to reflect a negative correlation of the $\delta^{13}C_{BC}$ values with the monsoon precipitation. We then developed a computational model to reconstruct the changes in annual precipitation over the Daihai Lake region. The inferred annual precipitation was highly variable, ranging from 170 mm lower to 310 mm higher than present during the middle Holocene, whereas the annual precipitation was generally ~70 mm lower than that at present during the early and late Holocene. The general features of the inferred precipitation changes are generally consistent with those reconstructed using pollen data of the same sediment core. Meanwhile, the $\delta^{13}C_{BC}$ values tend to register some extreme variations of monsoon precipitation, which were not reflected in the pollen assemblages. We conclude that the $\delta^{13}C_{BC}$ values in the Daihai Lake sediments may serve as a sensitive and reliable proxy for monitoring monsoon precipitation.

Dissolved iron and the co-limitation of phytoplankton growth in the Beaufort Sea, Arctic Ocean

Here we report six vertical profiles of dissolved Fe concentrations [DFe] and results of a shipboard grow-out experiment to investigate the potential for nitrate (NO_3^-), light, and Fe co-limitation of phytoplankton in the Beaufort Sea in late summer. A range of [DFe] from 0.11 to 2.04 nM is observed, with the maximum values occurring in subsurface waters near continental shelf sediments. Clear surface maxima in [DFe] exist at stations with freshwater input from melting sea ice.

Nitrate additions to incubation bottles enhanced phytoplankton growth, demonstrating that the late summer community was N limited. In the treatments with additions of NO3- but not Fe, biomass doubled with increasing light, indicating light limitation. In NO_3^- enriched treatments, co-limitation of primary production by Fe and light was observed at light levels ≤ 10 % surface irradiance, which corresponded to depths ≥ 33 m. These results suggest that, in addition to NO_3^- and light, Fe may control primary productivity in the Beaufort Sea, and seasonal changes in light, NO_3^-, and Fe availability may differentially control Arctic phytoplankton growth.

The effect of the inclusion of online aerosol-cloud feedbacks on solar radiation feedback

CURCI GABRIELE[1,*] AND PAOLO TUCCELLA[1]

[1]Department of Physical and Chemical Sciences, CETEMPS, University of L'Aquila, Via Vetoio, 67100 L'Aquila, Italy (* correspondence: gabriele.curci@aquila.infn.it)

The intricate feedbacks between aerosol and clouds are currently regarded as the single major uncertainty in future climate projections and are believed to have a significant role also on weather prediction. Aerosol-clouds interactions are explicitly simulated only in three-dimensional models that solve both meteorological and chemical processes at the same time (online models). One such model is WRF/Chem. Recent developments, carried out in collaboration with NOAA, include the implementation of cloud feedbacks with the up-to-date module for the organic fraction, based on the Volatility Basis Set (VBS) approach. We test the skills of this state-of-science model for short term (few days ahead) forecast of solar radiation at the European scale. Results are evaluated against ground based observations of the downward shortwave radiation from the Baseline Surface Radiation Network (BSRN), cloud cover information from the International Satellite Cloud Climatology Project (ISCCP), and satellite data. We highlight the importance of including the representation of interactions among meteorology, radiation and chemistry for a better solar energy forecast.

Atmospheric methane concentration at the ClimaDat network sites

[3]Institució catalana de Recerca i Estudis Avançats, Barcelona, Catalunya, Spain

Atmospheric concentrations of methane were obtained in continuous analyses by a Cavity Ring-Down Spectrometer (CRDS) [1] at six sites belonging to the ClimaDat network in Spain. ClimaDat measures the natural variability of the atmospheric gases related to processes that integrate changes, and that are influenced by the uncoupling and the displacement associated to climate change. Temporal and spatial heterogeneity are adressed and the source of air masses is inferred by Lagrangian backtrajectory models [2]. Synoptic meteorological situations acts a modulating drive of the pattern of the variability at the different sites, as shown in Figure 1 for the GIC3 site. A comparison of 2013 NRT series is presented.

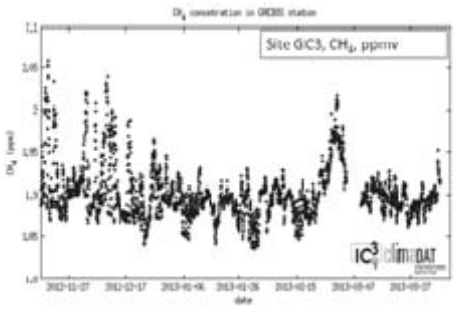

Figure 1: Time series of mean hourly values of CH_4 with a disrupted pattern of concentration cycles.

P-T modelling and geochronology of the Barberton Granite Greenstone Belt, South Africa: Rates of tectonic processes in the Archaean

CUTTS, K.A.[1]* , STEVENS G.[1], HOFFMANN J.E.[2], BUICK, I.S.[1], FREI, D.[1] AND MÜNKER, C.[2]

[1]Centre for Crustal Petrology, Department of Earth Sciences, Stellenbosch University, Private Bag X1, Matieland 7602, South Africa, *(correspondence: cuttsk@sun.ac.za;)
[2]Universität zu Köln, Institut für Geologie und Mineralogie, Zülpicher Str. 49b, 50674 Köln, Germany

The Barberton Granite Greenstone Belt (BGGB) of South Africa is an exceptionally well preserved Meso-Paleoarchean metamorphic supracrustal belt, within which metamorphic studies have considerable potential to advance our understanding of tectonic processes in the Archean crust. In this study, metamorphic P-T analysis has been combined with garnet Lu-Hf and monazite U-Pb geochronology, to directly date the amphibolite facies metamorphism within the Stolzburg terrane of the BGGB and constrain the P-T path. A garnet-biotite-chlorite bearing sample yields a Lu-Hf garnet age of 3233 ± 17 Ma and a garnet-staurolite-kyanite bearing sample produces a U-Pb monazite age of 3191 ± 9 Ma. Phase diagrams and garnet compositional modeling indicate a clockwise P-T evolution reaching peak P-T conditions of 8.5 kbar and 640 °C. The duration of metamorphism is estimated to be 50 to 20 Ma based on differences in age between U-Pb and Lu-Hf systems and durations needed to fit models of diffusionally modified garnet chemical zoning. Based on similar shaped clockwise P-T paths over the entire Stolzburg terrane it is probable that the metamorphism occurred in response to crustal thickening due to an accretionary tectonic process.

The difference in the ages obtained from the Lu-Hf and U-Pb systems constrains the rate of burial to 0.5-2.5 mm/yr, while the time required for garnet diffusion provides estimates on rates of exhumation (0.25-0.5 mm/yr). These estimates are consistent with burial via crustal thickening in modern orogens, however the exhuamtion rates are an order of magnitude slower than what is expected for exhumation of continental crust in the modern plate tectonic regime (cm-mm/yr). Plausibly, higher volumes of mafic and ultramafic rocks in the meso-Archaean proto-continental crust reduce the bouyancy of the lower crust compared to modern orogens leading to slower rebound. Against this scenario of slower exhumation, the high-pressure amphibolite fcaies conditions documented imply a relatively cool Meso-Archean continental crust.

An *in situ* trace element study of peridotites from the Gakkel Ridge

M.E. D'ERRICO, J.M. WARREN[1] AND M. GODARD[2]

[1]Stanford University, 450 Serra Mall, Stanford, CA 93405 (mderrico@stanford.edu); (warrenj@stanford.edu)
[2]Université Montpellier II, Montpellier, France mgodard@univ-montp2.fr

Abyssal peridotites from the Gakkel Ridge provide constraints on the roles of ridge segmentation, on-axis cooling, and pre-existing heterogeneity on melt generation at ultraslow spreading rates. At a rate of 6-15 mm/yr, the Gakkel Ridge has a very thin crust and no major transform faults along its entire length. A thick lithospheric lid due to on-axis conductive cooling is predicted to limit the degree of melting. However, we present geochemical data that demonstrates significant compositional depletion in peridotites.

Peridotites in this study span the boundary between the Western Volcanic Zone and the Sparsely Magmatic Zone. We report *in situ* laser ablation ICP-MS trace element data for Cpx, Opx and olivine from a total of 14 samples. Based on lithology and rare earth element (REE) patterns, the harzburgite and lherzolite samples have each been divided into two groups. Group I harzburgites and lherzolites display typical REE patterns, with depletions in light REE relative to heavy REE. A single harzburgite in group II has a spoon-shaped pattern with enriched light REE, yet another sample within the same dredge has a typical REE pattern. Group II lherzolites have the highest degrees of depletion of any samples in this study. The small length-scale of compositional variability combined with thin oceanic crust suggests that pre-existing heterogeneity accounts for some of the depletion observed in peridotite compositions. The Gakkel peridotites thus provide evidence for a mantle that is the consequence of both inherited depletion and recent melting.

Mysteries of subseafloor sedimentary life

STEVEN D'HONDT[1]*

[1]Graduate School of Oceanography, University of Rhode Island, Narragansett Bay Campus, Narragansett, RI 02882, USA (dhondt@mail.uri.edu)

In recent years, multiple research groups have tremendously advanced understanding of subseafloor sedimentary life. Microbes in subseafloor sediment are now known to be abundant, diverse and characterized by extraordinarily low mean rates of activity.

Some discoveries challenge our sense of what is possible. For example, per-cell energy fluxes are far below the rates believed necessary for reproduction. What mechanisms might allow cells to reproduce at such low rates? Or do many of them live for millions of years without reproducing?

Bulk population studies show that a very large fraction of these cells is active. However, we know essentially nothing about cell-to-cell variation in respiration, biomass turnover or reproduction. Furthermore, we do not clearly understand how organic-fueled respiration can persist for tens of myrs at very slow rates.

Subseafloor community structure is largely unexplored. We have very limited understanding of the ways in which subseafloor microbes compete and almost no understanding of how they cooperate. Roles of viruses, eukaryotes, resting stages and bacterial spores in subseafloor ecosystems are largely unknown.

The proximate causes and ultimate consequences of natural selection in subseafloor communities remain unknown. For the most part, we do not yet know the genetic potential of subseafloor microbes, the extent to which their potential is expressed, or the conditions under which they are expressed. The actual limits to subseafloor life are not yet known.

Advancing understanding of these issues will yield fundamental insight into the nature of life.

Characteristics of olivine and diopside crystals in magma erupted at Stromboli during the 2003, 2007 and 2009 paroxysms: implications for magma ascent dynamics

C. D'ORIANO[1]*, M. PISTOLESI[2], A. BERTAGNINI[1], R. CIONI[13], M. POMPILIO[1] AND N. MÉTRICH[4]

[1]Istituto Nazionale di Geofisica e Vulcanologia, sezione di Pisa, Italy (*correspondence: doriano@pi.ingv.it)
[2]Dip.to di Scienze della Terra, Università di Pisa, Italy
[3]Dip.to di Scienze della Terra, Università di Cagliari, Italy
[4]Institut de Physique du Globe de Paris, Paris, France

We present the results of morphological and compositional study on crystals associated with three paroxysmal explosions occurred at Stromboli in 2003, 2007 and 2009. Although with variable volume of emitted products, all the eruptions involved a deep-seated, volatile-rich, low-porphyricity magma (LP) ejected as pumice. Pumices are almost aphyric, highly vesicular and include portions of a shallow-derived, crystal-rich, moderately vesicular scoria (high porphirycity, HP magma type). We extracted about 1000 crystals (olivine and diopside) in the size interval between 1 and 0.125 mm. Three types of crystals are characterized by complex textures and compositions related to variable degrees of interaction between the LP and HP melts. The fourth type consists of transparent, light coloured crystals (light green for pyroxene), euhedral or sub-euhedral with some skeletal edges. They contains in some cases melt inclusions and are characterized by an homogeneous composition, and in some cases by a more evolved rims. Only this type of crystals is in equilibrium with the LP magma. The variable abundances of the different crystal types in the studied samples suggest the occurrence of different pre-eruption dynamics associated with the paroxysms at Stromboli. Real CSD was performed on olivine and diopside crystals in equilibrium with the LP magma. Results show that, during the 2003 event, crystallization occurred in a single step, while two different events of nucleation can be identified in the 2007 eruption. Equilibrium crystals are very rare in the 2009 paroxysm (the smallest of the three events considered) and they mainly occur as fine grained crystals (0.250-0.125 mm).

Results of this study are discussed in terms of crystallization – degassing processes, timing and modalities of magma ascent during paroxysms at Stromboli and possible relationships with signals recorded by the monitoring network.

Thermodynamics of almandine-spessartine garnet solid solutions

EDGAR DACHS, CHARLES A. GEIGER, ARTUR BENISEK AND MICHAEL GRODZICKI

Material Science and Physics, Universität Salzburg, Hellbrunnerstrasse 34, A-5020 Salzburg, Austria

The heat-capacity, C_p, behavior of a series of well characterized natural and synthetic almandine (Alm)-spessartine (Sps) garnets $[(Fe_xMn1_{-x})A1_2Si_3O_{12}]$, was measured between 3 and 300 K using relaxation calorimetry and between 282 and 764 K using DSC methods.

All garnets show a λ-type anomaly at low temperatures resulting from a paramagnetic-antiferromagnetic phase transition. The temperature of the magnetic transition for Alm-rich garnets lies between those of end-member Alm at 9.2 K and Sps at 6.2 K, but is shifted to lower values between 3.5 and 4.5 K for garnets with $X_{Sps} > 0.5$. The low-temperature C_p data yield calorimetric entropies at 298 K (S_{298}), from which the excess entropy of mixing (ΔS_{ex}) of the join was calculated. By applying the phonon dispersion model of Komada and Westrum (1997), the lattice heat capacity was calculated for each solid-solution member. This allowed a decomposition of S_{298} into its vibrational (S_{vib}) and magnetic (S_{mag}) contributions.

The C_p data show that $\Delta S_{ex} \approx 0$ at 298 K for the Alm-Sps binary and thus the entropic interaction parameter $W_S \approx 0$. An analysis of published Fe-Mn exchange experiments between garnet and ilmenite giving W_G, together with this W_S term, allows W_H to be calculated. The resulting value is in satisfactory agreement with that calculated from phonon line broadening in infrared spectra of Als-Sps garnets using the autocorrelation method. ΔH_{ex} is asymmetric with a maximum in Sps-rich compostions. ΔG_{ex} is also asymmetic with a maximum of ~0.7 kJ/mol at X_{Sps} ~0.60 for temperatures between 500 °C and 1000 °C.

Our new subregular activity model for Alm-Sps garnets yields temperatures for Mn-rich metamorphic assemblages that agree with those from Fe-Mg biotite-garnet thermometry.

U isotopes disentangle atmosphere-ocean oxygenation dynamics

TAIS W. DAHL[1], JAMES N. CONNELLY[1], BENJAMIN C. GILL[2], DONALD E. CANFIELD[3] AND MARTIN BIZZARRO[1]

[1]Natural History Museum of Denmark, University of Copenhagen, DK1350 Copenhagen, Denmark.
[2]Dept. of Geosciences at Virginia Tech, Blacksburg, VA 24061, USA.
[2]Nordic Center for Earth Evolution, Insitute of Biology, Univ. of Southern Denmark, DK5230 Odense, Denmark.

Anoxic marine zones were common in early Paleozoic oceans (542-400 Ma) [1-4], and they profoundly influenced atmospheric pO_2 via feedbacks associated with marine phosphorous recycling, global primary productivity and marine organic carbon burial [5-6]. Uranium (U) isotopes in carbonate rocks track the extent of ocean anoxia, and carbon (C) and sulphur (S) isotopes track the burial of organic carbon and pyrite sulphur and thus the sources of oxygen to the atmosphere. When used in combination, these proxies allow one to study the dynamics between ocean anoxia and oxygen liberation to the atmosphere over million-year time scales.

Here, we report high-precision uranium isotopic data in marine carbonates deposited during the Late Cambrian 'SPICE' event. Results document a well-defined -1.7 negative $\varepsilon^{238}U$ excursion that occurs at the onset of positive carbon and sulphur isotope excursions, consistent with expanded marine sinks of reduced C, S and U as expected during the expansion of marine anoxia. However, the $\varepsilon^{238}U$ excursion peaks before the $\delta^{13}C$ and $\delta^{34}S$ excursions, marking a period of continued O_2 release from the marine C and S cycles after the oceanic anoxic event. Simple biogeochemical ocean modeling reveals that the different behaviors of the various isotope systems occurred because organic carbon and pyrite were buried with negligible U at high deposition rates in shallower oxygenated settings.

This second stage of the SPICE event suggests high weathering rates and P delivery from the continents to overcome the limited P-recycling from smaller anoxic marine zones. Intriguingly, this marine nutrient boost, perhaps induced by a tectonic-driven sea level drop, comes before the diversification of phytoplankton and the development of more extended trophic chains marking the beginnings of the Great Ordovician Biodiversification Episode.

Micro-X-ray-diffraction investigations of an altered cement-clay interface

R. DÄHN[1*], P. SCHAUB[1], D. POPOV[2], P. PATTISON[3], A. JENNI[4], U. MÄDER[4] AND E. WIELAND[1]

[1]Paul Scherrer Institut, 5232 Villigen, Switzerland (*correspondence: rainer.daehn@.psi.ch)
[2]Carnegie Institution of Washington, Argonne 60439, USA
[3]EPFL, 1015 Lausanne, Switzerland
[4]University of Bern, 3012 Bern, Switzerland

Cement-based materials and argillaceous rocks play an important role in multi-barrier concepts developed worldwide for the safe disposal of radioactive wastes in deep geological repositories. An approximately 180 million year old marine clay-rich sediment (Opalinus Clay) was identified and selected as the first-priority host-rock for the disposal of high-level radioactive waste in Switzerland. Both materials, i.e. Opalinus Clay and cement used for construction of the repository, are heterogeneous mineral assemblages with discrete nano- to micro-scale particles. Hardened cement paste (HCP) consists of mainly calcium (aluminium) silicate hydrates, portlandite, calcium aluminates, and some minor phases such as calcite and hydrotalcite, in hyper-alkaline environment (pH > 11), while Opalinus Clay (OPA) is a mineral assemblage consisting mainly of illite, illite-smectite mixed layers, kaolinite, quartz and calcite in near neutral conditions. Micro-scale information on the chemical reactions and the secondary phases formed in the disturbed zone at the HCP/OPA interface with its large chemical gradients is almost completely lacking.

In this study synchrotron-based micro-X-ray-diffraction (microXRD) was employed to characterise the complex heterogeneous phase assemblages at the HCP/OPA interface. MicroXRD with a beam size focussed down to a few micrometres makes it possible to perform a variety of novel diffraction experiments on fine-structured materials with a high spatial resolution. For example, micro-diffraction experiments allow probing of heterogeneously composed materials, which show chemical and structural alteration zones on a micrometre scale. The investigated samples were obtained from a long-term Cement/OPA-Interaction experiment ("CI-project") in the Mont Terri Rock Laboratory (St-Ursanne, Switzerland). The alteration zone was found to extend over a few hundred micrometres into the concrete material. First microXRD data of the HPC/OPA interface will be presented here.

Geochemical assessment in environmental assessment of human settlements

DEYI DAI[1]*, YINGXUE RAO[2] AND SHENGGAO CHENG[1]

[1]School of Environmental Studies, China University of Geosciences, Wuhan, PRC
(*correspondence author: xintata@yahoo.com.cn)
[2]College of Public Administration, South-Central University for Nationalities, Wuhan PRC.

Introduction and Methods

Environmental assessment of human settlements (EAHS) has two types in different levels, one is strategic environmental assessment(SEA), another is environmental impact assessment of project(EIA). From Geochemical perspective, EAHS reveal the relationship between human health and environmental characteristics or changes[1]. It use Geochemical principle and method to Evaluation the environmental quality of human settlements, and also to predict the environmental change(figure 1).

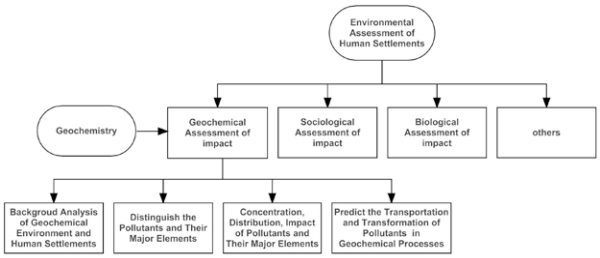

Figure 1: Relationship between EAHS and geochemistry.

The focus of assessment is to confirm the geochemical factors in environment. It base on comprehensive analysis of environmental characteristics and human settlements' characteristics. Then, relative indexes would be selected for EAHS. Assessment establish on evaluation of the selected indexes. Finally, it proposed protective measures of environmental engineering, and conclusions of EAHS would be made.

Geochemical analysis is an important basis for EAHS. Environmental impact formed by the Interaction between geochemical environment and human settlement. Strategic environmental assessment (SEA) of human settlements proposes more promptly support in policy and technology for environmental protection.

Redox-sensitive controls on the Proterozoic nitrogen cycle

STUART DAINES[1*], TIMOTHY M. LENTON[1]

[1]University of Exeter, UK,
([*]correspondence: s.daines@exeter.ac.uk)

Primary production in the Proterozoic ocean is thought to have been strongly nutrient limited, with a range of hypotheses focusing on lack of phosphorus, nitrogen and/or trace metals. It has been argued that phosphorus lost its controlling role as ultimate limiting nutrient, and that all nitrogen could have been drained from the ocean by denitrification in the transition from anoxic to oxic conditions [1], resulting in a feedback maintaining low atmospheric oxygen, and ecological constraints on eukaryote diversification. However, high rates of nitrogen fixation in contemporary anoxic basins and during Phanerozoic OAEs suggest enhanced nitrogen fixation can compensate [2].

Here we use a spatially structured biogeochemical model, GENIE, to examine the role of the nitrogen cycle in controlling ecosystem productivity and ocean redox state. The physiological cost of nitrogen fixation is considerably reduced in low oxygen environments [3], hence nitrogen fixation can maintain production in a mixed anoxic/oxic regime at a level set by P as the ultimate limiting nutrient.. Extensive denitrification is predicted, with small NO_3 and NH_4 reservoirs and a short N residence time ~ 300–500yr.

Spatial redox structure influences the expression of isotope fractionation, hence scenarios could potentially be constrained by N isotope data [4].

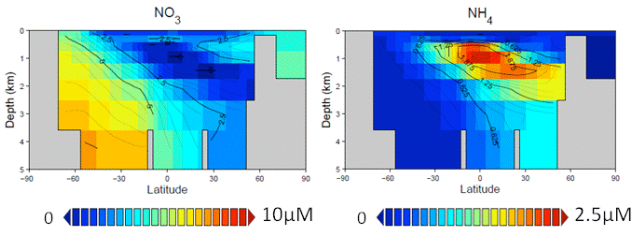

Figure 1: Meridional sections for [NO_3] and [NH_4] in mixed oxic/anoxic regime.

Making natural materials clean – and model samples dirty.

K. N. DALBY*, N. BOVET, M.P. ANDERSSON, K. JUHL AND S.L.S. STIPP

Nano-Science Center, Department of Chemistry, University of Copenhagen, Denmark
(*kdalby@nano.ku.dk)

To improve interpretion of experimental geochemical data, simulations are used. However, theoretical approaches require a certain number of assumptions; otherwise computational requirements become astronomical. Thus, molecular models usually use flat or minimally stepped, pure, "clean" surfaces, e.g., no carbon contamination of the sort that comes from the environment, called "adventitious carbon" (AC). AC is extremely difficult to remove and ubiquitous on all mineral surfaces exposed to air or water.

However, surface analysis with X-ray photoelectron spectroscopy (XPS) and atomic force microscopy (AFM) clearly demonstrate that such a layer modifies the reactivity of quartz (SiO_2) surfaces. New density functional theory (DFT) modelling of carbon containing compounds on calcite surfaces also supports previous XPS results - that AC can change the affinity of the surface for organic molecule attachment, even simple alcohols..

We have developed a fast and easy method for producing "clean" surfaces analogous to those used in modelling (Figure 1) which does not change surface structure. Combined with the development of organic self assembled (SAM) monolayers, for use in deriving experimental data of a model "dirty" system that can be explored theoretically, we can begin to bridge the gap between experiments and models.

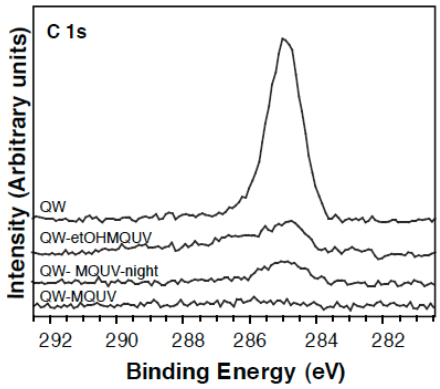

Figure 1: XPS C 1s spectra from quartz wafers (QW) treated (with ethanol (etOH), MilliQ water (MQ) and UV ozone (UV)) to remove the adventitious carbon peak at 285.0 eV.

The Carnian Pluvial Event negative CIE at Cave del Predil (early Late Triassic, Italy): a new link to Wrangellia volcanism

J. DAL CORSO[1]*, G. ROGHI[2], M. RIGO[1,2], P. GIANOLLA[3], M. CAGGIATI[3], G. GATTOLIN[1], R.J. NEWTON[4], H.C. JENKYNS[5] AND N. PRETO[1]

[5]Department of Earth Sciences, University of Oxford, South Parks Road, OX1 3AN, Oxford, UK.

A ~4‰ negative C-isotope excursion (CIE) in higher plant *n*-alkanes has recently been discovered coincident with the onset of the Carnian Pluvial Event (CPE) [1], during which a major climatic and biotic turnover occurred [2]. This C-cycle disturbance has been linked to the eruption of the Wrangellia oceanic plateau (western North America), a Large Igneous Province (LIP) that is thought to have extruded up to 1 million cubic kilometres of basalts during the early Late Triassic [3].

C-isotope analyses of bulk organic matter from stratigraphic sections in the Cave del Predil area (Julian Alps, north eastern Italy) reveals an early Carnian ~6‰ negative CIE corresponding to the onset of the CPE [4]. The negative CIE occurs just below the level recording the first major terrigenous input and change in vegetation type to a hygrophytic flora that can be correlated with the existing stable C-isotope curve from the Dolomites [1].

Our new data show that the major negative CIE at the onset of the CPE can be correlated at least regionally and likely represents a global signal. This C-cycle perturbation could have been caused, directly or indirectly, by the release of large amounts of CO_2 during the coeval eruption of the Wrangellia LIP that led to the Carnian climatic, environmental and biological changes.

Clumped isotopes and concretions: The Prairie Canyon member of the Mancos Shale, Colorado

A. DALE[1*], C. M. JOHN[1], P. MOZLEY[2], P. C. SMALLEY[3] AND A. H. MUGGERIDGE[1]

[1]Royal School of Mines, Imperial College London, UK, SW7 2BP (*correspondence: annabel.dale07@imperial.ac.uk)

[3]BP, Chertsey Road, Sunbury-on-Thames, Middlesex TW16 7BP, UK

Carbonate concretions and septarian fracture fills have been key in developing our understanding of early burial processes in siliciclastic rocks [1]. Often, septarian fractures and concretion matrix cements have unusually light $\delta^{18}O$ values. A common explanation for near-shore marine concretions is that they precipitated at the sediment-water interface in aquifers of mixed meteoric-marine water [2][3]. Alternatively, the light $\delta^{18}O$ could be due to precipitation at higher temperatures during burial. It is often difficult to distinguish between the two hypotheses, which has hindered previous interpretations of the mechanisms of concretion formation and the timing of diagenetic processes.

Here, we apply the novel carbonate 'clumped' isotope palaeothermometer [4] to Fe-dolomite/ankerite concretions and calcite septarian fracture fills from the Upper Cretaceous Prairie Canyon Member. The derived temperature is independent of the bulk isotopic composition, so the parent fluid can be back-calculated. Our results show that the fracture fill precipitated between 107-117°C, corresponding to depths of up to ~3 km. The parent fluid has a $\delta^{18}O$ value of 0.5 ± 0.13 (VSMOW), consistent with slightly ^{18}O-enriched Cretaceous seawater. Interpretation of the concretion matrix is complicated by mixed phases of cements and by the non-linear mixing of clumped isotopes, which can lead to an uncertain temperature. However, even accounting for this, a temperature trend from cooler cores (34°C ± 8) to hotter edges (53°C ±1) is observed. Therefore, the light $\delta^{18}O$ values, at least in the Praire Canyon, are caused by higher temperatures during burial and not meteoric mixing.

We would like to acknowledge a BP–EPSRC Case Studentship for funding this project.

Rapid core formation and an early 'veneer' on Earth: Highly siderophile elements in pre-lunar mantle domains

CHRISTOPHER W. DALE[1] KEVIN W. BURTON[1], ABDELMOUHCINE GANNOUN[2], IAN J. PARKINSON[3], HELEN M. WILLIAMS[1] AND STEPHEN MOORBATH[4]

[4]Dept. Earth Sciences, University of Oxford, OX1 3PR, UK

Highly siderophile elements (HSEs) are strongly sequestered into metallic planetary cores, leaving silicate mantles almost devoid of HSEs. Late accretion of primitive meteoritic material, after core formation had ceased, partially replenished HSEs in planetary mantles and occurred within a few million years of solar system formation on most parent bodies (1), but probably later on Earth, after a final episode of core formation associated with the giant Moon-forming impact (50-150 million years later (2)).

Ancient isolated domains in Earth's mantle, which formed prior to the giant impact, have recently been recognised by anomalies in the short-lived ^{182}Hf-^{182}W isotope system. These domains - such as the source of 3.8 billion-year-old Isua basalts (3) - might represent mantle that largely escaped late accretion. Here we show, however, that the Isua source mantle had HSE abundances at ~60% of the present-day mantle, inconsistent with a pre-late accretion model.

Such early-formed domains require preservation through the Moon-forming giant impact and isolation thereafter, precluding subsequent addition of HSE by mixing with material accreted later. Thus, their HSE contents were set by early 'pre-lunar' late accretion, while the Hf-W system was still extant. This early HSE replenishment requires that core formation was rapid and ceased early, and therefore, on the basis of W isotope evidence, implies a high degree of equilibration of metal with mantle silicate during accretionary impact events. The retention of such early HSE-enriched mantle also implies incomplete giant impact-related melting of Earth's mantle. Conversely, the HSE budget of the Moon was reset during its formation, thereby partially accounting for the disparity in HSE content and apparent late accretion rates between the Earth and Moon.

Organics in the Mix during SAPUSS

M. DALL´OSTO[1], X. QUEROL[1] AND THE SAPUSS TEAM[2]

[1]IDAEA-CSIC, c/Jordi Girona 18-26, Barcelona, Spain (manuel.dallosto@gmail.com)
[2]see reference below [1]

In this work we illustrate the results of the organic aerosols measurements taken during the SAPUSS experiment (Solving Aerosol Problems By Using Synergistic Strategies) in Barcelona (Spain) during autumn 2010 [1]. Two supersites were chosen: Urban background (UB) and Road site (RS) on which

Simultaneous measurements with High Resolution Aerosol Mass Spectrometry (HR-ToF-AMS) were taken; Positive Matrix Factorization (PMF) was applied revealing five different organic aerosol factors.

Simultaneous single particle mixing state measurements with Aerosol Time Of Flight Mass Spectrometry (ATOFMS) were classified by ART-2a algoritm, resulting in eighteen specific particle types internally mixed with a number of organic and inorganic species.

Simultaneous aerosol filter measurements at 12 hours resolution were taken, and concentrations of thirtysix neutral and polar organic compounds were obtained by GC-MS; subsequentally classified by MCR-ALS apportioning six OA components (two were of primary anthropogenic OA origin, three of secondary OA origin while a sixth one was not clearly defined).

This presentation aims at summarising key SAPUSS findings on organic aerosol source apportionment, on the role of organics in new-particle formation and on the interactions of organics and inorganics components.

Activity of cable bacteria and electro-physical properties of gradient systems studied with a novel microsensor for electric potential

LARS RIIS DAMGAARD*, NILS RISGAARD-PETERSEN AND LARS PETER NIELSEN

Insitute for Biosciences, Aarhus University, Ny Munkegade 114-116, DK-8000 Aarhus C, Denmark. (*correspondence: lrd@biology.au.dk)

Activity in sediments and biofilm are thought to be confined to steep chemical gradients and cascades of coupled co-localized redox processes. Recently, however, filamentous bacteria of the family Desulfobulbaceae were found to transfer electrons over centimeter distances to couple spatially separated oxidation and reduction processes (1, 2). For this new exciting research area we have developed a novel microscale sensor for measuring electric potential at micrometer and microvolt scales. Microprofiles of electric potential in marine sediment dominated by such ‘cable bacteria’ allowed identification of involved electron donors and acceptors as well as the localization and quantification of the bio-electrical currents. Electrical conductivity – and in turn diffusivity – of sediment and other soft substrates could also be measured with the aid of the electric potential microsensor, and possibly it can help elucidate the nature of conductivity in microbial nanowires and cable bacteria.

Dissolved iron behavior in the estuarine waters; Irt and Esk River, west Cumbria, UK

EHSAN DANESHVAR[1]

[1]Tyn e Coed, Llandudno, LL30 1SA, (ehsan.daneshvar@cgg.com)2

The aqueous geochemistry of the Ravenglass estuary and its feeding rivers (Irt and Esk) has been studied to assess if, where and when aqueous iron is lost from the river water and accumulates as part of the sediment in the estuary. The River Irt contains twice as much dissolved iron as the River Esk but all iron concentrations are much lower in the estuary samples than in the feeding rivers. Aqueous iron undergoes large-scale accumulation in the Ravenglass estuary. Iron concentrations are lowest at high tide at all sampling sites on the Ravenglass estuary. Iron concentrations are highest at low tide for the Irt arm of the estuary but are highest on the falling tide between high and low tide. Iron in estuary samples decrease rapidly as salinity increases with low iron in all estuary samples once salinity exceeds 5,000 mg/lit. Iron also decrease as pH increases. The loss of iron is presumably due to flocculation of colloidal iron oxides, hydroxides and iron-organic complexes. Fluvial aqueous iron does not behave conservatively on mixing with seawater; most iron is lost from the water column at an early stage of river water mixing with estuary water. The site of primary iron-loss from the water occurs towards the heads of estuaries but this site will move as a function of time within the tide cycle.

Geochemistry and significance of Carboniferous-Permian volcanic rocks in the western of Inner Mongolia, China

BEN DANG[12]*, HONG ZHAO[12], LU-JUN LIN[1], QIAN-QIAN GAO[1] AND MING LIU[1]

[1]College of Earth Sciences and Resources, Chang'an University, Xi'an 710054, China;

[2]Key Laboratory of Western China's Mineral Resources and Geological Engineering, Xi' an 710054, China (*correspondence: dangben@126.com)

The western region of Inner Mongolia located in the south rim of Central Asian Orogenic Belt[1], which belong to the key component of Tianshan-Xing'An Orogenic system. Carboniferous-Permian volcanic rocks are widespread in the area. However, at present, the study of petrogenesis and tectonic setting are weak relatively. Based on the regional geological survey, combined with the analysis of petrology and petrogeochemistry characteristics of Carboniferous-Permian volcanic rocks, the genesis of the rocks and tectonic setting have been discussed. It provides petrogeochemistry proofs for clarifying the properties of Carboniferous-Permian basin and palaeo-tectonic setting. The volcanic rocks in the area are intermediate-acidic volcanic rocks mainly and a small amount of basic volcanic rocks. The geochemistry characteristics of the basic volcanic rocks (Basalts, basaltic-andesite) show as follows. Most of the sample of the basic volcanic rocks belong to sub-alkaline series, a little are alkaline series. Mg# ranges from 0.29 to 0.86. The high field strength elements Nb, Ta and Ti are strong depletion. Light rare earth element (LREE) is mild richer than heavy rare earth element (HREE). (La/Yb)N ranges from 1.68 to 10.1. Eu anomalies is not obvious (δEu=0.64~1.08). REE distribution patterns are slightly right-inclined. Nb/U is generally low 1.35~9.78. Ti/V ranges from 20 to 100 (centralized in 50). εNd(t) is higher(+1.10~+6.35). Geochemistry comprehensive analysis indicate that Carboniferous-Permian volcanic rocks in the area show not only the signature of within plate setting as a whole, but also that of subduction zone. Synthesizing the regional geological characteristic and the research achievement in the neibouring area, we conclude that the Carboniferous-Permian magmatic activity in study area generated in within-plate rift valley setting, and probably related to mantle plume affair, with variable degrees of contamination of crust during magma ascending.

Non-adiabatic calculations of ultraviolet absorption cross section of Sulfur Monoxide; Isotopic effects on the photodissociation reaction

SEBASTIAN O. DANIELACHE[1], TOMOYA SUZUKI[1] AND SHINKOH NANBU[1]

[1]Faculty of Science & Technology, Sophia University, Japan (sebastian.d@sophia.ac.jp)

Understanding the mechanism of the sulfur isotopic fractionation of SO_2 in a reduced atmosphere and under high fluxes of UV light has become a key feature in explaining the mechanisms that produced the large sulfur mass independent fractionation (S-MIF) signal deposited in the geological record [1,2]. However, all modeling studies conducted for the Archean atmosphere assume that the life time of the intermediate product after the photodissociation of SO_2 (SO) is short lived and no further photochemistry can produce additional isotopic enrichment or depletion. We set out to test this hypothesis by theoretically calculating the ultraviolet absorption cross sections of the main and substituted sulfur monoxide isotopologues. The theoretical framework for this work includes a newly developed R-Matrix expansion. The calculated absorption cross section of ^{32}S ^{16}O were compared with reported experimental spectra, calculations and experiments are in good agreement although the there is some come concern with certainty of the experimental data. Our calculations show that according to the energy of the photon flux the involved exited states can produce a fast photodissociation or a long lived SO* photoexited fragment. In order to test these new results the obtained spectra were introduced in an improved sulfur isotope photochemical Archean model [3]. The improvement to our model includes the addition of hydrocarbon chemistry, chemical formation and deposition of organic sulfur haze.

The Earth's climate is changing and the release of carbon dioxide (CO_2) and other greenhouse gases into the atmosphere is recognised as the principal cause. Long-term and secure geological storage of CO_2 through Carbon Capture and Storage (CCS) within reservoirs is seen as a solution; however, knowledge of the trapping mechanisms, in conjunction with understanding the effect of injected CO_2 on the reservoir formations themselves, is fundamental to assessing the viability of long-term storage. Developing a greater understanding of the flow of CO_2 through a porous medium and the associated reactions between the host rock formation and the fluid is therefore of great importance to understanding whether a CO_2 storage site is likely to fail.

Dissolution of CO2 into ambient brine is a prospective stable trapping mechanism. This study examines the enhanced rates of dissolution found during injection into a layered, heterogeneous formation using analogue experiments and numerical models. The analogue experiments, designed to approximate an Enhanced Oil Recovery (EOR) setting, show that during fluid propagation, pore-scale viscous fingers grow and retreat providing an increased surface area between the flow and the ambient reservoir fluid, which is likely to enhance the dissolution of CO_2 in reservoir brines. The numerical simulations provide a useful comparison with the analogue experiments and give constraints on the timescale and magnitude of CO_2 dissolution and the consequent fluid-mineral reactions in a heterogeneous reservoir. The study addresses whether carbonate or silicate mineral dissolution can provide the CO_2 with a leakage pathway through corroded caprocks and fault seals, or assist pathway sealing.

Influence of organic molecules on aggregation of TiO_2 nanoparticles

KARIN DANIELSSON*, JULIÁN GALLEGO-URREA, MARTIN HASSELLÖV AND CAROLINE M. JONSSON

University of Gothenburg, Department of Chemistry and Molecular Biology, Gothenburg, Sweden (karin.danielsson@chem.gu.se) (* presenting author) (julian.gallego@chem.gu.se), (martin.hassellov@chem.gu.se), (caroline.jonsson@chem.gu.se)

Nanotechnology is a rapidly growing industry, which leads to an increased amount of synthetic nanoparticles released into the environment. However, the fate and behavior of synthetic nanoparticles in the environment are not well-known. Titanium dioxide (TiO_2), a naturally occurring mineral, is one of the most used metal oxide nanoparticles due to its special properties. Nanoparticles generally have higher reactivity than larger particles of the same material. As the particle size is decreased to the nanometer size range (1-100nm), the surface chemistry changes and this might influence the surface charging and aggregation behavior. Further, nanoparticles can interact with natural organic material (NOM), such as humic and fulvic acids, which is present in most natural waters. Adsorption of NOM affects the surface speciation and net charge of the nanoparticles and is therefore of great importance for their colloidal stability. This might alter the mobility of nanoparticles in surface waters and in soils, thus determing their bioavailability and toxicity.

The focus of the present study was to investigate the aggregation behavior of synthetic nanoparticles in aqueous solution as a function of time and pH in the presence of organic molecules. Synthesized and well-characterized TiO_2 (anatase) nanoparticles were used as test nanoparticles and selected phenolic carboxylic compounds were used as model substances to mimic the interactions of nanoparticles with NOM. The aggregation and surface charging of the particles were studied by simultaneously monitoring the changes in particle size and zeta potential during the reactions. Results show that the concentration of organic molecules, and the type and number of functional groups affect the aggregation behavior of TiO_2 nanoparticles in aqueous solution.

Testing accuracy of combined zircon ($^{238}U/^{230}Th$) and (U-Th)/He dating against radiocarbon dating

[6]University of California, Irvine, USA
[7]Australian National University, Canberra, Australia
[8]Victoria University, Wellington, New Zealand

Combined $^{238}U/^{230}Th$ disequilibrium and (U-Th)/He dating of zircon [1] is a novel approach for dating young (<350 ka) volcanic eruptions. This method has been successfully applied in various settings [2,3], however its accuracy has not been rigorously tested and validated by independent methods.

In this study we apply the combined $^{238}U/^{230}Th$ disequilibrium and (U-Th)/He zircon dating to the deposits of the coeval Rotoiti (ROR) and Earthquake Flat (EQF) eruptions in the Taupo Volcanic Zone, New Zealand, to investigate consistency of the method. In addition, wood sampled below and above the Rotoiti tephra is dated by high-precision radiocarbon method to provide independent constraints on the accuracy of the zircon eruption ages.

The two independent methods revealed concordant ages, which are also in accord with the stratigraphic position of the samples. Based on these results we assign new ages of ~45 ka to the ROT and EQF eruptions, which is by ~16 kyr younger than the currently accepted age, which has implications for paleoclimatic reconstructions and hazards assessment. This study proves the combined $^{238}U/^{230}Th$ disequilibrium and (U-Th)/He dating of zircon reliable at late Quaternary time scale and also demonstrates reliability of the radiocarbon dating method at higher end of its sensitivity at ~50 ka.

Measuring denudation rates with the $^{10}Be(meteoric)/^{9}Be$ isotope ratio in catchments with different lithologies

N. DANNHAUS[1*], F. VON BLANCKENBURG[1], H. WITTMANN[1], P. KRAM[2] AND M.CHRISTL[3]

[1] GFZ German Research Centre for Geosciences, Potsdam, Germany (*correspondance: nadine.dannhaus@gfz-potsdam.de)
[2] Czech Geological Survey, Prague, Czech Republic (pavel.kram@geology.cz)
[3] ETH, Zurich, Switzerland (mchristl@phys.ethz.ch)

Unlike *in situ*-produced cosmogenic nuclides, determining denudation rates with the new $^{10}Be(meteoric)/^{9}Be$ ratio does not depend on the presence of quartz. In the Critical Zone cosmogenic ^{10}Be and its stable counterpart ^{9}Be mix to a characteristic rate that is dependent on the denudation rate, the fraction of ^{9}Be released from primary minerals, and the ^{9}Be concentration of the parent bedrock [1]. This rate can be determined either on the reactive phase (adsorbed onto or precipitated in secondary minerals) of sediment or on the dissolved phase in stream water. The reactive beryllium can be separated by a sequential extraction method described in [2]. Dissolved cosmogenic ^{10}Be is concentrated from a water sample by co-precipitation with iron(III)-hydroxide.

We applied this new method to three small catchments in the Slavkov Forest, Czech Republic. Each catchment is underlain by different bedrock, namely granite, amphibolite, and serpentinite. These diverse lithologies are ideal to investigate the potential of the $^{10}Be/^{9}Be$ isotope system under various geochemical conditions (e.g. different acid-base chemistry of stream and soil water). Resulting $^{10}Be/^{9}Be$ ratios in the reactive and dissolved phase differ only within a factor of two for each catchment, indicating almost complete equilibration of the isotopes. We used these $^{10}Be/^{9}Be$ ratios to calculate denudation rates that turned out to be highest for the ultramafic and lowest for the granitic catchment.

One advantage of this new approach is that it can be applied to any lithology, provided that the bedrock ^{9}Be concentration is known. The second novelty of this system is that a denudation rate can be determined from a $^{10}Be/^{9}Be$ ratio measured in the dissolved fraction of stream water.

Influence of geological setting on geochemical baselines of heavy/trace elements in soils of Medak district, Andhra Pradesh, India

SUJATHA DANTU

CSIR - National Geophysical Research Institute, Hyderabad, India – 500 007
(sujathadantu@rediffmail.com)

A collection of 878 soil samples (557-topsoil 0-25 cm depth interval, 321-subsoil 70-95 cm depth interval) were taken from 557 sites (representing a density of 1 site/17 km^2) derived from the major rock types in the Medak district of Andhra Pradesh, India. The concentration of 29 elements (major: Si, Al, Fe, Mn, Mg, Ca, Na, K, Ti, P and trace: As, Ba, Cd, Co, Cr, Cu, F, Mo, Ni, Pb, Rb, Se, Sr, Th, U, V, Y, Zn, Zr) was determined on the < 2 mm soil fraction by X-ray fluorescence spectrometry. The sampling sites were not directly influenced by any external pollution. The geochemical baseline values for each element in soils developed on different litho-units are presented. The median concentrations of Ni, Pb, Rb, Sr, Y, Zn, Zr, Si, Al, Fe, Mn, Mg, Ca, Na, Ti and P were measured to be significantly lower while the median concentrations of Ba, Cd, Co, Cr, Cu, F, Mo, Se, Th, U and K were found to be higher than the world median soil values. The distribution patterns of element concentrations are primarily influenced by the lithology. By contrast, the concentrations of Co, Cu, Fe, Mn, Ti, V and Zn are high in soils developed on basaltic terrain while the soils developed on granitic and gneissic terrain exhibited high elemental concentrations of K, Pb, Rb, Si, Th and Y. High concentration of radioactive elements in soils in certain pockets of the study area appear to characterize the igneous rocks formed over considerable periods of time and also by subsequent addition of Th derived from the erosion of the neotectonically uplifted rocks [1]. Enrichment of the elements in the soils developed on different rock variants reflected the elevated levels in the parent material and or fixation (adsorption) in soils by weathering processes. Further elemental concentrations are also related to the size of soil particles therefore, the loss or gain in clay, silt and sand size fractions of soil by wind or hydrological transport may cause differences in element enrichment at regional or local scale. It is therefore, evident that most of the differences in geochemical values of elements are controlled by the bed rock. These results indicate that regional geology is an important determinant of soil geochemical baselines for soil pollution assessment.

LA-ICPMS imaging of micro-inclusions and high compositional gradients in minerals

L.V. DANYUSHEVSKY[1]*, S.J.M. MEFFRE[1] AND S.E. GILBERT[1]

[1]CODES CoE, University of Tasmania, Private Bag 79, Hobart, Tasmania, 7001, Australia (*correspondence: l.dan@utas.edu.au), (Sebastien.Meffre@utas.edu.au), (sgilbert@utas.edu.au)

Imaging of trace element distribution in a range of geological materials using quadrupole LA-ICPMS is an actively expanding area of geochemical micro-analysis. Determining compositions of diagenetic and hydrothermal suphide minerals using in-situ analytical techniques presents a significant challenge due to common high compositional gradients (several orders of magnitude over several microns) and wide-spread occurrence of micro-inclusions. Accurate imaging of trace and minor element distribution in such minerals offers significant advantages for genetic interpretations [1], complementing conventional spot analyses. Simultaneously resolving high concentration gradients for a wide range of elements with LA-ICPMS requires fast-response, small-volume ablation cells; minimal mixing within the laser-ICP interface; and short dwell and total sweep times on the ICPMS. The technique developed uses a set of parallel lines with spacing equaling the laser beam size, thus covering the entire sample surface. Pre-ablation of each line is essential for removing surface deposition from previous ablations. Regular measurements of the background and calibration standards are required for controlling memory effects and instrumental drift in sensitivities. Use of square rather than round beam shape is preferred, although not critical for this application. The beam size is determined by size and composition of bands and micro-inclusions of interest. Lines are ablated at 10 Hz and a constant speed covering the size of the beam in 1 sec, resulting in each position on the surface being ablated 10 times. Total sweep times are 0.2-0.3 seconds resulting in 3 to 5 sweeps being recorded each second. The effective pixel size along the lines is dependent on instumentation design and can be minimised by advanced image processing, to be ~ 1.3-1.5 times the beam sizes. Accurate imaging of gentle compositional gradients (<10 times), especially over short distances (up to several beam diameters) requires a different approach with signal smoothing and slower rastering. Challenges of image quantification will be discussed.

Reactivity of U(VI) with H_2, CH_4 and C under hydrothermal conditions

M. DARGENT[1], L. TRUCHE[1] AND J. DUBESSY[1]

[1]GéoRessources, Université de Lorraine, 54500 Vandoeuvre-lès-Nancy, France (*correspondence: maxime.dargent@univ-lorraine.fr)

Giant Unconformity-type U deposits are characterized by massive uraninite often associated with graphite. It has been demonstrated that U was first transported by acidic brines under the form of uranyl chloride complex and further reduced locally into uraninite [1]. However, the reaction mechanism and kinetics of U(VI) reduction into immobile U(IV) remain poorly understood [2]. The objective of our experimental investigations is to measure uranyl chloride reduction rate as a function of the nature of the reducing agent and under hydrothermal conditions relevant for unconformity-type deposits.

We demonstrate that U(VI) reduction occurs readily at temperature above 100°C whatever the reducing agent considered. 10 µm octahedral uraninite crystals precipitated. The initial activation stage probably corresponds to the first uraninite crystals nucleation. Reaction rate measurements allow us to rank the efficiency of electron donors: H_2 > CH_4 > C, and to evaluate the respective activation energies. Furthermore the reaction rate also depends on chlorinity. This suggests that the reaction mechanism is partly controlled by the speciation of uranyl in chloride solutions. This point is highlighted by a Raman spectroscopic study [3].

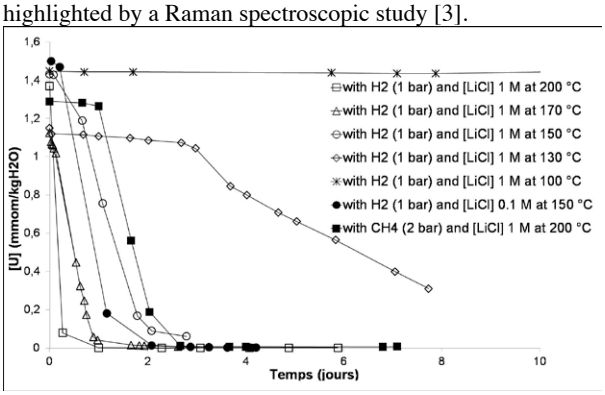

Figure 1: U(VI) concentration (mmol/kgH_2O) vs time (day) for different chlorinity, reductants and temperatures.

The shocking state of baddeleyite in basaltic shergottite NWA 5298

J.R. DARLING[1]*, D. E. MOSER[2], I. BARKER[2], K.T. TAIT[3], K. CHAMBERLAIN[4] AND A.K. SCHMITT[5]

[1]University of Portsmouth, UK (*darling@port.ac.uk)

[3]Royal Ontario Museum, Toronto, Ontario, CAN
[4]University of Wyoming, Laramie, Wyoming, USA
[3]UCLA, Los Angeles, USA

Meteorites from Mars offer unique insights into the age and evolution of the planet's crust. In order to fully understand this precious archive, it is critical to separate the effects of shock metamorphism that occurs during ejection from endogenic crustal processes.

Here we show that in the case of the highly shocked shergottite NWA 5298, this evolution can be resolved by combining electron beam microstructural techniques (CL, EBSD) with in-situ U-Pb SIMS analyses. We focus upon the effects of shock metamorphism on the U-Pb systematics of baddeleyite (ZrO_2) – a mircon-scale phase common to many shergottites. Unlike zircon, the relationship of shock heating and deformation with retention of radiogenic Pb is poorly known.

Baddeleyite grains from a single polished thin section show a wide array of deformation microstructures. These include fracturing, varying degrees of amorphization and granulation, plastic deformation, and recrystallization due to post-shock fluids: reflecting local variations in shock pressures and waste heat. SIMS U-Pb isotope analyses of these grains reveal variable degrees of age resetting, broadly correlated with microstructure and preservation of primary igneous CL zonation. Of the 19 analysed grains, four of the oldest six U-Pb dates are from grains which exhibit oscillatory growth banding. Degree of Pb loss (as much as 80%) is also broadly correlated with degree of growth of post-shock zircon reaction rims. The zircon reaction rims are linked to release of Si-rich fluids during quenching of shock melt pockets during transit to space. These findings, contrary to the results of shock loading experiments [1], indicate that baddeleyite U-Pb ages can be reset under certain shock metamorphic pathways. The U-Pb data are thus useful for determining both the primary age of the meteorite assemblage and bracketing the time of its Earthward launch.

Interstellar and interplanetary solids in the laboratory

E. DARTOIS[1,2]*

[1]CNRS-INSU, Institut d'Astrophysique Spatiale, UMR 8617, 91405 Orsay, France (*correspondence: emmanuel.dartois@ias.u-psud.fr)
[2]Université Paris Sud, Institut d'Astrophysique Spatiale, UMR 8617, bât 121, 91405 Orsay, France

The interstellar medium is a physico-chemical laboratory where extremes conditions are encountered, and whose environmental parameters (e.g. density, reactant nature, radiations, temperature, time scales) define the composition of matter.

Whereas cosmochemists can spectroscopically examine collected extraterrestrial material in the laboratory [e.g. 1,2,3,4,5,6], astrochemists must rely on remote observations to monitor and analyze the physico-chemical composition of interstellar solids [e.g. 7,8,9,10,11].

The observations give essentially access to the molecular functionality of these solids, rarely elemental composition constraints and isotopic fractionation only in the gas phase. Astrochemists bring additional information from the study of analogs produced in the laboratory, placed in simulated space environments.

In this presentation I will briefly touch some observations of the diffuse interstellar medium (DISM) and molecular clouds (MC), setting constraints on the composition of organic solids and large molecules in the cycling of matter in the Galaxy and try to draw some commonalities and differences between materials found in the Solar System and Interstellar dust.

Tracing whole-Earth carbon from the Hadean to present

RAJDEEP DASGUPTA[1]

[1]Dept of Earth Science, Rice University, Houston, TX, USA

In response to the evolving thermal vigor and fugacity of oxygen and other volatiles, the behavior and fate of carbon and its partitioning between various layers of Earth - atmosphere, silicate Earth, and metallic core - varied through geologic time [1].

During the first few tens of millions of years of the Hadean Eon, carbon that participated in the core-forming, deep magma ocean, partitioned strongly into the metallic core. The Moon on the other hand, having a much shallower magma ocean likely held on to a large fraction of its bulk carbon. With almost all carbon of the chondritic building blocks being lost to space, restricted to nascent atmosphere, or sunk to the core, the silicate liquid mantle soon after core segregation was probably carbon-poor. Processes such as late bombardment of volatile-rich material, entrapped C-bearing metallic liquid in lower mantle solids, and ingassing from a C-rich atmosphere had opportunities to replenish mantle carbon by the end of the Hadean Eon. The crustal recycling zone temperature also likely was hotter until ~1.5 Ga; such slab thermal structure along with inconsistent subduction cycle might have hindered deep ingassing of surficial carbon. Massive release of CO_2 at the Archean and Paleoproterozoic volcanic arcs thus might have supplied the necessary dose of greenhouse gas in the atmosphere to offset the dimmer early Sun, sustaining liquid water on Earth's surface.

The P-T paths of subducting slabs of the Phanerozoic support transporting crustal carbonates past arc-magmatic depths, setting up systematic deep transfer of surficial carbon to the interior. Magmatic release of CO_2 balances the subduction input of carbonates and organic carbon. The proximal carrier-magma delivering mantle carbon to the exosphere depends chiefly on the thickness of the thermal boundary layer and mantle potential temperature – most strongly carbonated magma being the key agent beneath cratons, mildly carbonated magma for mature oceanic lithosphere, and basalts with trace amount of dissolved carbon beneath mid-oceanic ridges.

This talk will trace the origin of mantle carbon in the Earth-Moon system from the time of accretion, core formation, and magma ocean crystallization and will attempt developing a framework of carbon ingassing and outgassing fluxes in different time periods of whole Earth evolution.

Deep subduction of carbon and sulfur constrained by laboratory experiments

RAJDEEP DASGUPTA[1]*, MEGAN DUNCAN[1], SÉBASTIEN JÉGO[1] AND KYUSEI TSUNO[1]

[1]Dept of Earth Science, Rice University, Houston, TX, USA
(*correspondence: Rajdeep.Dasgupta@rice.edu)

The fate of volatile elements such as carbon and sulfur during subduction is critical because of their influence in a number of key aspects of planetary differentiation including partial melting, atmospheric chemistry and habitability, mobility and enrichment of ore forming metals, and redox evolution of the planetary interior. Yet, the efficiency of carbon and sulfur via subduction of crust is unresolved. Here we use phase equilibria experiments on carbonate-, sulfide-, and sulfate-bearing crust and sediments, plus experimental data and models of CO_2 and sulfur solubility in hydrous siliceous melt as a function of fO_2 to constrain the recycling efficiency of carbon and sulfur.

Carbon: Carbonate minerals are stable along P-T paths of most downgoing slabs and generation of carbonatitic melt is only possible for hot subductions and/or from deeply (>200 km) subducted sediments. In the absence of carbonate melting, transfer of carbon to sub-arc mantle is limited by solubility of CO_2 in rhyolitic melts. Experiments and thermodynamic modeling suggests that wt.% level CO_2 may be dissolved in rhyolitic melts generated by hydrous-fluid-fluxed melting of crust and sediments, with solubility diminishing with decreasing fO_2 in the presence of graphite. However, the extent of graphite and carbonate breakdown remains limited by the extent of hydrous melting, with the latter being controlled chiefly by bulk water content.

Sulfur: Sulfur content of downgoing crust is estimated to be lower than that of carbon, but sulfur content of pyrrhotite-saturated, slab melts is only ~100 ppm [1]. For anhydrite-saturared crust (fO_2>FMQ+3), slab melts contain 1000s of ppm S, yet elimination of sulfate from slab requires large extent of slab melting and extensive flushing by hydrous fluids. With subducting slab being largely dehydrated approaching sub-arc depths, stability of sulfur-bearing phases in ocean crust is likely at all fO_2. Further, sulfur addition to wedge mantle is most efficient via fluid addition (rather than melt) and fluids even at reduced conditions may be sufficiently rich in sulfur to elevate mantle wedge abundance.

Constraints on relative efficiency of deep subduction of carbon and sulfur will be presented and likely carrier of carbon versus sulfur to the arc source will be evaluated.

Reduction of Cu(II) adsorbed to bacterial cells: A role for Fe(II)?

CHRISTOPHER J. DAUGHNEY[1*], PETER J. SWEDLUND[2], MAGALI MOREAU-FOURNIER[3], SARAH L. HARMER[4], BERNT JOHANNESSEN[5], RACHEL FRANZBLAU[6] AND CHRISTOPHER G. WEISENER[6]

[1]GNS Science, Lower Hutt, New Zealand (*correspondence: c.daughney@gns.cri.nz)
[2]University of Auckland, Auckland, New Zealand, (p.swedlund@auckland.ac.nz)
[3]GNS Science, Wairakei, New Zealand (m.moreau-fournier@gns.cri.nz)
[4]Flinders University, Bedford Park, Australia, (sarah.harmer@flinders.edu.au)
[5]Australian Synchrotron, Clayton, Australia, (bernt.johannessen@synchrotron.org.au)
[6]University of Windsor, Windsor, Canada (franzbl@uwindsor.ca, weisener@uwindsor.ca)

Laboratory experiments were performed to track the fate of dissolved Cu(II) and Fe at a fixed pH of 5.2 during the gradual, incremental oxidation of dissolved Fe(II) and precipitation of iron oxide in the presence of *Anoxybacillus flavithermus* cells. X-ray absorption spectra of wet pastes were collected at the Cu K-edge and the Fe K-edge at the Australian Synchrotron and at the Australian National Beamline Facility in Japan. The samples consisted of 3 ppm Cu(II) that had been allowed to equilibrate with the bacteria alone, abiotic iron oxide without bacteria, or the bacteria-iron oxide composites. Standards included aqueous solutions of Cu(II) perchlorate, Cu(II) formate and Cu(II) nitrile(tris)methylphosphonic acid, and powdered Cu_2O. Fe standards included aqueous solutions of Fe(II), Fe(II) citrate and Fe(II) phosphate, and powdered lepidocrocite and ferrihydrite. The EXAFS data for the bacteria-iron oxide composites showed that under the experimental conditions Cu in the solid phase was associated predominantly with carboxyl structures on the bacterial cell walls, not with bacterial phophoryl structures or with binding sites on the iron oxide. These results are consistent with previous studies. The XANES data indicated that the solid phase Cu existed partially as Cu(I), with a ratio of Cu(I) to Cu(II) that was proportional to the concentration of solid phase Fe(II). Tests revealed that beam damage was negligible under the conditions employed. Hence, the occurrence of Cu(I) was not an artefact, and so we hypothesise that reduction to Cu(I) was facilitated by oxidation of Fe(II) that was co-adsorbed to the bacterial cells. This type of reaction that has direct relevance to natural environments, where bacteria and Fe(II) often coexist, and may play an important role in the transport of many different types of redox-sensitive contaminants. The immobilization of metal cations in bacteria-bearing settings should not be examined independently of progressive oxidation, hydrolysis and precipitation of iron.

MC-ICPMS and NRIXS: A Stereo View of Iron Isotopic Fractionation in Silicic Magmas

Silicic rocks show trends of increasing δ^{56}Fe values with increasing SiO_2 content [*e.g.*, 1-3]. These trends have been ascribed to Soret effect, fluid exsolution, and magmatic differentiation. To understand the cause of Fe isotopic variations in silicic magmas, we measured the Mg, Fe, Zn, and U isotopic compositions of a range of migmatites, granites, and pegmatites with well-characterized petrologic and geochemical contexts [3]. No clear positive correlation is found between the isotopic compositions of Mg, U and Fe, which rules out the process of Soret diffusion. Zinc can easily be mobilized by aqueous fluids as chloride complexes. Pegmatites and some granitic rocks with high δ^{56}Fe values also have high δ^{66}Zn values. However, some granites with high δ^{56}Fe values have unfractionated δ^{66}Zn values and were presumably poor in fluids (A-type granitoids). For these samples, iron isotopic fractionation during magma differentiation is the most likely interpretation. We used the technique of Nuclear Resonant Inelastic X-ray Spectroscopy at the Advanced Photon Source to measure the mean force constant of Fe in basalt, andesite, dacite, and rhyolite glasses. We find a sudden increase in the force constant of Fe^{2+} from dacite to rhyolite. The β-factors derived from these force constants [4,5] were used in a model of magma differentiation using Rhyolite-MELTS. The correlation between δ^{56}Fe and SiO_2 is well explained by magmatic differentiation.

The interfacial zone between a bulk fluid and a mineral surface is where all exchange of matter and energy occurs during chemical weathering. However, our knowledge is still limited with respect to understanding where and how the rate-determining dissolution reactions take place. A complicating factor is the commonplace formation of amorphous Si-rich surface layers (ASSL), which may hinder contact between the fluid and the mineral surface. Previous studies showed that the protective ability of ASSL critically depended on properties inherited from the parent silicate mineral, which remain yet to be unraveled.

To address the role of ASSL, we investigated the dissolution of a common silicate (diopside), and related the bulk dissolution rate (determined in classical flow-through experiments) with the nanoscale dissolution rate and surface chemistry of its individual prevalent faces (by combining vertical scanning interferometry (VSI) measurements of the topography of reacted cleavages and transmission electron microscopy (TEM) characterizations of the ASSL). While ASSL were evidenced on all of the investigated faces, only those formed on (110) and (1-10) were passivating, thereby controlling the reactivity of the underlying faces. The (110) and (1-10) faces intersect the highest density of Mg-O-Si and Fe-O-Si bonds, and this specificity may explain the passivating behavior of the corresponding ASSL. Moreover, we evidenced an inverse relation between aqueous silica concentration and the bulk dissolution rate of crushed diopside grains, which suggest that the (110) and (1-10) faces are predominant in a powder. By considering ASSL as a separate phase that can control silicate dissolution rates, extrapolated laboratory-based rates at conditions relevant to the field can be lowered by up to several orders of magnitude, thereby decreasing the large gap between laboratory and natural rates. This has important implications for more accurately modeling chemical weathering reactions.

In situ real time infrared spectroscopy study of (poly)molybdate ions sorption into layered double hydroxides

A. DAVANTES[1], C. ARDAU[2], G. LEFEVRE[1,*]

[1]LECIME, UMR7575 CNRS-Chimie ParisTech, 75005 Paris, France (*correspondence : gregory-lefevre@enscp.fr)

[2]Department of Chemical and Geological Sciences, University of Cagliari , Via Trentino 51, 09127 Cagliari, Italy

Due to the high anion-exchange capacities (2-3 meq/g) and their relatively low cost, layered double hydroxides (LDHs), also known as anionic clays or hydrotalcite-like compounds (described with the general formula $[M^{2+}_{1-x}M^{3+}_{x}(OH)_2](A^{n-})_{x/n}.mH_2O$) have been studied for application in wastewater treatment by intercalated oxyanions [1,2].

The aim of this study was to investigate the sorption mechanism of molybdate anion and to obtain the speciation of molybdate inside the LDH structure after sorption in a Zn/Al sulphate-carbonate LDH.

To the best of our knowledge, it is the first time that sorption of molybdate anion into layered double hydroxides is studied by attenuated total reflection (ATR) FTIR spectroscopy [3]. *in situ* analysis of the sorption processes into the LDHs interlayer (exchanged of (poly)molybdate ions with sulfate or carbonate ions) allowed us to identify the high affinity of LDH towards $Mo_7O_{24}^{6-}$, which sorbs even though it is a minor species in comparison with other protonated heptamolybdate ions.

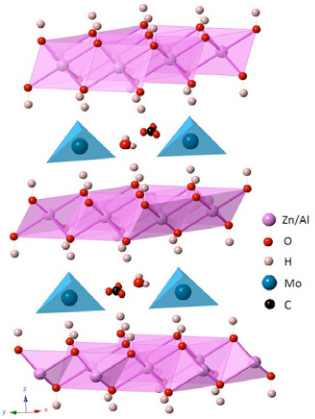

Figure 1: Structure of a layered double hydroxide, with interlayer molybdate and carbonate anions.

Radon activity around active faults in a geothermal environment

JONATHAN DAVIDSON*[1], DARREN GRAVLEY[1], ANDY NICOL[2] AND JERRY FAIRLEY[3]

[1]University of Canterbury, 22 Kirkwood ave, Ilam, Christchurch, New Zealand (*correspondence : jrjdavidson@gmail.com)
[2]GNS Sciences, Lower Hutt
[3]University of Idaho, Moscow, ID

Variation in radon gas concentration has been associated with faults and faulting processes at several locations globally. The Central Taupo Volcanic Zone (TVZ) is an active volcanic rift which hosts more than 20 geothermal fields. The geothermal activity is only occasionally associated with fault traces visible at surface, however it is possible that many active faults have been buried by recent volcanic deposits (blind faults). In order to detect these faults and their prospectivity for geothermal energy, soil gas Radon surveys have been proposed over areas potentially hosting blind faults.

We surveyed soil gas around the Rehi fault and the Paeroa fault, both substantial faults (i.e. slip rates 0.5-1.5 mm/yr) in the TVZ, with the purpose of showing the relationship between soil gas Radon activity and active faults. We used a electrostatic precipitation Radon detector (Durridge RAD7) to measure Radon activity of two Radon Isotopes (^{220}Rn and ^{222}Rn) in soil gas sampled at 1m depth. We also collected several soil samples at the location and depth of the gas measurements, for further testing of Radon emanation potential in a laboratory setting.

Our data show a clear relationship between faults and Radon activity at several locations. However, the isotope activity ratios and the laboratory testing show that this activity variation is in most cases due to shallow and local soil processes, not faulting processes This leads us to conclude that in the TVZ measuring Radon activity in soil gas may not be a reliable technique for detecting faults in the sub-surface.

Exceptionally high Radon activity for ^{220}Rn and ^{222}Rn isotopes was however recorded in steam vents around the Waikite geothermal spring, a boiling bicarbonate spring which flows at ~60 l/s at the base of the Paeroa fault scarp. Preliminary data support the idea that the Radon isotopic ratio can be used to determine the travel time and flow path of steam from the source to the detector. These Radon isotopes constrain the flow model for the Waikite geothermal spring and could be used in envrionmental and hydrological studies of other bicarbonate geothermal springs.

Characterization of Baddeleyite Oxygen Isotopes and Microstructure

JOSHUA H.F.L. DAVIES*[1], RICHARD A. STERN[1], LARRY M. HEAMAN[1], DESMOND E. MOSER[2] AND ERIN L. WALTON[3]

[1]University of Alberta, Edmonton, Alberta, Canada *(jdavies1@ualberta.ca)
[2]University of Western Ontario, London, Ontario, Canada
[3] Grant McEwan University, Edmonton, Alberta, Canada

The oxygen isotopic composition of Precambrian mafic and alkaline rocks is often difficult to determine by conventional methods due to overprinting by hydrothermal alteration or metamorphism. Baddeleyite (ZrO_2) is a uranium-bearing accessory phase in these rocks, and due to improved extraction and *in situ* techniques is increasingly targeted for U-Pb geochronology. We have investigated the $\delta^{18}O$ composition of baddeleyite from various settings to assess its suitability for recording primary $\delta^{18}O$ values, potentially creating a valuable tool for tracing magma petrogenesis through time.

SIMS oxygen isotope analyses of potential mineral standards (baddeleyite megacrysts from Phalaborwa and Mogok) have uncovered various analytical complexities relating to matrix and orientation effects between baddeleyite and the incoming ion beam.

Here we present oxygen isotope data from metamict and thermally annealed baddeleyite. We have characterised the degree of metamictization using Raman spectroscopy, cathodoluminescence imaging and EBSD analysis. With the crystallographic information, we show how crystal orientation and degree of metamictization affect the instrumental mass fractionation during SIMS analysis, and how these affects can potentially be mitigated.

Interaction between CO_2-rich brine and marly shale under supercritical CO_2 conditions

G. DÁVILA[1], L. LUQUOT[1], J. M. SOLER[1] AND J. CAMA[1*]

[1]Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Jordi Girona 18-26, Barcelona 08034, Catalonia, Spain (*correspondence: jordi.cama@idaea.csic.es)

Geological CO_2 sequestration at a pilot-plant scale is going to be performed at Hontomin (Spain). The reservoir rocks are mainly fractured limestones and the caprock is made up of marly shales, with an average composition (wt%) of 56% calcite, 21% quartz, 17% illite, 3% clinochlore and albite and trace amounts of pyrite, gypsum and anhydrite. An experimental study was performed to (1) evaluate mineral dissolution/precipitation processes as a sulfate- and CO_2-rich brine circulates through an open fracture and (2) to quantify the effects these processes may exert on fracture permeability.

Percolation experiments under CO_2 supercritical conditions (p_total = 15 MPa, pCO_2= 8 MPa, T = 60°C) were performed using two synthetic CO_2-rich brines (sulfate-free and sulfate-rich) that circulated at constant flow rates (0.2, 1 and 60 mL/h) through artificially fractured shale cores (7.5 mm in diameter and 18 mm in length).

The pH of the injected solution was acidic (~3). In the case of the sulfate-free solution the interaction mainly promoted the dissolution of calcite. Permeabilities remained almost constant. At flow rates 0.2 and 1 mL/h, fracture permeability ($k_{initial}$ ~$1x10^{-12}$ m^2) decreased slightly ($k_{final}/k_{initial}$ = 0.8). Under the highest flow rate (60 mL/h), permeability ($k_{initial}$ = $17x10^{-12}$ m^2) increased slightly ($k_{final}/k_{initial}$ = 1.2). In the experiments with sulfate-rich solution (synthetic Hontomin groundwater), calcite dissolution and gypsum/anhydrite precipitation were the dominant processes. At the lower flow rates rates (0.2-1 mL/h), the fracture permeabilities ($k_{initial}$ 1-$20x10^{-12}$ m^2) decreased remarkably ($k_{final}/k_{initial} \leq 0.03$), as expected from the precipitation of sulfates. However, at the highest flow rate (60 mL/h) the permeability ($k_{initial}$ = $22x10^{-12}$ m^2) increased significantly ($k_{final}/k_{initial}$ = 4), showing a dominant dissolution effect under those fast-flow conditions.

The Chicago Instrument for Laser Ionization: progress and promise

A. M. DAVIS[1,2,3]*, T. STEPHAN[1,2], M. J. PELLIN[1,2,3,4], D. ROST[1,2], M. R. SAVINA[1,4], R. TRAPPITSCH[1,2] AND N. LIU[1,2]

[1]Chicago Center for Cosmochemistry
[2]Dept. of Geophysical Sciences, Univ. of Chicago, Chicago, IL 60637 (*correspondence: a-davis@uchicago.edu)
[3]Enrico Fermi Inst., Univ. of Chicago, Chicago, IL 60637
[4]Materials Science Div., Argonne National Laboratory, Argonne, IL 60439

Current state-of-the-art secondary ion mass spectrometers (SIMS) have reached lateral resolution of 50–100 nm and useful yields of a few percent or less. CHILI (the CHicago Instrument for Laser Ionization), a resonance ionization mass spectrometry (RIMS) nanobeam instrument, is designed for isotopic and chemical analysis at the few-nm scale with a useful yield of ~40%. CHILI is equipped with a COBRA-FIB high resolution liquid metal ion gun for sputtering samples and an e⁻CLIPSE Plus field emission electron gun for imaging samples, both at the few-nm scale. Both Orsay Physics guns are installed and tested. A built-in optical microscope is installed and demonstrates a diffraction-limited resolution of <1 μm. It will be used for overview imaging and for laser ablation (with a Photonics Inc. 351 nm Nd:YLF laser) of larger samples. A piezoelectric stage capable of reproducible nm-scale motions and equipped with a sample holder that will accept a wide variety of sample mounts is operational. The flight tube for the time-of-flight mass spectrometer is mounted vertically above the sample chamber, under vacuum and leak-free. Resonance ionization will be done with six Ti:sapphire tunable solid state lasers of our own design pumped with three Photonics 527 nm 40W Nd:YLF lasers, which will allow isotopic analysis of two to three elements simultaneously. The pump and tunable lasers have been shown to meet specifications, but are awaiting completion of a beam combiner to introduce all tuned laser beams on a single line through the sample chamber.

CHILI will have broad applications in geochemistry and cosmochemistry. Its strengths will be in isotopic and chemical analysis at lateral resolutions and concentrations beyond the current state-of-the-art. Among the applications currently planned are isotopic analyses of material returned to Earth by spacecraft: Stardust–cometary and contemporary interstellar dust; Genesis–solar wind; Hayabusa–asteroidal material. Also well-suited to CHILI's capabilities are presolar grains, which inform us about stellar nucleosynthesis, and refractory inclusions and chondrules, useful for early solar system chronology.

Episodic growth of vein calcite in a stable continental setting: potential application of U-Pb dating by LA-ICPMS and ID-TIMS methods

D. W. DAVIS[1], A. PARMENTER[2] AND A. CRUDEN[3]

[1] Dept. of Earth Sciences, University of Toronto, 22 Russell St. Toronto. ON Canada M5S 3B1, (correspondance: dond@es.utoronto.ca)
[2]Nuclear Waste Management Organization, 22 St. Clair Avenue East. Toronto. ON. Canada M4T 2S3
[3]School of Geosciences, Monash University, Building 28. Clayton, Australia 3800

The application and utility of LA-ICPMS and ID-TIMS for U-Pb isotopic dating of secondary fracture calcite infilling has been explored. These complementary methods were applied to test a hypothesis regarding the timing of emplacement of joints and calcite-filled veins within the Devonian Lucas Formation on the eastern flank of the Michigan Basin, in southern Ontario, Canada.

Outcrop fracture cross-cutting relationships, vein morphology consistent with generation under high pore fluid pressure, and knowledge of a basin-scale concentric fracture pattern were interpreted to suggest that prominent NNW-striking and broadly ENE-striking fracture populations were emplaced contemporaneously during the Paleozoic Era.

Initial trials determined that calcite-filled vein samples collected from shallow core (< 35 m depth) and shoreline outcrops had high U (1-10 ppm) concentrations and sufficent radiogenic Pb to permit successful dating by laser ablation. LA-ICPMS analyses of the calcite infilling (n = 141) defined two age clusters in all veins regardless of their orientation, one with a relatively small number of analyses at around 56 Ma and a broader peak around 100 Ma. These results were independently confirmed by ID-TIMS with single-grain analyses at 51±2 Ma and over the range 85±2 Ma to 109±4 Ma.

Agreement between the two methods suggests that the LA-ICPMS ages are reliable. The results indicate that new crystal growth occured episodically during the Late Cretaceous and early Paleogene, although the age of fracturing may have been older. The LA-ICPMS method appears to be suitable for yielding meaningful U-Pb isotopic ages and represents a useful geochronologic tool for interpreting the timing of vein emplacement.

Berea Sandstone permeability pre and post reaction with supercritical CO_2 in 1% NaCl brine

G.K.W. DAWSON[1]*, D. BIDDLE[2], C. KHAN[2], X. JIANG[2], S.D. GOLDING[1] AND V. RUDOLPH[2]

[1]School of Earth Sciences, University of Queensland, Brisbane, Australia (*correspondence: g.dawson@uq.edu.au)
[2]School of Chemical Engineering, University of Queensland, Brisbane, Australia (v.rudolph@uq.edu.au)

The injectivity of CO_2 into saline formations greatly depends upon the properties and behaviour of geological materials close to injection points. We have constructed custom built geochemical reactors and permeability apparatus to investigate the behaviour of geological materials in response to CO_2 sequestration. Samples being tested include drill core material from a future Australian CO_2 sequestration reservoir-seal set [1, 2] and well-characterised materials such as Berea Sandstone to validate our procedures. Two different sized cubic sister sample sets of Berea Sandstone cut aligned to bedding laminations were obtained for initial experiments.

The permeability of as-received samples of Berea Sandstone was found to be compromised by surface deposits of mineral fines thought to be the product of sample cutting and milling. Permeability in the bedding plane for as-received samples was also less than the orthogonal to bedding orientation. In contrast, the permeability of samples gently cleaned using a sonic bath was significantly higher, and gave the expected result of bedding plane permeability being greater than the perpendicular to bedding orientation.

The brine permeability of sonic bath cleaned Berea Sandstone increased 14% (from 240 to 275 mD) following reaction with supercritical CO_2 immersed in 1% NaCl for 360 hours at 50 ºC and 10 MPa. Geochemical analysis of the dissolved ions in the experiment water indicated significant mobilisation of cations, especially calcium, magnesium, iron, manganese, potassium, and silicon, thought to be the product of carbonate and reactive silicate dissolution and clay cation exchange. SEM-EDS analysis of unreacted samples detected partially pore-filling ankerite and also vermiculite-smectite alteration of phlogopite flakes. Dissolution of reactive minerals observed, especially ankerite, is one possible reason for the measured permeability increase [3].

Hydrogen isotope fraction in lipids of syntrophically associated sulfate-reducing bacteria

K.S. DAWSON[1]*, A.L. SESSIONS[1] AND V.J. ORPHAN[1]

[1]Division of Earth and Planetary Science, California Institute of Technology, Pasadena, CA 91125, USA (*correspondence: kdawson@caltech.edu)

The microbially mediated anaerobic oxidation of methane (AOM) is carried out by methanotrophic archaea (ANME) in syntrophic association with sulfate-reducing bacteria (SRB). This energetically limited metabolism is made thermodynamically feasible by the exchange of hydrogen, electrons, fixed nitrogen and potentially other unknown chemical species between the archaeal and bacterial partners. Understanding the metabolic interplay between the ANME and SRB in consortia is made difficult by the lack of cultured representatives. However, methanogenic archaea, closely related to their AOM counterparts, and SRB also form syntrophic consortia in both the environment and in laboratory grown co-cultures.

Zhang *et al*.. [1] demonstrated that the central metabolic pathway is reflected in the hydrogen isotopic fractionation between bacterial fatty acids and growth water. Here we examine the metabolic role of the sulfate reducing bacterial partner through hydrogen isotopic fractionation of bacterial fatty acids from both cocultures of *Desulfococcus multivorans* and *Methanosarcina acetivorans* and sediment cores associated with a variety of active methane seep settings in Hydrate Ridge (offshore Oregon, USA).

Stalagmite trace-element reconstruction of terrestrial hydrology: Results from cave-analogue studies

DAY, C.C.[1] AND HENDERSON, G.M.[1]

[1]Department of Earth Sciences, University of Oxford, UK, (chrisd@earth.ox.ac.uk)

We report trace-element data from a series of carbonate growth experiments in cave-analogue conditions with the goal of better understanding environmental controls on trace-element incorporation in stalagmites. The experimental setup closely mimics natural processes (e.g. precipitation driven by CO_2-degassing, low ionic strength solution, thin solution film) but with a tight control on growth conditions (temperature, pCO_2, drip rate, calcite saturation index and the composition of the initial solution). Calcite is dissolved in deionized water in a 20,000 ppmV pCO_2 environment, with trace-elements (Li, Na, Mg, Co, Sr, Cd, Ba, U) at appropriate concentrations to mimic natural cave drip-waters. This solution is dripped onto glass plates (coated with seed-calcite) for controlled stalagmite growth [1].

Over a wide range of temperatures (7, 15, 25, 35˚C), drip rates (2, 6 and 10 drips per minute) and solution calcite saturation indices ($SI_{calcite}$ = 0.1, 0.2, 0.3, 0.4, 0.5, 0.6 at 15˚C), D(Sr) was shown to be statistically invariant. D(Mg) has a relationship with temperature defined by $D(Mg) = 0.01e^{0.02[\pm 0.006]T}$, but temperature is not expected to be the dominant control on Mg/Ca in cave calcite due to the larger impact of calcite precipitation on Mg/Ca. Over short timescales, in conditions where temperature is well buffered in most caves, the fraction of calcium remaining in solution (f) is likely to be the dominant control on Mg/Ca and other trace-element ratios. Cd/Ca is shown to be highly-sensitive to variation in the amount of calcite precipitated from solution, with high $Cd/Ca_{stalagmite}$ particularly indicative of a low amount of prior calcite precipitation (PCP). Overall, the varied response of trace-elements to temperature and to hydrological factors (e.g. PCP and drip rate) ensure that their combined use, together with other proxies, is well suited for reconstructing terrestrial hydrological conditions.

Timing and nature of late accretion

JAMES M.D. DAY[1]

[1]Scripps Institution of Oceanography, La Jolla, CA 92093-0244, USA (jmdday@ucsd.edu)

There is overwhelming evidence for varying amounts of late accretion additions of the highly siderophile elements (HSE: Re, Os, Ir, Ru, Rh, Pt, Pd, Au) after core formation to fully differentiated inner Solar System planetary bodies. HSE abundances in rocky mantles of planets point to the cessation of core formation and continued accretion of broadly chondritic materials as a key process during the final stages of planet formation. Here I consider the fundamental relationships between late accretion additions, their timing, and potential correlations of HSE abundances with mantle oxidation state and volatile contents. On Earth, there is direct access to upper mantle materials, albeit these sample sets may not be completely unbiased. There is also the possibility that some diogenites represent lower crustal or mantle samples from their parent body. Because of a lack of definitive mantle samples from most fully differentiated bodies, establishing estimated HSE abundances of mantles occurs though derivative melts. A means for estimating mantle HSE abundances is to utilise the compatible behaviour of the HSE and MgO. Using this method, it is possible to estimate mantle HSE abundances for Earth, the Moon and Mars at ~0.009 ±0.003, ~0.0002 ±0.0001, ~0.007 ±0.004 (2σ), respectively. Using these mantle estimates, apparent correlation between HSE abundances and fO_2 in planetary bodies breaks down.

It has been shown that the petrology of diogenites are consistent with HSE being set within these meteorites during crystallization, within ~2-3 Ma of Solar System initial (SSI). The timing of post-core formation accretion to diogenites contrasts with timing constraints from Mars, within the first 100 Ma of SSI, and with the Moon within the first ~150 Ma as defined by crystallization ages of the oldest ferroan anorthosites. Constraints on post-core formation accretion for Earth are less well constrained, but must have been set prior to 4 Ga. These results suggest that, in some manner, parent body size exerts influence on post-core formation late accretion. Simplistically, smaller-sized bodies melt, differentiate and cool faster than larger-sized bodies, inpart because of more limited accretion of increasingly massive impactors. Thus HSE abundances in rocky planets reflect the timing of cessation of core formation, as well as the degree to which planetary mantles are able to convect and homogenise the HSE. As planetary mantles become more convectively sluggish, additions of HSE will lead to increasing mantle heterogeneity.

Highly siderophile element constraints on intraplate magmatism

JAMES M.D. DAY[1]

[1]Scripps Institution of Oceanography, La Jolla, CA 92093-0244, USA (jmdday@ucsd.edu)

Ocean island basalts (OIB) and continental flood basalts (CFB) represent volcanic rocks that are unassociated with conventional plate tectonic boundary magmatic processes and that may require anomalous thermo-chemical and/or tectonic conditions to induce small- to large-scale melting of their mantle sources. Studies of the highly siderophile element (HSE) geochemistry of these and other forms of intraplate magmas have the potential to provide answers to questions regarding mantle sources and potential core-mantle interactions, if the effects of assimilation, fractional crystallization and melting processes can be elucidated.

HSE (Os, Ir, Ru, Pt, Pd, Re) abundance and $^{187}Os/^{188}Os$ data for OIB and CFB illustrate the importance of sulphides during both mantle partial melting and modification of primary melts during transit through the lithosphere. The interplay of partial melting and lithological/mineralogical heterogeneity of the mantle source are also important, with lower degrees of partial melting resulting in sampling of more fusible materials (e.g., grain-boundary sulphides [1]). This relationship suggests that intraplate magmas derived from large degrees of partial melting will provide a broader mantle sampling than those derived from lower degrees of partial melting. Alkalic HIMU (high $^{238}U/^{206}Pb$) OIB with high-Os abundances (>50 ppt) that have elevated $^{187}Os/^{188}Os$ (ratios up to 0.175), and hence long-term (>1 to 2 Ga) Re/Os fractionations, have $^{186}Os/^{188}Os$ within the range of abyssal peridotite compositions. Likewise, enriched mantle (EM) OIB that have $^{187}Os/^{188}Os$ that dominantly reflect contributions from peridotite with only minor contributions from recycled sediment or continental crust and/or lithospheric mantle materials lack evidence for long-term Pt/Os fractionations. In contrast, some Hawaiian picrites have $^{186}Os/^{188}Os$ ratios consistent with a mantle source with high time-integrated Pt/Os with respect to average upper mantle composition [2]. Evidence for long-term Pt/Os fractinations retained in higher-degree tholeiites may implicate radiogenic outer core contributions, or sampling of isolated mantle source reservoirs that have evolved with supra-chondritic Pt/Os over >2 to 3 Ga time-scales.

Unconventional shale gas

A. M. DAYAL, SNIGDHARANI MISHRA AND DEVLEENA MANI

CSIR-National Geophysical Research Institute
Uppal Road, Hyderabad -700007, India
(dayalisotope@rediffmail.com)

Shale gas is natural gas produced from carbonaceous shale formations that typically function as both the reservoir and source rocks for the natural gas. Carbonaceous shales are organic-rich shale formations that were previously regarded only as source rocks and seals.

Shales are deposited as muds in low-energy environments such as tidal flats and deep water basins. During the deposition of these very fine-grained sediments, there can also be accumulation of organic matter in the form of algae, plant, and animal derived organic debris. Natural gas is stored in shale in three forms: free gas in rock pores, free gas in natural fractures, and adsorbed gas on organic matter and mineral surfaces.

For gas-shale production in 1998, light sand fracturing (water fracture treatment) was introduced and has been successful in many areas. Micro-seismic fracture mapping has also been successfully used to improve the evaluation of hydraulic fracturing in horizontal wells. The unconventional gas reservoir will produce less gas for the longer period of time compared to the high permeability reservoir. It is estimated that we have 16,000 Tcf gas as shale gas. This data indicates that there is enough opportunity to explore unconventional energy as future source of energy.

Anomalous kinetics of reactive Fronts in porous media

PIETRO DE ANNA, TANGUY LE BORGNE, MARCO DENTZ AND ALEXANDRE TARTAKOVSKY

[1]MIT, Cambridge (MA)
[2]University of Rennes 1 (FR)
[3]CSIC, Barcellona (SP)
[4]PNNL (WA)

The dynamics of reactive transport phenomena in porous media derive from the interaction of microscopic mass transfer and reaction processes. The understanding of observed reaction behavior requires the quantification of these microscale processes and their impact on the large scale reaction and transport behavior. Here we study the mixing limited (fast) reaction A + B --> C at the pore-scale, and its effective behavior on the mesoscale, as a paradigmatic case that allow us to provide a connection between local mixing properties and global reaction kinetics.

Interpreting Molybdenum isotopes as a proxy for the spatial distribution and intensity of ocean de-oxygenation events in an Earth System Model

ROS DEATH[1]*, ANDY RIDGWELL[1], SANDRA ARNDT[1], FANNY MONTEIRO[1], DAVE SHERMAN[2] AND DEREK VANCE[3]

[1]School of Geographical Sciences, University of Bristol, University Road, Bristol, BS8 1SS (*correspondence: ros.death@bristol.ac.uk)
[2]School of Earth Sciences, University of Bristol, Queens Rd, Bristol, BS8 1RJ
[3]Institute of Geochemistry and Petrology, ETH Zurich, Main Building, Rämistrasse 101, 8092 Zurich, Switzerland.

Molybdenum (Mo), and its isotopes, are used as a proxy for global ocean redox states. This proxy has already been applied to investigate the degree of euxinia in the Proterozoic ocean[1] and the spatial extent of de-oxygenation during the Mesozoic[2]. However, at intermediate oxygen states the interpretation of $\delta^{98/95}$Mo is difficult because of the complex non-linear system controlling the spatial and temporal pattern of Mo sequestration into the sediments. We aim to investigate this complexity in the Earth System Model GENIE. The model will be enabled with a relatively complete description of redox-dependent dynamics of marine iron and sulphur cycling and so providing us with a powerful tool to describe the water column dynamics of Mo (plus its sources and sinks). In particular the model will allow us to examine the role of iron-sulphide minerals in the scavenging of Mo, which is a key process in its removal from the global oceans.

Here we present preliminary results of the evaluation of the model for the present-day ocean and an outline for its application to past climatic states where ocean euxinia is present, taking OAE2 as a test study.

[4]Imperial College London, London SW7 2AZ, UK
[5]Max Planck Institute for Chemistry, Mainz, Germany

Cadmium has a biochemical function in the carbonic anhydrase (CA) class of enzymes for CO_2 metabolism in photosynthesis by algae [1,2]. This occurs either by substitution for Zn in the common Zn-CA, or as a genuine Cd-CA as found in certain marine diatoms [2]. The CA enzyme class is pivotal for conversion of bicarbonate [HCO_3^-] to CO_2. This CA also appears responsible for high Cd/P uptake ratio by plankton at low ambient aqueous CO_2 [1]. The uptake of Cd has been related to ambient Cd, Zn, Mn and Fe [3, 4]. Also the Mn/P uptake ratio of plankton has been shown to be dependent [5] on ambient dissolved Fe [6] in the Southern Ocean.

Here we report the first ever observations of strong correlations in ocean surface waters of dissolved aqueous CO_2 with dissolved Cd and with the stable isotope ratio $^{114}Cd/^{110}Cd$ [7,8]. This is observed along the 0ºW meridian in both the Antarctic Circumpolar Current and the Weddell Gyre, as well as in the Weddell Sea proper and also in Drake Passage. This uniform trend in several surface water masses hints at a uniform biochemical mechanism. The relationships in the Southern Ocean between the relative uptake of aqueous [CO_2] versus [HCO_3^-] by algae [9] and the biological Cd isotope fractionation [7,8] will be discussed. Parallel trends of apparent Cd/PO_4 uptake ratio and interactions with Mn, Zn and Fe will be presented. Conceivable implications for paleoceanography will be mentioned.

Measuring mineral dissolution kinetics using an automated flow-through module

B. DE BAERE*, K.U. MAYER AND R. FRANCOIS

Department of Earth, Ocean and Atmospheric Sciences, University of British Columbia, Vancouver BC, Canada V6T 1Z4 (*correspondence: bdebaere@eos.ubc.ca)

We have developed a purpose-built flow-through dissolution sample introduction module. Until now, this experimental set-up has been used to carry out sequential leaching [1]. The application we present here is the quantification of mineral dissolution rate constants.

As a proof of concept study, we measured the dissolution kinetics of the mineral calcite. Individual calcite fragments from Chihuahua, Mexico were gradually dissolved using a leaching sequence covering pH 2-6 (using time-dependent proportions of DIW to HNO_3). The effluent was sent to an Agilent 7700 ICP-MS and analysed for $^{43,44}Ca$.

In parallel, we developed a simple geochemical reactive transport model in PHREEQC based on the forward rate equations as published by Plummer *et al*.. [2]. Surface area was estimated from the geometric surface area of the fragment. In order to optimize the forward model dissolution rate constants to best reflect the experimental data, PEST software (model-independent parameter estimation) was used to run a reverse model in a weighted least squares sense.

We are able to generate optimized dissolution rate constants ($k_1 = 1.18 \times 10^{-6}$ and $k_3 = 8.73 \times 10^{-11}$ moles cm^{-2} sec^{-1}, correlation coefficient between optimized model and experimental data $R^2 = 0.998$) which are within an order of magnitude or less of previously published studies [3, 4].

The key benefits of this newly developed technique include (1) time efficiency – in this study a typical leaching sequence lasted ~ 100 minutes; (2) extensive data coverage (here, n = 2000) which is of particular value to optimize the fit between model and data; and (3) automation – the entire leaching sequence is fully programmed. This approach has thus the potential to rapidly generate a large database of dissolution rate constants for a wide range of minerals.

Can diffusion cause discrepant Lu-Hf isochrons in meteorites?

V. DEBAILLE*[1], Q.-Z. YIN[2] AND Y. AMELIN[3]

[1]Lab. G-Time, Université Libre de Bruxelles, Belgium (*correspondance: vinciane.debaille@ulb.ac.be)

[2]Dept. of Geology, University of California in Davis, USA (qyin@acdavis.edu)

[3]Research School of Earth Sciences, Australian National University, Australia (yuri.amelin@anu.edu.au)

The ^{176}Lu-^{176}Hf isotopic system, widely used for dating cosmochemical and geological processes, still suffers from two uncertainties. First, Lu-Hf isochrons for some early Solar System materials have excess slope of unknown nature. Second, unlike the well constrained Sm/Nd value to within 2% for chondritic uniform reservoir (CHUR), the Lu/Hf ratios in chondrites vary up to 18% [1], hence questioning the CHUR value for Lu/Hf. Even the 3% dispersion of Lu/Hf ratios [2] among the chondrites of low metamorphic grade, is greater than the dispersion of Sm/Nd among all studied chondrites. In order to better understand the Lu-Hf systematic of chondrites, we analyzed mineral fractions from the Richardton H5 chondrite to construct an internal Lu-Hf isochron, and set up a model to evaluate the role of diffusion in perturbing the Lu-Hf system.

The isochron yields an age of 4647±210 millions years (Ma) (MSWD= 9.4). Low precision is caused by relatively small spread the $^{176}Lu/^{177}Hf$ ratios from 0.02 to 0.05. Combining this study with the phosphate fractions measured in [3] yields a slope of 0.08855±0.00072, translating to a ^{176}Lu decay constant of $1.862\pm0.016 \times 10^{-11}$ $year^{-1}$, in agreement with the terrestrial value of $1.867\pm0.008 \times 10^{-11}$ $year^{-1}$ [4]. Richardton phosphates show an extreme variation of the $^{176}Lu/^{177}Hf$ ratios from 0.8 to 143 [3], identifying phosphates as a major host of Lu. This is critical as apatite has substantially higher diffusion rates of REE [5] than most silicate minerals that comprise meteorites.

The model shows that preferential diffusion of Lu compared to Hf from apatite to other minerals can produce apparent older isochron, and that among parameters that influence the rate of diffusion, the temperature seems the main factor influencing the disturbance. This suggests, similarly to [2], that only type 3 chondrites with lowest metamorphic grade should be used to determine the Lu decay constant and the CHUR values.

Iron oxidation state in serpentine during subduction: implications on the nature of the released fluids at depth

DEBRET B.[1]*, ANDREANI M.[2], MUNOZ M.[3], BOLFAN N.[1], CARLUT J.[4], NICOLLET C.[1] AND SCHWARTZ S[3]

[1]LMV, Université Blaise Pascal, Clermont-Ferrand, France (*correspondence: B.Debret@opgc.univ-bpclermont.fr)
[2]Laboratoire de Géologie de Lyon, ENS- Université Lyon 1, France (muriel.andreani@univ-lyon1.fr)
[3]ISTerre, Université Grenoble 1, France (manuel.munoz@ujf-grenoble.fr)

Serpentinites may be present in more than 40% of the oceanic lithosphere that formed at slow to ultra-slow spreading centers. Serpentine could thus be one of the most abundant hydrated minerals recycled into the mantle in subduction zones. Prograde metamorphism in subducted serpentinites is characterized by the destabilization of lizardite into antigorite, and then into secondary olivine. The nature of the released fluid (e.g. H_2O vs H_2) during those phase transitions is controlled by redox reactions and can be inferred from Fe oxidation state of serpentine. We used whole rock analyses, magnetic measurements, SEM observations and μXANES to establish the evolution of Fe_{total} and magnetite content in serpentinite as well as Fe speciation in serpentine minerals from the ridge to the subduction setting.

At the mid-ocean ridge, during the alteration of peridotite into serpentinite, the iron is mostly redistributed between magnetite and oceanic serpentine (usually lizardite). The Fe^{3+}/Fe_{total} ratio in lizardite and the modal magnetite progressively increase with the local serpentinization degree to reach 0.8 and 7 wt% respectively in fully serpentinized peridotites.

During subduction, the Fe_{total} of serpentinite remains constant (=7-10 wt.%, depending on the primary mode of the peridotite) while the magnetite mode decreases from greenschist to eclogite facies to reach less than 2% under the eclogite facies. Also, the Fe^{3+}/Fe_{total} ratio in serpentine progressively decreases down to 0.2 during the transition from lizardite to antigorite.

Our results show that, in the first 70 km of subduction, the transition from lizardite to antigorite is accompanied by a global reduction of Fe in serpentinite and in serpentine. This redox reaction allows the oxidation of reduced oceanic phases such as sulfurs, and the formation of oxidized fluid. At greater depths, the beginning of antigorite dehydration leads to an increase of Fe^{3+}/Fe_{total} in the remaining antigorite implying the formation of reduced fluids (e.g. H_2, CH_4).

The National Geochemical Survey of Australia (NGSA) project

PATRICE DE CARITAT[1]

[1]Geoscience Australia, GPO Box 378, Canberra ACT 2601, Australia

The National Geochemical Survey of Australia (NGSA) project (www.ga.gov.au/ngsa), part of Geoscience Australia's Onshore Energy Security Program 2006-2011, was carried out in collaboration with all state and territory geological surveys. It delivered Australia's first national geochemical atlas, the underpinning geochemical database, and a series of reports and papers.

Catchment outlet sediments (mostly similar to floodplain sediments) were sampled in 1186 catchments covering ~6.2 million km^2 or ~81% of the country (on average one sample per 5200 km^2). Samples were collected at two depths (0-10 cm and ~60-80 cm), each sieved to two grain size fractions (<2 mm and <75 μm) and analysed for total, aqua regia, and Mobile Metal Ion® element contents; other analyses (pH, electrical conductivity, grain size distribution, spectroscopy, etc.) were also performed.

Results to date have been used to: (1) investigate first-order controls on the geochemical makeup of Australian regolith in comparison to Europe; (2) compile preliminary, multi-continental, empirical 'Global Soil' reference values; (3) produce continental-scale soil pH maps; (4) map Fe oxide mineralogy and soil colour; (5) investigate the level and distribution of bioavailable elements in Australia; (6) determine element associations by multivariate statistical methods and compare resulting patterns to independent geoscience datasets; (7) model the distribution of soil carbonate using multiple environmental covariates; (8) assess the potential of the dataset for mineral prospectivity analysis (e.g., for base metals, U, Au and REEs); (9) select salt lakes to be investigated for their potential to host potash, Li and B resources; (10) ground truth, infill and 'correct' airborne radiometric concentration data for K, U and Th; and (11) shed light on the phenomenon of disequilibrium in the radioactive decay chain of U by comparing actual to estimated U concentrations at the continental scale.

The NGSA project was Australia's first national-scale geochemical survey, requiring certain strategic decisions to be taken about sampling medium, density, etc. The resulting atlas and dataset have proven useful and applicable to many end-uses, but limitations and challenges exist as in every geochemical survey.

Atmospheric aerosol nucleation in the Po Valley during the PEGASOS-SUPERSITO experiment

S. DECESARI[1], A. MARINONI[1], G. P. GOBBI[1], A. HAMED[2], A. LAAKSONEN[2], H. E. MANNINEN[3], V. POLUZZI[4] AND M.C. FACCHINI[1]

[1]Institute of Atmospheric Sciences and Climate, National Research Council of Italy, Bologna, I-40129, Italy (*correspondence: s.decesari@isac.cnr.it)
[2]Department of Applied Physics, University of Eastern Finland, Kuopio, FI-70211, Finland
[3]Division of Atmospheric Sciences, Department of Physics, University of Helsinki, Helsinki, FI-00014, Finland
[4]Centro Tematico Regionale Aree Urbane, Arpa Emilia-Romagna, Bologna, I-40138, Italy

Aerosol nucleation, or new particle formation (NPF), is a very common phenomenon in the atmosphere, exerting an important feedback on the climate system by sustaining cloud condensation nuclei (CCN) concentrations in areas relatively far from pollution sources. In forest areas, NPF was put in relation to biogenic VOC photochemistry, while the mechanisms triggering nucleation in more anthropized environments are more elusive. North Italy is exemplificative of such an environment, with forested mountain ridges and urban and rural areas extending over the low lands (the Po Valley). During the PEGASOS-SUPERSITO field campaign in June-July 2012, the frequency of NPF in the rural Po Valley was very high (87% of the days) compared to the Apennine mountain ridge (35%). At the low-elevation rural site, nucleation started in the first two hours following sunrise, before the mixing layer development, in an atmospheric layer characterized by reduced ozone concentrations, high NOx, relatively high anthropogenic VOC levels (200 ppt of toluene), ppt-level of isoprene, and moderate SO_2 concentrations (1 ppb). Clearly, the pool of possible precursors for nucleating particles in the Po Valley was dominated by anthropogenic species. Finally, the combination of the observations carried out at the ground stations with simultaneous measurements performed with mobile platforms provided evidence of the fact that NPF in the Po Valley was not driven by emissions from point pollution sources (such as power plants) but occurred in the background air over vast sectors of the valley. Continuing developing experimental and modelling tools to understand the subtle mechanisms underlying new particle formation will greatly improve our ability to assess the impacts of such pervasive aerosol source at the global and regional scales.

KINETIC14 : A PHREEQC compatible mineral kinetic database

J. DECLERCQ[1*] AND E.H. OELKERS[2]

[1] Geosciences Environnement Toulouse (GET), 14 av. Edouard Belin, 31400 Toulouse, France (*correspondence: declercq@get.obs-mip.fr)
[2] Geosciences Environnement Toulouse (GET), 14 av. Edouard Belin, 31400 Toulouse, France (oelkers@get.obs-mip.fr)

Developped within the CarbFix project [1], KINETIC14 is an add on to PHREEQC [2], allowing calculation of the temporal evolution of mineral-fluid reactions during natural geochemical and industrial processes, and laboratory experiments.

Building upon previous efforts [3,4] this KINETIC14 has been built from a detailed synthesis of dissolution and precipitation rate data available in the literature. When coupled with PHREEQC, KINETIC14 provides the dissolution rates for 98 minerals as a function of temperature, fluid phase composition, and the chemical affinity of the fluid phase with respect to the mineral phase of interest. Mineral-fluid interfacial surface areas required for modelling the evolution of the fluid phase with these rates can be calculated using a variety of geometric models or from user input.

The rate equations chosen to fit available data within KINETIC14 are based on transition state theory and dissolution mechanisms that take explicit account of reactions occuring on mineral surfaces, including metal for proton exchange reactions, multi oxide minerals and proton adsorption/desorption for simple oxides. Despite the substantial scatter that is pervasive in dissolution rate data reported in the litterature, the majority of fitted rates are within 0.8 log units of their experimentally measured counterparts.

Mineral precipitation rates are generated directly from the corresponding dissolution rate equations; the validity of this approach will need to be assessed with future research.

Upon final validation, KINETIC14 will be made publicly available.

Origin of heterogenite (CoOOH) as illustrated by rare earth element fractionation

SOPHIE DECRÉE[1] AND OLIVIER POURRET[2]

[1]Royal Museum for Central Africa, Tervuren, Belgium (sophie.decree@africamuseum.be)
[2]HydrISE, LaSalle Beauvais, Beauvais, France (olivier.pourret@lasalle-beauvais.fr)

The Katanga Copperbelt (DR Congo) hosts around half of the world's known reserve of mineable cobalt. Heterogenite (CoOOH) is the most abundant oxidized cobalt mineral in this belt. It was ultimately derived from the oxidation of carrolite ($CuCo_2S_4$), during a Pliocene weathering event. The latter led to heterogenite concentration in the near-surface, as "cobalt cap" [1]. However, the detailed processes leading to the formation of heterogenite are not yet well constrained. Here, these processes are investiguated through the study of REE distribution, which is an underexplored but powerful tool to understand the formation of oxyhydroxides [2]. Indeed, since these elements behave as a coherent group, REE fractionation can be used as tracer of processes. In this way, studied heterogenite REE patterns display two major types: (i) the first type is Middle REE enriched, with negative cerium anomaly and relatively low REE content; (ii) the second one is Light REE enriched, without cerium anomaly and with higher REE content.

Weathering processes leading to heterogenite mineralisation mainly consist of water-rock equilibrium. At high Co activity, heterogenite precipitates at near-neutral pH as well as manganese oxide (i.e., pyrolusite). REE are mainly fractionated in between these two solid phases: heterogenite REE patterns are clearly the opposite ones of manganese oxides. As cobalt activity decreases, heterogenite stability field shifts to alkaline pH. In these conditions, REE speciation is mainly driven by carbonate complexation, resulting in the formation of the heterogenite type with a LREE enriched REE pattern.

Both REE signatures are consistent with the formation of heterogenite in a two-step *per descensum* model, in which this mineral (i) forms as residual deposits - similar to laterite - in association with Mn oxide, in the immediate near-surface environment, and (ii) is deposited from a carbonate-bearing fluid, due country rock dissolution, in deeper part of the oxidation profile.

Crustal versus source processes on the Northeast volcanic rift zone of Tenerife, Canary Islands

DEEGAN, F.M.[1,2*], TROLL, V.R.[2], BARKER, A.K.[2], HARRIS, C.[3], CHADWICK, J.P.[4], CARRACEDO, J.C.[5] AND DELCAMP, A.[6]

[1]Dept. Geosciences, Swedish Museum of Natural History, Stockholm, Sweden. Frances.Deegan@nrm.se

[5]Dept. de Física, Universidad de Las Palmas de Gran Canaria, Spain.
[6]Dept. Geography, Vrije Universiteit Brussels, Belgium.

The Miocene-Pliocene Northeast Rift Zone (NERZ) on Tenerife is a well exposed example of a major ocean island volcanic rift. We present elemental and O-Sr-Nd-Pb isotope data for dykes of the NERZ with the aim of unravelling the petrological evolution of the rift and ultimately defining the mantle source contributions.

Fractional crystallisation is found to be the principal control on major and trace element variability in the dykes. Differing degrees of low temperature alteration and assimilation of hydrothermally altered island edifice and/or sediments elevated the primary $\delta^{18}O$ and the Sr isotope composition of many of the dykes, but had little to no discernible effect on Pb isotopes. Minor degrees of sediment contamination, however, may be reflected in the Pb isotope composition of a few samples that plot to slightly higher $^{207}Pb/^{204}Pb$ values.

Once the data are screened for alteration and shallow level contamination, the underlying isotope variations of the NERZ reflect a mixture essentially of Depleted Mid-Ocean Ridge-type Mantle (DMM) and young High-μ (HIMU, where $\mu = {}^{238}U/{}^{204}Pb$)-type mantle components. Furthermore, the Pb isotope data of the NERZ rocks ($^{206}Pb/^{204}Pb$ and $^{207}Pb/^{204}Pb$ range from 19.591-19.838 and 15.603-15.635, respectively) support a model of initiation and growth of the rift from the Central Shield volcano (Roque del Conde), consistent with latest geochronology results [1]. The similar isotope signature of the NERZ to both the Miocene Central Shield volcano and the Pliocene Las Cañadas central edifice suggests that the central part of Tenerife Island was derived from a mantle source of semi-constant composition through the Miocene to the Pliocene. This can be explained by the presence of a discrete "blob" of HIMU material, $\leq$ 100 km in vertical extent, occupying the melting zone beneath central Tenerife throughout this period. The most recent central magmatism on Tenerife appears to reflect greater entrainment of DMM material, perhaps due to waning of the blob with time.

Genetic classification based on AFM

[1]DEEVSALAR, R., [1]GHORBANI, M.R., [1]GHADERI, M AND [2]AHMADIAN, J

(Deevsalar@gmail.com), (ghorbani@modares.ac.ir), (mghaderi@modares.ac.ir); Department of Geology, Tarbiat Modares University, Tehran 14115-175, IRAN; Payam Noor University, P.B: 19395-3697 Tehran, IRAN (Jamshidahmadian@yahoo.com)

Genetic relationship between different groups of rocks in an association of basic to intermediate rocks from a cogenetic suite (Malayer-Boroujerd Plutonic Complex, western Iran), including basic dykes, mafic bodies and intermediate rocks plotted on AFM digram makes such trends on the diagram that can be easily distinguished and therefore a conjunction point with one of the three lines on AFM triangle by best fitted trend line is expected. Olivine fractionation can be properly projected on FM line of the AFM diagram. Any point on the FM line has an MgO/FeO ratio that can be calculated using the values of these oxides in the plotted samples and equations of best fitted line for them on two variable diagrams MgO-(K_2O-Na_2O), FeO-(K_2O-Na_2O) and FeO-MgO. MgO/FeO is covnerted to Mg# and indicates the olivine composition. With different degrees of fractionation of this mineral from mafic parent magma, new compositions on previous trend can be calculated and their position on this line can be correlated with the plotted samples.

Figure 1. Differentiation trend for the basic dikes.

Mineral fractionation vector on Harker diagrams shows that olivine along with plagioclase fractionation plays an important role in generation of these samples (MBPC). Therefore, AFM diagram has properly exaggerated the role of olivine and can be used as an indicator of parental classification and investigation on petrogenesis and intra-group genetic relationships of samples on Harker diagrams

Isotopic composition of Sulfur in enstatite meteorites

C.DEFOUILLOY[1], F. MOYNIER[2], E. PRINGLE[2], J.-A. BARRAT[3] AND P. CARTIGNY[1]

[1]Institut de Physique de Globe de Paris, 1 rue Jussieu, 75238 Paris, France (correspondence: defouilloy@ipgp.fr)
[2]Washington University in St Louis, One Brookings Drive, St Louis, MO 63130, USA. (moynier@levee.wustl.edu)
[3]Université de Brest, lace Nicolas Copernic, 29280 Plouzane cedex, France. (barrat@univ-brest.fr)

Enstatite meteorites are the most reduced meteorites. They comprised two groups: the Enstatite Chondrites, considered to be primitive meteorites and subdivided into EH and EL (respectively, Fe-rich, and Fe-poor), and the Enstatite Achondrites (or Aubrites), which are differentiated meteorites. Several elements (O, Cr, Xe, Mo, Ni, but not Si) show similar compositions between Enstatites and Earth, suggesting a possible Enstatite origin for the Earth [1]. Yet, the genetic relationship between Enstatite groups remain unclear, some authors proposing a single Enstatite Chondrite parent body, while others have shown discrepencies between Enstatite groups and argued they could not be related.

Sulfur is a volatile element which could help apprehend the mechanisms underwent by the Enstatite parent body or parent bodies. We therefore initiated an extended database of high-precision S isotopic compositions ($^{33}S/^{32}S$, $^{34}S/^{32}S$, $^{36}S/^{32}S$) in Enstatite meteorites. Preliminary results show that sulfide content may vary from one group to another, from nearly 0 up to 3 wt% in Aubrites and EL6 and 3 to 5 wt% in EH3). Seventeen Enstatite meteorites have been studied so far. 11 of them contained enough Sulfur to be measured (5 EH3, 5 EL6 and one Aubrite). Sulfur isotopic composition is measured on a Mat 253 Mass Spectrometer, with a precision of 0.01 per mil for ^{32}S, ^{33}S and ^{34}S and 0.1 per mil for ^{36}S. No clear distinction appear in isotopic composition between the 3 groups studied (EH3, EL6 and Aubrite). The average $\delta^{34}S$ is of -0.40 ± 0.26 (1σ), which is lower than chondritic values, but also slightly lower than the previously reported $\delta^{34}S$ for Enstatites [2]. $\Delta^{33}S$ (-0.026 ± 0.005) is very homogeneous and within error of the CDT value. $\Delta^{36}S$ shows a greater variability (-0.012 ± 0.144), with several positive values measured in EH3 and the Aubrite. A larger number of samples will allow us to determine the extend of spallation processes and the slight differences with other chondrites [3].

Redundant data in geochemical calculations: Helpful or not?

F. DE GASPARI[1,2*], M.W. SAALTINK[1] AND J. CARRERA[2]

[1] GHS, Department of Geotechnical Engineering and Geosciences, Universitat Politecnica de Catalunya, UPC-BarcelonaTech, Barcelona, Spain (*correspondence: francesca.de.gaspari@upc.edu, maarten.saaltink@upc.edu)

[2] GHS, Institute of Enviromental Assessment and Water Research (IDAEA), CSIC, Barcelona, Spain (jesus.carrera.ramirez@gmail.com)

Geochemical speciation problems require the solution of non-linear systems by means of numerical methods that can be computationally demanding and sometimes can even fail to reach convergence. The performances of those numerical methods have been therefore studied in the last decades in order to increase their robustness and to find the most suitable ones for different types of systems and constraints [1, 2].

Often the amount of information available about a geochemical system can be redundant, that is, exceed the requested minimum so that a least square fitting may be necessary [3]. In those cases, models can account for data uncertainty. The effect of error in data has been studied for specific problems such as solubility equilibrium or mixing fraction calculations [4, 5].

However, little attention has been paid to the contribution that redundant data might have in the characterization of geochemical systems and in particular which types of systems are most likely to take advantage of additional data.

We present an algorithm able to handle redundant uncertain constraints and the systems that have been analyzed in order to understand the importance of considering different types of extra data in equilibrium calculations.

Continuous soil CO_2 flux measurements in a fumarole field of Mt Etna

S. DE GREGORIO*, M. CAMARDA, S. CAPPUZZO AND S. GURRIERI

Istituto Nazionale di Geofisica e Vulcanologia, sezione di Palermo, via Ugo La Malfa 153, 90146 Palermo, Italy (*Correspondence: s.degregorio@pa.ingv.it)

We present data from seven months of continuous measurements in the summit area of the Mt Etna volcano. The monitoring began in September 2012 and continued without any maintenance until the present (April 2013). The monitoring site is placed at “Belvedere” on the southeastern flank of the volcano, about 1.5 km away from the New Southeast Crater (NSEC) at altitude of about 2700 m a.s.l. This site is characterized by a low-temperature fumarole field. Performing soil CO2 flux measurements in such a hostile environment, particularly during the winter, is extremely challenging, and we took advantage of an innovative device named CADEMASO [1]. This device determines soil CO_2 flux by measuring the pressure transient in a closed polymeric tube inserted into the soil. The station recorded hourly soil CO_2 flux and soil temperature. The data set revealed two distinct periods with different characteristics. During the first period, which lasted until the second decade of November, the soil temperature was almost constant around 80°C with small fluctuations, whereas the soil CO_2 flux displayed wide oscillations. During the second period, the soil temperature values displayed sharply and long lasting increments, as high as the measurement limit (225°C).As regards the soil CO_2 flux, an overall decrement of the values was observed and several clearly defined peaks were recorded. The beginning of the last period coincides with the first signs of a new reactivation of the activity of the NCSE, after a period of rest of about seven months.

Heavy boron isotopes in secondary olivine from the HP Voltri Massif: implications for the boron cycle in subduction zones

J.C.M. DE HOOG[1]* AND K. HATTORI[2]

[1]Grant Institute, School of Geosciences, Edinburgh, United Kingdom EH9 3JW (*correspondence: ceesjan.dehoog@ed.ac.uk)

[2]Dept. of Earth Sciences, University of Ottawa, Ottawa, Canada (khattori@uottawa.ca)

The Erro-Tobbio peridotite (Voltri Massif, Ligurian Alps, Italy) contains high-pressure rocks that have been subducted to peak conditions close to the upper stability limit of serpentine (650°C at 25 kbar; [1]). Secondary olivine occurs in partially dehydrated serpentinites in association with Ti-clinohumite (Ti-Chu). It has high Mg# (Fo86-87), MnO (0.3-0.4 wt%) and NiO (0.2-0.3 wt%) and contains magnetite inclusions attesting to its secondary origin. Olivine has variable but very high H_2O (up to 0.7 wt%) which correlates with high TiO_2 (up to 0.85 wt%) and F contents (5-51 ppm). FTIR spectroscopy indicates a high proportion of Ti-Chu-like defects in the olivine as the cause of high H_2O, F and TiO_2. Olivine also has very high B (8-20 ppm) and Li (3-70 ppm) contents, but these are not correlated with H_2O contents. Antigorite from the same sample has lower B (8-10 ppm) and Li (0.1 ppm) contents than olivine while F contents are comparable (15-47 ppm).

In-situ boron isotope analysis (Cameca 1270 SIMS) shows that olivine is enriched in heavy B ($\delta^{11}B_{SRM951}$ = +17 to +23‰). No difference exists between Ti-rich and Ti-poor olivine. These high values are nearly identical to those of whole-rock high-pressure serpentinites from the same area ($\delta^{11}B$ = +17 to +24‰; [2]). This indicates that little B isotope fractionation occurs during subduction dehydration of serpentine. Moreover, the high B and F contents of secondary olivine imply that these elements remain in the rock during serpentine dehydration. Hence, subduction of ultramafic rocks may introduce significant B isotope anomalies and fluorine into the deeper mantle.

Evaluation of the corrosion behaviour of potential plutonium wasteforms under conditions relevant for geological disposal

G. DEISSMANN[1,2*], F. BRANDT[1], S. NEUMEIER[1], G. MODOLO[1] AND D. BOSBACH[1]

[1]Forschungszentrum Jülich GmbH, Institute of Energy and Climate Research IEK-6: Nuclear Waste Management and Reactor Safety, 52425 Jülich, Germany (*correspondence: g.deissmann@fz-juelich.de)

[2]Brenk Systemplanung GmbH, 52080 Aachen, Germany

One important component of a safety case for a geological disposal facility for radioactive waste is to demonstrate an understanding of the corrosion behaviour of and the consequent radionuclide release from the disposed wastes. Plutonium is generated during the operation of nuclear reactors from uranium present in the nuclear fuels through capture of neutrons and can be recovered during reprocessing. Although the current preferred policy on the long-term management of separated civil plutonium in the UK is reuse as MOX fuel, at least a part of the UK plutonium inventory is likely to be designated for geological disposal. However, experimental data on the durability of plutonium wasteforms under repository conditions is rather limited to date and a detailed understanding of relevant processes that govern long-term radionuclide releases from the wasteforms on a molecular level is still missing [1].

On behalf of the NDA RWMD, we performed a review on the performance of plutonium wasteforms under conditions relevant for geological disposal in the UK. This work included the elicitation of corrosion rate data for the potential wasteforms, based on available experimental data and analogue evidence from other nuclear wasteforms, such as HLW-glasses and spent nuclear fuels. Generic candidate plutonium wasteform types addressed in this study comprised nuclear waste glasses (i.e. borosilicate glasses and phosphate glasses), ceramic wasteforms, and low-specification "storage" MOX. Due to the character of the current UK disposal programme, which is in a generic stage where no preferred disposal concept or type of host rock has yet been selected, a range of possible environmental conditions in the repository near-field were considered. The elicited ranges and distributions of the corrosion rates for the various wasteforms can be used in Post-Closure Safety Assessment models to calculate performance measures such as mean annual individual risks related to plutonium disposal with time.

Insights into the uranium speciation in the mill tailings of the COMINAK mine at Akouta, Niger

A. DEJEANT[1,2,*], L. GALOISY[1], G. CALAS[1], V. PHROMMAVANH[3] AND M. DESCOSTES[3]

[1] Institut de Minéralogie et de Physique des Milieux Condensés, Université Pierre et Marie Curie, Paris, France (dejeant@impmc.upmc.fr) (*presenting author),
[2] Université Paris-Diderot, Paris, France
[3] AREVA, BG Mines, R&D, Paris la Défense

The world's largest uranium underground mine, at Akouta (Niger), has been mined for more than 40 years. About 14 million tons of mill tailings were accumulated on site. The ore beneficiation process, based on an oxidative dissolution in sulfuric acid, reaches an extraction efficiency of up to 92-96% with some U remaining in the tailings. This study aims to assess the U mobility and trapping mechanisms in mill tailings for reprocessing/rehabilitating.

The Akouta U deposit (Guezouman) occurs in continental lower Carboniferous sandstone, containing quartz and feldspar with detritical clays and organic matter. Micro-phases of pitchblende are associated with coffinite and minor U-Ti and U-Mo oxides, with an average U concentration of 4000 ppm associated with trace metals (e.g. V, Zr, Mo).

U concentration measured along a vertical profile within the 30m high tailings pile shows that U is reconcentrated at three levels: at the base, at 14.5m and in the gypsum-rich surface crust, referred to as *gypcrete*. U speciation has been investigated by scanning electron microscopy (SEM) and synchrotron-based X-ray Absorption Spectroscopy (XAS). All tailings samples contain U^{IV} and U^{VI} with an increase in U-oxidation state at shallower depth in the pile. Fresh tailings collected right out of the mill, before storage, are the most reduced. The presence in fresh tailings of ore-inherited U^{VI}-phases, identified by SEM, is in agreement with XAS analyses, showing that they mainly contain non-uranyl species. Older stored tailings where U reconcentrates contain micron-sized secondary U^{VI}-phases (uranyl sulfates and phosphates). This illustrates the importance of post-storage U-transport and trapping. The post-disposal dissolution of residual pitchblende/coffinite is a source of mobile U. However, further precipitation of secondary U-phases and efficient U sorption on Fe oxides and clays limit the extent of U migration within the tailings.

Mediterranean Sapropel S1: Synchronous basin-wide Preservation versus Productivity Signals

GERT J. DE LANGE*[1], C. SLOMP[1], C. CORSELLI[2], ELISABETTA ERBA[3], J. THOMSON[4] AND A. REITZ[5]

[1]Geosciences-Utrecht, NL; gdelange@geo.uu.nl

[3]Universita degli Studi di Milano, IT
[4]Southampton, UK
[5] Geomar-Kiel, DE

Formation of the most-recent eastern Mediterranean S1 sapropel occurred from ~ 11 - 5 kyr 14C ago. The timing of deposition of all such distinct, organic-rich units (sapropels), is precession-related and associated with humid climate conditions. The last of such 'humid periods', simultaneous with a sustained circum-Mediterranean wet period including a vegetated Sahara. The end of this period coincides with a high manganese-oxide peak in all 30 studied cores and concurs with an abrupt re-ventilation event at 5.7 kyr for the deep-water.

We demonstrate that the most recent sapropel (S1) formed synchronously between 9.8 and 5.7 14C ky BP at all water depths greater than a few hundred metres. As a consequence of increased fresh water (monsoon) input, surface waters had a reduced salinity and concomitantly the deep (> 1.8 km) eastern Mediterranean Sea was devoid of oxygen during 4,000 years of S1 formation (De Lange ea., 2008). This has resulted in a differential basin-wide preservation of S1 determined by water depth, as a result of different ventilation/climate-related redox conditions above and below 1.8 km. Climate-induced stratification of the ocean may thus contribute to enhanced preservation of organic matter, i.e. formation of sapropels (and potentially black shales).

De Lange G.J., Thomson J., Reitz A., Slomp C.P., Principato M.S., Erba E., and Corselli C. (2008) Synchronous basin-wide formation and redox-controlled preservation of a Mediterranean sapropel. Nature Geo 1, 606-610.

Temporal change from young HIMU to EM1 source along the Pitcairn-Gambier chain

H. DELAVAULT[1], C. CHAUVEL[2]

[1] (helene.delavault@ujf-grenoble.fr)
[2] (catherine.chauvel@ujf-grenoble.fr)

Plume volcanism is one of the most puzzling features of present-day activities of the earth. The origin of this type of volcanism is matter of debate but it is generally agreed that its source is hot material containing some potentially recycled material. Most studies concentrate on strong plumes (Hawaii, Réunion) but weaker plumes such as Polynesia or St Helena can provided complementary information.

Here we present geochemical data on samples coming from the Pitcairn-Gambier alignment in Polynesia. This chain consists of Mururoa (11.9-10.7 Ma), Fangataufa (11.5-9.6 Ma), Gambier (7.1-5.3 Ma) and Pitcairn Islands (0.95 Ma) as well as the Pitcairn seamounts (0.45 Ma). We report trace elements and Pb isotopic data on basaltic samples with MgO>7% and we use these data to constrain the source of magmas and its evolution through time.

The most striking feature is the presence of Nb (and Ta) positive anomalies (defined as Nb/Nb* with Nb*=(Th+La)/2) in most lavas. In addition, the size of this Nb anomaly decreases with time: it equals 1.6-1.7 in Mururoa, Fangataufa and Gambier lavas; the value decreases to 1.2 in the younger Pitcairn Island and it is absent in the most recent lavas of Pitcairn seamounts. Because the size of the Nb anomaly is not correlated to MgO, its presence cannot be associated with fractionation of a mineral phase. We believe that it is a source feature because it correlates with Pb isotopic compositions that also decrease with time: $^{206}Pb/^{204}Pb$ is about 19.57 in Mururoa, 19.04 in Gambier, 18.31 in Pitcairn Island and finally only 17.71 in the Pitcairn seamounts.

To our knowledge, the only islands where positive Nb anomalies were observed are Tubuai and Mangaia, two HIMU Islands with $^{206}Pb/^{204}Pb>21$ but in both islands, the size of the Nb anomaly never exceeds 1.5. The similarities between the trace element and isotopic characteristics of typical HIMU islands and the old islands in the Pitcairn chain suggest that they share a common origin but the lower Pb isotopic ratios observed in Mururoa, Fangataufa & Gambier suggest a more recent enrichment of U and Th relative to Pb. Finally, both trace element and isotopic changes through time along the Pitcairn-Gambier chain suggest that the source that melted to produce the lavas, started with "young HIMU" characteristics and evolved with time to a clear EM1 type in the most recent volcanic products.

DFT studies of the interaction of water with (Fe,Ni)-sulfide surfaces and clusters

NORA H. DE LEEUW,* ALBERTO ROLDAN, SAIMA HAIDER, DAVID SANTOS CARBALLAL AND UMBERTO TERRANOVA

Department of Chemistry, University College London, London WC1H 0AJ, UK. (n.h.deleeuw@ucl.ac.uk)

Reactive iron sulfide compounds that are formed at hydrothermal vents are implicated as catalysts in Origin of Life theories, which suggestion is lent credence by their widespread presence as redox centres in contemporary enzymes – thereby also suggesting their potential as benign modern-day catalysts for CO_2 conversion. These applications highlight the need for a thorough understanding of the properties of these minerals and especially their surface reactivity as well as nucleation and growth from solution.

We have used Density Functional Theory calculations (GGA+U [1]) to investigate the interaction of water with the spinel-structured greigite Fe_3S_4 and violarite $FeNi_2S_4$ minerals, and compared them with the oxide analogue magnetite Fe_3O_4. We have studied water adsorption at the (001) and (111) surfaces, where the metal ions are in different oxidation states. Using the Nudged-Elastic-Band and Dimer methods we have calculated the energy barriers to the dissociation of water at the surfaces, and the role of co-adsorbed water, through a number of pathways, where the presence of nickel in the surfaces notably affects the surface reactivity towards water, which also influences the co-adsorption and activation of CO_2 at the surfaces.

We also present preliminary findings on *ab initio* molecular dynamics simulations of the nucleation of $(FeS)_n$ clusters from aqueous solution. Iron sulfides are widespread in the environment, but although the formation of the principal geologically stable iron sulfide, pyrite (FeS_2), via meta-stable Fe-S precursors, is reasonably well understood, still little is known about the reactions that control the nucleation and growth of the precursor Fe-S compounds that are crucial in the pyrite pathway, e.g. mackinawite and greigite. Field and laboratory data have shown the existence of small aqueous species (FeS_{aq}), whose role in the formation mechanism of the first condensed FeS mackinawite phase is crucial [2]. However, despite these studies, the stoichiometry and size of FeS_{aq} are still unknown. Our simulations predict hydration shells and stability constants and compare with experiment, where available.

Calcium carbonates are well known to contain significant concentrations of trace metals; Manganese for example is incorporated into calcite via dissolution-recrystallization processes, where the maximum solubility of Mn is controlled by its reaction with calcite and the mixing thermodynamics of the $(Mn,Ca)CO_3$ solid solutions.

Sr and Mg found in coral fossils are used as proxies for the reconstruction of past climates, based on correlations found between the Sr/Ca or Mg/Ca ratios and the sea surface temperature (SST) during biomineralization. Magnesium is always present in corals but with typical Mg/Ca ratios well below the ratio of in seawater. The variation found for the Mg/Ca ratio with SST is about four times that of the Sr/Ca ratio, thus promising higher resolution in climate change reconstructions. However, although it was initially thought that the Mg in corals occupies lattice positions in aragonite, recent experimental data seem to suggest otherwise.

We have used a combination of molecular dynamics simululations and grand-canonical statistical mechanics to investigate the mixing thermodynamics of Ca, Mn, Sr and Mg in carbonate solid solutions. Our results show a small degree of Ca/Mn ordering in calcite-structured minerals, in agreement with recent experiment, whereas most aragonite-structured Ca/Sr solid solutions are metastable with respect to separation into a Ca-rich and Sr-rich phase. However, the concentration of Sr in coral aragonites lies in the miscibility region of the phase diagram and formation of separated Sr-rich phases in coral aragonites is therefore thermo-dynamically unfavourable.

We have also calculated the equilibrium partitioning of Mg between aqueous solution and the bulk and surfaces of aragonite, including the effect of the different Mg and Ca chemical potentials. Results show that the total Mg content in the aragonite particles was found to be highly surface-dependent but too small to account for the measured Mg/Ca ratios in corals. It is therefore likely that most Mg in corals is either highly metastable in the aragonite lattice or located outside the aragonite phase of the coral skeleton, which has clear implications for its use as a proxy in paleothermometry.

Mesoarchean Tectonic Evolution of the Carajás Domain, Carajás Province, PA, Brazil.

M.A.S. DELINARDO*[1], L.V.S. MONTEIRO[2], R.P. XAVIER[1], C.P.N. MORETO[1], G.H.C. MELO[1], R.C. BENEDETTI[1] AND D.F.M. SOUSA[1]

[1]Geoscience Institute, Univ. of Campinas., SP 13083-870 (correspondence: *marcodelinardo@gmail.com)
[2] Univ. of São Paulo, São Paulo, SP 05508-080

The Carajás Province represents an Archean block located in the southeastern part of Amazon Craton, in the north of Brazil. The province is subdivided into two domains (1) Carajás at north and (2) Rio Maria at south.

The Carajás Domain is composed of Mesoarchean basement represented by orthogranulitic rocks and migmatites of tonalitic to granodioritic composition and several intrusive and tectonically imbricated calc-alkaline granites [1][2][3][4][5]. The Mesoarchean evolution of the Carajás Domain occurred between 3.0 and 2.83 Ga [5]. Tonalitic to granodioritic crust with high La/Yb was formed between 3.0 and 2.92 Ga. It was followed by events of high-grade metamorphism, migmatization and emplacement of calc-alkaline I-type tonalites, monzogranites, and granites with volcanic arc signature between 2.87 and 2.83 Ga [2][3][4]. The basement is covered by ca. 2.76-2.73 Ga metavolcano-sedimentary units of the Carajás Basin and crosscut by 2.74 Ga granites and grabbronorites and 1.88 Ga A-type granites [5][6].

The geochemical and geochronological date suggest that the development of a subduction zone related to an arc setting may be responsible for formation of the most ancient rocks of the Carajás Domain. The youngest Mesoarchean rocks may have formed in an event of crustal reworking associated with the final subduction stage, as indicated by metamorphic, structural and geochemical evidences.

The relationship of these events with the juxtaposition of the two tectonic domains of the Carajás Province is still uncertain. However, Neoarchean magmatic and tectonic events have been recorded only in the Carajás Domain.

Location of cation impurities in NGRIP deep ice revealed by cryo-cell UV-laser-ablation ICPMS

DAMIANO DELLA LUNGA[1], WOLFGANG MÜLLER[1], SUNE OLANDER RASMUSSEN[2] AND ANDERS SVENSSON [2]

[1] Dept. of Earth Sciences, Royal Holloway University of London, Egham TW20 0EX, United Kingdom (*correspondence: damiano.dellalunga.2011@live.rhul.ac.uk)
[2] Centre for Ice and Climate - Niels Bohr Institute, University of Copenhagen, Juliane Maries Vej 30, 2100 Copenhagen Ø, Demark.

The nature and location of cations impurities in ice cores provide useful insights about paleoclimate. Proxies for sea ice extension, dust atmospheric supply and the identification of annual layers are based on seasonal variabilities of soluble and not soluble impurities in ice. Furthermore, impurities play an important role in ice grain growth, which generally increases with depth, but is interrupted by many periods where the grain size sharply decreases, in correspondence of glacial-interglacial transitions [1]. The distribution of different impurities, led by this phenomenon, has never been directly observed in experiments on ice [2].

Using a recently developed methodology unique at Royal Holloway University of London [3], *in situ* chemical analysis of ice with unprecedented spatial (and thus time) resolution is achievable using cryo-cell UV-laser ablation inductively-coupled-plasma mass spectrometry (UV-LA-ICPMS). A volume of NorthGRIP ice (50x11x11 mm, HxWxD) have been analysed by using a series of 2D grids of laser spots at a resolution >300 μm over the surface of the volume. The sample surface (depth ~ 2717 m) has been smooth and cleaned using a metal free ZrO_2 blade mounted on a custom-built teflon vice used to remove ~2mm of ice to avoid contamination. A small liquid nitrogen reservoir covered by a teflon worksurface has been embedded in the proximity of the cryo cell, for keeping samples below -20 °C during loading procedures. N_2 is constanly blown on samples via a custom-made hood fitted with a vent, preventing contamination and refrosting from air.

Major elements indicative of sea salt contribution (Na, Mg) and dust concentration (Al, Ca, Fe, K) were measured simultaneously. Results proves the reliability of the technique in identify where impurities preferentially lies and which type of impurity they are (soluble or insoluble).

Silicate weathering reactions constitute a major aspect of the Earth's engine as they consume atmospheric CO_2 and influence the composition of the ocean and continental crust over long time scales. The investigation of past climatic variations requires geochemical proxies of silicate weathering. Lithium isotopes are a promising new geochemical proxy for silicate weathering and have notably been used recently to demonstrate the change of weathering regime during the Cenozoic based on the marine record [1]. However, the parameters controlling the extent of Li isotope fractionation during continental weathering and the associated fractionation factor are still poorly known. Here, we report the Li isotope composition of river-borne material in the largest Earth's River system, the Amazon River basin to characterize Li isotope fractionation at continental scale.

The Li isotopic composition of the dissolved load (δ^7Li) is highly fractionated toward heavy values (up to 31‰) compared to river bed sand (–1.39 to +3.85‰) and suspended sediments (–6.80 to –0.50‰). The dissolved Li concentrations are the highest in the headwater of the Beni River that drains shale rocks (0.3 to 2 μmol.L^{-1}) and the lowest in the rivers draining the shield areas (< 0.1 μmol.L^{-1}). In the Madeira basin, the δ^7Li of the dissolved load increases from the Andes to the floodplain and displays a global inverse relationship with the Li/Na ratio. The fraction of Li incorporated into secondary weathering products during the contemporary weathering cycle is the dominant control of the dissolved Li isotope composition and is related to the geomorphic regime. This work has important implications for the determination of weathering mass budget based on Li isotope and about the importance of secondary product formation.

Uptake of SO_2, HCl and O_3 on volcanic ash

P. DELMELLE[1*] AND M. ROSSI[2]

[1] Earth & Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium ([*]correspondence: (pierre.delmelle@uclouvain.be),
[2] Laboratorium für Atmosphärenchemie, Paul Scherrer Institut, Villegen, Switzerland (michel.rossi@psi.ch)

Mineral dust linked to soils from arid and semi-arid regions represents a significant fraction of the tropospheric aerosol mass. Many studies suggest that surface reactions involving mineral dust aerosol influence tropospheric chemistry. A largely neglected source of airbone mineral dust is silicate ash produced during explosive volcanic eruptions. The flux of ash into the atmosphere is not well constrained but may be >20 % of the annual mineral soil dust load. However, a single major eruption can inject a mass of fine (100 μm) ash with a total solid surface area on par with that emitted annually to the atmosphere by Saharan desert dust storms. In contrast to mineral dust, surface reactions of trace atmospheric gases on ash have not been studied. As a consequence, we have a limited understanding of the effects of volcanic activity on the chemical composition of the atmosphere.

The heterogeneous reactions of SO_2, HCl and O_3 on representative volcanic ash samples were investigated at room temperatures using a Knudsen cell. Volcanic ash varies in composition and mineralogy depending on source magma conditions. It is expected that natural ash samples will have different reactivities. Our results indicate that the uptake coefficients of SO_2, HCl and O_3 on volcanic ash compare with the values reported for mineral dust. No evidence was found for a significant compositional effect, and measurements performed with synthetic materials suggest that it is the glassy component which primarily drives the ash surface reactivity. Additional experiments are being performed and the new dataset will be integrated to provide a mechanistic description of the heterogeneous reaction of SO_2, HCl and O_3 on volcanic ash.

An inverse modelling approach for assessing CO_2-exposure experiments on Ketzin sandstone

M. DE LUCIA*, S. FISCHER, A. LIEBSCHER AND M. KÜHN

GFZ German Research Centre for Geosciences, Telegrafenberg, 14473 Potsdam, Germany (*delucia@gfz-potsdam.de)

For 24 months, reservoir sandstone samples from the Stuttgart Formation at the Ketzin pilot CO_2 storage site in Germany were exposed to synthetic brine and pure CO_2 at 55 bar and 40 °C [1]. Only minor mineralogical changes were directly observed after the experiments, making it difficult to discriminate natural variability of the samples from CO_2-induced alterations. During the progress of the experiments fluid samples were taken from the autoclaves in order to track the reactivity of the rock samples as reflected by changes in brine composition. Even these results show high variability and at times qualitatively opposite concentration trends for some dissolved species.

In order to assess the significance and plausibility of the analytical results and to reproduce the experiments numerically we developed and applied a computational two-step inverse modeling approach. Firstly, an extensive set (several thousands) of equilibrium simulations was generated representing all possible combinations from a predetermined pool of minerals supposed to represent all phases in the sandstone samples. These simulations were ranked based on their matching the average brine analysis. Highest ranked simulations were then re-run including kinetics of mineral reactions, with rate laws taken from literature [2]. Secondly, a more fine-grained iterative calibration of selected kinetic models, including a quantitative assessment of reactive surfaces, was built up in conformity to likelihoods estimated from the ensemble of generated simulations. Major uncertainties in the Ketzin sandstone experiments concern reactions involving Fe^{2+}, K^+ and Al^{3+}; the other measured brine data were well matched.

This inverse modeling approach is computationally intensive (the simulations were run using a Pitzer database and generated via the R/PHREEQC interface [3]) but allows setting up models that are consistent to a set of otherwise intricate observations, where it is difficult to discriminate between measurements errors, biased thermodynamic data and erroneous parametrization of the models themselves. The outcome is a set of *possible* models and *ranges* in the parameters, which will then be considered i.e. for long-term predictions of the fate of Ketzin reservoir.

Seawater as the common Si source for both Archean BIF and cherts: insights from silicon isotopes

C. DELVIGNE [1,2], A. HOFMANN [3], D. CARDINAL [2,*] AND L. ANDRÉ [1,2]

[1]Department of Earth Sciences and Environment, Université Libre de Bruxelles, Brussels, Belgium
[2]Department of Geology and Mineralogy, Royal Museum of Central Africa, Tervuren, Belgium
[3] Department of Geology, University of Johannesburg, South Africa
[*]Now at Laboratoire d'Océanographie et du Climat: Expérimentations et Approches Numériques, Université Pierre et Marie Curie, Paris, France

In an attempt to bring new insights into the identification of the silicon source(s) of Archean BIF, we compare silicon isotopic compositions of Si-rich mesobands of BIF and S-cherts ranging in age from 3.25 Ga to 2.5 Ga. We observe a progressive temporal 0.6‰ increase in δ^{30}Si signatures of Si-rich mesobands of BIF from -1.80±0.62‰ at 3.25 Ga to -1.18±0.37‰ at 2.5 Ga. Interstingly, this trend is parallel to the increasing δ^{30}Si trend recorded in cherts [1, 2, 3]. The common gradual change in the Si isotopic composition through time suggests that both Si-deposits had a main common Si-conveyor: the seawater. However, the comparison of both trends also reveals a systematic 1.5‰ difference between the two parallel trends where the BIF trend is the light one. We suggest here that such systematic 1.5‰ difference is most likely related to the respective genetic process that gave rise to both types of Si-rich deposits: a high to low-temperature geothermal seawater circulation for cherts [4] and a Si adsorption onto Fe-oxyhydroxides for BIF in which Si-rich mesobands are of diagenetic origin [5].

[5]Environment Department, University of York, UK (mark.hodson@york.ac.uk)

Many species of earthworm secrete granules of calcium carbonate. The earthworms *Lumbricus terrestris* and *L. rubellus* are the main granule producers in European soils. The granules begin as micron-scale spherulites of amorphous calcium carbonate within the earthworm's calciferous glands. These spherulites agglomerate and crystallise prior to secretion of granules up to 2 mm in diameter into the digestive tract and, ultimately, into the soil. The secreted granules are predominantly calcite but may contain aragonite, vaterite and amorphous calcium carbonate [1, 2, 3].

Granules subsampled from granule sets recovered from a range of chemically distinct soils and stored dry for over two years since their production contained between 2 and 14 % amorphous calcium carbonate and had elevated relative concentrations of glutamic acid / glutamine (Glx). After a further two year period amorphous calcium carbonate concentrations measured on further subsamples of these granule sets lay in the range 0 – 13 %; the relative amino acid composition of the granules was investigated by reverse-phase HPLC. No significant relationship was found between granule elemental composition and amorphous calcium carbonate content nor between the amorphous calcium carbonate contents determined after two and four years.

We ascribe the lack of relationships to the compositional heterogeneity of the granules and are currently performing spatially explicit analysis of the granules using Fourier transform infrared spectroscopy, electron microprobe analysis and electron backscattered diffraction. Controls on amorphous calcium carbonate stability will be discussed.

A novel method of stable H and O isotope analyses of inclusion-hosted waters based on laser spectroscopy

DEMÉNY, A.[1] AND CZUPPON, GY.[1]

[1]Institute for Geological and Geochemical Research, RCAES, Hungarian Academy of Sciences, Budapest, Budaörsi ut 45., (demeny@geochem.hu), (czuppon@geochem.hu)

Laser spectroscopy is a relatively recently developed technique that can be effectively used for coupled H and O isotope analyses of water samples. Since the aim of the present study was to extract water from fluid inclusions, a vacuum-based liquid water isotope analyser was chosen (Los Gatos Research, LWIA-24d). Inclusion-bearing samples were vacuum-crushed in stainless steel tubes and the released water was cryogenically transferred to the spectroscope's inlet using a vacuum line. When the fluid contained CO2 (e.g. on the base of microthermometric analyses), the water was purified by releasing CO2 at –80 °C. Memory and amount effects, as well as isotope shifts related to the isotope range measured were determined by introducing standard waters injected into glass capillaries. Amount effects for both H and O isotope compositions were quantified by multiple analyses of a calcite vein. On the base of a set of samples (calcite, quartz and fluorite veins, as well as speleothems), whose H isotope compositions had been measured by IRMS it can be stated that the precision of H isotope analyses achieves or even exceeds that of the IRMS analyses with a significant reduction in analysis time and cost. The determination of O isotope compositions raises more problems. It is demonstrated that the d18O values are prone to alteration during the water release depending on extraction temperature and duration. Although the measured values may not be equal to the real compositions, internal variations can have a meaning, e.g., in paleohydrological studies.

The study was supported by the Hungarian Research Fund and the Hungarian State (project No. CK 80661).

Episodic fluid flow in a subduction zone

C. DE MEYER[1*], L.P. BAUMGARTNER[1], D. RUBATTO[2] AND A.-S. BOUVIER[1]

[1]ISTE, University of Lausanne, Switzerland (*correspondence: caroline.demeyer@unil.ch)

[2]Research School of Earth Sciences, Australian National University, Canberra, Australia

The Zermatt-Saas Zone in the Western Alps contains the remnants of the Jurassic Piemonte-Ligurian ocean subducted to eclogite facies metamorphic conditions during the Eocene. The garnets have complex zonation documenting multiple resorption and growth periods. In-situ SHRIMP analyses of oxygen isotopes measured along profiles across the central sections of the garnets show multiple steps in $\delta^{18}O$ values with variations of up to 5 ‰. The core of the garnet has $\delta^{18}O$ values of 14-15 ‰. A sharp decrease to 9-10 ‰ is followed by a gradual increase to 14-15 ‰. The oxygen isotope variations in the garnets correlate with sharp jumps in grossular content. The decrease of the $\delta^{18}O$ value during garnet growth indicates infiltration of an isotopic lighter fluid. Fluid infiltration drives the metamorphic decarbonation reactions, promoting garnet growth. The ultramafic and mafic rocks, which are intercalated with, or underlying the calcschists are the likely source of the fluids. Preliminary $\delta^{13}C$ in-situ SIMS analyses of graphite inclusions suggest variable fluid sources during garnet growth. The multiple growth intervals suggest multiple pulses of fluid infiltration. While zones of adjacent garnet grains can be correlated, individual garnets have different size zones. This points towards localized fluid pathways on sub-centimeter scale. Mineral zoning in subducted carbonate-bearing rocks do not only register changing pressure and temperature conditions, but also changes in fluid composition due to circulation of fluids between ultramafic, mafic and meta-sedimentary units of the subducting slab.

The multiple structures of vaterite

RAFFAELLA DEMICHELIS[1*], PAOLO RAITERI[1] AND JULIAN D. GALE[1]

Nanochemistry Research Institute, Department of Chemistry, Curtin University, Perth WA, Australia.
(*presenting author - raffaella.demichelis@curtin.edu.au)
(p.raiteri@curtin.edu.au, j.gale@curtin.edu.au)

Vaterite ($CaCO_3$) is a metastable polymorph that plays a fundamental role in the nucleation and crystal growth of calcium carbonate under biogenic conditions. In particular, the nucleation of vaterite is often observed from amorphous calcium carbonate precursors, with biomolecules acting as structural stabilizers [1,2].

Because of the role of vaterite in biomineralization, the nature of its disordered structure has been object of intense debate for several decades, leading to a multitude of different structural models [3,4,5]. Through first principles calculations, a link between the most recent models proposed in the literature has been established [6]. This new model, consisting of multiple structures, is in agreement with all of the current experimental evidence. The disorder of vaterite is here interpreted in terms of different orientations of the carbonate anions, different stacking sequences of the carbonate layers, and possible chiral forms. Hence, vaterite should be considered as a combination of different forms exhibiting similar average properties, rather than a single "disordered" structure. Furthermore, chirality represents a new and important direction for future investigation that may influence which of the possible vaterite structures is obtained.

More generally, a wide variety of structures exhibiting minor structural and energetic differences might exist in nature, as a result of nucleation in different environments and at different conditions, which might promote the formation of a particular stacking sequence or chirality.

Comparison of trace metal bioaccumulation potential in the three different ocean's zones

L.L DEMINA

Shirshov Institute of Oceanology, 117997, Nakhimovsky pr, 36, Moscow, Russia.
l_demina@mail.ru)

An estimation of the trace metal' accumulation potential (TMAP) of the biological communities based on the integrated median average content of metals and average biomass of the dominated organisms was proposed [Demina, 2011]. A comparison of the TMAP in the three geochemically different zones such as: 1. coastal and estuarine areas (plankton, macroalgaes and mollusks) 2. euphotic layer of the ocean (phytoplankton), and 3. deep-sea hydrothermal vent fields (bottom fauna), is made in this work (table). These areas are known to be a highly productive ones, where the biogeochemical processes are very intensive. Average biomass of In the hydrothermal biotopes the *Bathymodiolus spp*. bivalve mollusks demonstrate the largest biomass (whole bodies) – up to 60 $kg \cdot m^{-2}$ [1].

Metal	1	2	3
Mn	470	6.3	894
Fe	9128	105	63060
Co	19.4	0.54	258
Ni	78.5	1	1092
Cu	102	6.3	4272
Zn	656	24.7	17100
As	7.8	5.7	2142
Cd	7.1	0.3	142
Pb	87	4.19	1013

Table: Trace metal bioaccumulation potential in the biomasses of the dominant communities ($mg \cdot m^{-2}$of the biotope).

From the comparison it follows that benthic fauna of hydrothermal fields (column 3) is characterized by the highest value of bioaccumulation potential of nine metals, which exceeds from tens to thousands times that in the estuaries (column 1) and euphotic zone of the open ocean (column 2). Thus, the hydrothermal fauna may be considered as a newly discovered local biological filter of the ocean.

Geochronological and geochemical constraints on the construction of the Lluta pluton, Tacna (Peru)

SOPHIE DEMOUY[1] MATHIEU BENOIT[1]
MICHEL DE SAINT-BLANQUAT[1]
AND JEAN-LOUIS PAQUETTE[2]

[1] GET - 14 av. Edouard Belin, F-31400 Toulouse
[2] LMV - 5 rue Kessler, F-63038 Clermont-Ferrand

Looking at the active margin scale, subduction-related magmatism leads to the emplacement of voluminous intrusive rocks into the crust, forming large plutonic belts parallel to the trench. Due to long-term magmatic activity in single region, these plutonic belts become highly complex in terms of structural features, emplacement history, and geochemical signatures.

Along the Western margin of South America, subduction has been ongoing since ~570 Ma. In this study, we present the emplacement history of the Lluta pluton, located at the southeastern end of the peruvian Coastal Batholith, in the Tacna area. This pluton can be considered as an archetype of the Cretaceous to Paleocene magmatic arc activity and gives insight to the emplacement mechanisms of composite batholiths.

To unravel the emplacement history of the Lluta pluton, we performed major and trace element whole rock analyses on 21 samples, Sr and Nd isotopic measurements on 8 samples, and laser-ablation inductively coupled mass spectrometry (LA-ICPMS) U-Pb analysis on 5 samples.

The Lluta pluton intruded sedimentary jurassic strata, after which the whole crustal sequence was tilted about 28° towards the west. The pluton has since been exhumed exposing more than 70 km^2 at the surface, and providing a cross section through the different levels of the pluton. The lithologies vary from gabbro to granite.

The gabbroic intrusion, located at the base of the pluton yields an age of 72.4 ± 0.5 Ma, whereas the various dioritic to granitic intrusions at lower crustal levels yield younger ages between 62.8 ± 0.4 and 62.0 ± 0.4 Ma. The entire dataset however displays a strong geochemical arc signature, that fits within the range of plutonic arc signatures in southern Peru. Initial Sr isotope ratios range is 0.70445-0.70575 and initial Nd isotope ratio range is 0.51248-0.51260.

Integration of the entire dataset illustrates the discontinuous contruction of a single pluton in a subduction context. Isotopic signatures suggest either a varying amount of crustal contamination or magma mixing processes for the different lithological units, and show that the parental magmas are slighly more juvenile than those of the northern Coastal Batholith section of Arequipa.

Effects of carbonate assimilation on magma from Sumbing volcano, central Java, Indonesia and implications for Merapi

SCOTT DEMPSEY[1], COLIN G MACPHERSON[1],
ROBERT HALL[2] AND JON DAVIDSON[1]

[1]Department of Earth Sciences, Durham University, Durham, UK, DH3 1LE. (scottdempsey@chemostrat.com)
[2]Southeast Asia Research Group, Department of Earth Sciences, Royal Holloway university of London, UK, TW20 0EX

Sumbing volcano is situated at the southern end of a NNW-SSE trending chain of volcanoes in central Java that lies ~ 50 km east of a parallel chain, which includes Merapi. Sumbing has received little attention partly due to its dormancy since 1730. New petrological and mineralogical data along with whole rock major and trace element and Sr-Nd-Hf-Pb isotopic analyses were conducted for 20 volcanic rocks collected from Sumbing in 2009.

There are two petrographic and chemical magma groups. *Pyroclastic deposits* are predominantly fragments in lahars at the base of the volcano and contain ubiquitously higher percentages of Ca-bearing mineral phases such as clinopyroxene and highly altered plagioclase feldspar. The latter display a large range in anorthite (An) content. In contrast, a group of *lavas* show much less evidence for mineral-melt disequilibrium, are orthopyroxene (enstatite) rich and display more restricted plagioclase compositions.

The pyroclastic deposits are more silica undersaturated than the lavas and contain higher concentrations of CaO, Ba, Sr and have elevated $^{87}Sr/^{87}Sr$, all of which overlap fields for Merapi. Correlations between degrees of silica saturation, Sr/Nb and $^{87}Sr/^{86}Sr$ suggest that these magmas become progressively enriched in Ca, Sr and$^{87}Sr/^{86}Sr$ with increasing silica undersaturation i.e. more contaminated rocks have lower SiO_2. In contrast, the lavas display little variation in these properties, beyond what would be expected from closed system differentiation. We interpret the two groups as originating from similar parental magma but displaying the effects of having experience (pyroclastic) or escaped (lava) interaction with carbonate in the arc crust.

The lavas at Sumbing suggest that all magma erupted from Merapi has interacted with crustal carbonate. Therefore, Sumbing lavas provide the best estimate of parental melt characteristics of the arc front in central Java.

Geochemistry of Betul Mafic Layered Intrusion, Central India: Implications on Proterozoic Mantle Evolution and Ni-Cu-PGE Metallogeny

SUBBA RAO DENDULURI VENKATA, MANAVALAN SATYANARAYANAN AND DRONA SRINIVASA SARMA

CSIR-National Geophysical Research Institute, Uppal Road, Hyderabad 500007. Mail: (dvsubbarao3s@rediffmail.com)

Precambrian crust of Central India is divided into northern Bundelkhand craton and southern Bastar craton separated by Central Indian Tectonic Zone (CITZ). The Betul Layered Complex (BLC) emplaced into the Mesoproterozoic Betul supracrustal belt (1.5-0.85 Ga) occur in CITZ. In this study we present the geochemical characteristics of the mafic-ultramafic rocks with particular relevance to the nature of contemporaneous sub-continental lithospheric mantle and Ni-Cu-PGE mineralization. BLC is characterized by metamorphosed ultramafic-mafic rocks emplaced into Betul belt consisting of bimodal volcanics and metasediments hosting VMS ores formed under a continental arc setting. The BLC exhibits primary mantle mineralogy (ol, opx, cpx, amp, phl) with secondary metamorphic mineral assemblages. The BLC rocks are subalkaline tholeiites and record Fe enrichment and fractionation trends. High concentrations of Cr, Ni and Cu indicate the presence of accessory chromite and Ni-Cu sulphides. Compositional heterogeneity is noticed with enrichments of LILE and Pb, and depletion of Nb, Zr-Hf suggesting mantle wedge of these rocks has been metasomatically enriched with the fluids derived from subducting slab. SEM-EDS study on gabbros from BLC has revealed that they contain unusual native gold, Ni-Cu, Ni-Co, Fe-Cu sulphide and Fe-Ti-Si phase with platinum group mineral inclusions and are genetically related to the magmatic hydrothermal fluids. PGE geochemistry is characterized by a high total PGE content of 1.2-1.5 ppm and have fractionated patterns (PPGE>IPGE; high Pd/Ir = 11 to 147) resembling the interstitial variety of mantle sulphide type and also fractionated PGE patterns of basalt (Mondal, 2011). It is considered that the Mesoproterozoic period witnessed extensive ultramafic-mafic magmatism with orthomagmatic ores and existence of a long lived metasomatically enriched mantle source, VMS ores and convergent margin tectonic settings. The geochemical characteristics of the BLC rocks corroborates the above proposition.

Mondal SK (2011). Jour. Geol. Soc. India, 7: 295-302.

Assessing the dissolution of marine sediment with ^{230}Th, and the impact of dissolution on sedimentary ^{231}Pa/^{230}Th

FEIFEI DENG[1*], GIDEON M. HENDERSON[1], ALEX L. THOMAS[1], WILLIAM B. HOMOKY[2] AND RACHEL A. MILLS[2]

[1]Department of Earth Sciences, University of Oxford, Oxford, (*feifei.deng@earth.ox.ac.uk)

[2]Ocean and Earth Sciences, National Oceanography Center, Southampton, University of Southampton, SO14 3ZH, United Kingdom (w.homoky@sotom.ac.uk)

Dissolution of marine sediment at the seafloor takes place in all ocean basins and is an important process controlling the release of chemicals from sediment back into seawater, and in setting the composition of marine particulates buried in sediment. Assessing the rate and extent of this dissolution is therefore critical for understanding of internal cycling of many chemical species in the ocean. In this study, we test the use of ^{230}Th, whose flux to the seafloor is assumed constant and well known, to assess sediment dissolution.

Sediment samples were collected during UK-GEOTRACES Cruise GA10E (D357) from the slope of the Cape Basin in the SE Atlantic. Intact core-top sediments and three short cores were selected for this study from a range of water depths. Samples of shallow-margin and deep-sea sediments are bathed in different water masses and vary in particle flux and compositions. Our results show that ^{230}Th concentrations increase from low core-top values to a depth of~3cm and are constant below this depth. These observations can be best explained as a result of sediment dissolution in the upper centimetres of the sediment core. Core-top ^{230}Th measurements thus provide a tool to quantify the rate of sediment dissolution at the seafloor and assess the magnitude of this process in various ocean settings. Dissolution rates derived from ^{230}Th measurements have been used on these cores to assess the burial of organic biomarkers, and the fluxes of metals from upper centimetres of sediment back to overlying water column.

Meaurements of ^{231}Pa on the same sediment aliquots were also conducted to assess the impact of the observed sediment dissolution on ^{231}Pa/^{230}Th ratios (a proxy for past rates of ocean circulation, and particle flux). Results show that, despite the large dissolution indicated by ^{230}Th profiles, ^{231}Pa/^{230}Th ratios appear to be almost unaffected, indicating the robustness of sedimentary archives as records of the ^{231}Pa/^{230}Th as a paleoceaongraphic proxy.

Rethinking primary organic aerosol emission inventories with a focus on wood combustion in Europe

H. A. C. DENIER VAN DER GON [1]*, A. J. H. VISSCHEDIJK[1], R. BERGSTRÖM[2], D. SIMPSON[3], J. GENBERG[4], C. FOUNTOUKIS[5] AND S. N. PANDIS[5]

[1] TNO, PO Box 80015, 3508 TA, Utrecht, the Netherlands (*correspondence: hugo.deniervandergon@tno.nl)

[4]Division of Nuclear Physics, Department of Physics, Lund University, Lund, Sweden
[5]Institute of Chemical Engineering Sciences, Foundation for Research and Technology Hellas (FORTH), Patras, Greece

In Europe, residential wood combustion (RWC) is the largest source of organic aerosol (OA). Recently OA modelling has significantly improved since the introduction of the Volatility Base Set approach [1]. However, these new insights had no impact on the primary particulate matter (PM) emission inventories in Europe. To quantify the importance of RWC our "traditional" OA inventory derived from reported PM emissions was used as input for 2 CTMs, PMCAMx and the EMEP model, revealing major underestimations of OA in winter time, especially for regions dominated by RWC. A new RWC emission inventory was constructed that also accounted for condensable particles, increasing RWC emissions with a factor of 2-3 but with substantial inter-country variation.

The new emission grid served as input for the CTMs and a signifcant improvement between measured and predicted black carbon (BC) [2] and organic carbon (OC) was found, further supported by levoglucosan campaign measurements. The results suggests that primary aerosol (PM) inventories need to be revised to include the semi-volatile OA that is formed almost instantaneously due to cooling of the flue gas or exhaust. A further analysis indicated that this is, based on the measurement protocol, not appropriate for European road transport emissions but industrial OA emissions may also be underestimated. We will also show that the choice of emission inventory influences the assesment of the effectiveness of reducing BC emisisons from RWC as a mitigation strategy for decelerating global warming.

[4]Aksaray Uni. Dept. of Geological Eng., Aksaray, Turkey
[5]Bozok Uni. Dept. of Geological Eng., Yozgat, Turkey

NW Anatolia was exposed to alkaline volcanic activity during Miocene to Quaternary. These alkaline volcanic rocks show potassic and ultrapotassic character. Alkaline volcanic activity can be differentiated into five main groups as a leucitites, leucite phonolite, phonolitic tephrite, thrachyandesite and alkaline basalts. The first stage volcanic activity is represented by leucitites which have hypocrystalline texture and composed of leucite, melilite, augite, diopsite, analcime, hematite and magnetite. Leucite phonolites and phonolitic tephrites have porphyritic texture and respectively leucite, sanidine, augite, nepheline, opaque minerals comprise the main mineral compositions. Thrachyandesites represent the third stage of volcanism and have hylopilitic porphyritic texture with augite, plagioclase, sanidine, nepheline and phlogopite. The last stage of volcanism contains alkaline basalts which show flow texture. The main mineral composition consist of augite, phlogopite, plagioclase and opaque minerals. Leucite gives a strong Raman shift in 500-530 cm^{-1}. Analcime gives a strong Raman shift in 389-484-673 cm^{-1} and 1113 cm^{-1}. Augite type pyroxene group gives Raman shift in 324-357-390 cm^{-1}, 506 cm^{-1}, 666 cm^{-1} ,835 cm^{-1} and 1010-1046 cm^{-1}. Diopsite gives different Raman shift from augite in 963 cm^{-1}. Opaque minerals are hematite and minor magnetite in composition. Hematite gives Raman shift in 395-487-599-1293 cm^{-1}. Magnetite gives Raman shift in 649 cm^{-1}. Sanidine gives a strong Raman shift in 470-520 cm^{-1}. Whole rock geochemical data reveal that alkaline volcanic rocks are ultrapotassic and metaluminous in compositions. The ultrapotassic rocks both show enrichment in LILE and LREE with respect to HFSE and HREE. The Ba, Rb and Sr contents are enriched relative to mantle component. *The data obtained from petrological studies suggest that Afyon ultrapotassic volcanic rocks derived from lithospheric mantle source and were affected by subduction zone metasomatism during late stage of Cenozoic extensional magmatism in Western Anatolia*.

Chemical Continuous Time Random Walks

MARCO DENTZ

(marco.dentz@csic.es)

The Gillespie algorithm models chemical reactions as random walks in particle number space. The reaction lag times are exponentially distributed based on the assumption that the system is well mixed. We propose a generalization of this method and introduce non-exponential reaction lag time distributions, which may reflect the impact of incomplete mixing on the chemical reactions. From such a chemical continuous time random walk, we derive a generalized chemical Master equation. We present test cases to study the impact of non-exponential reaction times on the overall reaction behavior.

Generation of a multi-annuli corona sequence in two-pyroxene gabbro, Fiordland, New Zealand: intrusion, rapid post-magmatic cooling and transformation of gabbro to high-*P* granulite

DE PAOLI, M. C.[1], FITZHERBERT, J. A.[2] AND CLARKE, G.[3]

[1] ETH Zürich, Institute of Geochemistry and Petrology, Zurich 8092, Switzerland.
[2] Geological Survey of NSW, Maitland, NSW 2320, Australia.
[3] School of Geosciences, University of Sydney, Sydney, NSW, 2006, Australia.

Arc-related gabbroic intrusives of the Pembroke Valley, New Zealand preserve an unusual and unique sequence of coronas developed between igneous Fe-Mg silicates, Fe-Ti oxides and matrix plagioclase. The igneous assemblage does not contain garnet, constraining the depth of gabbro intrusion to less than *c*. 35 km at temperatures above 1000ºC. Two distinct stages of corona crystallisation (C_1 and C_2) at lower-crustal levels have been identified. C_1 coronas involve symplectic intergrowths of Ca–amphibole-kyanite-clinopyroxene-K–feldspar-plagioclase-clinozoisite-quartz ± orthopyroxene, and formed during incipient hydration at the boundary between the two-pyroxene- and garnet granulite-facies at *c*. 25-35 km depth and temperatures of ≈ 800ºC. Both igneous and C_1 corona mineral assemblages are crosscut by a series of ramifying anorthositic veins. Adjacent and parallel to these veins, igneous and C_1 corona minerals are pseudomorphed by garnet-clinopyroxene-rutile-bearing C_2 coronas within the selvage zones to the central vein. C_2 coronas formed via dehydration and recrystallisation of igneous and C_1 mineral assemblages in the garnet granulite-facies at pressures of ≈ 1.1 GPa (*c*. 30-35 km depth) and temperatures of ≈ 750ºC. The sequence of corona annuli development at Pembroke represents the post-magmatic recrystallisation of gabbroic lithologies at constant or slightly increasing pressure and declining temperature. U-Pb isotopic ages of magmatic and recrystallised zircons indicate that the timing of intrusive and garnet granulite forming events were separated by as little as 11-17 Myr. This implies that the process of cooling (isobaric or up pressure) to produce high-pressure granulites is not just restricted to decreasing heat flow in old continental root zones, but may also occur in a transient setting during relatively rapid (11-17 Ma) isobaric cooling of young mafic under-plate in an intracontinental arc setting.

Geochemical characteristics of volcanites, as a reflection of subduction decay (Northern flank of Bureja-Jziamusy superterrain)

INNA DERBEKO

Institute of Geology and Nature Management FEB RAS, Blagoveshchensk, Russia, (derbeko@mail.ru)

The magmatic activity was widely shown in the end of Mesozoic on the territory of the Northern flank of Bureja-Jziamusy superterrain. The three complexes of andesite formations were formed during 120-105, 111-105 Ma. The volcanites of the complexes have got some geochemical differences. The rocks enriched with Sr (up to 1029 ppm) were formed at the first stage, with the depletion of Nb (4-10), Ta (0.49-0.80), Rb (20.4-43.5), Th (1.70-4.97), Y (8-29), Ti (3100-3300). The lowering of the content of Sr (230-910 ppm), but growth of Rb and Th occurred at the second stage. The quantity of the rest of the elements is the same as in the first complex. The content of Sr (190-642 ppm) reduces, but the amount of Zr (129 - 412), Hf (3 - 13), Nb (7 - 39) in ppm is heightened in the volcanites of the third complex. Geochemical characteristics of the third complexes rocks are displaced to the same characteristics of the intra plate formations. All the rocks of the researched complexes relate to the calc – alkali series and low and high potassic groups. The rocks are characterized with oversubductional type of microelements distribution. The diagram of Sc/Ni – La/Yb [2] confirms that the rocks are oversubductional. But the content of the complexes is different. Some of the authors unite the lowering of the Sr concentration and growth of Ce, Th with the decay of the subduction. The fact is observed in the rocks of the researched complexes in the direction from the volcanites of the first to the volcanites of the third complex.

Differences in shale weathering on ridgetops and slopes along a latitudinal climosequence

A. L. DERE[1], T. S. WHITE[1], L. E. LEIDEL[1] AND S. L. BRANTLEY[1]

[1]Penn State University, 315 Hosler Building, University Park, PA, USA (*corresponding author: ald271@psu.edu) (tsw113@psu.edu); (lel5098@psu.edu); (sxb7@psu.edu)

Regolith, the mantle of physically, chemically, and biologically altered material overlying parent material, covers much of Earth's continents but the rates and mechanisms of regolith formation are not well known. In an effort to quantify the influence of climate on shale weathering rates, a transect of study sites has been established on Silurian shales along a climatic gradient in the Northern Hemisphere as part of the Susquehanna Shale Hills Critical Zone Observatory, PA, USA. The climate gradient is bounded by a cold/wet end member in Wales and a warm/wet end member in Puerto Rico; in between, temperature and rainfall increase to the south through New York, Pennsylvania, Virginia, Tennessee and Alabama. Soil depth and geochemisty were measured both on ridgetop positions (where water flow is largely vertical through the soil profile) and on slope positions (where water moves both vertically and laterally downslope). The depth of ridgetop soils increases from north to south along the climate gradient, with shallow soils (~ 30 cm) in Wales and Pennsylvania and increasingly deep soils to the south (394 cm in Tennessee). Similarly, the extent of chemical depletion in ridgetop surface soils increases from <20% elemental depletion in the north to 100% depletion of some elements in the south. Soil depths on slopes, however, do not vary much along the transect and range from 52–86 cm across the Appalachian sites. In these slope soils the extent of weathering is similar across the Appalachian study sites; Mg, K and Al, for example, are ~40% depleted at the soil surface at all of the study sites. One working hypothesis based on limited quantitiative assessments of regolith age in the Appalachians suggests that ridgetop and slope soils may be more or less the same age. In this model, the increasing ridgetop soil thickness along the transect is a function of warmer and wetter climate to the south. In slope positions, however, where downslope water flow leads to decreased fluid residence time, thinner and less weathered soils are observed. Alternately, southern soils are much older than northern soils due to impacts of the Last Glacial Maximum and similar erosion rates across the study region have left an eroded mantle of uniform thickness on top of bedrock slopes.

Petrochemical characterization of the basalts and rhyolites erupted along the central axis of the Main Ethiopian rift

ROSANNA DE ROSA[1]*, CARMELO FERLITO[2], EUGENIO NICOTRA[1,2] AND PAOLA DONATO[1],

[1]Università della Calabria, Via P. Bucci 15/B, 87036 Arcavacata di Rende (CS), Italy. (derosa@unical.it)
[2]Università di Catania, Corso Italia 57, 95129 Catania, Italy

In continental domain rift zones are the sites of the most extensive magma production. The opening of continental rifts and their consequent oceanization are accompanied by the intrusion and emission of magmas. The relationship between the timing and style of the rift opening and the type of magma associated is still not fully understood. The Main Ethiopian Rift (MER) represents one of the most active continental rifts in which the volcanic activity has produced basaltic flows from fissural eruptions and rhyolitic central volcanoes. In order to characterize the products cropping out within the northern and central branches of the MER, we have carried out an extensive sampling of lava flows, monogenetic scoria cones and obsidianaceous central edifices (Fantale, Kone, Boseti). On the collected samples major and trace elements analysis and mineralogical and petrographic observations have been performed. Preliminary data confirm a close relationship between geochemical composition and the morphology of the volcanic edifices and structures. In particular, central edifices present a rather homogeneous rhyolitic compositions, whereas recent fissural activity is dominated by basaltic lava fields. These two distinct types of products occur along en-echelon tectonic segments, located within the central portion of each branch of the rift. Branches are joined by transitional areas, in which monogenetic scoria cones with the most primitive compositions crop out. The chemical data have been used to model the features of the magma sources and the processes affecting magmas during their ascent towards the surface.

Metal mobility in hydrothermal fluids: experimental investigations

I. T. DERREY*, R. E. BOTCHARNIKOV, M. ALBRECHT, I. HORN, S. WEYER AND F. HOLTZ

Institut für Mineralogie, Leibniz Universität Hannover, GER (*correspondence: i.derrey@mineralogie.uni-hannover.de)

Hydrothermal fluids are crucial in the formation of ore deposits, as they are the main transport medium leading to the selective concentration of elements in the Earth's crust and, among others, metals of economic interest. Fluid inclusions in minerals do not just enable us to probe natural fluids from depth, but also provide an opportunity to investigate fluids in high P/T experiments [1]. With the development of LA-ICP-MS techniques it has become possible to analyze major, minor and trace element concentrations in fluid inclusions [2].

Thus, synthetic fluid inclusion studies are an ideal tool to study metal transport and partitioning in hydrothermal fluids and to provide key data necessary for the quantification of transport properties. Partly due to difficulties in producing decent sized synthetic fluid inclusions at low temperatures, previous studies were mostly focused on conditions above. By combining the two current methods of host mineral pretreatment (thermal cracking [1] and HF etching [3]), we are able to synthesize fluid inclusions in quartz with a size in excess of 20 μm at T down to at least 400 °C. This gives us the opportunity to study the conditions and processes responsible for the mobility of metals at low temperatures. Experiments are conducted in cold seal pressure vessels at T=400-600 °C and P up to 200 MPa with the aim to unravel the transport and partitioning of metals occurring in porphyry copper deposits.

We have been implementing a new technique to analyze fluid inclusions by LA-ICP-MS, which is based the combination of a femtosecond laser with a heating-freezing cell and a sectorfield ICP-MS. During the ablation with a fs-laser the inclusion remains frozen until entirely evaporated, resulting in a considerably longer signal analysis time. This allows reducing the analytical error on the analyzed element concentrations.

Results for Au and Mo solubility in fluids of varying composition obtained at different P and T will be presented. Preliminary data indicate that solubilities of Mo are higher than expected if extrapolated from high T data of [4].

Resolvong inconsistent sedimentary carbon mass balances: Implications for ancient C and S cycles

L. A.DERRY[1]

[1]Dept. of Earth & Atmosphierc Sciences, Cornell University, Ithaca NY USA (derry@cornell.edu)

Inventory and isotope mass balance estimates of the organic carbon/∑carbon ratio (X_{org})of the upper crust (dominated by sediments) appear to differ systematically. Inventory-based estimates yield $X_{org} \approx 0.10$ to 0.17, while $\delta^{13}C$ mass balance estimates are 0.19 to 0.34. The $\delta^{13}C$ mass balance approach typically assumes a steady state form $\delta_{in} = f_{org}^{bur}\delta_{org} + f_{carb}^{bur}\delta_{carb}$, where f_{org}^{bur} is the burial fraction of organic carbon. Over long times the time integrated value of f_{org}^{bur} should approach the value of X_{org}, and δ_{in} should approach the mean $\delta^{13}C$ value of the upper crust. If the inventory-based estimates of X_{org} are approximately correct, the isotope mass balance approach as conventionally applied cannot be. Two modifications to the $\delta^{13}C$ mass balance can reconcile the discrepancy. First, increasing data indicates that even in the modern environment with $pO_2 = 0.21$, the oxidation of old carbon is incomplete [1]. Second, a substantial fraction of carbon is returned to the ocean-atmosphere system as isotopically depleted CH_4 [2]. At low pO_2 though to be characteristic of the Precambrian, the oxidative weathering efficiency of kerogen was lower, implying a larger fraction of C recycling via methanogenesis. In that case the revised steady state isotopic mass balance implies both lower absolute and fractional burial rates of sedimentary organic carbon than for Phanerozoic conditions. The generation and oxidation of CH_4 was a dominant term in the organic carbon mass balance at low pO_2. Model results show that large CH_4 fluxes result in low steady state marine SO_4 levels via AOM, consistent with inferences from $\delta^{34}S$ studies of Proterozoic sediments [3].

Pb-Zn-Cd-Hg multi isotopic characterization of the Loire River Basin, France

A.M. DESAULTY[1], R. MILLOT[1], D. WIDORY[1,2], C. GUERROT[1], C. INNOCENT[1], X. BOURRAIN[3], G. BARTOV[4] AND T.M. JOHNSON[4]

[1]BRGM, Laboratory Division, Orléans, France (*correpondance : am.desaulty@brgm.fr)
[2]UQAM/GEOTOP, Earth Atm. Sci. Dept., Montréal, Canada
[3]Agence de l'Eau Loire Bretagne, Orléans, France
[4]University of Illinois, Department of Geology, Urbana, USA

The Loire River in Central France is approximately 1010 km long and drains an area of 117 800 km^2. Upstream, the Loire river flows following a south to north direction from the Massif Central down to the city of Orléans, 650 km from its source. The Loire River is one of the main European riverine inputs to the Atlantic Ocean. Over time, its basin has been exposed to numerous sources of anthropogenic metal pollutions, such as metal mining, food industry, agriculture and domestic inputs. The Loire River basin is thus an excellent study site to develop new isotope systematics for tracking anthropogenic sources of metal pollutions.

We have chosen to analyze the isotope composition of cadmium (Cd), zinc (Zn), mercury (Hg) and lead (Pb). These heavy metals have been chosen for their toxicity, even at low levels, to humans. The main goal of this study is to characterize 1) the sources and behavior of these heavy metals in the aquatic environment, and 2) their spatial distribution using a multi-isotope approach. Sources responsible for the release of Pb-Zn-Cd-Hg in the Loire basin were sampled and analysed for their concentrations and corresponding isotope compositions. We also analyzed river waters and suspended solids samples, known to play an important role in the transport of heavy metals through river systems. Biota samples (mussels, oysters), as natural accumulators of metal pollutants, were also analyzed.

All trace elements were analysed in the BRGM laboratories using a Q-ICPMS. Pb-Zn-Cd isotope compositions were measured using a Neptune MC-ICPMS at the BRGM. Hg isotope compositions were measured at the U. of Illinois using a Nu Plasma MC-ICPMS. To analyse Zn and Cd, we carried out a two-steps analytical development: 1) a chromatographic separation, followed by 2) analysis on the MC-ICPMS.

The results showed that, on their own, each of these isotope systematics reveals important information about the geogenic or anthropogenic origin of these metals. Considered together, they are however providing a more integrated understanding of the overall budgets of these pollutants at the scale of the Loire River Basin.

Swelling induced by alpha decay in monazite and zirconolite ceramics: a XRD and TEM comparative study.

X. DESCHANELS[1], A.M. SEYDOUX-GUILLAUME*[2], V. MAGNIN[3], A. MESBAH[1], M. TRIBET[4], S. PEUGET[4]

[1] ICSM, UMR 5257, BP 17171, 30207 Bagnols-Sur-Cèze, France.
[2] GET, CNRS-UPS-IRD, Université De Toulouse, 14 Av E. Belin, 31400 Toulouse, France.
[3] Isterre, UMR5275 CNRS, Université Joseph Fourier, 38041 Grenoble, France.
[4] CEA/DTCD/LMPA Centre De Marcoule, BP 17171, 30207 Bagnols-Sur-Cèze, France.

Zirconolite and monazite are potential ceramics for the containment of actinides (Np, Cm, Am, Pu) produced by reprocessing spent fuel. Alpha decay is the main disintegration mode for actinide elements. This phenomena induces structural changes on the ceramics (amorphisation, swelling…). In order to study these effects two parallel approaches based on external irradiations and short-lived actinides doping (^{238}Pu) were used. On one hand, plutonium oxide was incorporated into the monazite and the zirconolite structure. On the other hand, external irradiations with Au ions were used to simulate energy deposits corresponding to the recoil nucleus.

For both irradiations, zirconolite samples become amorphous at room temperature for a critical dose close to 0.3 dpa and the magnitude of the swelling at saturation is similar (about 6%). Ballistic processes are predominant in the damaging of this structure. On the contrary the swelling and the amorphisation of monazite sample depend on the nature of the irradiation. Ion irradiated samples present a saturation swelling close to 7% and are metamict for a critical dose close to 0.3 dpa while the swelling measured on ^{238}Pu doped samples is only 2% and they remain crystalline up to 7.5 x $10^{18}\alpha$/g, i.e. 0.7 dpa. The different behavior observed between doped and externally irradiated monazite samples can be interpreted in terms of annealing effects induced by ionizing radiation. The ratio electronic-to-nuclear stopping seems to be a key parameter for the damage recombinaison in monazite. Evidence of alpha annealing is observed on the monazite structure.

Timescales of partial melting and UHP exhumation, Papua New Guinea

DESORMEAU, J.W.[1], GORDON, S.M.[1], LITTLE, T.A.[2], BOWRING, S.A.[3]

To understand how crustal rocks are subducted to mantle depths and subsequently exhumed, it is crucial to determine the relative timing and relationship of the host migmatites to the UHP–HP eclogites. The Pliocene UHP terrane of southeastern Papua New Guinea (PNG), exposes large areas of migmatitic gneiss within domal structures found throughout the D'Entrecasteaux Islands, including Goodenough, Fergusson, and Normanby Islands. These gneisses reveal abundant evidence for partial melting during exhumation. Zircons analyzed using U-Pb chemical abrasion thermal ionization mass spectrometry (CA-TIMS) geochronology from eclogite suggest UHP metamorphism began at ca. 5 Ma, and Ar-Ar thermochronology indicates exhumation of the rocks to the surface by ca. 2 Ma. To evaluate the role of partial melting in the exhumation of this UHP terrane, U-Pb CA-TIMS geochronology was applied to zircons separated from multiple leucosomes and dikes across the three islands. Previous U-Pb results from the UHP locality and other parts of the western Fergusson Island dome reveal melt-present deformation in the form of foliation-parallel leucosomes with crenulated margins that formed from ca. 3.5–3.0 Ma and weakly-deformed cross-cutting dikes at ca. 2.4 Ma. In comparison, zircons from a similarly deformed foliation-parallel leucosome within Goodenough dome to the west reveal melt crystallization from ca. 4.7–2.7 Ma. The youngest igneous rocks are felsic non-deformed intrusions which contain zircons as young as ca. 1.8 Ma. Finally, in the south, Normanby dome records the development of the host orthogneiss by ca. 5.9 Ma and emplacement of deformed granodiotite sills by ca. 4.1 Ma. Zircons from non-deformed granodioritic and andesitic dikes yield similar crystallization ages to Goodenough Island, with zircons as young as 1.8 Ma. The emplacement of the gneiss domes within the upper crust occurred by ca. 1.9–1.8 Ma, based on the late dikes, and is similar across the entire PNG UHP–HP terrane. The results indicate that exhumation of the PNG UHP–HP terrane was aided by multiple stages of partial melting that increased the overall bouyancy of the subducted crustal material.

Silicon stable isotope constraints on the pathways of thermocline nutrient replenishment

G. F. DE SOUZA*, R. D. SLATER AND J. L. SARMIENTO

Program in Atmospheric and Oceanic Sciences, Princeton University, Princeton, New Jersey, USA (*correspondence: gfds@princeton.edu)

The continued action of the ocean's biological carbon pump, driven by photosynthetic productivity at its sunlit surface, is contingent upon the supply of nutrients from the nutrient-rich abyss to the permanent thermocline. Increasingly compelling evidence implicates the Southern Ocean in this replenishment of thermocline nutrients, via the wind-driven upwelling of deep waters and the subduction of Subantarctic Mode Water (SAMW) to the base of the permanent thermocline [1].

The recent modelling study of Palter *et al*.. [2] estimated that SAMW supports between 33% and 75% of photosynthetic productivity at low latitudes, a range that hinges upon uncertainties in the pathways of the meridional overturning circulation (MOC). A novel opportunity to reduce this uncertainty is presented by the oceanic distribution of the stable isotope composition of silicic acid in seawater, δ^{30}Si. It has been argued by de Souza *et al*.. [3,4] that the oceanic δ^{30}Si distribution, and particularly the meridional gradient in Atlantic deep water δ^{30}Si values, provides strong support for a dominant Southern Ocean supply of silicic acid to the thermocline. Here, we combine these novel data constraints with a suite of ocean general circulation models in order to provide improved quantitative estimates of the importance of the SAMW contribution to the thermocline nutrient inventory.

Model variants that upwell a greater proportion of deep water within the Southern Ocean produce a more pronounced Atlantic deep water δ^{30}Si gradient, a result that provides further support for the importance of nutrients supplied by the Southern Ocean in maintaining low-latitude productivity. More broadly, these results pertain to the role of the Southern Ocean in the closure of the MOC, and ultimately to the driving mechanisms thereof [5].

Dynamic of organic carbon in small volcanic mountainous tropical watersheds (Guadeloupe, FWI)

C. DESSERT[1,2], E. LLORET[3], M.F. BENEDETTI[1], E. LAJEUNESSE[1,2], O. CRISPI[2] AND J. GAILLARDET[1]

[3]Department of Renewable Resources, University of Alberta, Canada (lloret@ualberta.ca)

In the tropical zone, small mountainous watersheds are affected by intense meteorological events. If the increase of the frequency and/or intensity of these extreme meteorological events (storms, cyclones) is confirmed [1, 2], it could lead to an increase of the export of dissolved and suspended material derived from soils.

We studied the geochemistry of three small watersheds around the Basse-Terre volcanic Island (FWI) during a four years period, by measuring dissolved organic carbon (DOC) and particulate organic carbon (POC) concentrations [3]. The mean annual yields range between 1.9-8.6 tC km^{-2} yr^{-1} and 8.1-25.5 tC km^{-2} yr^{-1} for DOC and POC, respectively. Floods and extreme floods account for 43% of the yearly water flux and represent 55% of the annual DOC flux, and more than 85% of the annual POC flux. These results show that organic carbon fluxes are largely underestimated if high temporal resolution sampling is not performed.

The important carbon export in Guadeloupe is induced by high intensity of precipitation leading to high runoff, high slopes, and high organic matter contents in Andosols and ferralitic soils. Even if the surface of volcanic and mountainous tropical islands is low compared to continental area, organic carbon yields in this specific context are so important that this surface can represent a significant proportion of the global annual carbon export. This total export is estimated to 2.4 ±0.6 MtC yr^{-1} for DOC and at 5.9 ±2.4 MtC yr^{-1} for POC. In addition, the quality of terrestrial organic matter (POC/DOC and C/N ; slightly degraded) arriving to the ocean is different from the one of large tropical river origin.

Our results show that tropical volcanic islands are significant pools of organic carbon for oceans and the effect on global carbon budget is still a matter of debate.

CO_2 injection into submarine, CH_4-hydrate bearing sediments: geochemical implications of a hydrate conversion technology

C. DEUSNER, E. KOSSEL, N. BIGALKE, M.G. GHARASOO, AND M. HAECKEL

GEOMAR Helmholtz Centre for Ocean Research Kiel, Wischhofstr.1-3, D-24148, Kiel, Germany

With the aim of emission neutral energy production, combined CH_4-hydrate exploitation from and CO_2 storage in marine gas hydrate reservoirs is investigated. Little is known about the geochemistry of hydrates and their host sediments before, during and after production. Results from the recent *Ignik Sikumi* gas hydrate field trial have indicated that the injection of a CO_2-rich fluid into the hydrate reservoir produces mixed hydrates in a slow conversion process. This and the awareness of potential effects of natural and technically induced heterogeneity drives the ambition to understand hydrate conversion on the pore scale.

Our recent studies suggest that the injection of heated, supercritical CO_2 is beneficial for both CH_4 production and CO_2 retention at different hydrate reservoir temperatures ranging from 2 °C to 10 °C [1]. Yet, our findings can only be explained by the induction of a variety of spatial and temporal processes which result in substantial bulk heterogeneity, characterized by formation of mixed CO_2-CH_4-hydrates, hold-up of hydrate-derived CH_4 gas in pore spaces, permeability changes and temperature dependent CO_2-channeling. Interestingly, while CH_4 production and CO_2 retention yields varied considerably between different experiments, water production was largely similar. Using online IR-based sensor technology and Raman spectroscopy, distinct intervals of water and gas production could be identified, which suggest, that the slow formation of CO_2- or mixed CO_2-CH_4-hydrates was responsible for increased CH_4 production yields. Additional Magnetic Resonance Imaging (MRI) experiments were performed to visualize the intrusion of liquid CO_2 into the sediment/hydrate matrix.

It is a central objective of our studies to improve available transport-reaction models and strengthen the link between pore scale and reservoir modelling, by finding empirical relations suitable for implementation in current numerical simulators.

Isotopic and stoichiometric constraints on marine denitrification from a global inverse circulation model

C. DEUTSCH[1*], T. DEVRIES[1], P. RAFTER[2] AND F.PRIMEAU[3]

[1]Department of Atmospheric and Oceanic Sciences, University of California, Los Angeles, CA, USA
[2]Departamento of Geosciences, Princeton University, Princeton, New Jersey, USA
[3]Department of Earth System Sciences, University of California, Irvine, USA

A major impediment to understanding long-term changes in the marine nitrogen (N) cycle is the persistent uncertainty about the rates, distribution, and sensitivity of its largest fluxes in the modern ocean. We use a global ocean circulation model to obtain the first 3-dimensional estimate of marine denitrification rates that is maximally consistent with available observations of nitrate deficits and the nitrogen isotope ratio of oceanic nitrate. We find a global rate of marine denitrification in suboxic waters and sediments of 120–240 TgN/yr, which is lower than many other recent estimates. The difference stems from the ability to represent the spatial structure of suboxic zones, where denitrification rates of 50–77 TgN/yr result in up to 50% depletion of nitrate. This depletion reduces the effect of local isotopic enrichment on the rest of the ocean, allowing the N isotope ratio of oceanic nitrate to be achieved with a sedimentary denitrification rate about 1.3–2.3 times that of suboxic zones. This balance of N losses between sediments and suboxic zones is shown to obey a simple relationship between isotope fractionation and the degree of nitrate consumption in the core of the suboxic zones. The global denitrification rates derived here suggest that the marine nitrogen budget is likely close to balanced.

Little attention has been given to Holcene pre-anthropogenic dust records in terrestrial environments, especially in the Southern Hemisphere. Yet they are important to 1/ better understand the different particle sources during the Holocene and 2/ to tackle the linkage between atmospheric dust loads and climate change and 3/ to better understand the impact of dust on Holocene palaeoclimate and palaeoenvironments in a critical area for ocean productivity. In the PARAD project, we explore the use of a broad range of trace elements and radiogenic isotopes (Pb, Nd) as dust proxies. By coupling these findings with biological proxies (plant macrofossils) and detailed age-depth modelling, we expect to identify and interpret new links between atmospheric dust chemistry and climate change. In this contribution, we will present the elemental and isotopic signatures of two peat records from Chilean and Argentinean Tierra del Fuego, covering the Holocene. We provide here the first high-resolution dust flux records for the Southern South American Holocene. Results will also encompass density, ash content, grain size analyses, macrofossil determination and radiocarbon age modelling. Preliminary linkage of dust fluxes with change in vegetation and climate can be seen in our results. Single dust peaks originate from volcanic events while others are to be explained by regional to long range dust transport from Southern South dust source (local soils, glaciers, fluvioglacial plains, dry lakes and valleys and perhaps, pampa materials).

High performance reactive transport simulation of hyperalkaline plume migration in fractured rocks

L.M. De Vries[1*], J. Molinero[1], H. Ebrahimi[1], U. Svensson[2] and P. Lichtner[3]

Integration of hydrogeology and geochemistry is crucial for several problems in Earth Sciences and Engineering. One of the challenges for such integration is the large amount of computational resources needed due to the high non-linearity of the resulting system of equations. Taking advantage of new developments of powerful numerical tools, and based on high performance parallel computing, the solution of regional-scale hydrogeochemical models has become possible. A software solution, denoted iDP, has been developed which serves as an interface between DarcyTools [1] and PFLOTRAN [2]. The project is financed by SKB, the Swedish Nuclear Fuel and Waste Management Company. iDP has been applied for the first time in the Mare Nostrum III, a new facility of the Barcelona Supercomputing Centre. A total of 25,000 processor cores during 5 days were used to solve a large-scale (100 Mcells), long-term (10,000 years) simulation of the hydrogeochemical behaviour of an hyperalkaline plume produced by the dissolution of grout used during the construction of a deep geological repository for spent nuclear fuel. The simulation integrates the complex 3D groundwater flow accounting for the Discrete Fracture Network (DFN) of the site, and the complexity of the geochemical system involved in cement grout dissolution and secondary minerals precipitation within the flowing fractures.

Method development and validation for B isolation from Roman glass

V. DEVULDER[1,2*], P.DEGRYSE[1] AND F. VANHAECKE[2]

[1] Katholieke Universiteit Leuven, Celestijnenlaan 200E, Heverlee, Belgium (*correspondence:Veerle.Devulder@ees.kuleuven.be) (Patrick.Degryse@ees.kuleuven.be)

[2] Ghent University, Krijgslaan 281-S12, Gent, Belgium (Frank.Vanhaecke@ugent.be)

The provenancing of the raw materials used in Roman glass production is of great interest in archaeological sciences as the corresponding information can give more insight into the trade routes in ancient times and the glass manufacturing process. Glass is made from sand as silica source and natron as a flux. The major source of this flux is thought to be the evaporites from the Wadi Natrun region in Egypt. This assumption is mainly based on the writing of Pliny the Elder, a Roman author, and some geochemical evidence [1]. However, Pliny also mentions other sources [2]. But until now, no unambiguous evidence exists for the exploitation of other natron sources for glass production in the Roman empire. The isotopic composition of B, determined by means of multi-collector ICP-MS (MC-ICP-MS), might provide this valuable information as B is introduced into the glass with the flux and different flux sources (i.e. lakes) can have different B isotopic signatures. Therefore, a method for isolation of B from archaeological glass was developed and validated. After sample dissolution, B is isolated via a two-step separation process, based on the use of a strong cation and an anion exchange resin. Only Sb (which is used as decolorizer or opacifier) was not completely separated from B, but its presence did not exert a significant influence on the $\delta^{11}B$ determination. The sample preparation method and some first sample results will be presented.
