33 **Abstract**

34 COVID-19 vaccine effectiveness (VE) studies are limited in low- and middle-income
35 countries. A case-control study was conducted among COVID-19 and other pneumonia
36 patients admitted to a hospital in the Philippines during the pre-Omicron and Omicron
37 periods. To elucidate factors associated with in-hospital death, 1782 COVID-19 patients were
38 assessed. To estimate absolute VE for various severe outcomes, 1059 patients were assessed
39 (869 [82.1%] COVID-19 cases; 190 [17.9%] controls). Factors associated with in-hospital
40 death included older age, tuberculosis (adjusted odds ratio [aOR] 2.45 [95% confidence
41 interval {95%CI} 1.69–3.57]), HIV (aOR 3.30 [95%CI 2.03–5.37]), and current smokers
42 (aOR 2.65 [95%CI 1.72–4.10]). Pre-Omicron, the primary series provided high protection
43 within a median of 2 months (hospitalization: 85.4% [95%CI 35.9–96.7%]; oxygen
44 requirement: 91.0% [95%CI 49.4–98.4%]; invasive mechanical ventilation (IMV): 97.0%
45 [95%CI 65.7–99.7%]; death: 96.5% [95%CI 67.1–99.6%]). During Omicron, the primary
46 series provided moderate-high protection within a median of 6–9 months (hospitalization:
47 70.2% [95%CI 27.0–87.8%]; oxygen requirement: 71.4% [95%CI 29.3–88.4%]; IMV: 72.7%
48 [95%CI -11.6–93.3%]; death: 58.9% [95%CI -82.8–90.8%]). Primary series VE against
49 severe COVID-19 outcomes was consistently high for both pre-Omicron and Omicron in a
50 setting where approximately half of vaccinees received inactivated vaccines.

51 **Main text**

52 **Introduction**

53 Coronavirus disease (COVID-19), caused by severe acute respiratory syndrome coronavirus
54 2 (SARS-CoV-2), has resulted in substantial morbidity and mortality globally.¹ Once the
55 COVID-19 vaccines were rolled out based on trial results,²⁻⁷ there was a need to monitor the
56 real-world effectiveness of the vaccines (vaccine effectiveness; VE), given concerns due to
57 waning immunity and the emergence of variants with immune escape capacity.⁸⁻¹² There have
58 been numerous studies to evaluate VE, mostly from high-income countries (HICs), but the
59 evidence is very limited in low- and middle-income countries (LMICs). This is especially
60 true for Southeast Asia (specifically, the Western Pacific Region) and Africa.¹³ It was
61 considered valuable for more LMICs, especially low- and lower-middle income countries, to
62 conduct VE studies for several reasons, including: (1) vaccines rolled out in LMICs differed
63 from HICs; (2) cold chain breach may be more likely in LMICs (e.g., some vaccines required
64 ultra-cold temperatures); (3) cumulative infection burdens were considered much higher in
65 LMICs and this may affect VE estimates (e.g., individuals with prior infection are protected
66 against subsequent infection/disease); (4) substantial variation in public health and social
67 measures among countries, which may also affect VE estimates; (5) VE results in local or
68 regional contexts may result in further vaccine confidence within and among surrounding
69 countries; and (6) capacity building to conduct operational research to inform public health
70 response for COVID-19 as well as future epidemics and pandemics. Also, specifically for
71 inactivated vaccines, which were widely rolled out in LMICs, VEs against hospitalization
72 outcomes from previous reports were highly varied, and data against the Omicron variant is
73 especially limited.¹³⁻¹⁴ This variability in hospitalization outcomes may be due to different
74 criteria for hospitalization and incidental diagnosis of SARS-CoV-2 infection during routine
75 admission screening.¹⁵⁻¹⁶ This can potentially result in lower VE estimates against severe

76 disease due to generally lower VE against infection than against severe disease.^{13,15,16}
77 Therefore, we conducted a study to elucidate factors associated with in-hospital death among
78 SARS-CoV-2-positive hospitalized patients and to evaluate COVID-19 VE against
79 hospitalization in the Philippines during the pre-Omicron and Omicron periods. For VE
80 estimates, we used various outcomes, including more severe and specific outcomes such as
81 oxygen use and invasive mechanical ventilation use.

Accepted Manuscript

82 **Methods**

83 *Study design and setting*

84 Our study, ‘Moderate-to-severe diseases requiring Oxygen Therapy, Intubation, and
85 Ventilation And The Effectiveness of COVID-19 vaccines in the Philippines’ (MOTIVATE-
86 P study), is a single-center study at San Lazaro Hospital (SLH) in Manila with two
87 objectives: (1) to elucidate factors associated with in-hospital death among SARS-CoV-2-
88 positive hospitalized patients; and (2) to estimate the real-world effectiveness of COVID-19
89 vaccines against severe disease. Outside the context of the COVID-19 pandemic, SLH is a
90 government-retained specialty referral hospital for infectious diseases. During the COVID-19
91 pandemic, SLH routinely admitted patients with COVID-19 and pneumonia caused by other
92 pathogens and routinely tested individuals admitted using polymerase chain reaction (PCR)
93 for clinical diagnostic and screening purposes.¹⁷ It has also been functioning as one of the
94 main COVID-19 response sites in the country. We followed the same design as a study
95 conducted and published previously by some of the authors in Japan.¹⁵

97 *Study period*

98 The study period was between 1 March 2021 (when the COVID-19 vaccination rollout
99 started in the Philippines) and 31 March 2023 (before Omicron subvariant XBB became
100 dominant). Based on genomic surveillance data, the Omicron variant was first detected in the
101 Philippines in November 2021 and quickly replaced the Delta variant (**Figure 1**).¹⁸
102 Therefore, we defined 1 March to 31 October 2021 as the pre-Omicron (Alpha, Gamma,
103 Delta) period and 1 November 2021 to 31 March 2023 as the Omicron period. In the
104 Philippines, the primary series (one dose for Janssen and two doses for all other vaccine
105 types) rollout started on 1 March 2021.¹⁹ The primary series followed manufacturer-
106 recommended intervals. The first booster dose rollout began on 16 November 2021 for

107 healthcare workers (HCWs), on 22 November 2021 for senior citizens and
108 immunocompromised persons, and on 3 December 2021 for all adults aged 18 years or
109 above. The second booster dose rollout started on 25 April 2022 for HCWs and individuals
110 who were ≥ 60 years old and on 27 July 2022 for individuals who were ≥ 50 years old and
111 individuals aged 18–49 years with comorbidities.

112

113 *Inclusion and exclusion criteria*

114 The inclusion criteria were SARS-CoV-2-positive hospitalized patients and SARS-CoV-2-
115 negative hospitalized pneumonia patients. Pneumonia caused by tuberculosis was not
116 included as the clinical presentation would be different from the one caused by COVID-19
117 pneumonia or common bacterial pneumonia with acute onset. Patients were excluded for the
118 following reasons: symptom onset during hospitalization; tested ≥ 15 days before or ≥ 15 days
119 after admission; and unknown test date.

120

121 *Data collection*

122 Data, including outcomes, were collected via a review of medical charts and other relevant
123 hospital documents by trained research nurses. Vaccination status (number of doses, vaccine
124 type [e.g., manufacturer], and vaccination dates) was recorded from the medical charts, case
125 investigation form (CIF), and/or other relevant hospital documents and checked for
126 plausibility. The CIF was a form that was required to be completed when conducting SARS-
127 CoV-2 testing during the study period and was generally filled out by referencing the
128 vaccination card. To ensure the quality of data entry, ten charts were randomly selected soon
129 after the initiation of the study, entered by two different nurses, and checked for consistency.

130

131 *Data description and analysis of factors associated with in-hospital death among SARS-CoV-*
132 *2-positive hospitalized patients*

133 Characteristics of SARS-CoV-2-positive hospitalized patients admitted during the study
134 period were described overall and by pre-Omicron and Omicron period. Logistic regression
135 was used to estimate the factors associated with in-hospital death. The model was adjusted
136 for age group (categorical), sex, risk score categories (0, 1, 2, 3-4, 5+; categorical [detailed
137 later]), calendar week of hospitalization (biweekly), and vaccine doses (except for the factor
138 of interest). The risk score for severe disease developed in a study published by some of the
139 authors in Japan was incorporated as a covariate.^{15,20,21} Here, we assigned 2 points for the
140 presence of either diabetes mellitus, chronic kidney disease (CKD), dementia, Down
141 syndrome, or obesity and assigned 1 point for the presence of cardiovascular disease
142 (including hypertension), dyslipidemia, chronic liver disease, chronic obstructive pulmonary
143 disease, cancer, depression/schizophrenia, stroke, tuberculosis, immunocompromised
144 condition (HIV infection or other immunodeficiency, or immunosuppressant use), pregnancy
145 while hospitalized, or overweight; the points were added up to calculate the risk score for
146 each patient.

147

148 *Additional exclusion criteria for VE analysis*

149 For the VE analysis, patients were further excluded for the following reasons: being <50
150 years of age, past SARS-CoV-2 infection (based on medical chart review), and (for controls)
151 diagnosis of pneumococcal pneumonia or influenza. The rationale for including patients who
152 were tested up to 14 days before admission and excluding those who were tested ≥ 15 days
153 before admission is that it takes from a few days to 2 weeks from symptom onset for patients
154 to develop severe disease, and these patients may be tested right after onset and later
155 hospitalized. The rationale for restricting to individuals ≥ 50 years of age was to aim for better

156 internal validity among those most at risk of severe COVID-19, and because individuals aged
157 50 years and above were eligible for the second booster. This, we considered, would allow us
158 to reduce confounding through different socioeconomic factors and vaccine prioritization.
159 Finally, co-circulation of influenza and COVID-19 can result in biased VE estimates as the
160 propensity to get vaccinated may be similar for COVID-19 and influenza vaccines.²² In
161 theory, the same concern applies to *Streptococcus pneumoniae* pneumonia and pneumococcal
162 vaccination. Therefore, we excluded patients with pneumococcal pneumonia or influenza.

163

164 *Estimation of vaccine effectiveness*

165 Patients who tested positive before or after admission based on the above inclusion and
166 exclusion criteria were defined as cases; other pneumonia patients who tested negative before
167 or after admission based on the above criteria were defined as controls.

168 To measure absolute VE compared against the unvaccinated, we used various severe
169 outcomes. Outcomes included all COVID-19 hospitalizations, disease requiring oxygen
170 therapy, disease requiring invasive mechanical ventilation, death, outcomes restricting to
171 “true” severe COVID-19 (where oxygen requirement is due to COVID-19 rather than other
172 differential diagnoses), and progression from oxygen use to mechanical ventilation or death.

173 A “true” severe COVID-19 outcome was based on the judgment of the treating physicians
174 (chart record) and trained nurses responsible for chart review. The chart review was
175 conducted between June 2023 and May 2024 to ensure that at least 6 months had passed
176 since participants were hospitalized to allow for sufficient time to reach the final discharge
177 outcome for participants.

178 Patient characteristics for the VE analysis dataset were described first overall then by
179 case/control status. Vaccination status was classified by dose and/or time since vaccination.

180 Logistic regression was used to estimate the odds of being vaccinated among cases relative to
181 controls. The model was adjusted for age group (categorical), sex, risk score categories (0, 1,
182 2, 3-4, 5+; categorical), smoking history, and calendar week of hospitalization (biweekly).
183 These potential confounders were determined *a priori* based on published reports.^{10,15} VE
184 was estimated using the following equation: $VE = (1 - \text{adjusted odds ratio [aOR]}) \times 100\%$.
185 Data analyses were performed using STATA version 18.0.

186

187 *Ethics statement*

188 Ethics approval was obtained from the San Lázaro Hospital Research Ethics Committee.

189 Informed consent was deemed unnecessary due to the retrospective nature of the study.

Accepted Manuscript

190 **Results**

191 *Study participants*

192 A total of 1800 SARS-CoV-2-positive hospitalized patients and 637 SARS-CoV-2-negative
193 hospitalized pneumonia patients were initially included. For the description of SARS-CoV-2
194 hospitalization, after excluding 18 patients based on exclusion criteria, the final analysis
195 included 1782 patients: 1342 for the pre-Omicron period and 440 for the Omicron period
196 (**Figure 2**). For the cases in VE analysis, after further excluding 913 patients based on
197 exclusion criteria, the final analysis included 869 patients: 750 for the pre-Omicron period
198 and 119 for the Omicron period. For the controls in VE analysis, after excluding 447 patients
199 based on exclusion criteria, the final analysis included 190 patients: 55 for the pre-Omicron
200 period and 135 for the Omicron period.

201

202 *Description of SARS-CoV-2-positive hospitalized patients*

203 The median age (interquartile range [IQR]) was 53 (37–66) years for the pre-Omicron period
204 and 33 (24–54) years for the Omicron period (**Table 1**). Most individuals had at least one risk
205 factor for severe COVID-19 (1078 [80.3%] for the pre-Omicron period, 315 [71.6%] for the
206 Omicron period). The majority of individuals received oxygen therapy (1299 [72.9%]), and
207 some received invasive mechanical ventilation (263 [14.8%]). Most individuals improved
208 and discharged (1074 [80.0%] for the pre-Omicron period and 320 [72.7%] for the Omicron
209 period) (**Table 1**). However, in-hospital death occurred in 252 (18.8%) for the pre-Omicron
210 period and 114 (25.9%) for the Omicron period.

211

212 *Factors associated with in-hospital death among SARS-CoV-2-positive hospitalized patients*

213 Among hospitalized cases, older age was associated with in-hospital death in an incremental
214 manner (compared to individuals who were in their 20s; adjusted odds ratio [aOR] for 40s:

215 2.03 [95% confidence interval {CI} 1.11–3.71]; aOR for 50s: 2.01 [95% CI 1.10–3.65]; aOR
216 for 60s: 2.94 [95% CI 1.10–3.65]; aOR for 70s: 4.54 [95% CI 2.43–8.46]; aOR for 80s: 4.96
217 [95% CI 2.43–10.1]; aOR for <10 years of age: 0.31 [95% CI 0.10–0.97]; p-value for trend:
218 $p < 0.001$) (**Table 1**). Other factors associated with in-hospital death included male sex (aOR
219 1.60 [95% CI 1.17–2.17]); the comorbidities of chronic kidney disease (aOR 4.39 [95% CI
220 1.52–12.67]), tuberculosis (aOR 2.45 [95% CI 1.69–3.57]), and HIV infection (aOR 3.30
221 [95% CI 2.03–5.37]); hospitalization in the past year (aOR 3.38 [95% CI 2.01–5.67]); and
222 current smoker (aOR 2.65 [95% CI 1.72–4.10]) (**Table 1**).

223

224 *Baseline characteristics for the vaccine effectiveness analysis*

225 The median age (interquartile range [IQR]) was 64 (57–71) years for the pre-Omicron period
226 and 64 (57–72) for the Omicron period, and it was similar between cases and controls (**Table**
227 **2**). Most individuals had at least one risk factor for severe COVID-19 (716 [88.9%] for the
228 pre-Omicron period, 228 [89.8%] for the Omicron period). During the pre-Omicron period,
229 118 (56.7%) received CoronaVac (SinoVac), 43 (20.7%) received AZD1222 (AstraZeneca),
230 24 (11.5%) received Ad26.COV2.S (Janssen/J&J), 10 (4.8%) received BNT162b2 (Pfizer), 7
231 (3.4%) received mRNA-1273 (Moderna), and 2 (1.0%) received Sputnik V (Gameleya), with
232 4 (1.9%) unknown (**Table 2**). During the Omicron period, for the primary series, 72 (49.3%)
233 received CoronaVac (SinoVac), 23 (15.3%) received AZD1222 (AstraZeneca), 18 (12.3%)
234 received BNT162b2 (Pfizer), 18 (12.3%) received Ad26.COV2.S (Janssen/J&J), 10 (6.9%)
235 received mRNA-1273 (Moderna), 1 (0.7%) received Sputnik V (Gameleya), and 1 (0.7%)
236 received BBIBP-CorV (Sinopharm), with 3 (2.1%) unknown (**Table 2**). For the first booster,
237 14 (48.3%) received BNT162b2 (Pfizer), 6 (20.7%) received AZD1222 (AstraZeneca), and 5
238 (17.2%) received mRNA-1273 (Moderna), with 4 (13.8%) unknown. For the second booster,

239 3 (75.0%) received BNT162b2 (Pfizer), and 1 (25.0%) received mRNA-1273 (Moderna)
240 (none were unknown).
241
242 *Vaccine effectiveness against all COVID-19 hospitalization, COVID-19 requiring oxygen*
243 *therapy, COVID-19 requiring mechanical ventilation, and fatal COVID-19*
244 During the pre-Omicron period, VE estimates for 2 doses were 85.4% (95% CI 35.9–96.7%)
245 against all COVID-19 hospitalization, 91.0% (95% CI 49.4–98.4%) against COVID-19
246 requiring oxygen therapy, 97.0% (95% CI 65.7–99.7%) against COVID-19 requiring
247 invasive mechanical ventilation, and 96.5% (95% CI 67.1–99.6%) against fatal COVID-19
248 (**Table 3**). During the Omicron period, VE estimates for 2 doses were 70.2% (95% CI 27.0–
249 87.8%) against all COVID-19 hospitalization, 71.4% (95% CI 29.3–88.4%) against COVID-
250 19 requiring oxygen therapy, 72.7% (95% CI -11.6–93.3%) against COVID-19 requiring
251 invasive mechanical ventilation, and 58.9% (95% CI -82.8–90.8%) against fatal COVID-19
252 (**Table 3**). During the Omicron period, some individuals received 3 or 4 doses, but the
253 confidence intervals were very wide due to the small sample size. Similarly, we attempted to
254 estimate VE by time since vaccination, but failed to estimate some, and even if we could, the
255 confidence intervals were wide (by dose in **Supplementary Table 1**, regardless of dose in
256 **Supplementary Table 2**).

257 Discussion

258 In this descriptive and case-control study in the Philippines, we described the characteristics
259 and outcomes of COVID-19 patients requiring hospitalization and estimated the real-world
260 effectiveness of COVID-19 vaccines against severe disease during the pre-Omicron and
261 Omicron periods.

262 Among SARS-CoV-2-positive hospitalized patients, in-hospital death occurred in 20.5%,
263 which was in line with what was observed in a systematic review/meta-analysis published
264 early in the pandemic,²³ although cautious interpretation is warranted given varied
265 hospitalization criteria among countries and hospitals. The numerically higher percentage of
266 in-hospital deaths during the Omicron period (25.9%) compared to the pre-Omicron period
267 (18.8%) may be partially due to numerically higher percentages of individuals with either TB
268 (pre-Omicron: 9.5% versus Omicron: 40.5%) or HIV (pre-Omicron: 3.2% versus Omicron:
269 27.1%). We found several factors associated with in-hospital death, including increasing age,
270 male sex (aOR 1.60), CKD (aOR 4.39), tuberculosis (aOR 2.45), HIV (aOR 3.30),
271 hospitalization in the past year (aOR 3.38), and current smokers (aOR 2.65). All these are in
272 line with previous reports,^{21,22,24-26} although these findings were new in LMICs in the Western
273 Pacific Region and Southeast Asia.

274 Next, in the VE analysis, during the pre-Omicron period, over half (56.7%) of vaccinees
275 received CoronaVac, 32.2% received viral vector vaccines, and 8.2% received mRNA
276 vaccines (**Table 2**). With these vaccine types, 2 doses provided high (85–97%) protection for
277 a range of severe COVID-19 outcomes during the pre-Omicron (Alpha, Gamma, Delta)
278 period for the approximate median interval since the last vaccination of 2 months (all
279 hospitalization: 85.4%; oxygen requirement: 91.0% [restricted to “true” severe COVID-19:
280 90.9%]; invasive mechanical ventilation: 97.0%; fatal: 96.5%) (**Table 3**). These findings
281 were in agreement with other observational studies,¹³ including studies that assessed

282 inactivated vaccines such as CoronaVac.¹⁴ Also, a trend towards higher VE for more severe
283 and specific outcomes was observed.^{15,16}

284 During the Omicron period, approximately half (49.3%) of the primary series vaccinees
285 received CoronaVac, 27.6% received viral vector vaccines, and 19.2% received mRNA
286 vaccines (**Table 2**). For boosters, the majority received either mRNA or viral vector vaccines
287 (only mRNA vaccines for the second booster doses). Here, 2 doses also provided variable
288 moderate-to-high (59–77%) protection (all hospitalization: 70.2%; oxygen requirement:
289 71.4% [restricted to “true” severe COVID-19: 76.9%]; invasive mechanical ventilation:
290 72.7%; fatal: 58.9% [some with wide CI]) (**Table 2**). The numerically lower VE against more
291 severe outcomes such as mechanical ventilation and death may be due to a longer period
292 since the last vaccination (median interval of approximately 9 months vs. 6 months) in
293 addition to small sample sizes. Unfortunately, we could not estimate VE for booster doses,
294 VE by vaccine type (e.g., manufacturers), and VE by time since vaccination in detail, due to
295 sample size limitations.

296 The strengths of the current study include analyzing data from an understudied country, data
297 on different vaccine platforms, and outcome data across different severity levels.

298 *Limitations*

299 This study has several limitations. First, biases, confounding, and misclassifications inherent
300 in observational studies are possible. However, using specific and severe outcomes, we aimed
301 to minimize the inclusion of incidental SARS-CoV-2-positive cases which could have
302 occurred as admission screening was in place at the time of the study. Second, the current
303 hospital-based case-control study was not strictly a test-negative design, as controls included
304 all patients who required oxygen even for severe outcomes such as mechanical ventilation
305 use and death. However, individuals who require oxygen therapy are likely to seek care
306 regardless of SARS-CoV-2 infection or vaccination status due to shortness of breath and

307 other manifestations, resulting in the same advantage of control for healthcare-seeking
308 behavior. Third, the present study was a single-center study, and thus, the results may not be
309 generalizable to the whole country. Fourth, wide CIs for some estimates warrant careful
310 interpretation of point estimates, and the small sample size in some multivariable models
311 resulted in possible sparse data bias. Fifth, our analysis was a complete case analysis with
312 more missing data during the pre-Omicron period, as the first version of the CIF for SARS-
313 CoV-2 testing used during this period did not include vaccination information. However, it is
314 possible that these patients with missing data were unvaccinated (being early in the course of
315 the vaccination rollout), and we obtained very similar VE estimates for various outcomes
316 when we treated missing as unvaccinated (data not shown). Also, this missing proportion is
317 comparable to data-linkage studies.²⁷ Sixth, we could not classify individual COVID-19 cases
318 as infected with specific variants during the pre-Omicron period. Seventh, our VE estimates
319 measured within a median of 2 months during the pre-Omicron period and 6–9 months
320 during the Omicron period. Finally, as above, we could not estimate VE by vaccine type
321 (e.g., manufacturer) due to sample size limitations, but we consider this is still of value to see
322 the context in the Philippines.

323 *Conclusions*

324 In this descriptive and case-control study in the Philippines, we identified increasing age,
325 male sex, certain comorbidities (CKD, tuberculosis, and HIV), hospitalization in the past
326 year, and current smoking as factors associated with in-hospital death among hospitalized
327 COVID-19 patients. Also, VE estimates against severe COVID-19 resulting in
328 hospitalization, oxygen, mechanical ventilation, and death were high for 6 months during
329 both the pre-Omicron and Omicron periods in a setting where over half of vaccinees received
330 inactivated vaccines for the primary series. Our findings will support policies implemented in

331 lower-middle and low-income countries, where many rolled out inactivated vaccines but with
332 scarce real-world data.

333 **Conflicts of interest**

334 Authors declare no conflicts of interest.

335

336 **Funding**

337 This work was supported by the World Health Organization, the Nagasaki University WISE

338 Programme, the Japan Agency for Medical Research and Development (AMED) (grant

339 numbers 23fk0108684j0101, 24fk0108684j0102), and the Korea Disease Control and

340 Prevention Agency, Republic of Korea.

341

342 **Acknowledgements**

343 We thank all staff members at San Lazaro Hospital for patient care and administrative

344 assistance for the study.

345

346 **Data availability statement**

347 Individual-level data of patients included in this manuscript after de-identification are

348 considered sensitive and will not be shared. The study methods and statistical analyses are all

349 described in detail in the Methods and throughout the manuscript.

460 ^a Median (interquartile range).

461 ^b The following points were added up for each patient: assigned 2 points for the presence of either diabetes
462 mellitus, chronic kidney disease, dementia, Down syndrome, or obesity and assigned 1 point for the presence of
463 cardiovascular disease (including hypertension), dyslipidemia, chronic liver disease, chronic obstructive
464 pulmonary disease, cancer, depression/schizophrenia, stroke, pregnancy while hospitalized, or overweight.
